Cracked and split teeth may present with a large and variable collection of signs and symptoms that are potentially confusing.[16,18,78] Only by being aware of the *process* leading from early to late manifestations can clinicians interpret these signs and symptoms and identify the specific point they are encountering on the potential timeline of this process.

A definitive combination of factors, signs, and symptoms that, when collectively observed, allows the clinician to conclude the existence of a specific disease state is termed a *syndrome*. However, given the multitude of signs and symptoms that cracked roots can present with, it is often difficult to achieve an objective definitive diagnosis. For this reason, the terminology of *cracked tooth syndrome*[18] should be avoided.

Diagnosis

As in the case of a cracked cusp, early detection is imperative in order to resolve the patient's symptoms as well as increasing the prognosis. However, the use of the Tooth Slooth device (see Fig. 21-2) may or may not provide as clear a result for a symmetrically cracked tooth, as each of the parts of the tooth may be rather stable. Asking the patient to chew on a cotton roll[9] or on the tip of a cotton-tip applicator placed at a particular site may reproduce the pain. Nevertheless this method may not indicate whether the source is a maxillary or mandibular tooth and need further measures to pinpoint the involved tooth. *Magnification* using either loupes or an operating microscope can be helpful for detecting a fracture line. In addition, dyes, such as methylene blue or tincture of iodine, which are applied either to the outer surface of the crown or to the dentin after the removal of an existing intracoronal restoration, can be

http://dentalebooks.com

helpful for visualizing the crack (see Fig. 21-3). Transillumination can also be applied to the suspected tooth and, if the tooth has no restorations, this method may yield an impressively straightforward diagnosis (see Fig. 21-3). Anesthetizing the suspected tooth, followed by asking the patient to chew again on the cotton roll, may further confirm the diagnosis and finally differentiate the origin as a mandibular or maxillary tooth. At a later stage, when splitting of the tooth has occurred, wedging of a sharp explorer into the fracture line will provide a clear diagnosis of a split tooth.

Generally speaking, the diagnosis of a crack in a tooth can be difficult. When there are signs and symptoms of a pulpitis or necrosis, it is incumbent upon the clinician to determine the source that initiated the signs and symptoms. In the case of a problematic tooth with no apparent reason for the pulpitis or necrosis, like a tooth with minimal or no caries, restoration, or trauma, a crack or fracture must be considered.[13] In some cases, an objective diagnosis may not be possible; however, with the possibility of a crack or fracture, the patient should be advised of a potential decrease in the endodontic or restorative prognosis.[5,12]

Etiology

Masticatory forces are the cause of cracked teeth.[22,34,45,47,70,71,90] Thus, the dietary habit of chewing on coarse food has been proposed as a contributing factor.[22,90] Bruxism or clenching of the teeth as well as occlusal prematurities are also frequent causes of cracked teeth.[18,22,34,45,47,70,71,90] For this reason, certain teeth may be more prone to developing cracks, such as mandibular second molars and maxillary premolars.[18] Masticatory habits such as chewing ice may also predispose teeth to cracks. The term *fatigue root fracture,* proposed by Yeh,[90] encompasses all of these causes.

In certain cases, traumatic injuries, such as a severe upward blow to the mandible (e.g., during a car or sports accident) can also cause a tooth crack or fracture. Another potential cause is the unexpected chewing of a hard object (e.g., a cherry pit or an unpopped corn kernel in popcorn). The occlusal forces applied by the first molars are as high as 90 kg,[45] which, when fully applied unexpectedly, may damage the tooth structure. However, in most cases, a tooth crack can be attributed to no specific cause other than normal or excessive masticatory forces.[22,34,45,47,70,71,90]

Treatment Planning

Cracked Tooth

When a cracked tooth is either suspected or determined, the patient should be informed that the prognosis is reduced and sometimes questionable.[5,9,12] Protecting a tooth from the propagation of a crack and improving comfort while chewing are the principal goals in the treatment of cracked teeth. Both goals can often be immediately achieved by placing an orthodontic band around the tooth[3,9,16] or by placing a provisional crown. These procedures allow the clinician to evaluate the extent of pulp involvement by checking whether the pulpal symptoms subside in response to the intervention.[3,9,16]

Protecting the tooth from further splitting forces by the placement of a permanent crown is essential in these cases.[3,5,9,16,39] Unfortunately, a crown alone is often not sufficient to resolve symptoms, and endodontic treatment may be considered prior to the placement of the permanent crown, depending on the pulpal symptoms.[9]

A root canal treatment followed by a permanent crown has the benefit of immediately eliminating the long-lasting, painful symptoms as well as early protection from occlusal forces that may cause propagation of a cracked tooth to become a split tooth. Nevertheless, when 127 cracked teeth with reversible pulpitis were treated with a crown alone, 20% of these teeth converted to irreversible pulpitis within 6 months and required root canal treatment.[51] In contrast, none of the other teeth needed a root canal over a 6-year evaluation period.[51] However, it should also be understood that varying percentages of crowned teeth, cracked or noncracked, may also require endodontic treatment, merely from the trauma of the crown preparation. By comparison, it has been shown that when suspected cracked teeth were restored with resin bonded restorations, only 7% required subsequent endodontic treatment or extraction.[64]

After removal of an intracoronal restoration or when penetrating the dentin to prepare for endodontic access, one may observe discoloration along the crack in the dentin. Once the access cavity has been completed, the floor and the distal and mesial walls of the pulp chamber should be carefully inspected to check for the presence and extent of any cracks. Upon evaluating 245 restored teeth, cracks were observed preoperatively in 23.3% of the teeth; however, when the restorations were removed, 60% of these teeth were found to have cracks.[1] Methylene blue dye may be helpful in this type of examination. If a crack is found that reaches from the mesial wall, through the floor of the pulp chamber and into the distal wall, then the prognosis for the tooth is poor, and extraction should be considered (see Fig. 21-6).[5,9,12] If the crack does not reach the pulp chamber or is limited to the coronal parts of the mesial or distal wall, the subsequent protection of the tooth with a crown may save the tooth. Nevertheless, as mentioned previously, the patient should be advised that the treatment success may be compromised and that long-term follow-up will be required.[5,9,12]

Given that such cracks occasionally occur in teeth with minimal or no restorations and that all of the pain may cease once the pulp is removed, it may be tempting to limit the final restoration to an intracoronal amalgam or composite restoration. This temptation should be resisted by all means, as the forces that caused the crack are still present, and the apical propagation of the crack and loss of the tooth is still likely.

Split Tooth

When the tooth is split either through its whole length or diagonally (Fig. 21-7), extraction is typically the only treatment option.[5,9] However, if the fracture line is such that the split results in large and small segments, and if the removal of the small fragment preserves enough tooth structure that is restorable, then retention and restoration of the tooth may be considered.[5]

VERTICAL ROOT FRACTURE (VRF)

Definition

A *vertical root fracture* (VRF) is a longitudinally oriented complete or incomplete fracture initiated in the root at any level and is usually directed buccolingually[5] (Figs. 21-1 and 21-8 through 21-11). By definition, these types of fractures do not arise from the propagation of a fracture that originated in the crown. This definition separates a VRF from a split tooth,

http://dentalebooks.com

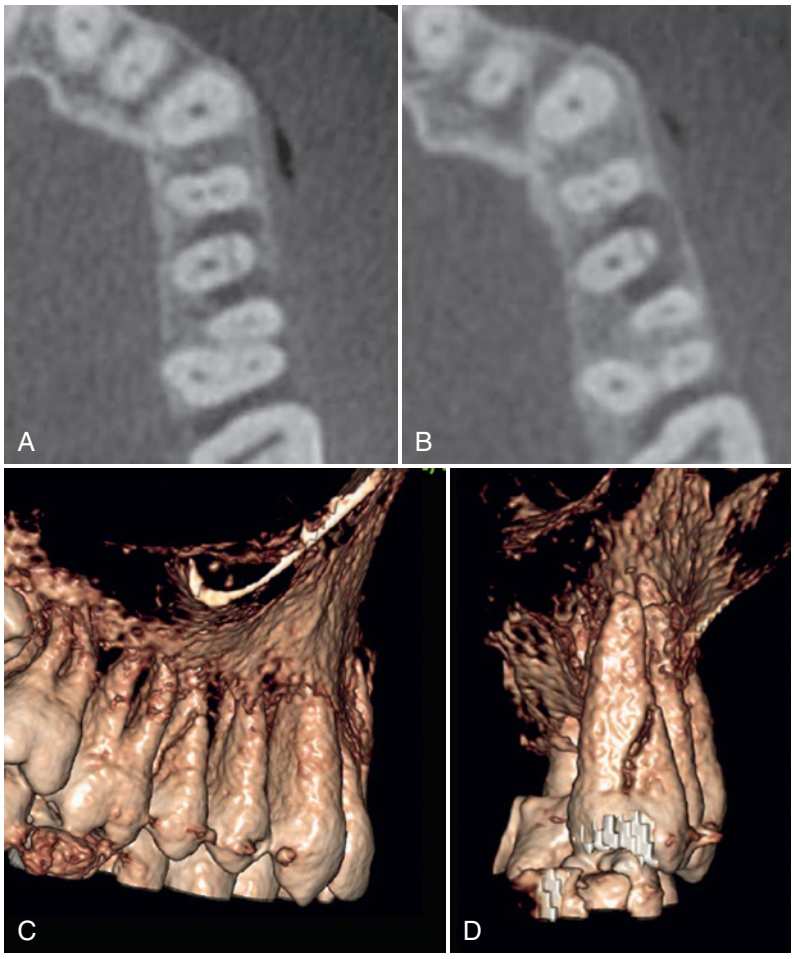

FIG. 21-7 Diagonally split tooth. A maxillary right second premolar presented with a mesiodistal coronal fracture. **A, B,** CBCT axial views revealing a mesiodistal fracture at two different levels, with associated mesial and distal bone loss. The more coronal view has mesial and buccal bone loss **(A)**. A more apical view reveals mesial, distal, and buccal bone loss **(B)**. **C, D,** the three-dimensional reconstruction clearly reveals the nature and direction of the fracture and defined the tooth as unrestorable. Both bone loss and the thick dimensions of the fracture line indicate a longstanding case in which bone resorption allowed opening of the fracture to dimensions that could be detected by CBCT. It is unlikely that such clear demonstration of the fracture line could appear at earlier stages of its formation. (Courtesy Dr. Anda Kfir, Tel Aviv, Israel.)

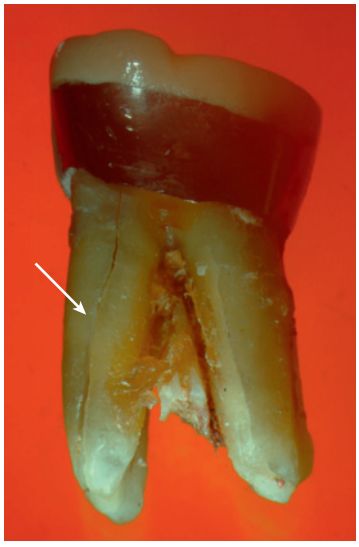

FIG. 21-8 Diagonal VRF in a molar. A lingual view of a right first mandibular molar revealing a diagonal VRF in the mesial root.

which begins with a crack of the crown that propagates apically into the root as a longitudinal fracture. Although both are catastrophic longitudinal factures, a vertical root fracture should be clearly differentiated from a split tooth in that the causes, origins, and typical planes of fracture are substantially different.

Diagnosis

Patient History

In the case of a VRF, a patient may complain of pain or sensitivity related or adjacent to a given tooth. Sensitivity and discomfort while chewing are also common complaints.[80] Swelling may occasionally occur in the area. There is often a long history of failing to diagnose the cause of the pain and discomfort. A history of repeated clinical and radiographic examinations that revealed no cause for the pain is also common in VRF cases. After recent endodontic retreatment, if the symptoms remain and the dentist is unable to determine the cause of the symptoms, the patient may lose confidence in the dentist. Often retreatment or surgical retreatment may have

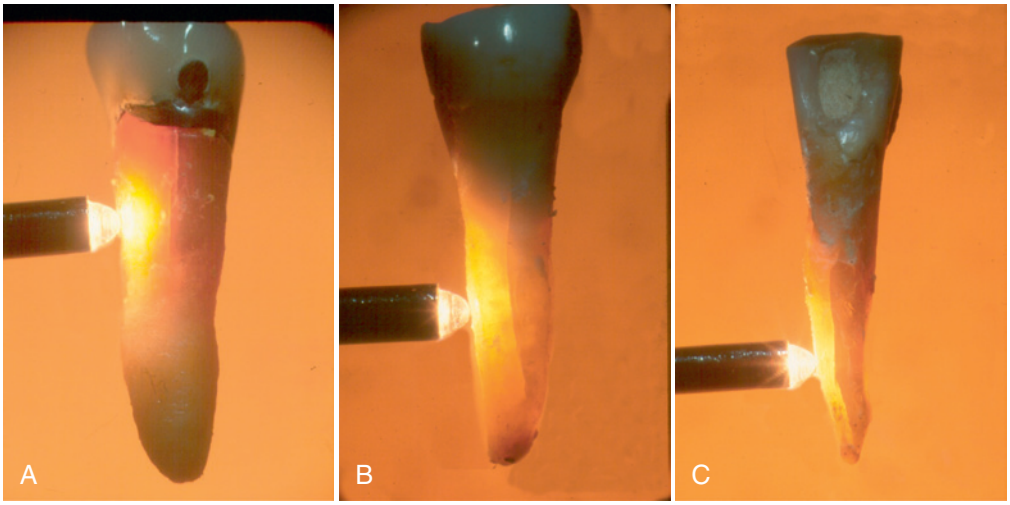

FIG. 21-9 Three types of VRFs. **A,** A coronally located VRF extending apically as far as one third of the root. **B,** A midroot VRF extending along the middle third of the root. **C,** An apically located VRF extending coronally as far as the apical two thirds of the root.

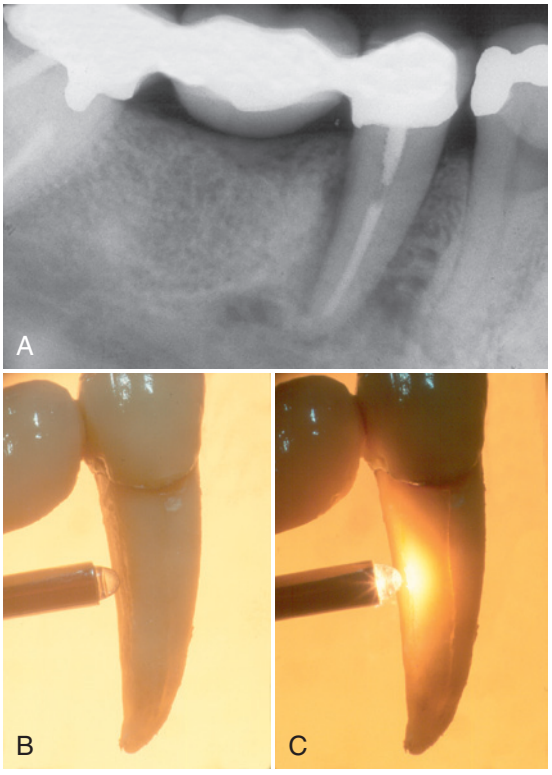

FIG. 21-10 Radiographic presentation of VRF-associated bone loss. A second right mandibular bicuspid was endodontically treated and restored using a short post. Two years later the patient started experiencing discomfort and sensitivity upon chewing. Initially no radiographic signs were present. This lasted for 9 months until a radiograph **(A)** revealed an extensive bone resorption and the tooth extracted. **A,** A large radiolucent lesion was present along the root on the distal side. **B,** The tooth was extracted, but the buccal VRF was not readily evident. **C,** Transillumination with an intense but small light source was used after extraction to clearly demonstrate the VRF. (Courtesy Dr. Ramy Levi, Israel.)

been attempted to reveal the accurate diagnosis.[1] Unfortunately, such ineffective treatment attempts may only worsen the dentist-patient relationship.

Clinical Manifestations

Susceptible Teeth and VRF Location

Vertical root fractures are commonly associated with endodontically treated teeth with or without a post.[5] Nevertheless, VRFs can also occur in teeth with no previous root canal treatment.[22] The most susceptible sites and tooth groups are the maxillary and mandibular premolars, the mesial roots of the mandibular molars, the mesiobuccal roots of the maxillary molars, and the mandibular incisors.[81] However, VRFs may occasionally occur in other teeth and roots as well.

Vertical root fractures may progress in the buccolingual direction in these teeth and roots, which are typically narrow mesiodistally and wide buccolingually.[40] However, VRFs may also propagate diagonally, thus affecting the mesial or distal aspect of the root (see Fig. 21-8). VRFs may be initiated at any root level.[5] They may be initiated at the apical part of the root and propagate coronally (see Fig. 21-9, *C*). Nevertheless, certain VRFs originate at the coronal, cervical part of the root and extend apically (see Fig. 21-9, *A*), and in other cases, a VRF may be initiated as a midroot fracture (see Figs. 21-9, *B*; 21-10, *C*; and 21-11, *D*).

It is commonly believed that VRFs begin as microcracks at the root canal surface of the radicular dentin and gradually propagate outward until the full thickness of the radicular dentin is fractured.[5,10,21,56,87] Studies[14,17,50,76,91] indicate that microcracks can also be initiated at the outer surface of the root and propagate inward. Therefore, the correlation between microcracks in the radicular dentin and the formation of VRFs should be further investigated.

Early Manifestation

In the early stages of a VRF, there may be pain or discomfort on the affected side of the tooth. In particular, the tooth may feel uncomfortable and sensitive upon chewing, although this pain is often of a dull nature, as opposed to the sharp pain typical of

http://dentalebooks.com

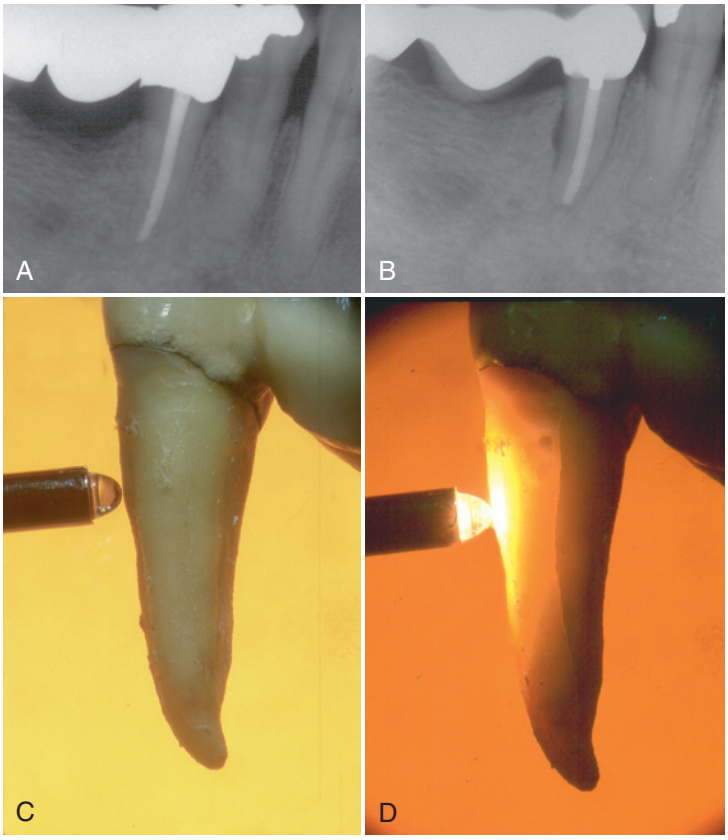

FIG. 21-11 Small isolated radiographic presentation of VRF-associated bone loss. A second right mandibular bicuspid was endodontically treated and restored with no dowel. A year later the patient started complaining about sensitivity on the lingual side. Three months later the radiograph **(A)** was taken and the tooth extracted. A small radiolucent lesion was present along the root on the distal side. The tooth was extracted, but the lingual VRF was not readily evident **(B)**. Transillumination with an intense but small light source was used after extraction to clearly demonstrate the VRF **(C, D)**. (Courtesy Dr. Ramy Levi, Israel.)

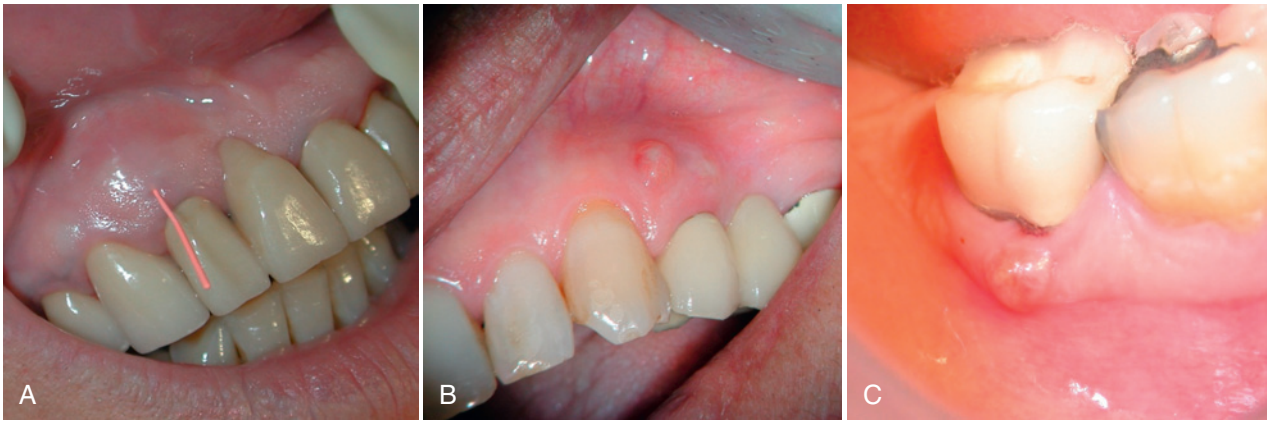

FIG. 21-12 Coronally located sinus tracts. Maxillary lateral incisors are *not* among the teeth with high prevalence of VRFs. **B,** A draining sinus tract at a coronal location originating from a buccal VRF in the first left maxillary premolar. **C,** A draining sinus tract at the gingival margin of a right first mandibular molar with a buccal VRF in the mesial root. (*A* and *B,* Courtesy Dr. Russ Paul, Zichron Yaakov, Israel.)

a cracked cusp or tooth with a vital pulp. As the fracture and subsequent infection progresses, swelling often occurs, and a sinus tract may be present at a location more coronal than a sinus tract associated with a case of chronic apical abscess[79,81] (Fig. 21-12). These signs and symptoms are frequently similar to those encountered from nonhealing root canal treatment.[57,86] In the early stages, radiographic findings are unlikely because (1) the root canal filling may obstruct the detection of the fracture (Fig. 21-13, *A*), and (2) the bone destruction (which still has limited mesiodistal dimensions) may be obstructed by the superimposed root structure (Fig. 21-14).

A deep, narrow, and isolated periodontal pocket may be associated with the root, which often cannot be explained by, as it is inconsistent with, the surrounding periodontal examination.[79,81,85] This specific type of periodontal defect occurs secondary to the bony dehiscence caused by the vertical root fracture. It is substantially different from the pockets caused by advanced periodontitis (discussed later).

http://dentalebooks.com

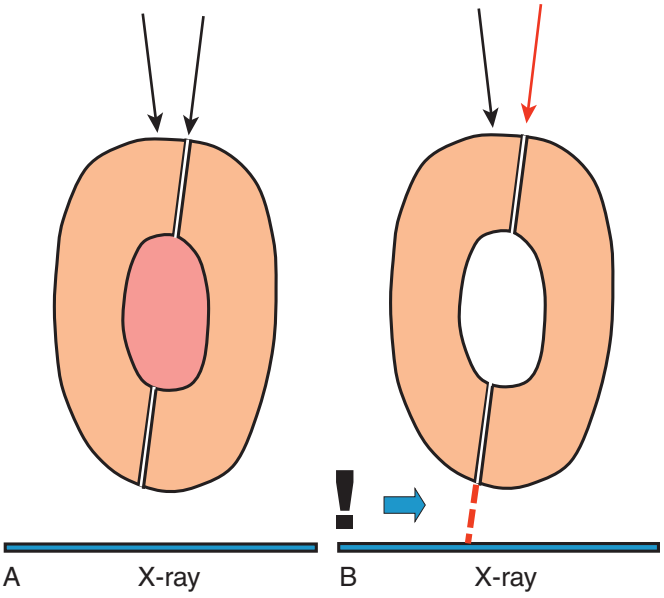

FIG. 21-13 Radiographic examination of filled versus empty canals. **A,** The buccolingual projection of a filled root will fail to detect a VRF at an early stage. **B,** The removal of the root filling and use of radiography at different mesiodistal angulations may reveal the VRF.

Late Manifestation

A longstanding vertical root fracture is easier to detect. The major destruction of the alveolar bone adjacent to the root has already occurred, allowing the VRF to be more likely revealed in a periapical radiograph (see Fig. 21-7). One of the most typical signs is the *J-shaped* or *halo radiolucency*, which is a combination of periapical and periradicular radiolucency (i.e., bone loss apically and along the side of the root, extending coronally)[82,83] (Fig. 21-15). In addition, the pocket along the fracture, which was initially tight and narrow, may become wider and easier to detect. In longstanding cases in which the bone destruction is extensive, the segments of the root may also separate, resulting in a radiograph that clearly reveals an objective root fracture (Fig. 21-16).

Diagnosis

Importance of Early Diagnosis

Accurate and timely diagnosis is crucial in VRF cases, allowing the extraction of the tooth or root before extensive damage to the alveolar bone can occur. Early diagnosis is particularly important when implants are a potential part of the future restorative procedure; when an extraction is performed at an early stage, the uncomplicated placement of an implant is likely. When the tooth is extracted after extensive damage has already occurred (see Fig. 21-14), bone regeneration procedures may be required,[42] adding cost and time to the restoration procedure.

The American Association of Endodontists stated in 2008[5] that a sinus tract and a narrow, isolated periodontal probing defect associated with a tooth that has undergone a root canal treatment, with or without post placement, can be considered pathognomonic for the presence of a VRF.

However, the combination of the following two factors makes the early diagnosis difficult: (1) many of the clinical symptoms associated with VRFs mimic apical periodontitis or periodontal disease, and (2) the narrow and tight pocket associated with early stages of VRF is difficult to detect using rigid probes (see the VRF Pocket section). Consequently, a delay in the accurate diagnosis or a misdiagnosis of a VRF may often occur.

Misdiagnosis of VRFs

Certain cases of longstanding VRFs are so discernible that no dentist can miss the diagnosis (see Fig. 21-16). Nevertheless, two retrospective case series, one by Fuss and colleagues[32] and the other by Chan and associates,[22] reported that general practitioners often misdiagnose VRFs. The teeth that were extracted in these studies had often been diagnosed as endodontic failures or refractive periodontal pockets, only to realize after extraction that in some of them the actual cause was a VRF.

VRF Pockets

The pockets that are typical of the early stages of VRFs differ substantially from the deep pockets associated with advanced periodontal disease. The deep pockets associated with periodontal disease develop as a result of the bacterial biofilm that initially accumulates at the cervical areas of the tooth and the destructive host response to these bacteria.[38] Therefore, deep periodontal pockets are typically wider coronally and relatively loose. This pocket structure allows the easy insertion of rigid periodontal probes (Fig. 21-17). These types of periodontal pockets typically present with the deeper part of a pocket at the mesial or distal aspects of the tooth. Periodontal disease often affects groups of teeth rather than an isolated location of a single tooth.

The pockets associated with VRFs develop due to bacterial penetration into the fracture, triggering a destructive host response that occurs in the periodontal ligament along the entire length of the fracture. These bacteria may leak from an infected root canal[87]; however, when the VRF extends to the cervically exposed root, the microbes in the fracture may also originate from the oral cavity. In the early stages, the periodontal ligament is affected and destroyed along the longitudinal opening of the fracture, initially with a limited resorption to the adjacent bone. This permits the penetration of a periodontal probe. The pocket associated with a VRF is typically isolated and present only in a limited area adjacent to the affected tooth. This pocket is often located at the buccal or lingual convexity of the tooth. In the early stages, the pocket is deep but has a narrow coronal opening (see Fig. 21-17). The insertion of a probe first requires the detection of the coronal opening; often, light pressure is necessary for the insertion of the probe. Because the pocket is narrow, probe insertion may result in the blanching of the surrounding tissue (Fig. 21-18). This is specially the case when a plastic probe is used, as its coronal part is thicker than an equivalent metal probe (Figs. 21-18 and 21-19).

The pocket associated with the early stages of a VRF is quite different from a common periodontal pocket. This difference has been widely recognized, and terms such as *osseous defect*[28] and *probing defect*[5] have been used to emphasize the point. Nevertheless, these pockets do possess enough unique features to justify them being specifically termed a *VRF pocket*.

Rigid metal periodontal probes may be ineffective in probing VRF pockets in the early stages of a VRF. Given that the pocket is deep, narrow, and tight, the bulge of the tooth's crown may prevent the insertion of a metal probe into the pocket (see Fig. 21-19). A flexible probe should be used instead, such as a probe available from Premier Dental Products (Plymouth

http://dentalebooks.com

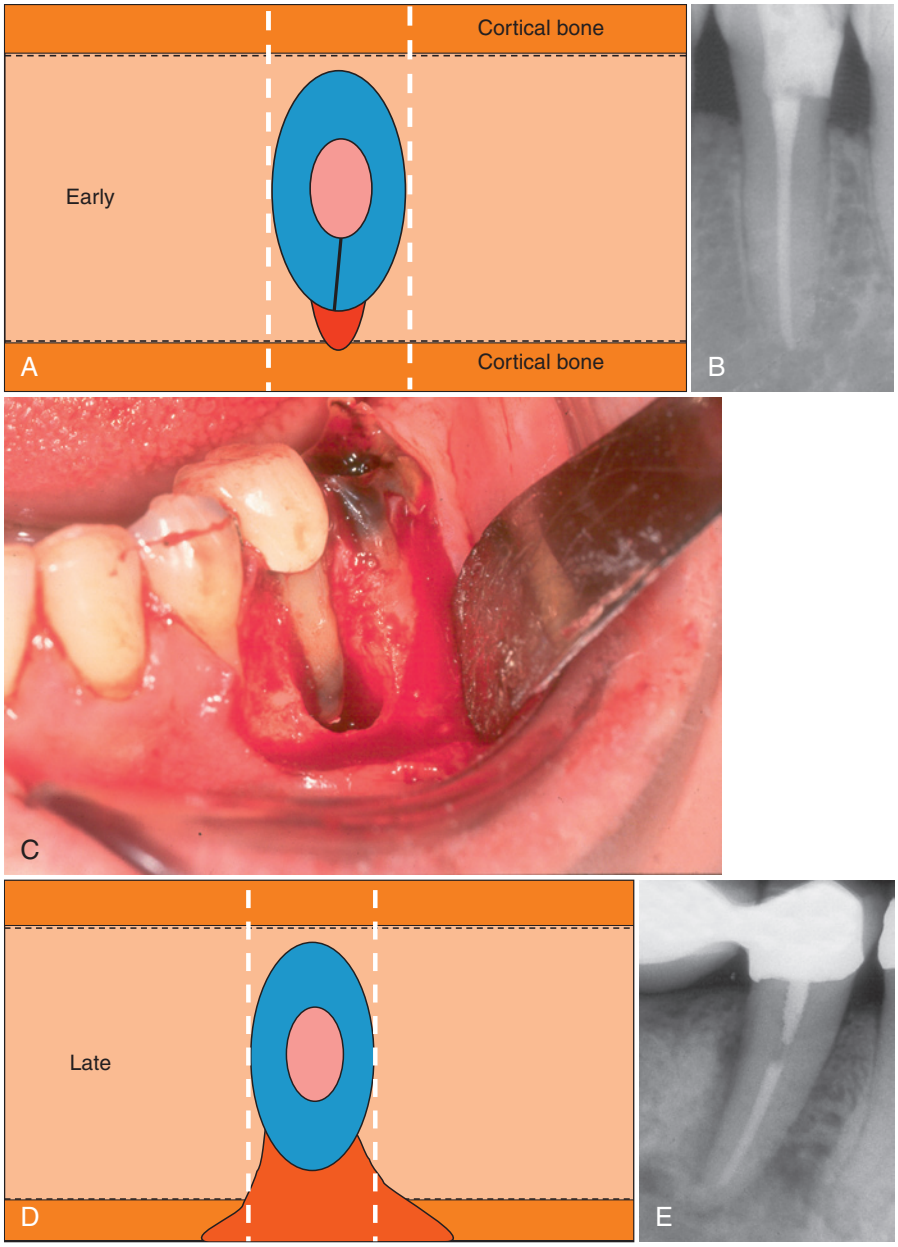

FIG. 21-14 Early versus late radiographic presentation of a VRF-associated bone defect. At an early stage, a bone defect *(red)* is not likely to be detected in a periapical radiograph, as the root will overlap with the defect **(A, B).** At later stages, when major damage has occurred to the cortical plate **(C),** the bone defect may be large enough to extend beyond the silhouette of the root **(C, D)** and appear as a radiolucent defect along the root **(E).** (Surgical image courtesy Dr. Devora Schwartz-Arad, Ramat-Hasharon, Israel.)

Meeting, Pennsylvania) (see Fig. 21-19) or a similar device. This type of flexible probe should be included on every endodontic examination tray and is an essential tool when checking for potential VRF pockets.

A typical VRF pocket was observed in 67% of the VRF cases reported by Tamse and colleagues.[81] However, because the early detection of such pockets is technique sensitive and because traditional metal probes were used in the aforementioned study, the incidence of these pockets may in fact be higher than reported. When a typical VRF pocket is located on the convex flank of the root on the buccal or lingual side, it is likely that the root has a VRF. In contrast, when such a pocket is located at the furcation of a molar, the pocket may indicate either a VRF or a sinus tract from an apical abscess that found a point of least resistance at the furcation area. In cases with a furcation pocket, when a VRF diagnosis cannot be conclusively determined, a positive healing response to the elimination of infection by initiating root canal retreatment may differentiate between these two types of pathoses.

Coronally Located Sinus Tract

Sinus tracts that originate from a chronic apical abscess are typically detected at the site of least bone resistance, against the apical part of the root or in the area of the junction of the

http://dentalebooks.com

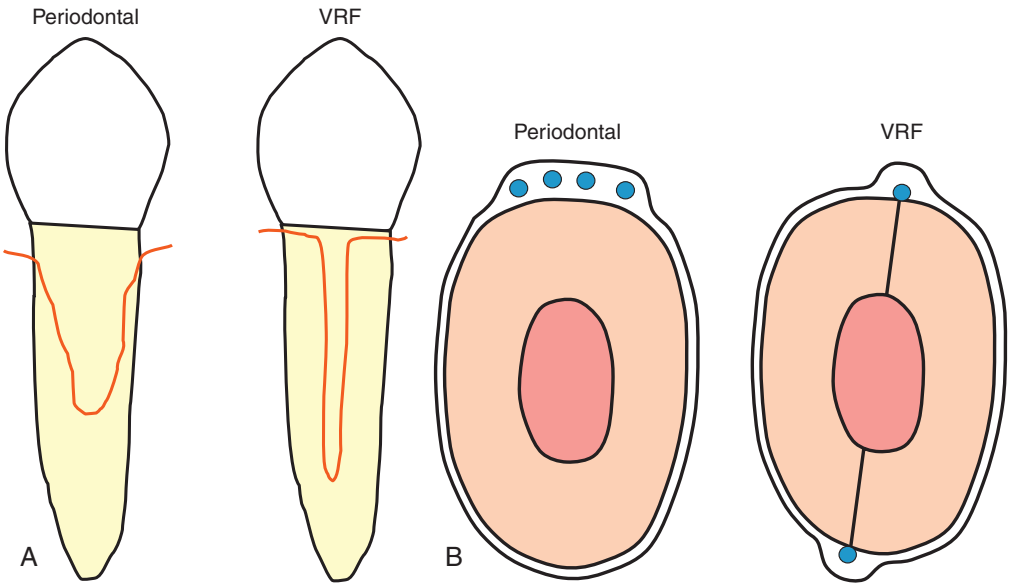

FIG. 21-17 VRF pocket. A, Periodontal pockets *(left)* are wide coronally, whereas VRF pockets *(right)* are narrow and deep. **B,** Periodontal pockets *(left)* are loose and allow probing at various sites, whereas VRF pockets *(right)* are narrow and tight. If not checked carefully at every millimeter of the sulcus, an early VRF pocket can easily be missed. Please note that periodontal pockets appear more commonly in the proximal sides of the root, whereas VRF pockets are more common on the buccal or lingual sides.

attached gingiva and the oral mucosa. Sinus tracts that are associated with a VRF pocket are often found in a more coronal position, as the source is not from a periapical lesion[80] (see Fig. 21-12).

In four clinical retrospective case series, coronally located sinus tracts were found in 13% to 35% of these cases.[58,79,81,85] As in the case of a VRF pocket, if the sinus tract is located at the furcation of a molar, this observation does not necessarily indicate a VRF, as periapical abscesses from a failing root canal treatment can also drain in this coronal location.

Radiographic Features

A definitive VRF diagnosis can sometimes be made based on the radiographic appearance of a thin radiolucent line extending longitudinally down the root.[72] Such lines, however, are difficult to detect and are commonly not seen in routine orthoradial, periapical radiographs because either the root canal filling has "masked" the fracture line or the angulation of the radiograph is not optimal for discerning the fracture (see Fig. 21-13) (Figs. 21-20 and 21-21). Rud and Omnell[72] claimed that it was possible to observe fracture lines in 35.7% of cases, but many of these cases were not true VRF instances. In clinical practice, it is still rare to observe a VRF on a radiograph, especially when only a single periapical radiograph is taken. Such an observation requires the x-ray beam to align with the plane of the fracture as well as the fracture line not being superimposed over the radiopaque root filling (Fig. 21-20, *A*). Therefore, two or three periapical radiographs should be exposed from different horizontal angulations when a fracture is suspected[80] (see Figs. 21-21 and 21-22).

In most VRF cases, the clinician must make *interpretations* or *predictions* based on the various patterns of periradicular bone destruction, which, unfortunately, are also shared by other periodontal and endodontic-like lesions.[58,75,88]

In the early stages of a VRF, no radiolucent bone lesions may be observed[20] (see Fig. 21-14), which may be the reason why VRFs often remain undetected, delaying diagnosis and treatment. Rud and Omnell[72] correlated the direction of the fracture, the degree of bone destruction, and the radiographic appearance, and emphasized that the extent of bone destruction around a fractured root depends on the location of the root fracture and the time elapsed since the inception of the fracture. The significance of time was confirmed by Meister and colleagues,[58] who demonstrated that immediate radiographic detection is difficult due to the time required for bone resorption to occur or for the fractured segments to separate and be radiographically visible. In a study of the patterns of bone resorption in 110 VRF cases, Lustig and associates[57] found that in 72% of patients with either chronic signs and symptoms (i.e., pertaining to a sinus tract, osseous defect, or mobility) or acute exacerbations, there was greater bone loss recorded compared to patients for whom a VRF diagnosis was made at an early stage.[57]

Despite the difficulty of diagnosing *early stage* VRFs in endodontically treated teeth, there are often several radiographic signs associated with *later stages* that are strong indicators of VRF.

The J-shaped or halo appearance, a combination of periapical and periradicular radiolucencies, was associated with a high probability of a VRF in a double-blind radiographic study involving 102 endodontically treated maxillary premolars[82] (see Fig. 21-15). An angular resorption of the crestal bone along the root on one or both sides, without the involvement of the periapical area, mimicking a "periodontal radiolucency" (see Fig. 21-15), was found in 14% of the cases. Tamse and coworkers[83] also reported the radiographic appearance of "halo" (see Fig. 21-10) and "periodontal" radiolucencies (see Fig. 21-10) in vertically fractured mesial roots of

http://dentalebooks.com

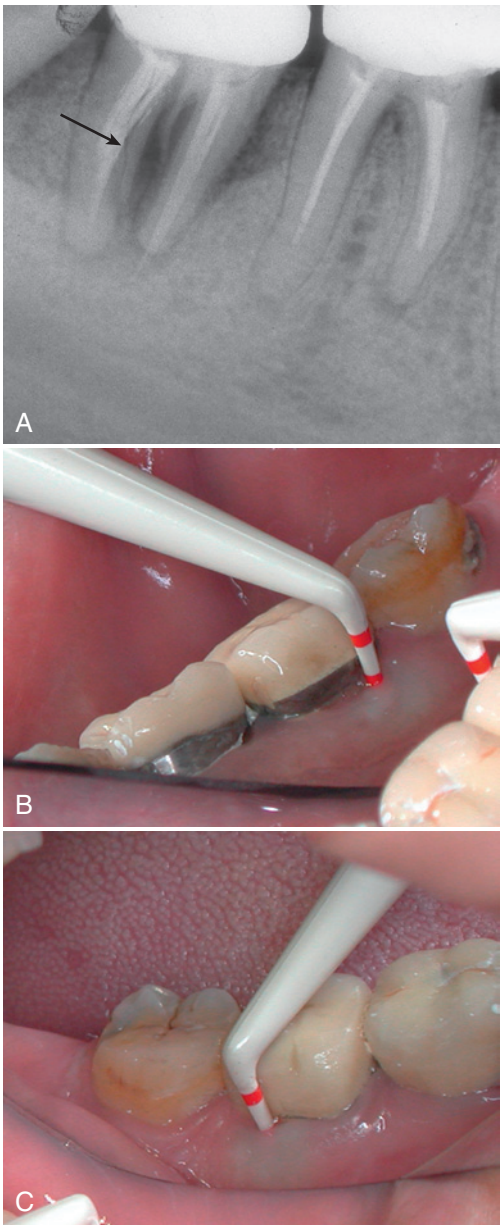

FIG. 21-18 **Tight VRF pockets. A,** The distal root of a second right mandibular molar with a VRF. VRF pockets were found on both the lingual **(B)** and the buccal **(C)** sides. VRF pockets are tight, so inserting a probe into these pockets causes pressure blanching of the surrounding tissues.

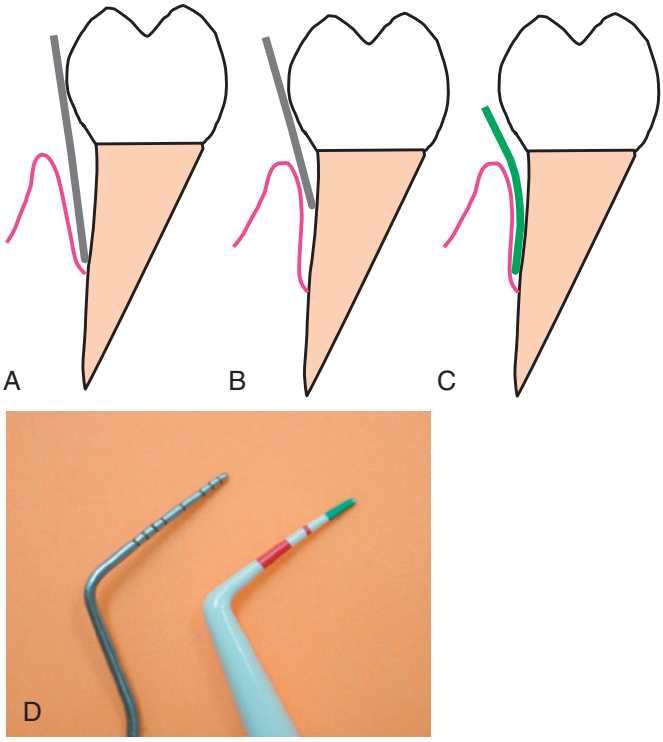

FIG. 21-19 **Rigid versus flexible probes. A,** In a loose periodontal pocket, a rigid metal probe can easily reach the depth of the pocket. **B,** In a tight, early-stage VRF pocket, a rigid probe may be of limited value, as the bulge of the crown often prevents the insertion of the probe into the tight, deep pocket. **C,** A flexible probe **(D)** is more likely to detect VRF pockets at an early stage.

mandibular molars (37% and 29%, respectively). In that study, the use of these two variables, combined with bifurcation involvement (63%) and the presence of an amalgam dowel (67%), predicted fracture in 78% of the cases. Others have reported similar findings.[24,62] Despite the different sample sizes, study designs, and objectives, the most common radiographic feature in these studies was a lateral radiolucency appearing longitudinally along the root and a halo appearance.

Radiolucency in the Bone Along Root

The type of periradicular radiolucency associated with a vertical root fracture is not and should not be interpreted as a thickening of the PDL. Instead, it represents a substantial destruction of the cortical plate of the alveolar bone[57] (see Fig. 21-14). In the case of a VRF in the buccolingual plane, often the bone resorption is limited at early stages, and any associated radiolucency may be obscured by the superimposition of the root (see Fig. 21-14). As the bone loss increases, the radiolucency becomes greater than the dimensions of the root, allowing it to be detected more clearly in the above-mentioned manner (see Fig. 21-14). As the VRF progresses to an intermediate stage, radiographs taken at different horizontal angulations may detect bone resorption (see Fig. 21-22), whereas a conventional orthoradial radiograph may not (see Figs. 21-14 and 21-22). This radiographic feature should be differentiated from a split tooth, in which the fracture plane is typically mesiodistal, with the bone resorption occurring in the earlier stages on the mesial or distal aspects of the root.

Radiograph of Empty Canal

As mentioned previously, the direct clinical detection of an early stage VRF from a periapical radiograph is unlikely, especially when there has been endodontic treatment. Because most VRFs are in the buccolingual plane, the radiopaque obturation often obstructs the view of the hairline radiolucency of the fracture (see Figs. 21-13 and 21-20). When a VRF is suspected, one may initiate root canal retreatment, removing the root obturation, and taking radiographs at two or three different horizontal angulations. The detection of a hairline radiolucency may provide a more definitive diagnosis of a VRF[80] (see Figs. 21-20 and 21-21).

http://dentalebooks.com

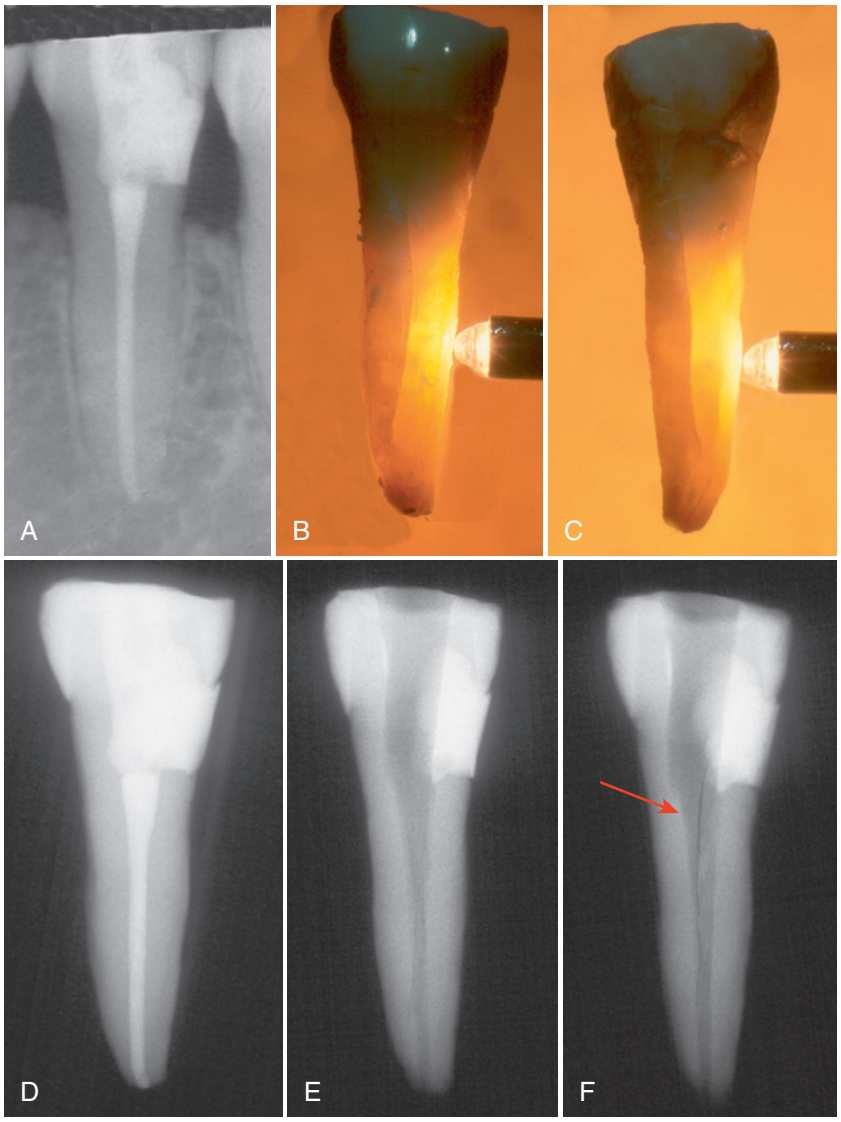

FIG. 21-20 Radiography of an ex vivo empty canal. The second left mandibular bicuspid underwent a root canal treatment, with no post required. Thirteen months later, the patient complained about pain and sensitivity to palpation on the lingual side. A radiograph provided no further information **(A)**. An isolated, 7-mm pocket was detected on the lingual side, and the tooth was extracted. Midroot VRFs were visible on the buccal **(B)** and lingual sides **(C)**. An ex vivo radiograph of the same tooth with no findings **(D)**. The root filling was removed, and radiographs were taken from different mesiodistal angulations **(E, F)**. One of the radiographs clearly revealed the VRF **(F)**.

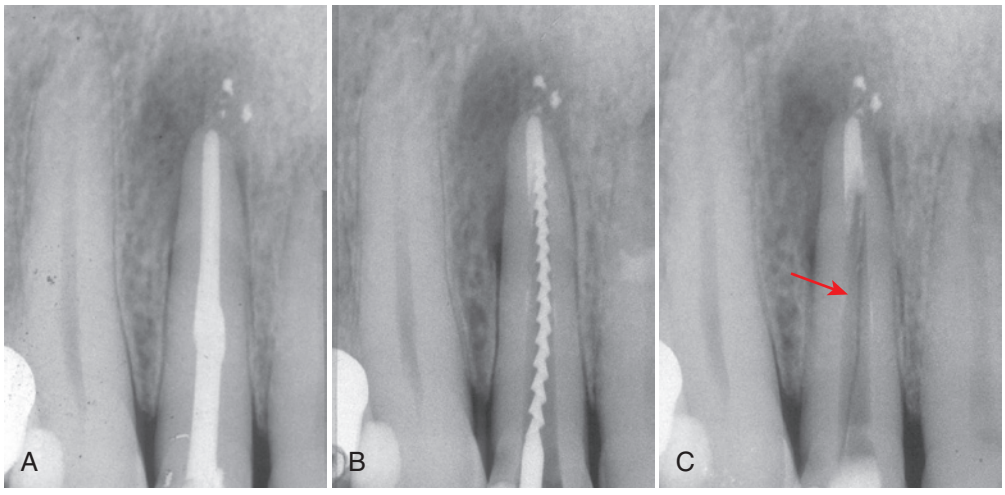

FIG. 21-21 Radiography of an empty canal: a clinical case. The right maxillary lateral incisor underwent a root canal treatment a few years ago. The patient complained about occasional pain on the palatal side. The tooth was sensitive to percussion and palpation on the palatal side. Radiography revealed a periapical radiolucency **(A)**. An isolated, deep, and narrow pocket was found on the palatal side of the root. Both the patient and the referring dentist were reluctant to extract the tooth, assuming that the pocket could potentially be a sinus tract, and decided on retreatment. A radiograph taken with a file during the process **(B)** could have missed essential information that was obscured by the file, which was an evident VRF **(C)**.

http://dentalebooks.com

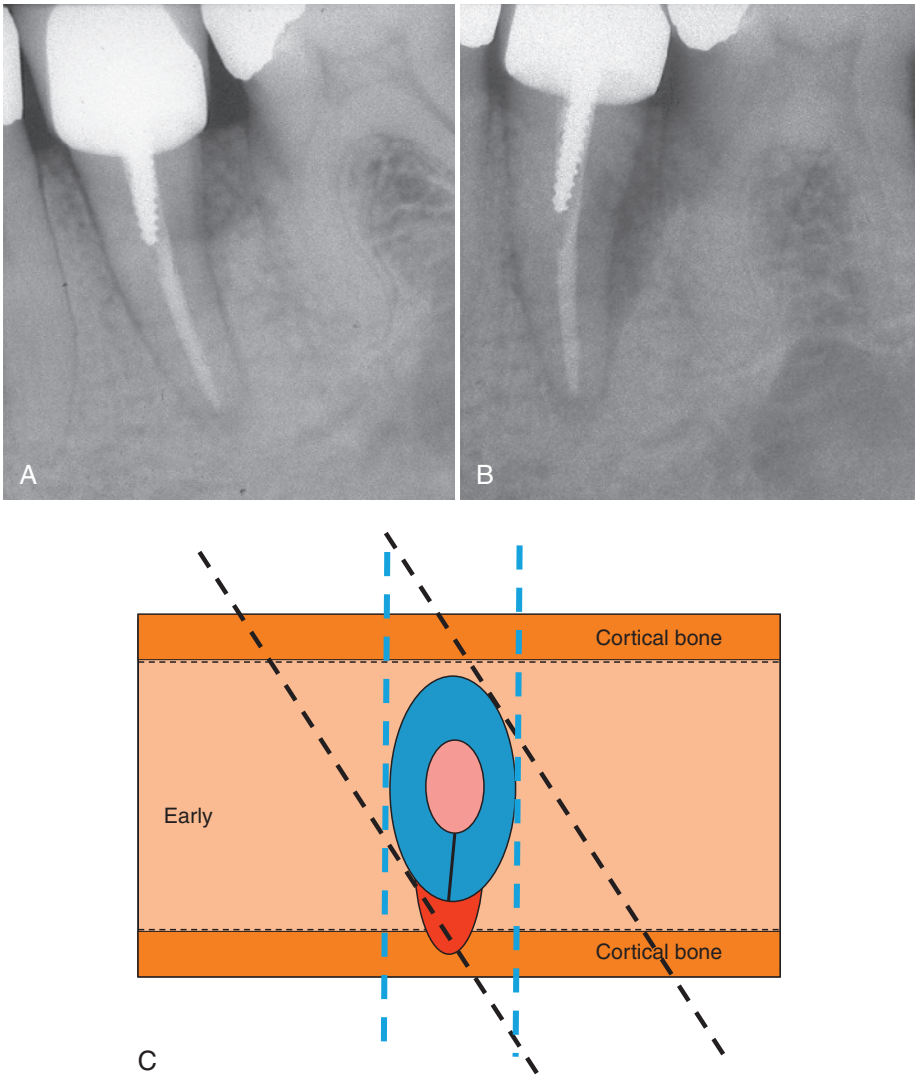

FIG. 21-22 Diagonal radiographs for detection of VRF. A, Orthoradial radiograph: very limited bone loss is seen. **B,** A different horizontal angulation reveals a radiolucent lesion along the root. **C,** Schematic presentation. Although a radiograph in an orthoradial direction *(blue lines)* cannot pick up the radiolucency along the root, diagonal angulation *(black lines)* may do so, as in **B.**

Cone-Beam Computed Tomography in VRF Diagnosis

Modern cone-beam computed tomography (CBCT) has a much smaller radiation dose compared to traditional medical spiral CT imaging, thus rendering CBCT a reasonable diagnostic tool for the use in selected endodontic cases.[6,31,31a,65]

One of the unique features of CBCT is its ability to study the suspected tooth and associated bone in an axial plane. Axial views may provide detailed information regarding the cross-sectional appearance of the tooth and its surrounding bone (Fig. 21-23). With the CBCT devices currently available, the width of an unseparated fracture may be too small and undetectable (see Fig. 21-23) (SEDENTEXCT guidelines[31]). Traditional planar, periapical radiographs are also of limited value for the *early* detection of VRFs. More specifically, bone damage or separation of the fragments is only radiographically evident at a relatively late stage. Several studies suggested that the detection of early-stage VRFs by a CBCT scan set to an axial view may be possible.[41,42,59] Yet such detection may greatly depend on the resolution of the machine (i.e., the voxel size). At a voxel size of 0.3 mm, the detection of early, unseparated VRFs is not reliable; however, when smaller voxel sizes were used in these in vitro studies, the reliability greatly increased.[41,42,59] Although the detection level of a fracture is thought to be twice the voxel size of CBCT imaging, there is presently no literature available to support this theory. Therefore, given that the smallest voxel size currently available for a CBCT device is about 0.075 mm, CBCT imaging would not be able to visualize a root fracture unless the fracture width was greater than 0.15 mm. It should also be noted that the intracanal presence of gutta-percha or a metal post often causes artifacts that make it extremely difficult to differentiate a VRF from such artificial lines.[59]

Although early VRFs may still be below the detection level of many CBCT machines, the *early destruction of the bone* along the suspected fracture may be visible in the cancellous bone (i.e., with an axial view) at relatively early stages, whereas this early bone destruction would not be detectable in traditional planar, periapical radiographs; such bone resorption may help to establish a VRF diagnosis (see Fig. 21-23).

http://dentalebooks.com

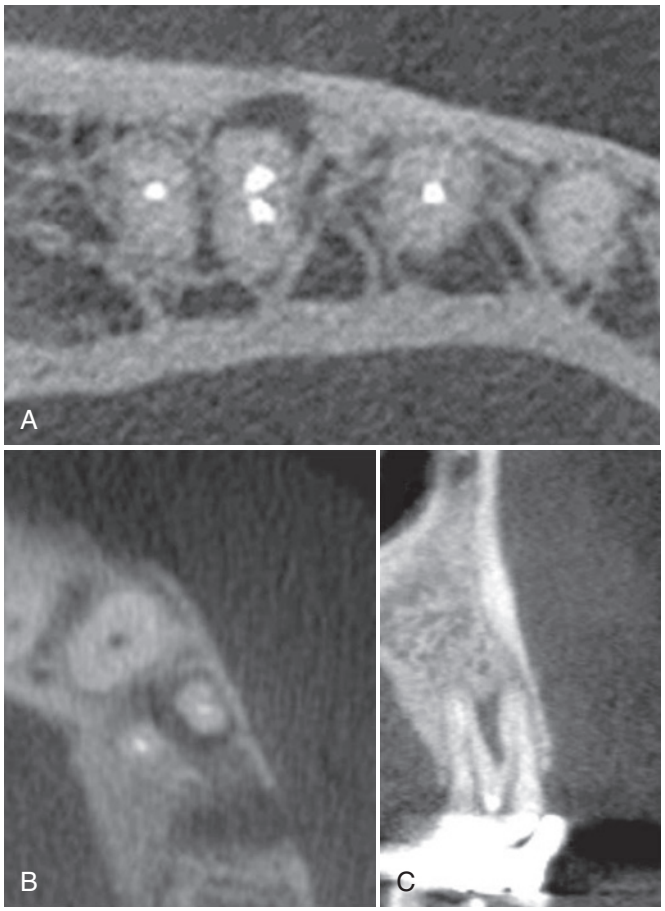

FIG. 21-23 "Invisible" bone destruction associated with early VRFs. **A,** Buccal VRF was present in the mesial root of a first left mandibular molar. At this early stage a typical VRF pocket was evident, yet no associated bone destruction was observed in a periapical radiograph. The VRF-associated bone destruction was evident in an axial plane of a CBCT. **B,** A VRF was present in the palatal side of the buccal root of the first maxillary premolar. A draining sinus tract was present with no radiographic signs to explain it. **C,** CBCT revealed a radiolucent lesion on the palatal side of the buccal root, which was verified, after extraction, as caused by VRF. Please note that in neither of these cases could the actual VRF fracture line be seen in the CBCT scan. (*B,* Courtesy Dr. Anda Kfir, Tel Aviv.)

With likely increased resolution in the near future, CBCT may become an important diagnostic tool for the detection of VRFs. For the present, neither the most updated Joint Position Statement of the American Association of Endodontists and American Academy of Oral and Maxillofacial Radiology (2010), nor the European Society of Endodontology position statement on the use of CBCT in endodontics (2014) recommend the use of CBCT for diagnosis of VRF.[6,31a]

Improvements of CBCT imaging—such as achieving a better signal-to-noise ratio, obtaining a smaller voxel size, and by applying advanced algorithms to segment fracture lines—may promise the potential to enhance the ability to detect early-stage VRFs in the future.

Exploratory Surgery

When clinical and radiographic evaluations are equivocal in detecting a suspected vertical root fracture, exploratory surgery may be indicated. When a full-thickness flap is raised and the granulation tissue is removed, a VRF may often be directly visualized[80] (see Figs. 21-14 and 21-24). The bone resorption pattern associated with a VRF is mostly seen as a bony dehiscence, with the greater bone destruction being present on the buccal cortical plate located over the offending root. In a small percentage of the cases, fenestration can also be seen.[57] Furthermore, it has been shown that the longer a VRF-related infection persists, the greater the resulting periradicular bone destruction.[57]

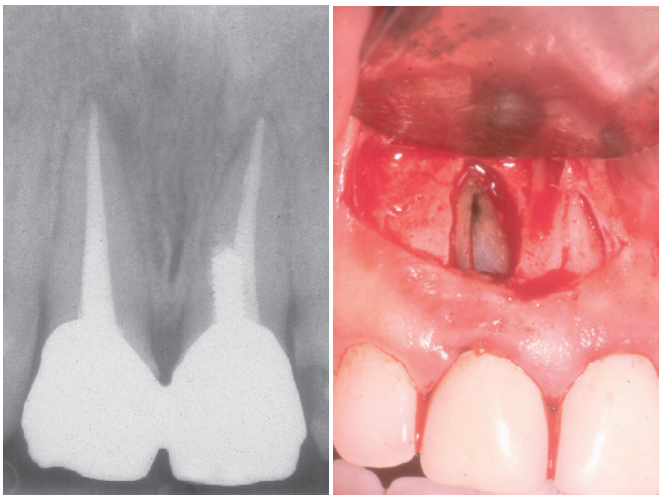

FIG. 21-24 An apical VRF with no pockets. The right maxillary central incisor was symptomatic despite an apparently adequate obturation. A radiolucent area was present around the apex, but no pockets were detected. Apical surgery was attempted, only to reveal a VRF at the apical part of the root that did not (yet) extend into the gingival margin and thus did not present with a typical VRF pocket. A semilunar flap design was used in this case, which was intended for apicoectomy. If surgical exploration for suspected VRF was initially intended, a conventional full flap would have been used. (Courtesy Dr. Ram Zeev, Rehovot, Israel.)

Etiology

Vertical root fractures may arise from a series of factors, some of which are natural whereas others are iatrogenic, arising from dental procedures such as endodontic treatment and the restorative procedures that follow it. The most common dental procedure contributing to vertical root fractures is endodontic treatment.[11]

Most vertical root fractures occur in endodontically treated teeth.[11,24] VRFs usually do not occur during the actual obturation of the root canal, but rather they occur long after the procedure has been completed.[81]

The etiology of VRFs is multifactorial.[33,79] It is likely that in the presence of one or an accumulation of more predisposing factors, the repeated functional or parafunctional occlusal loads may eventually lead, over months or even years, to the development of a VRF. Predisposing factors may include natural ones, such as the anatomy of the root, or iatrogenic ones, such as the excessive forces during root canal instrumentation, excessive tooth structure removal, or excessive obturation pressure.

Natural Predisposing Factors

Shape of Root Cross Section

One of the common anatomic features shared by teeth that typically develop VRFs is an oval cross section of the root, with

http://dentalebooks.com

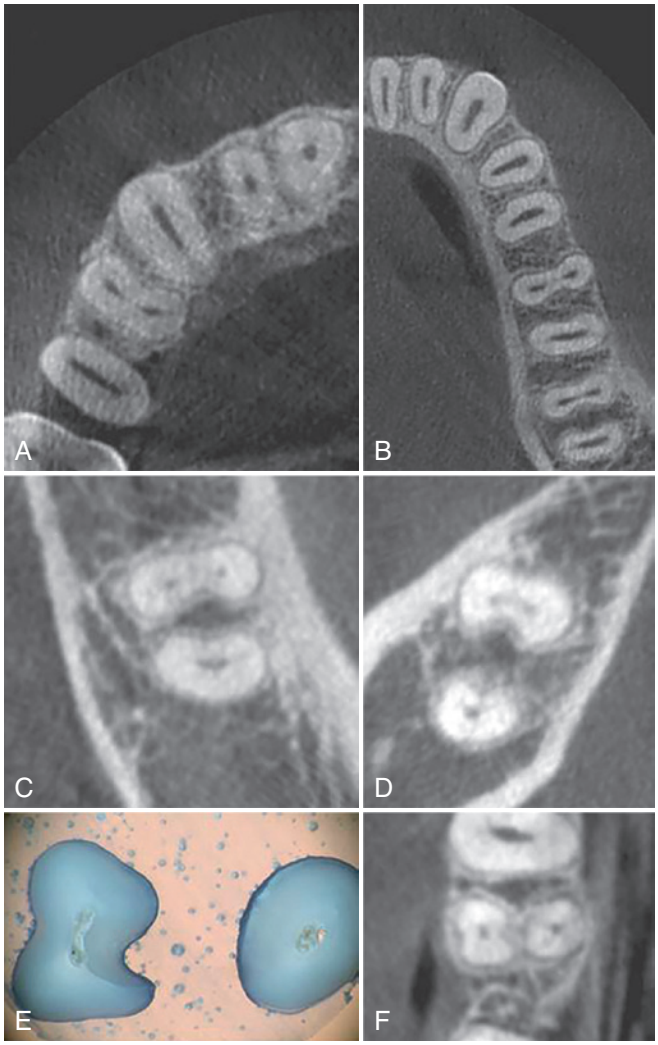

FIG. 21-25 Anatomic predisposing factors. A, An axial view of CBCT scan of a maxilla, revealing oval canals in the maxillary canine and second premolar. **B,** An axial view of a mandible, revealing oval canals in incisors, canine, premolars, and distal roots of the mandibular molars. Oval anatomy combined with endodontic treatment has been associated with a higher incidence of VRFs. **C, D,** Concavities on the distal aspect of the mesial roots of mandibular molar may establish a "danger zone" in which excessive instrumentation, combined with straightening of the canal, may result in a thinner dentin wall that may allow strain concentration. **E, F,** Concavities in the palatal side of the buccal root of maxillary first premolar (*E,* sections; *F,* axial view from a CBCT). These depressions may also represent a potential danger zone. Neither the concavity in **C** and **D** nor the concavity in **E** and **F** would be evident in a planar periapical radiograph. It should be noted that CBCT scans should not be used for routine screening but should be limited to the indications delineated in the joint statement of the American Association of Endodontists (AAE) and the American Academy of Oral and Maxillofacial Radiology (AAOMR).[5,6]

a buccolingual diameter being larger than the mesiodistal diameter.[36,40] These teeth include the maxillary and mandibular premolars, the mesial roots of the mandibular molars, and the mandibular incisors (Fig. 21-25, *A* and *B*). Such anatomy is easily observed in the axial plane of a CBCT scan (see Fig. 21-25, *A* and *B*). The fracture in these teeth typically starts in the buccolingual plane, specifically at the highest convexity of the oval root[21,80] (see Fig 21-25, *A* and *B*). This conclusion,

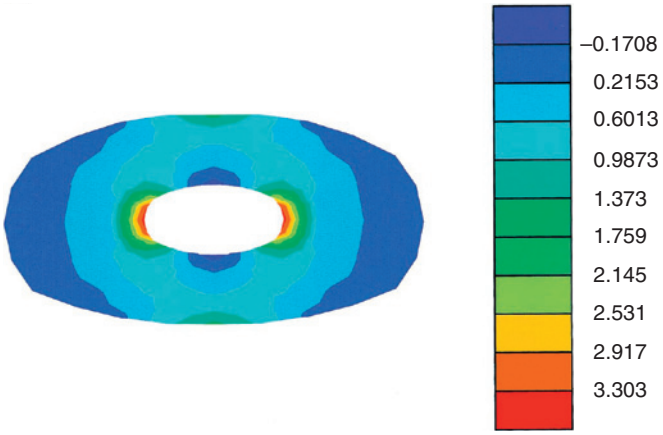

FIG. 21-26 Finite element analysis of the strain distribution in an oval root. Note the strain concentration on the inner side of the highest convexity of the remaining dentin wall. Red and orange represent areas of higher strains than blue areas. (From Lertchirakarn V, Palamara J, Messer HH: Patterns of vertical fractures: factors affecting stress distribution in the root canal, *J Endod* 29:523, 2003.)

derived from large case series, is also supported by finite element analysis.[64] Such analysis clearly demonstrated strain concentration on the inner side of the remaining dentin wall at the highest convexity point (i.e., the buccal and lingual sides of the oval roots)[54,55] (Fig. 21-26).

Occlusal Factors

Excessive occlusal loads or concentration of such loads may be another natural predisposing factor. Load concentrations, such as those caused by occlusal prematurities in maxillary premolars, and excessive occlusal forces, specifically in the case of mandibular second molars, are examples.[18] In combination with other natural and iatrogenic predisposing factors, excessive occlusal loads may, over time, lead to VRFs.

Preexisting Microcracks

Preexisting microcracks may be present in the radicular dentin, likely resulting from repeated forces of mastication or occlusal parafunction.[15,63] Such fractures were also recently reported by Barreto and colleagues,[10] who have found these microcracks in 40% of intact maxillary incisors and canines.

Iatrogenic Predisposing Factors

Root Canal Treatment

VRFs mostly appear in endodontically treated teeth[5,80]; therefore, endodontic treatment per se may be considered an iatrogenic predisposing factor. Teeth were once thought to be more susceptible to fracturing after endodontic treatment because of a decrease in hydration.[43] However, later studies found no difference in the properties of dentin, as a material, after endodontic procedures.[46,75]

Although the physical characteristics of the dentin, as a material, may not be compromised by endodontic treatment, the radicular dentin, as a structure, may be compromised by the accumulative or combined effect of several natural or iatrogenic factors associated with the endodontic treatment and the restoration of endodontically treated teeth. This may be the reason for the often-reported association of VRF with endodontically treated teeth.

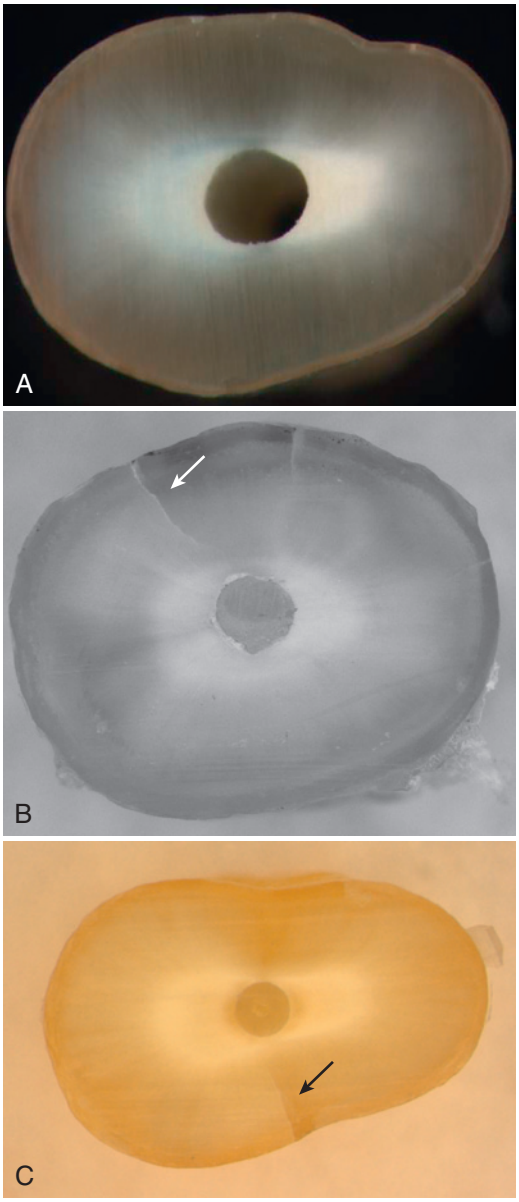

FIG. 21-28 Microcracks generated in single-root teeth by rotary nickel-titanium files. A, Control: hand instrumentation, generating no microcracks. **B, C,** Rotary instrumentation: microcracks generated in the remaining radicular dentin *(arrows).* (Courtesy Dr. H. Shemesh, Amsterdam, Holland.)

It is incumbent for the clinician to recognize this effect and take efforts to minimize any steps that may contribute to the development of a root fracture during endodontic treatment.

Excessive Root Canal Preparation

Excessive root canal preparation may be a predisposing factor for VRF development.[89] In one study, cracks detected by transillumination were more frequent when the same teeth were subjected to a gradually increasing endodontic canal preparation.[89] To reduce the risk of VRFs, less invasive methods may be considered, such as minimally invasive endodontic instrumentation[60,66] (Fig. 21-27; see also Chapter 6).

Microcracks Caused by Rotary Instrumentation

Shemesh and colleagues[76] and others[2,10,14,17,44,77,91] observed that root canal preparation using nickel-titanium rotary and reciprocating files often results in microcracks in the remaining radicular dentin (Fig. 21-28). This finding, which was originally noted for single-root teeth, has been further supported by Yoldas and coworkers,[91] who studied microcrack formation from rotary files in the mesial roots of mandibular molars. Each of the rotary file systems examined in this study caused frequent microcracks in the dentin, whereas both hand instrumentation with files and the self-adjusting file (see Chapter 6) did not cause such cracks (Fig. 21-29).

A finite element analysis by Kim and colleagues[50] supports and may explain these findings. These researchers reported that rotary files induce strain on the dentin, as measured in the surface layers of the root dentin, which likely exceeds the elasticity of the dentin, causing subsequent microcracks, as also reported by Shemesh, Bier, Adorno, Yoldas, and Bürklein, along with their research associates as well as by others.[2,10,14,17,44,76,77,91] Additional stress, by either root obturation with lateral compaction[10,76] or by retreatment[77] that was applied to roots that were previously instrumented with rotary files, caused some of the microcracks to propagate and become

http://dentalebooks.com

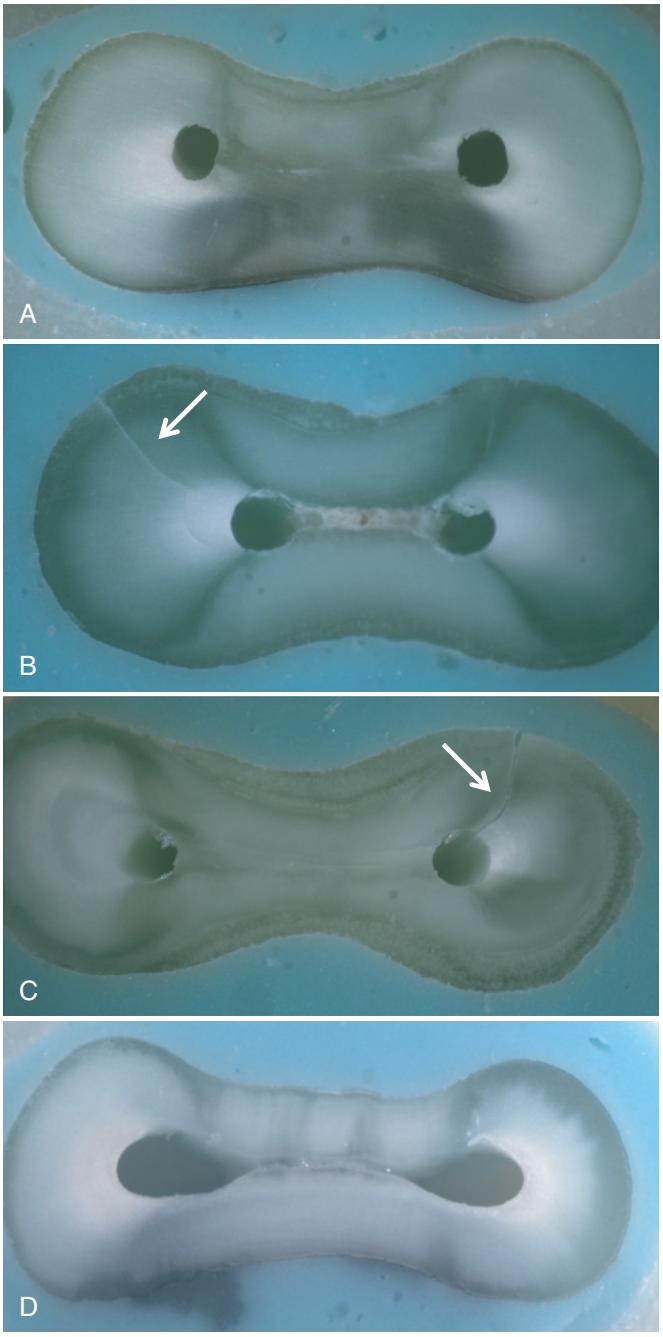

FIG. 21-29 **Microcracks generated in mesial roots of mandibular molars by rotary nickel-titanium files. A,** Control: hand instrumentation, generating no microcracks. Rotary instrumentation: microcracks generated in the remaining radicular dentin *(arrows).* **B,** A partial-thickness crack. **C,** A full-thickness fracture. **D,** Self-adjusting file instrumentation: no microcracks generated. (From Yoldas O, Yilmaz S, Atakan G, et al: Dentinal microcrack formation during root canal preparation by different NiTi rotary instruments and the self-adjusting file, *J Endod* 38:232, 2012.)

through-and-through fractures that were indistinguishable from VRFs.[10,76,77]

The relationship of these various findings to the subsequent clinical creation of a VRF has yet to be confirmed. In any event, considering the basic principles of fracture mechanics, the creation of microcracks should at least be considered as a potential predisposing factor.

Uneven Thickness of Remaining Dentin

The instrumentation of root canals often results in uneven thickness of the remaining dentin, particularly when curved canals are straightened by instrumentation.[67] Uneven dentin thickness can also occur upon excessive instrumentation of the mesial roots of the mandibular molars or first maxillary premolars, which may exhibit a distal or mesial concavity, respectively, that is not detectable in a common planar, periapical radiograph (Fig. 21-25, *C* and *D*). These areas, which have been referred to as "danger zones,"[30] may be characterized by a decrease in the remaining dentin thickness in which the application of internal strain may potentially lead to a fracture. The anatomic groove that is often found on the palatal side of the buccal root of maxillary bifurcated premolars is another example of such a hidden danger zone[48] (Fig. 21-25, *E* and *F*).

Lingual access, which is commonly used in incisors, may also result in a thinner buccal wall in the apical area as compared with the lingual wall. This phenomenon may be especially pronounced when thick, and thus rigid, instruments are used excessively. When lateral compaction was applied ex vivo in a similar case, the strain concentration was recorded on the thinner buccal side of the apical part of the tooth (Figs. 21-30 and 21-31).

The use of flexible nickel-titanium files and minimally invasive instrumentation with instruments such as the self-adjusting file may reduce such risks (see also Fig. 21-27 and Chapter 6).

Methods of Obturation

Certain obturation techniques, such as lateral compaction, involve the application of internal pressure with a spreader, which may cause strains[27,73] and subsequent propagation of microcracks into fractures across the full dentin thickness.[10,76] Other obturation methods may create less pressure, such as thermoplasticized gutta-percha, and may reduce the risk of VRFs (see Chapter 7).

Type of Spreader Used

The use of a more rigid and thick stainless-steel hand spreader may lead to increased strain in the radicular dentin and can result in an increased incidence of root fracture.[27,73] The introduction of more flexible finger spreaders, which have smaller diameter, may greatly reduce such risks.[27] Among the finger spreaders, devices composed of nickel-titanium allow insertion with less force than stainless-steel finger spreaders.[74] The nickel-titanium spreaders also allow a further reduction in the strain induced in the radicular dentin during obturation compared to traditional stainless-steel finger spreaders[68] (Fig. 21-32).

Post Design

Post selection, design, and seating have a significant effect on the strain distribution in the root. Excessively long or thick posts are considered a predisposing factor for VRFs.[23,25,61] The use of posts carries an inherent risk of root fracture, particularly if excessive sound dentin is removed during preparation. Posts should only be used when essential for core retention and should be avoided whenever a sufficient coronal tooth structure is available for the secure retention of the crown.[4,37]

Crown Design

When considering endodontically treated teeth, crowns with a ferrule margin (i.e., supported by a sound tooth structure all

PhD thesis, Tel Aviv University, 2007, supervised by Zvi Metzger and T. Brosh.)

http://dentalebooks.com

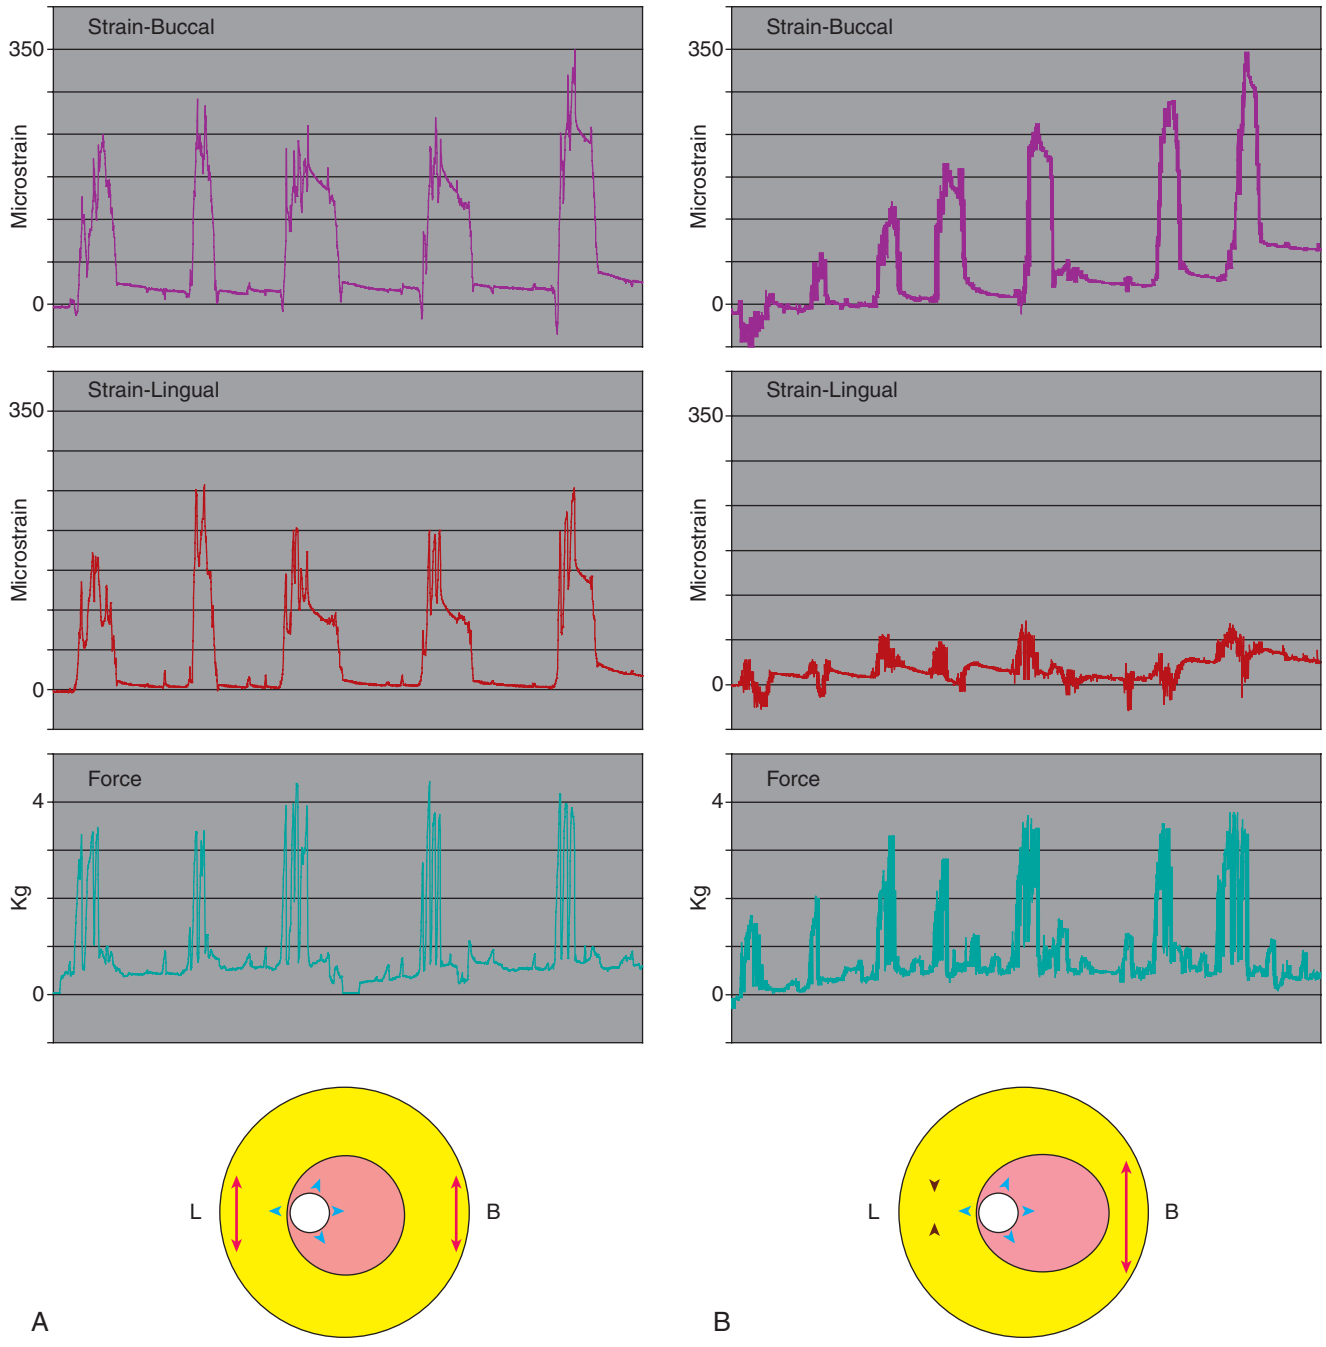

FIG. 21-31 Strain during lateral compaction: even versus uneven wall thickness. A pattern of the strain that develops in the buccal and lingual dentin of the apical area of a maxillary central incisor during lateral compaction. **A,** The thicknesses of the remaining buccal and lingual dentin were similar (even). Each manual insertion of the spreader was registered as a force peak. The tension strain was recorded for each insertion and was *similar* on the buccal and lingual sides. **B,** The thickness of the remaining dentin was lower on the buccal side than on the lingual side (uneven) due to the lingual access and rigidity of the instruments used. Each manual insertion of the spreader was registered as a force peak. The tension strain was recorded for each insertion on the buccal side, whereas compression was recorded on the lingual side. (From Pilo R: Development of strains and mechanical failure in dental roots undergoing root canal obturation and prosthetic rehabilitation. PhD thesis, Tel Aviv University, 2007, supervised by Zvi Metzger and T. Brosh.)

http://dentalebooks.com

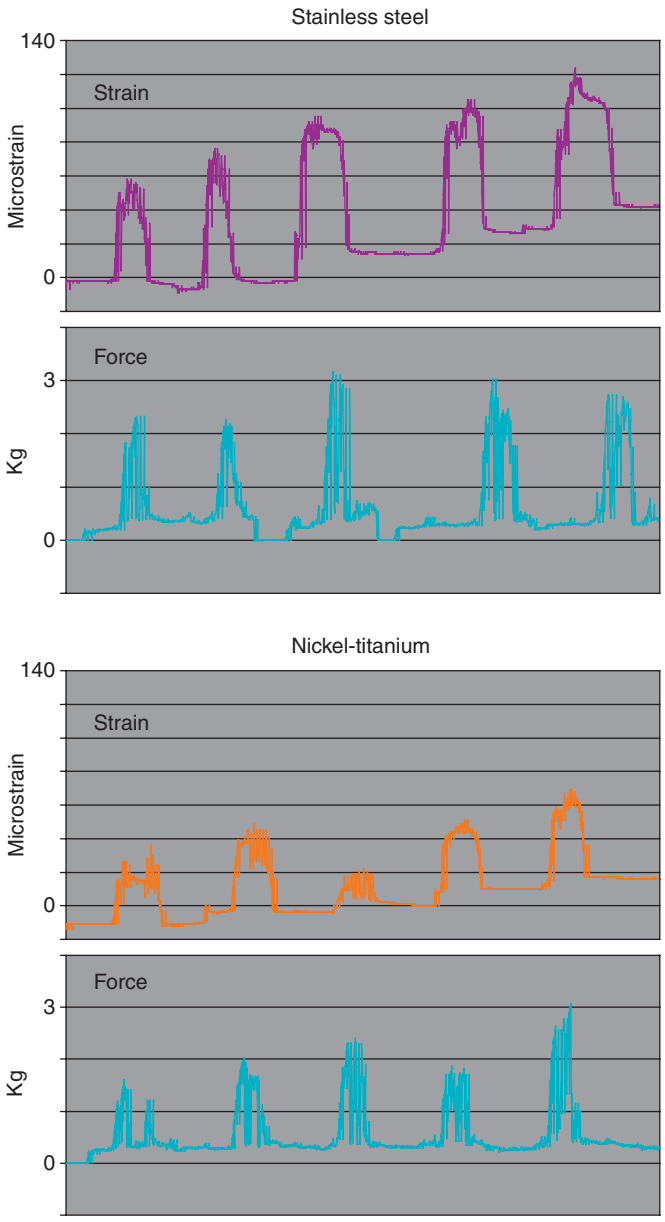

FIG. 21-32 Strain caused by stainless-steel versus nickel-titanium finger spreaders. The force applied to the finger spreader during lateral compaction caused strain on the buccal side of the apical part of the maxillary central incisors. Upper panels: the force and strain registered with a stainless-steel finger spreader. Lower panels: the root filling was removed, and another cycle of lateral compaction was completed for the same tooth using a nickel-titanium finger spreader. The spreader dimensions and depth of insertion were similar in both cycles. The nickel-titanium finger spreader required less force and generated lower strains than the stainless-steel finger spreader. (From Pilo R: Development of strains and mechanical failure in dental roots undergoing root canal obturation and prosthetic rehabilitation. PhD thesis, Tel Aviv University, 2007, supervised by Zvi Metzger and T. Brosh.)

around and beyond the gingival margins of the core) provide better strain distribution than similar restorations that are supported by the post and core alone.[4] This design may help to avoid yet another potential predisposing factor for VRFs.[26]

Conclusions

In conclusion, even though endodontic treatment may be necessary in many occasions, the impact of each of the iatrogenic predisposing factors should be minimized as much as possible, as they are likely to have a cumulative deleterious effect.

TREATMENT PLANNING

Prevention is the key to managing vertical root fractures. There are many predisposing factors and iatrogenic causes of these fractures, all of which should be minimized as much as clinically possible. VRFs may be present in teeth subjected to retreatment but are rarely present also in teeth that have never undergone endodontic treatment.[22] Therefore, comprehensive clinical, radiographic, and *periodontal examination* is imperative when evaluating any tooth that is planned for endodontic treatment or retreatment. A flexible periodontal probe is mandatory in such examinations.

When a VRF is determined to be present, extraction of the affected tooth or root is recommended as soon as possible. Any delay may increase the potential for additional periradicular bone loss and possibly compromise the placement of an endosseous implant. Thus the measures and means that may allow the dentist to make the diagnosis at early stages are important. Attempts to "repair" a fracture by filling the crevice with a variety of restorative materials have been reported; however, none of these repairs is considered a reliable long-term solution.[8,49,53,84]

SUMMARY

Because of the wide variety of different types of cracks and fractures in teeth, there may be a myriad of symptoms and presentations that may appear at different stages of the crack or fracture development, making their diagnosis often difficult. The awareness that many of these symptoms represent *stages in an evolving process* may make their interpretation easier for the operator.

The extensiveness of a crack may directly alter the prognosis assessment and treatment plan for a given tooth; the presence of a fracture may lead to the demise of a tooth and may compromise the periradicular bone. Therefore, developing a diagnosis, prognosis assessment, and treatment plan for teeth with suspected cracks and fractures is essential, with an emphasis on early detection. In addition, endodontic and restorative procedures should focus on minimizing any offending and predisposing factors that may perpetuate cracks and fractures.

Summary

SPECIAL FEATURES OF ENDODONTICALLY TREATED TEETH

Once endodontic therapy is completed, the tooth must be adequately restored. Indeed, given the large impact that poor or missing restorations have on the survival of endodontically treated teeth, one could make the argument that the restoration is actually the last step of endodontic therapy. However, it is important to realize that endodontically treated teeth are structurally different from nontreated vital teeth. Major changes following treatment include altered tissue physical characteristics, loss of tooth structure, and possibly discoloration. Research has analyzed these tissue modifications at different levels, including tooth composition, dentin microstructure, and tooth macrostructure. These studies indicate that it is critical to understand the implication of such features on tooth biomechanics, as they will largely influence the restorative approach and means (Table 22-1). Additional in vitro studies dealing with the complexity of the nonvital tooth substrate are reported in the literature; ultimately, clinical studies have documented the global effect of these changes on the long-term survival of endodontically treated teeth.

Compositional Changes in Nonvital Teeth and the Influence of Endodontic Therapy

The loss of pulpal vitality is accompanied by a slight change in tooth moisture content. This loss of moisture (9%) is attributed to a change in free water but not in water bonded to the organic and inorganic components.[65,69] This alteration was associated with a slight change in values for the Young modulus and proportional limit.[75] However, no decrease in compressive and tensile strength values was associated with this change in water content.[75] Only one study showed no difference in moisture content between vital and nonvital teeth.[123] No difference in collagen cross-linkage was found between vital and nonvital dentin.[140] Thus, nonvital teeth undergo rather minor changes in physical characteristics.

Sodium hypochlorite and chelators such as ethylenediamine tetra-acetic acid (EDTA), cyclohexane-1,2-diaminetetra-acetic acid (CDTA), ethylene glycol-bis-(β-amino-ethyl ether) N,N,N′,N′-tetra-acetic acid (EGTA), and calcium hydroxide ($Ca[OH]_2$) commonly used for canal irrigation and disinfection interact with root dentin, with either mineral content

TABLE 22-1
Specific Tissue Modifications and Possible Clinical Implications Following Loss of Vitality or Endodontic Treatment

Alteration Level	Specific Changes	Possible Clinical Implication
Composition	Collagen structure Tooth moisture Mineral composition and content	Increased tooth fragility Reduced adhesion to substrate
Dentin structure	Elasticity modulus and behavior Tensile and shear strength Microhardness	Increased tooth fragility
Tooth macrostructure	Resistance to deformation Resistance to fracture Resistance to fatigue	Increased tooth fragility Reduced retention/stability of the prosthesis

(chelators) or organic substrate (sodium hypochlorite).[78,116,119] Chelators mainly deplete calcium by complex formation and also affect noncollagenous proteins (NCPs), leading to dentin erosion and surface softening.[78,82,144] Depending on concentration, duration of exposure, and other factors (see Chapter 6), sodium hypochlorite can demonstrate a proteolytic action by hydrolysis of long peptide chains such as collagen.[68] These alterations are likely to impact dentin and root structure and alter bonding properties of this substrate.

Dentin Structure and Properties in Nonvital and Endodontically Treated Teeth

It is important to know that dentin displays a range of normal variations in its physical properties which must be distinguished from alterations related to loss of vitality or endodontic treatment. For instance, dentin microhardness and elasticity actually vary between peritubular and intertubular dentin and depend on tooth location. Peritubular dentin presents an elasticity modulus of 29.8 GPa, whereas intertubular dentin ranges from 17.7 GPa (close to pulp) to 21.1 GPa (close to the root surface).[70,85,101] Most if not all the decreases in hardness on approaching the pulp can be attributed to changes in hardness of the intertubular dentin.[84,85] Overall dentin elasticity modulus is considered to be in the range of 16.5 to 18.5 Gpa.[15,32,50,86,121,138]

The changes in mineral density due to the variation in the number and diameter of tubules within the tooth may also contribute to variations in the properties of dentin. Not surprisingly, dentin hardness values are inversely related to dentin tubule density.[124] Ultra microindentation measurements also demonstrated significantly higher values for hardness and elasticity modulus when forces were parallel to the tubules rather than perpendicular.[133] Differences in maximum strength and compressive strength were also found to vary according to tubule orientation.[121] The ultimate tensile strength (UTS) of human dentin is lowest when the tensile force is parallel to tubule orientation, showing the influence of dentin microstructure and anisotropy of the tissue.[93] No difference was found in the Young modulus of aged, transparent dentin (also called *sclerotic*) and normal dentin,[19,87,167] but the mineral concentration significantly increases and crystallite size is slightly smaller in transparent dentin, in relation with closure of the tubule lumens. Transparent dentin, unlike normal dentin, exhibits almost no yielding before failure. Its fracture toughness is also lowered by about 20%, whereas the fatigue lifetime is deleteriously affected.[87]

Interestingly, comparisons between vital and nonvital dentin of contralateral teeth demonstrate no or only minor differences in microhardness values after periods ranging up to 10 years after treatment.[94,154] Thus, the literature does not support a widely held belief that attributes particular weakness or brittleness to nonvital dentin. Others have suggested that nonvital teeth in older patients may have greater risk for fracture because the age-related generation of secondary or tertiary dentin would be lost. However, this is not the case because the only impact of age-related tissue changes is the aforementioned reduction in fracture toughness and fatigue lifetime attributed to dentin sclerosis.[87]

The chemicals used for canal irrigation and disinfection, as already mentioned, interact with mineral and organic contents and then reduce dentin elasticity and flexural strength to a significant extent,[64,157] as well as microhardness.[33,77,146] On the contrary, disinfectants like eugenol and formocresol increase dentin tensile strength by way of protein coagulation and chelation with hydroxyapatite (eugenol). Dentin hardness, however, did not prove to be influenced by the latter products.[112]

In conclusion, a possible decrease in tooth strength can be attributed to dentin aging and to a smaller extent to dentin alteration by endodontic irrigants.

Fracture Resistance and Tooth Stiffness of Nonvital and Endodontically Treated Teeth

In contrast to the aforementioned factors, the major changes in tooth biomechanics appear to be due to the loss of hard tissue following decay, fracture, or cavity preparation (including the access cavity prior to endodontic therapy).

The loss of hard tooth structure following a conservative access cavity preparation affects tooth stiffness by only 5%.[91,169] The influence of subsequent canal instrumentation and obturation lead only to a slight reduction in the resistance to fracture[91,169] and ultimately have little effect on tooth biomechanics.[91,137,169] From a clinical perspective, one can expect alteration of tooth biomechanics only in cases of nonconservative canal preparation or through the chemical or structural alteration triggered by endodontic irrigants, as previously mentioned.

In fact, the largest reduction in tooth stiffness results from excessive access preparation, especially the loss of marginal ridges. The literature reports a 20% to 63% and a 14% to 44% reduction in tooth stiffness following occlusal and MOD cavity preparations, respectively.[44,92,137] It was shown that an endodontic access cavity combined with an MOD preparation results in maximum tooth fragilization. The cavity depth, isthmus width, and configuration are therefore highly critical to the reduction in tooth stiffness and risk of fracture (Fig. 22-1).[74,83,96,122] This important point has profound clinical implications.

FIG. 22-1 The negative impact of poor initial biomechanical status on restoration success. **A, B,** Preoperative radiographic views following the removal of the old metallic foundation. **C,** A new amalgam core, using post and self-anchorage into mesial root structure, was performed. **D,** Prosthetic restorations on working model. **E,** Full arch view after 3 years. **F,** The tooth is symptomatic due to furcation involvement and periapical lesion. **G,** This untreatable tooth was finally extracted and replaced by an implant. **H,** Eight-year postoperative radiograph showing a stable situation. Other teeth with less extensive biomechanical damage overcame functional stresses.

The presence of residual hard tissue in the cervical area (which constitutes the *ferrule* for restorations) and a larger amount of residual mineralized tissue in general increase tooth resistance to fracture. It actually allows the axial walls of the crown to encircle the tooth, providing restoration retention and stabilization and reducing cervical tensile stresses.[6,23,161] Crown preparations with as little as 1 mm coronal extension of dentin above the margin double the fracture resistance of preparations, compared to those where the core terminates on a flat surface immediately above the margin[103,161]; therefore, a minimal 1-mm ferrule (and ideally 2 to 3 mm) is considered necessary to stabilize the restoration.[161] However, the widths of preparation shoulder and crown margin do not appear to influence fracture strength.[2] Taken together, the height of the ferrule is one of the most important elements in the long-term survival of restorations. These considerations have led to the conclusion that the most important part of the restored tooth is the tooth itself, and no contemporary restorative material or combination of materials will perfectly substitute for lost tooth structure.

Aesthetic Changes in Nonvital and Endodontically Treated Teeth

Several aesthetic changes may also occur in nonvital or endodontically treated teeth. For example, color change or darkening of nonvital teeth is a common clinical observation (Fig. 22-2). In addition, incomplete endodontic treatment can contribute to discoloration. For instance, inadequate cleaning and shaping can leave necrotic tissue in coronal pulp horns, resulting in tooth darkening. In addition, root canal filling materials (gutta-percha and root canal sealer cements, MTA-like materials) retained in the coronal aspect of anterior teeth can detract from the aesthetic appearance. Opaque substances also adversely affect the color and translucency of most uncrowned teeth. Biochemically altered dentin modifies tooth color and appearance. It is generally accepted that organic substances present in dentin (e.g., hemoglobin) might play an important role in this color change and also food and drink pigment penetration triggered by the absence of pulpal pressure. However, the respective contribution of these two phenomena and precise physicochemical mechanisms leading to discoloration are poorly understood or described in the literature.[34,67,131]

FIG. 22-2 Severe discoloration can significantly disturb aesthetics, even in the lateral area of the smile. When not treatable with bleaching agents or veneers, this condition might justify tooth preparation for a full crown.

Thin gingival tissue or, in general, thin biotype is considered a negative factor for aesthetic outcome of restorative and prosthetic treatment of discolored teeth.[110,111,118]

Endodontic treatment and subsequent restoration of teeth in the aesthetic zone require careful control of procedures and materials to retain a translucent, natural appearance. It is therefore strongly recommended that one avoid the use of potentially staining endodontic cements and clean all material residues left in the pulpal chamber and access cavity.

RESTORATIVE MATERIALS AND OPTIONS

As described previously, endodontic treatment, particularly excessive access preparations, can result in significant loss and weakening of tooth structure. Tooth structure lost during endodontic treatment increases the risk of crown fracture, with fatigue mechanisms mediating the fracture of roots over time. Restorations of endodontically treated teeth are designed to (1) protect the remaining tooth from fracture, (2) prevent reinfection of the root canal system, and (3) replace the missing tooth structure.

According to the amount of tissue to be replaced, restorations of endodontically treated teeth rely on different materials and clinical procedures. As a general rule, most structurally damaged teeth should be restored with an artificial crown.

Although the use of a crown built on post and core is a traditional approach, others have advocated the use of direct composite resins for restoring small defects in endodontically treated teeth. More recently, indirect restorations such as overlays or endocrowns made of composite resins or ceramics have also been used. The selection of appropriate restorative materials and techniques is dictated by the amount of remaining tooth structure. This is far more relevant to the long-term prognosis of endodontically treated teeth than any properties of post, core, or crown materials.

Direct Composite Restorations

When a minimal amount of coronal tooth structure has been lost after endodontic therapy, a direct resin composite restoration may be indicated. Composite resins are a mixture of a polymerized resin network reinforced by inorganic fillers. Contemporary composites have compressive strengths of about 280 MPa, and the Young modulus of composite resins is generally about 10 to 16 GPa, which is close to that of dentin.[134]

When properly cured, resin composites are highly aesthetic, exhibit high mechanical properties, and can reinforce the remaining tooth structure through bonding mechanisms. Typically, 500 to 800 mW/cm^2 of blue light for 30 to 40 seconds is necessary to polymerize an increment of composite that must be 1- to 3-mm thick. Unfortunately, the shrinkage that accompanies polymerization of contemporary composite resins remains a significant problem to the long-term success of these restorations. The use of an incremental filling technique, which helps to reduce shrinkage stresses during polymerization, is highly recommended. The amount of shrinkage will also depend on the shape of the cavity preparation and the ratio of bonded to unbonded (or free) surfaces.[36] This so-called C-factor is a clinically relevant predictor of the risk of debonding and leakage; restorations with high C-factors (> 3.0) are at greatest risk for debonding.[175] In other words, a direct composite

restoration may be indicated when only one proximal surface of the tooth has been lost; using an incremental filling technique is mandatory.

Classically, direct composite restorations have been placed in anterior teeth that have not lost tooth structure beyond the endodontic access preparation. In such cases, the placement of a direct composite restoration offers an immediate sealing of the tooth, which prevents coronal leakage and recontamination of the root canal system with bacteria. In vitro studies have demonstrated that the fracture resistance of small bonded restorations is nearly as great as that of intact teeth.[57,136]

Although direct composite resins may also be used for small restorations in posterior teeth, they are contraindicated when more than a third of coronal tissue has been lost. In one study,[136] it was reported that the resistance to fracture of endodontically treated teeth is reduced by 69% in cases where MOD cavities are present.[137] Under such conditions, a direct composite restoration may not be appropriate to prevent the tooth structure from fracture and reinfection. Furthermore, resin composite materials may require the use of reinforcing in vitro fibers to increase their mechanical resistance. Although most studies on the clinical performance of direct composite restorations were conducted on vital teeth, one clinical report indicates that direct in vitro fiber-reinforced composite restorations may represent a valuable alternative to conventional restorations of endodontically treated teeth.[37] On the contrary, inserting an in vitro fiber post in the root canal of an endodontically treated tooth before bonding a direct MOD restoration significantly reduces its fracture resistance compared to the same composite restoration without a post.[160]

Indirect Restorations: Composite or Ceramic Onlays and Overlays

Ceramic or resin composite onlays and endocrowns can also be used to restore endodontically treated teeth. Whereas overlays incorporate a cusp or cusps by covering the missing tissue, endocrowns combine the post in the canal, the core, and the crown in one component.[88,142] Both onlays and endocrowns allow for conservation of remaining tooth structure, whereas the alternative would be to completely eliminate cusps and perimeter walls for restoration with a full crown.[58] Onlays and overlays are generally constructed in the laboratory from either hybrid resin composite or ceramics.

Ceramics are a material of choice for long-term aesthetic indirect restorations because their translucency and light transmission mimic enamel. Whereas traditional feldspathic porcelains were sintered from a slurry, new ceramic materials may be cast, machined, pressed, or slip-cast, in addition to being sintered. New materials either are variations of feldspathic porcelains (e.g., In-Ceram, Cerec, IPS Empress) or may be fabricated from other ceramic systems, including alumina, zirconia, or silica.[3,38] Among these newer compositions is lithium disilicate, which offers high strength, high fracture toughness, and a high degree of translucency. Physical properties of these materials have improved to the point where they can survive high stress-bearing situations such as posterior restorations in endodontically treated teeth.[46,73] Researchers have examined 140 partial Cerec restorations (Vita MKII, feldspathic porcelain) adhesively cemented to endodontically treated teeth and found this treatment approach satisfactory after an observation period of 55 months.[9] Their results indicate that survival rates are higher for molars than for premolars.

Onlays, overlays, and endocrowns can also be fabricated from resin composites processed in the laboratory. Using various combinations of light, pressure, and vacuum, these fabrication techniques are claimed to increase the conversion rate of the polymer and consequently the mechanical properties of the restorative material. Other investigations have described the application of glass fiber–reinforced composite endocrowns on premolars and molars as single restorations or as abutment for fixed partial dentures.[58,59] One in vitro study by another research team indicates that composite inlays can partially restore the resistance to fracture of endodontically treated molars and prevent catastrophic fractures after loading.[28] Other investigators reported that composite resin MZ100 increased the fatigue resistance of overlay-type restorations in endodontically treated molars when compared to porcelain MKII.[97] Another study used three-dimensional finite element analysis to estimate bone resorption around endocrowns made up of high-(alumina) or low-elastic modulus materials (resin composites). They concluded that the higher resilience of resin composite restorations acts positively against the risk of periodontal bone resorption by reducing the amount of force transferred to root dentin.[4]

Full Crowns

When a significant amount of coronal tooth structure has been lost by caries, restorative procedures, and endodontics, a full crown may be the restoration of choice. In a few cases, the crown can be directly built on the remaining coronal structure, which has been prepared accordingly (see the Core Materials section). More frequently, the cementation of a post inside the root canal is necessary to retain the core material and the crown.[164] The core is anchored to the tooth by extension into the root canal through the post and replaces missing coronal structure. The crown covers the core and restores the aesthetics and function of the tooth.

An additional role of the post and core is to protect the crown margins from deformation under function and thereby to prevent coronal leakage. Because most endodontic sealers do not completely seal the root canal space, the coronal seal provided by the placement of a post and core will positively influence the outcome of the endodontic treatment.[148] The post's ability to anchor the core is also an important factor for successful reconstruction, because the core and the post are usually fabricated of different materials. Finally, the luting material used to cement the post, the core, and the crown to the tooth will also influence the longevity of the restoration. The post, the core, and their luting or bonding agents together form a *foundation restoration* to support the future crown.[106]

The Foundation Restoration: General Considerations

Although many materials and techniques can be used to fabricate a foundation restoration, no combination of materials can substitute for tooth structure. As a general rule, the more tooth structure that remains, the better the long-term prognosis of the restoration. The coronal tooth structure located above the gingival level will help to create a ferrule.[6,100,128] The *ferrule* is formed by the walls and margins of the crown, encasing at least 2 to 3 mm of sound tooth structure. A properly executed ferrule significantly reduces the incidence of fracture in

endodontically treated teeth by reinforcing the tooth at its external surface and dissipating forces that concentrate at the narrowest circumference of the tooth.[95,173] A longer ferrule increases fracture resistance significantly. The ferrule also resists lateral forces from posts and leverage from the crown in function and increases the retention and resistance of the restoration. To be successful, the crown and crown preparation together must meet five requirements:

1. The ferrule (dentin axial wall height) must be at least 2 to 3 mm.
2. The axial walls must be parallel.
3. The restoration must completely encircle the tooth.
4. The margin must be on solid tooth structure.
5. The crown and crown preparation must not invade the attachment apparatus.

Root anatomy can also have significant influence over post placement and selection. Root curvature, furcations, developmental depressions, and root concavities observed at the external surface of the root are all likely to be reproduced inside the root canal (see also Chapter 5). Within the same root, the shape of the canal will vary between the cervical level and the apical foramen.[62] As a result, severe alteration of the natural shape of the canal is often necessary to adapt a circular post inside the root. This increases the risk of root perforation, especially in mesial roots of maxillary and mandibular molars that exhibit deep concavities on the furcal surface of their mesial root.[16,89] The tooth is also weakened if root dentin is sacrificed to place a larger-diameter post. A study using three-dimensional electronic speckle-pattern interferometry (ESPI) evaluated the effects of root canal preparation and post placement on the rigidity of human roots.[93] ESPI has the major advantage of being able to assess tooth deformation in real time and can be used repeatedly on the same root because of the nondestructive nature of the test. Study results indicate that root deformability increases significantly after the preparation of a post space. Thus, preservation of root structure is also a guiding principle in the decision to use a post, the selection of the post, and the preparation of the post space. This is a reason why not every endodontically treated tooth needs a post and why more conservative approaches that do not rely on the use of a post are currently being developed. However, a post may be used in the root of a structurally damaged tooth in which additional retention is needed for the core and coronal restoration. Posts should provide as many of the following clinical features as possible:

- Maximal protection of the root from fracture
- Maximal retention within the root and retrievability
- Maximal retention of the core and crown
- Maximal protection of the crown margin seal from coronal leakage
- Pleasing aesthetics, when indicated
- High radiographic visibility
- Biocompatibility

From a mechanical point of view, an endodontic post should not break, should not break the root, and should not distort or allow movement of the core and crown. An ideal post would have an optimal combination of resilience, stiffness, flexibility, and strength. *Resilience* is the ability to deflect elastically under force without permanent damage. It is a valuable quality in endodontic posts, but too much flexibility in a narrow post compromises its ability to retain the core and crown under functional forces. *Stiffness* describes a material's ability to resist deformation when stressed. The stiffness of a material is an inherent physical property of that material, regardless of size. However, the actual flexibility of a post depends both on the diameter of a specific post and on the modulus of elasticity of the post's material. Posts with a lower modulus of elasticity are more flexible than posts of the same diameter with a higher modulus of elasticity. Posts made of nonstiff materials (low modulus of elasticity) are more resilient, absorb more impact force, and transmit less force to the root than stiff posts, but low-modulus posts fail at lower levels of force than do high-modulus posts.[99,120,143]

Excessive flexing of the post and micromovement of the core are particular risks in teeth with minimal remaining tooth structure, because these teeth lack their own cervical stiffness as a result of the missing dentin. Post flexion can also distort and open crown margins. Open margins can result in potentially devastating caries or endodontic leakage and apical reinfection. Extensive caries extending into the root can be as irreparable as root fracture. Because rigid posts flex and bend less than nonrigid posts, they can limit movement of the core and possible disruption of the crown margins and cement seal. However, the force must go somewhere. Force from a stiff post is transmitted to the root, next to the apex of the post. An attempt to strengthen a weak root by adding a stiff post can instead make the root weaker as a result of the force concentration of a stiff rod in a more flexible material. Stress concentration in the post/root complex can lead to the self-destructive process of cracking and fracturing. Root fracture is particularly a risk in teeth with minimal remaining tooth structure to support a ferrule.

Roots also flex under force, which is a function of both the modulus of elasticity of dentin and the diameter of the root. Dentin is relatively flexible, and posts can be flexible or stiff. Although no material can behave exactly like dentin, a post with functional behavior similar to that of dentin is beneficial when the post must be placed next to dentin. Posts have been developed with a modulus of elasticity closer to dentin than that offered by traditional metal posts. But posts are significantly narrower than roots, and the actual deflection of a post within dentin is a function of both the modulus of elasticity and the diameter. The modulus of elasticity of various posts, compared with that of dentin, represents only one aspect of flexion.

In summary, an ideal post would be resilient enough to cushion an impact by stretching elastically, thereby reducing the resulting stress to the root. It would then return to normal without permanent distortion. At the same time, this ideal post would be stiff enough not to distort, permanently bend, or structurally fail under mastication forces. Finally, the perfect post would combine the ideal level of flexibility and strength in a narrow-diameter structure, which is dictated by root canal morphology. Current post systems are designed to provide the best compromise between the desired properties and inherent limitations of available materials.

Why Roots Fracture

Structures subjected to low but repeated forces can appear to fracture suddenly for no apparent reason. This phenomenon, also known as *fatigue failure,* occurs when a material or a tissue is subjected to cyclic loading. Fatigue may be characterized as a progressive failure phenomenon that proceeds by the initiation and propagation of cracks; many failures of teeth or

materials observed in the mouth are fatigue-related. Because teeth are subjected to fluctuating cycles of loading and unloading during mastication, fatigue failure of dentin, posts, cores, crown margins, or adhesive components is likely to occur.[153] Mechanical loading will favor the propagation of microcracks that will progress from the coronal to the apical region of the tooth.

Initial failure of crown margins from fatigue loading is clinically undetectable. However, when measured in vitro, early failure resulted in significant leakage of crown margins, extending between the tooth, restoration, and post space. Particularly in teeth with minimal remaining tooth structure, fatigue can cause endodontic posts to bend permanently or break, or it can cause a fiber-matrix complex to disintegrate.

Fatigue failure of nonvital teeth restored with a post is more catastrophic because it may result in a complete fracture of the root. A post placed into a dentin root will function physically like any structural rod anchored in another material. This means that the forces applied on the post are transmitted to the root dentin with characteristic patterns depending on the modulus of elasticity of both the post and the dentin. If the post has a higher modulus than the dentin, the stress concentration is adjacent to the bottom of the post (Fig. 22-3). This is evident in clinical cases of root fracture originating at the apex of a rigid post.

When the stiffness of the endodontic post is similar to that of dentin, stresses are not concentrated in the dentin adjacent to the apex of the post but rather are dissipated by both the coronal and the root dentin (see Fig. 22-3). A resilient post can also prevent a sudden blow by stretching elastically, which reduces the transient forces against the tooth, but a post that is too elastic becomes too flexible for retaining a core and a crown when the tooth cannot do so on its own. A resilient post that is overloaded fails with less force than a stiffer post. This limits the amount of resilience that can be designed into a post.

Direct Foundation Restorations

In general, the evolution of foundation restorations has been to diminish invasiveness and eliminate some components in selected cases. When a sufficient amount of tissue is present at the periphery of the prepared tooth, a direct foundation restoration is indicated. In the direct technique, a prefabricated post is cemented inside the root canal, and the core is built directly on the prepared tooth. For other clinical situations, an indirect custom-cast post and core may be indicated.

Various materials can be used to fabricate a direct foundation restoration. Although there is growing interest in using resin-based materials such as resin composites or fiber-reinforced resin posts, more traditional materials such as amalgam are still used for that purpose.[27] For clarity, the components used for fabricating a direct foundation restoration (e.g., the endodontic post and core material) are described individually.

Posts

The large number of post designs and materials available on the market reflects the absence of consensus in that field. Based on what manufacturers or clinicians consider the most important properties, posts can be fabricated from metal (gold, titanium, stainless steel), ceramic, or fiber-reinforced resins. As a general rule, a post needs retention and resistance. Whereas *post retention* refers to the ability of a post to resist vertical

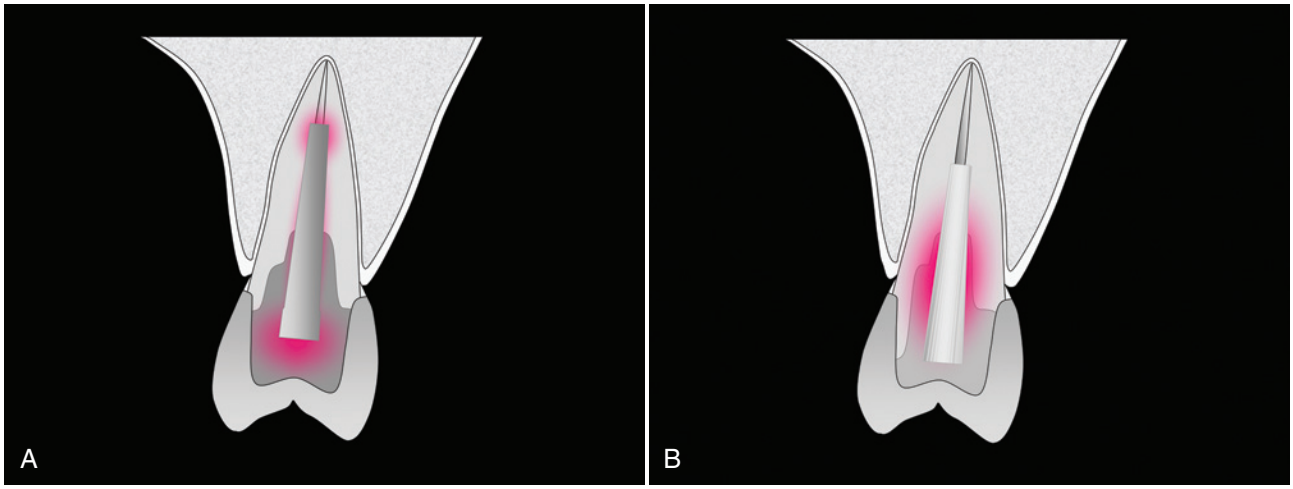

FIG. 22-3 **A,** Stress distribution within a metallic post and core foundation and residual tooth structure, according to photoelastic and FEM studies. The post is cemented and usually penetrates the apical portion of the root. Functional stresses accumulate inside the foundation, slightly around the post and further inside the canal, around the apex of the post; there is less stress buildup in the cervical area compared to that with a fiber post (as shown in Fig. 22-3, *B*). This configuration more ideally protects the coronocervical structures, but when failing, it results in severe untreatable root fractures. **B,** Stress distribution within a fiber post/composite foundation and residual tooth structure, according to photoelastic and FEM studies. The post is bonded to the canal walls and penetrates the canal less apically. Functional stresses mainly accumulate around the post in the cervical area. This configuration protects the cervical area less efficiently but tends to prevent untreatable root fractures. The presence of a ferrule is mandatory. (Adapted from Dietschi D, Duc O, Krejci I, Sadan A: Biomechanical considerations for the restoration of endodontically treated teeth: a systematic review of the literature—Part 1. Composition and micro- and macrostructure alterations, *Quintessence Int* 38:733, 2007.)

forces, *resistance* refers to the ability of the tooth/post combination to withstand lateral and rotational forces. Resistance is influenced by the presence of a ferrule, the post's length and rigidity, and the presence of antirotational features. A restoration lacking resistance form is not likely to be a long-term success, regardless of the retentiveness of the post.

Prefabricated Metallic Posts

Prefabricated metallic posts are frequently used for the fabrication of a direct foundation restoration. These posts are classified several ways, including by alloy composition, retention mode, and shape. Materials used to fabricate metallic posts include gold alloys, stainless steel, or titanium alloys. Metallic posts are very strong and, with the exception of the titanium alloys, very rigid.[90] One study indicates that the flexural strength of stainless steel posts is about 1430 MPa and that flexural modulus approximates 110 GPa.[130] On the other hand, titanium posts are less rigid (66 GPa) but exhibit a flexural strength (1280 MPa) similar to stainless steel.

The retention of prefabricated posts inside the root canal is also essential for successful restorations. Two basic concepts have been used to promote the retention of endodontic posts: active posts and passive posts. Active posts derive their primary retention directly from the root dentin by the use of threads. Most active posts are threaded and are intended to be screwed into the walls of the root canal. A major concern about threaded posts has been the potential for vertical root fracture during placement. As the post is screwed into place, it introduces great stresses within the root, causing a wedging effect.[163] Therefore, it is generally accepted that *the use of threaded posts should be avoided.* Furthermore, the improved retention once offered by threaded posts can now be achieved with adhesive luting cements (discussed later).[117] Passive posts are passively placed in close contact to the dentin walls, and their retention primarily relies on the luting cement used for cementation. The shape of a passive post may be either tapered or parallel.[139] A parallel post is more retentive than a tapered post but also requires removal of more root dentin during the preparation of the post space. Parallel posts are reported to be less likely to cause root fractures than tapered posts, although they are less conforming to the original shape of the root.[79,152,161] Unfortunately, modern techniques for root canal preparation use tapered nickel-titanium (NiTi) rotary shaping files, which result in a very wide tapered and unretentive canal exhibiting a significant divergence from apical to coronal.[145] Longer posts are often necessary to accommodate this problem and offer adequate retention; adequate length in the root canal is considered to be greater than 6 mm. When teeth are protected by crowns with an adequate ferrule, longer posts do not further increase fracture resistance.[80] Posts designed with mechanical locking features in the heads and roughened surface texture can show better retention of the core.[29]

Fiber Posts

A fiber post consists of reinforcing fibers embedded in a resin-polymerized matrix. Monomers used to form the resin matrix are typically bifunctional methacrylates (Bis-GMA, UDMA, TEGDMA), but epoxies have also been used. Common fibers in today's fiber posts are made of carbon, glass, silica, or quartz but the type, volume content, and uniformity of the fibers and the matrix are proprietary and vary among fiber post systems. These differences in the manufacturing process may reflect the large variations observed among different types of fiber posts subjected to a fatigue-resistance test.[63] Fibers are commonly 7 to 20 μm in diameter and are used in a number of configurations, including braided, woven, and longitudinal. The original fiber posts consisted of carbon fibers embedded in epoxy resin, but quartz-fiber posts are currently preferred for their favorable mechanical properties, aesthetic qualities, and ability to chemically bond to the polymer matrix.[49] One study indicates that the flexural strength of glass-, silica-, or quartz-fiber posts approximates 1000 MPa and that flexural modulus is about 23 GPa.[35] Current fiber posts are radiopaque and may also conduct the light for polymerization of resin-based luting cements. A light-transmitting post results in better polymerization of resin composites in the apical area of simulated root canals, as measured by hardness values.[141,174] To enhance bonding at the post/core/cement interfaces, several physicochemical pretreatments such as silanization or sand blasting of the post surface have been described. Research indicates that silanization, hydrofluoric etching, and sandblasting (with 30 to 50 μm Al_2O_3) do not modify the mechanical properties of different glass-, silica-, or quartz-fiber posts.[5]

It is generally accepted that bonding fiber posts to root canal dentin can improve the distribution of forces applied along the root, thereby decreasing the risk of root fracture and contributing to the reinforcement of the remaining tooth structure.[12,18] A well-adapted adhesively cemented fiber post is considered the most retentive with the least stress generated on the canal walls. In a retrospective study that evaluated three types of bonded fiber posts, investigators reported a 3.2% failure of 1306 fiber posts in recalls of 1 to 6 years.[54] More recently, another study reported survival rates of 98.6% and 96.8% for parallel-sided and tapered fiber posts, respectively, placed in anterior teeth covered with full-ceramic crowns after a mean observation period of 5.3 years.[156]

Zirconia posts are composed of zirconium dioxide (ZrO_2) partially stabilized with yttrium oxide and exhibit a high flexural strength. Zirconia posts are aesthetic, partially adhesive, rigid, but also brittle. Zirconia posts cannot be etched, and available literature suggests that bonding resins to these materials is less predictable and requires substantially different bonding methods than conventional ceramics.[11] When a composite core is built on a zirconia post, core retention may also be a problem. Controversies exist about the efficiency of airborne particle abrasion at establishing a durable resin bond to zirconia posts treated or not treated with a coupling agent.[1,127] Overall, there are concerns about the rigidity of zirconia posts, which tends to make those posts too brittle. Other reports indicate that the rigidity of zirconia posts negatively affects the quality of the interface between the resin core material and dentin when subjected to fatigue testing.[40,43]

Core Materials

The core replaces carious, fractured, or missing coronal structure and helps to retain the final restoration. Desirable physical characteristics of a core include (1) high compressive and flexural strength, (2) dimensional stability, (3) ease of manipulation, (4) short setting time, and (5) the ability to bond to both tooth and post. Core materials include composite resin, cast metal or ceramic, amalgam, and sometimes glass-ionomer materials. The core is anchored to the tooth by extension into the coronal aspect of the canal or through the endodontic post. The importance of retention between the

post, the core, and the tooth increases as remaining tooth structure decreases.

Composite Resin Core

Composite core materials take a number of strategies to enhance their strength and resistance; metal may be added, filler levels may be greater, or faster-setting ionomers may be used.[134] Composite core materials have been shown to exhibit slightly better mechanical values than conventional materials, but improvements are negligible.[176] However, they appear to be superior to silver-glass-ionomer cement and amalgam.[30] The advantages of composite core resins are adhesive bonding to tooth structure and many posts, ease of manipulation, rapid setting, and translucent or highly opaque formulations. Composite cores have been shown to protect the strength of all-ceramic crowns equally to amalgam cores. Bond strength of composite cores to dentin depends on a complete curing of the resin materials, so dentin bonding agents must be chemically compatible with composite core materials. Self-cure composite resins require self-cure adhesives and are mostly incompatible with light-cure adhesives.[26] However, no adhesive has been shown to completely eliminate microleakage at the margins of the restoration.[17] A degradation of the resin core or the marginal integrity of the crown can result in invasion of oral fluids. Therefore, as with all buildup materials for decimated teeth, more than 2 mm of sound tooth structure should remain at the margin for optimal composite resin core function.

Composite core materials can be used in association with metallic, fiber, or zirconia posts. This is frequently observed in the presence of structurally compromised teeth. They may provide some protection from root fracture in teeth restored with metal posts compared with amalgam or gold cores. Loosening of the post, core, and crown with composite core can occur, but composite cores have been shown to fail more favorably than amalgam or gold.[129] A retrospective study of the clinical performance of fiber posts indicates that fiber posts and cores have a failure rate ranging between 7% and 11% after a service period of 7 to 11 years and that post loosening may also occur.[53] Composite core materials are typically two-paste, self-cured composites, but light-curing materials are also available. The use of light-curing composite core materials generally eliminates the risk of chemical incompatibility between adhesives and self-curing resin core materials. Bonding light-cured resin composites to the irregular structure of the pulp chamber and canal orifices might eliminate the need for a post when sufficient tooth structure remains. Research indicates that bonding to the dentin walls of the pulp chamber is easier and superior to resin dentin bonds made on dentin canal walls.[7]

Amalgam Core

Dental amalgam is a traditional core buildup material with a long history of clinical success. Although there are many variations in the alloy's composition, more recent formulations have high compressive strength (400 MPa after 24 hours), high tensile strength, and a high modulus of elasticity. High-copper alloys tend to be stiffer (60 GPa) than low-copper alloys.

Amalgam can be used with or without a post. In the 1980s, investigators described the amalcore.[113] With the amalcore technique, amalgam is compacted into the pulp chamber and 2 to 3 mm coronally of each canal. The following criteria were considered for the application of this technique: the remaining pulp chamber should be of sufficient width and depth to provide adequate bulk and retention of the amalgam restoration, and an adequate dentin thickness around the pulp chamber was required for the tooth-restoration continuum rigidity and strength. The fracture resistance of the amalgam coronal-radicular restoration with four or more millimeters of chamber wall was shown to be adequate, although the extension into the root canal space had little influence.[81]

Amalgam can also be used in combination with a prefabricated metallic post when the retention offered by the remaining coronal tissue needs to be increased. Amalgam cores are highly retentive when used with a preformed metal post in posterior teeth; they require more force to dislodge than cast posts and cores.[102] Others have suggested the use of adhesive resins to bond amalgam to coronal tissue.[155]

Significant disadvantages of amalgam cores are the "nonadhesive nature" of the material, the potential for corrosion, and subsequent discoloration of the gingiva or dentin. Amalgam use is declining worldwide because of legislative, safety, and environmental issues.

Glass Ionomer Core and Modified Glass Ionomer Core

Glass ionomer and resin-modified glass ionomer cements are adhesive materials useful for small buildups or to fill undercuts in prepared teeth. The rationale for using glass ionomer materials is based on their cariostatic effect resulting from fluoride release. However, their low strength and fracture toughness result in brittleness, which contraindicates the use of glass-ionomer buildups in thin anterior teeth or to replace unsupported cusps. They may be indicated in posterior teeth in which (1) a bulk of core material is possible, (2) significant sound dentin remains, and (3) caries control is indicated.[172]

Resin-modified glass ionomer materials are a combination of glass ionomer and composite resin technologies and have properties of both materials. Resin-modified glass ionomers have moderate strength, greater than glass ionomers but less than composite resins. As a core material, they are adequate for moderate-sized buildups, but hygroscopic expansion can cause fracture of ceramic crowns and fragilized roots.[158] The bond to dentin is close to that of dentin-bonded composite resin and significantly higher than traditional glass ionomers. Today, resin composites have replaced glass ionomer materials for core fabrication.

Indirect Foundation Restorations: Cast Post and Core

For many years, use of the cast metal post and core has been the traditional method for fabricating the foundation restoration of a prosthetic crown. Classically, smooth-sided, tapered posts conforming to the taper of the root canal are fabricated from high noble alloys, although noble and base-metal classes of dental alloys have also been used. Noble alloys used for post and core fabrication have high stiffness (approximately 80 to 100 GPa), strength (1500 MPa), hardness, and excellent resistance to corrosion.[31]

One advantage of the cast post/core system is that the core is an integral extension of the post and that the core does not depend on mechanical means for retention on the post. This construction prevents dislodgment of the core from the post and root when minimal tooth structure remains. However, the cast post/core system also has several disadvantages. Valuable tooth structure must be removed to create a path of insertion

or withdrawal. Second, the procedure is expensive because two appointments are needed, and laboratory costs may be significant. The laboratory phase is technique sensitive. Metal casting of a pattern with a large core and a small-diameter post can result in porosity in the gold at the post/core interface. Fracture of the metal at this interface under function results in failure of the restoration. Most important, the cast post/core system has a higher clinical rate of root fracture than preformed posts.[47,159]

Studies on cast post retention have shown that the post must fit the prepared root canal as closely as possible to be perfectly retained. When a ferrule is present, custom cast posts and cores exhibit a higher fracture resistance compared to composite cores built on prefabricated metallic posts or carbon posts.[98] Cast posts are also known to exhibit the least amount of retention and are associated with a higher failure rate compared to prefabricated parallel-sided posts. In a classic retrospective study (1 to 20 years) of 1273 endodontically treated teeth in general practice, 245 (19.2%) were restored with tapered cast posts and cores. Among these, 12.7% were deemed failures. This failure rate was higher than that for the other passive post systems used. Of particular concern was the fact that 39% of the failures led to unrestorable teeth requiring extraction. Thirty-six percent of the failures were due to loss of retention, and 58% were due to the fracture of the root. It has been suggested that tapered smooth-sided posts have a "wedging" effect under functional loading, and it is this that leads to increased risk of root fracture.[162]

One 6-year retrospective study reported a success rate higher than 90% using a cast post and core as a foundation restoration.[8] The lower failure rate and fewer root fractures were attributed to the presence of an adequate ferrule and careful tooth preparation. Attention has also been drawn to the fact that the higher failure rate may be due to the fact that nearly half of the posts were shorter than recommended from the literature. A venting groove for the cement along the axis of the post results in less stress on residual tissues.

Luting Cements

A variety of cements have been used to cement endodontic posts and include traditional cements, glass ionomer cements, and resin-based luting cements.

Traditional Cements

Zinc phosphate cements or polycarboxylate cements are still used for cementation of posts and crowns. They are generally supplied as a powder and a liquid, and their physical properties are highly influenced by the mixing ratio of the components. Their compressive strength is about 100 MPa, and elastic moduli are lower than that of dentin (5 to 12 GPa). Zinc phosphate cement is mostly used for cementing metal restorations and posts; film thickness of the zinc phosphate cement is less than 25 μm. These cements provide retention through mechanical means and have no chemical bond to the post or to dentin but provide clinically sufficient retention for posts in teeth with adequate tooth structure.

Glass Ionomer Luting Cements

Glass ionomer cements are a mixture of glass particles and polyacids, but resin monomers may also be added. Depending on the resin content, glass ionomer cements can be classified as either conventional or resin-modified glass ionomer cements. Conventional glass ionomer cements have compressive strengths ranging between 100 and 200 MPa; the Young modulus is generally about 5 GPa. They are mechanically more resistant than zinc phosphate cements, and they can bond to dentin with values ranging between 3 and 5 MPa. Some authors still recommend the use of glass ionomer cements for the cementation of metallic posts. Major advantages of conventional glass ionomer cements are their ease of manipulation, chemical setting, and ability to bond to both tooth and post. On the contrary, resin-modified glass ionomer cements are not indicated for post cementation, because these cements exhibit hygroscopic expansion that can promote fracture of the root.

Resin-Based Luting Cements

Today there is a trend toward the use of adhesive cements for bonding endodontic posts during the restoration of nonvital teeth. The rationale for using adhesive cements is based on the premise that bonding posts to root canal dentin will reinforce the tooth and help retain the post and the restoration.[48] Contemporary resin-based luting cements have been shown to exhibit compressive strengths around 200 MPa and elastic moduli between 4 and 10 GPa.[24] These materials may be polymerized through a chemical reaction, a photopolymerization process, or a combination of both mechanisms. Photopolymerization of these resin-based materials is often necessary to maximize strength and rigidity.

Most luting cements require a pretreatment of the root canal dentin with either etch-and-rinse or self-etching adhesives. Both types of adhesives have been shown to form hybrid layers along the walls of the post spaces.[10] However, bonding to root canal dentin may be compromised by the use of endodontic irrigants such as sodium hypochlorite, hydrogen peroxide, or their combination.[115] Because these chemicals are strong oxidizing agents, they leave behind an oxygen-rich layer on the dentin surface that inhibits the polymerization of the resin.[151] Previous research has shown that the bond strength of C&B Metabond to root canal dentin was reduced by half when the dentin was previously treated with 5% sodium hypochlorite (NaOCl) or 15% EDTA/10% urea peroxide (RC Prep, Premier Dental, Plymouth Meeting, PA).[107] Other reports indicate that the contamination of the dentin walls by eugenol diffusing from endodontic sealers may also affect the retention of bonded posts.[66,168] Further, it is difficult to control the amount of moisture left in a root canal after acid etching, making impregnation of collagen fibers with etch-and-rinse adhesives problematic. The use of self-etching adhesives has been proposed as an alternative for the cementation of endodontic posts, because self-etching adhesives are generally used on dry dentin and do not require rinsing of the etchant. However, their efficiency at infiltrating thick smear layers like those produced during post space preparation remains controversial.[104,171] More recently, dual-curing adhesives have been developed to ensure a better polymerization of the resin deep inside the root canal. Dual-cured adhesives contain ternary catalysts to offset the acid-base reaction between the acidic monomers and the basic amines along the composite/adhesive interface.[105]

Although both self-curing and light-curing luting cements can be used for cementation of prefabricated endodontic posts, most resin cements have a dual-curing process that requires light exposure to initiate the polymerization reaction. Dual-curing cements are preferred because there are concerns as to whether light-curing materials are properly cured, especially

in areas of difficult light access such as the apical portion of the root canal. However, it has been reported that photocured composites generate more shrinkage stress and exhibit less flow than chemically cured composites.[52] Contraction stresses induced by polymerization also depend on the geometry of the post space and the thickness of the resin film. Previous research indicates that the restriction of flow of resin cements by the configuration of the root canal can significantly increase the contraction stress at the adhesive interface.[51,166]

In recent years, a number of techniques have been used to measure the adhesion of resin-based luting cements to root canal dentin. These methods include the pull-out tests, the microtensile bond strength tests, and the push-out tests.[45,61] Although laboratory tests confirmed that bond strengths ranging between 10 and 15 MPa can be obtained with modern resin-based luting cement, there is also evidence that frictional retention is a factor contributing to post retention.[14] It is generally accepted that bonding to dentin of the pulp chamber is more reliable than bonding to root canal dentin, especially at the apical level.[126] The lowered bond strength values recorded at the apical third of the root canal are likely to be related to the reduced number of dentinal tubules available for dentin hybridization. Shorter posts may be used when successful bonding occurs between fiber-reinforced posts and root dentin, because current adhesive luting cements can assist in the retention of posts in the root canal space.[132]

Another factor that may influence the performance of resin-based luting cements is the thickness of the cement layer. The cementation of endodontic fiber posts with thicker cement layers might be required when posts do not perfectly fit inside the root canal. Although a slight increase in cement thickness (up to 150 microns) does not significantly affect the performance of adhesive luting cements applied to root canal dentin, thicker layers may be detrimental to bond quality.[76,150]

One study indicates that bond strength to radicular dentin might be maximized by adopting procedures that compensate for polymerization stresses.[13] The bonding procedures are realized in two separate steps. The initial step allows optimal resin film formation and polymerization along the root canal walls, leading to more ideal resin-dentin hybridization without stresses imposed by the placement of the post. A second step bonds the post to the cured resin film. The polymerization shrinkage that occurs during the initial adhesive coating step reduces the effects of stress imposed when the resin-coated post polymerizes, thereby preserving the bond integrity.

Although the bonding performance of resin-based luting cements is well documented, other reports indicate that resin-dentin bonds degrade over time.[22,56] The loss of bond strength and seal are attributed to the degradation of the hybrid layer created at the dentin-adhesive interface. This is particularly true for etch-and-rinse adhesives, because the gelatinization of collagen fibers caused by phosphoric acids may restrict the diffusion of the resin within the interfibrillar spaces and may leave unprotected fibers available for degradation. Removing organic components from the demineralized dentin prior to bonding procedures has been suggested. The use of dilute NaOCl (0.5%) after acid etching or the conditioning of dentin smear layers with EDTA (0.1 M, pH 7.4) has been shown to produce more durable resin-dentin bonds made with single-step etch-and-rinse adhesives.[149]

Other research indicates that the degradation of denuded collagen fibrils exposed in incompletely infiltrated hybrid layers is driven by an endogenous proteolytic mechanism involving the activity of matrix metalloproteinases (MMPs).[21,125] The release of MMPs such as collagenases has been evidenced in both coronal and root dentin of fully developed teeth of young patients.[147] Researchers suggest that conditioning root canal dentin with a broad-spectrum protease inhibitor such as chlorhexidine (2 wt% chlorhexidine digluconate solution) might be useful for the preservation of dentin bond strength over time.[20]

Interestingly, these dentin-conditioning procedures, which may improve the resistance of the resin-dentin bond to chemical degradation, also act as antibacterial agents; this might be of interest in the endodontic context.

Self-Adhesive Cements

More recently, self-adhesive resin cements have been introduced as an alternative to conventional resin-based luting cements. Self-adhesive luting cements contain multifunctional phosphoric acid methacrylates that react with hydroxyapatite and simultaneously demineralize and infiltrate dental hard tissue.[108] They do not require any pretreatment of the tooth substrates, and their clinical application is accomplished in a single step. Therefore, the self-etching capability of these new cements reduces the risk for incomplete impregnation of the conditioned tissue by the resins and reduces technique sensitivity. The elastic moduli of chemically cured self-adhesive resin cements are relatively low (4 to 8 GPa) but generally increase when a dual-curing process is used. It is therefore recommended that all dual-cured resin cements receive maximal light to achieve superior material properties wherever clinically possible.[135] Adhesion performance to dentin was found comparable to multistep luting cements, but bonding to enamel without prior phosphoric acid etching is not recommended.[72] However, their long-term clinical performances need to be assessed before making a general recommendation for their use.

PRETREATMENT EVALUATION AND TREATMENT STRATEGY

Before any therapy is initiated, the tooth must be thoroughly evaluated to ensure treatment success. Each tooth must be examined individually and in the context of its contribution to the overall treatment plan and rehabilitation. This assessment includes endodontic, periodontal, biomechanical, and aesthetic evaluations. Planning of the restoration for endodontically treated teeth brings together all aforementioned biomechanical and clinical factors, as well as the various materials and procedures designed to address them.

Pretreatment Evaluation

Endodontic Evaluation

The prerestorative examination should include an inspection of the quality of existing endodontic treatment. New restorations, particularly complex restorations, should not be placed on abutment teeth with a questionable endodontic prognosis. Endodontic retreatment is indicated for teeth showing radiographic signs of apical periodontitis or clinical symptoms of inflammation. Restorations that require a post need a post space, which is prepared by removal of gutta-percha from the canal. Canals obturated with a silver cone or other inappropriate filling material should be endodontically retreated before

starting any restorative therapy. Because the probability for periapical tissue to heal after endodontic retreatment is reasonably high, the chances to retain a well-restored tooth in asymptomatic function over time are excellent.[119]

Periodontal Evaluation

Maintenance of periodontal health is also critical to the long-term success of endodontically treated teeth. The periodontal condition of the tooth must therefore be determined before the start of endodontic therapy and restorative phase. The following conditions are to be considered as critical for treatment success:

- Healthy gingival tissue
- Normal bone architecture and attachment levels to favor periodontal health
- Maintenance of biologic width and ferrule effect before and after endodontic and restorative phases

If one or more of the aforementioned conditions are not met owing to preexisting pathology or structural defects, treatment success or even feasibility can be compromised, sometimes suggesting extraction of weak teeth and replacement with dental implants rather than conventional therapy.

Biomechanical Evaluation

All previous events, from initial decay or trauma to final root canal therapy, influence the biomechanical status of the tooth and the selection of restorative materials and procedures. The biomechanical status can even justify the decision to extract extremely mutilated teeth that do not deserve extensive treatments that carry a limited probability of success. Important clinical factors include the following:

- The amount and quality of remaining tooth structure
- The anatomic position of the tooth
- The occlusal forces on the tooth
- The restorative requirements of the tooth

Teeth with minimal remaining tooth structure are at increased risk for the following clinical complications[114,165,170] (see Fig. 22-1 and Fig. 22-4):

- Root fracture
- Coronal-apical leakage
- Recurrent caries
- Dislodgment or loss of the core/prosthesis
- Periodontal injury from biologic width invasion

The amount and quality of remaining tooth substrate are far more important to the long-term prognosis of the restored tooth than any restorative material properties. One must consider that no restorative material can truly substitute for dentin or enamel and that a minimal amount of intact structure is mandatory to justify tooth maintenance and its strategic importance to the overall treatment plan. The presence of healthy adjacent teeth available as abutments or the option of dental implants are additional factors to be analyzed when justifying the restoration of endodontically treated teeth.

FIG. 22-4 Failure of prosthetic foundations can have dramatic consequences on both overlying restorations and surrounding tissues. A better understanding of compositional and structural changes that affect tooth resistance to repeated functional forces is mandatory to improve treatment success in endodontically treated teeth.

Tooth Position, Occlusal Forces, and Parafunctions

Teeth are subjected to cyclic axial and nonaxial forces. The teeth and associated restorations must resist these forces to limit potential damages such as wear or fracture. The degree and direction of forces depend on the location of the tooth in the arch, the occlusal scheme, and the patient's functional status.

In most occlusal schemes, anterior teeth protect posterior teeth from lateral forces through anterolateral guidance. In the context of very steep anterior guidance and deep vertical overbite, maxillary anterior teeth are sustaining higher protrusive and lateral forces from the mandibular anterior teeth. Restorations of damaged anterior teeth with heavy function should therefore be designed to resist flexion. Restorative components should be stronger than would be required for teeth with an edge-to-edge relationship and therefore vertical forces.

Posterior teeth normally carry more vertical forces, especially when maintaining canine and anterior guidance; they also sustain greater occlusal loads than anterior teeth, and restorations must be planned to protect posterior teeth against fracture. In the case of parafunctions, protection by anterior contacts is likely to be reduced or lost and posterior teeth then submitted to more lateral stresses, generating a higher demand for restorative materials.

The literature reports that average biting forces vary between 25 and 75 N in the anterior region and between 40 and 125 N for the posterior region of the mouth, depending on food type, dental status (dentate or edentulous), and patient anatomy and functional habits.[55,71] Those forces can easily reach 1000 N or above in case of parafunctions, showing how potentially destructive they can be for intact teeth and even more so for nonvital, fragilized teeth. Parafunctional habits (clenching and bruxism) are major causes of fatigue or traumatic injury to teeth, including wear, cracks, and fractures. Teeth that show extensive wear or sequelae from parafunctions, especially heavy lateral function, require components with the highest physical properties to protect restored teeth against fracture.

In general, modern strategy focuses on tissue preservation and also on the use of adhesion to stabilize the restoration for improved short- and long-term service. However, in certain conditions like reduced tooth support, conventional materials are not obsolete.

Aesthetic Evaluation and Requirements

Anterior teeth, premolars, and often the maxillary first molar, along with the surrounding gingiva, compose the aesthetic zone of the mouth. Changes in the color or translucency of the visible tooth structure, along with thin soft tissues or

TABLE 22-2

biotype, diminish the chance for a successful aesthetic treatment outcome.

Potential aesthetic complications should be investigated before endodontic therapy is initiated. For instance, metal or dark carbon fiber posts or amalgam placed in the pulpal chamber can result in unacceptable aesthetic results, such as a grayish appearance of the overlying prosthetic restoration (especially with modern, more translucent full-ceramic crowns) or gingival discoloration from the underlying cervical area or root (see Fig. 22-1). All teeth located in the aesthetic zone also require critical control of endodontic filling materials in the coronal third of the canal and the pulp chamber to avoid or reduce the risk of discoloration. Careful selection of restorative materials, careful handling of tissues, and timely endodontic intervention are important for preserving the natural appearance of nonvital teeth and gingiva.

Treatment Strategy

General Principles and Guidelines

The post, the core, and their luting or bonding agents together form the *foundation restoration* to support the coronal restoration of endodontically treated teeth. The evolution of foundation restorations has been to diminish invasiveness, to use adhesion rather than macromechanical anchorage, and to eliminate intraradicular components in selected cases. These changing clinical concepts derive from both an improved understanding of tooth biomechanics and advances in restorative materials.

The foundation and its different constituents are then aimed at providing the best protection against leakage-related caries, fracture, or restoration dislodgment. Therefore, all aforementioned local and general parameters are to be systematically analyzed in order to select the best treatment approach and restorative materials. Prosthetic requirements are also to be taken into consideration to complete each case analysis. In general, abutments for fixed or removable partial dentures clearly dictate more extensive protective and retentive features than do single crowns, owing to greater transverse and torquing forces. This modern biomechanical treatment strategy is summarized in Figure 22-5.

Structurally Sound Anterior Teeth

Anterior teeth can lose vitality as a result of a trauma with no or minimal structural damage. They generally do not require a crown, core, or post; restorative treatment is limited to sealing the access cavity and direct composite fillings. Discoloration, whenever present, is addressed by nonvital bleaching, or, for untreatable or relapsing ones, with conservative restorative approaches such as direct or indirect veneers (Table 22-2).

Nonvital Posterior Teeth with Minimal/ Reduced Tissue Loss

The loss of vitality in posterior teeth resulting from trauma, decay, or a restorative procedure does not necessarily lead to extreme biomechanical involvement and therefore allows, in certain conditions, for conservative restorations.

Occlusal cavities or mesio/disto-occlusal cavities can be restored with either direct- or indirect-adhesive intracoronal restorations, providing residual walls are thick enough (proximal ridges and buccolingual walls more than 1.5-mm thickness). The three additional clinical factors that must be analyzed to ensure optimal treatment success are the configuration factor (C-factor), cavity volume, and dentin quality. For instance, a large class I cavity with contaminated and sclerotic dentin would clearly be a contraindication to the direct approach, despite the fact that it apparently falls within the indications of direct techniques. Conservative options must, however, always be analyzed under the light of functional and occlusal environment. They can only be considered in the absence of parafunctions and with anterior guidance, which limits overall functional loading and lateral or flexural forces.

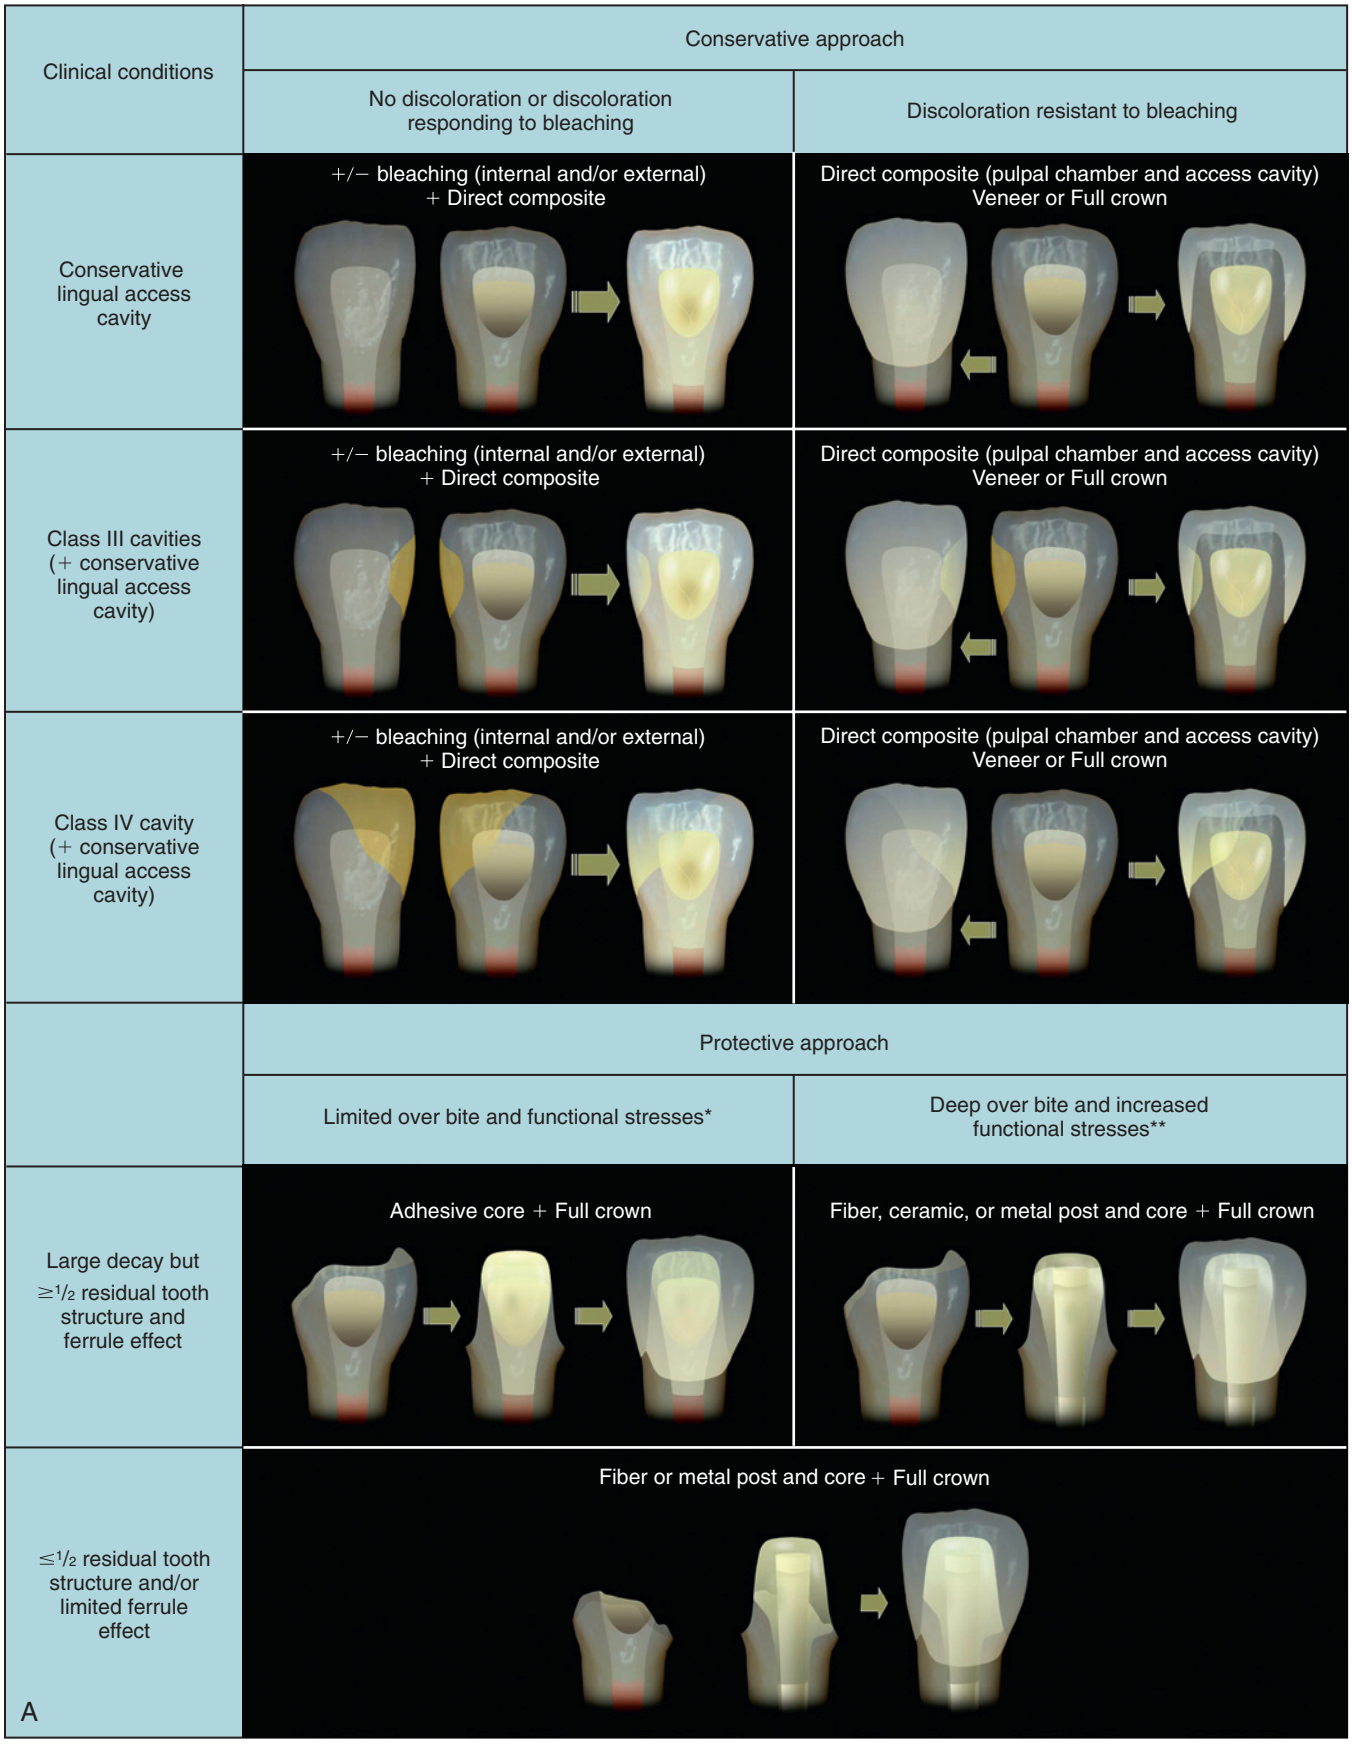

FIG. 22-5 A, Current recommendations for the treatment of nonvital anterior teeth. *Normal function and anterior guidance; **moderate to severe parafunctions and abnormal occlusion/anterior guidance.

Continued

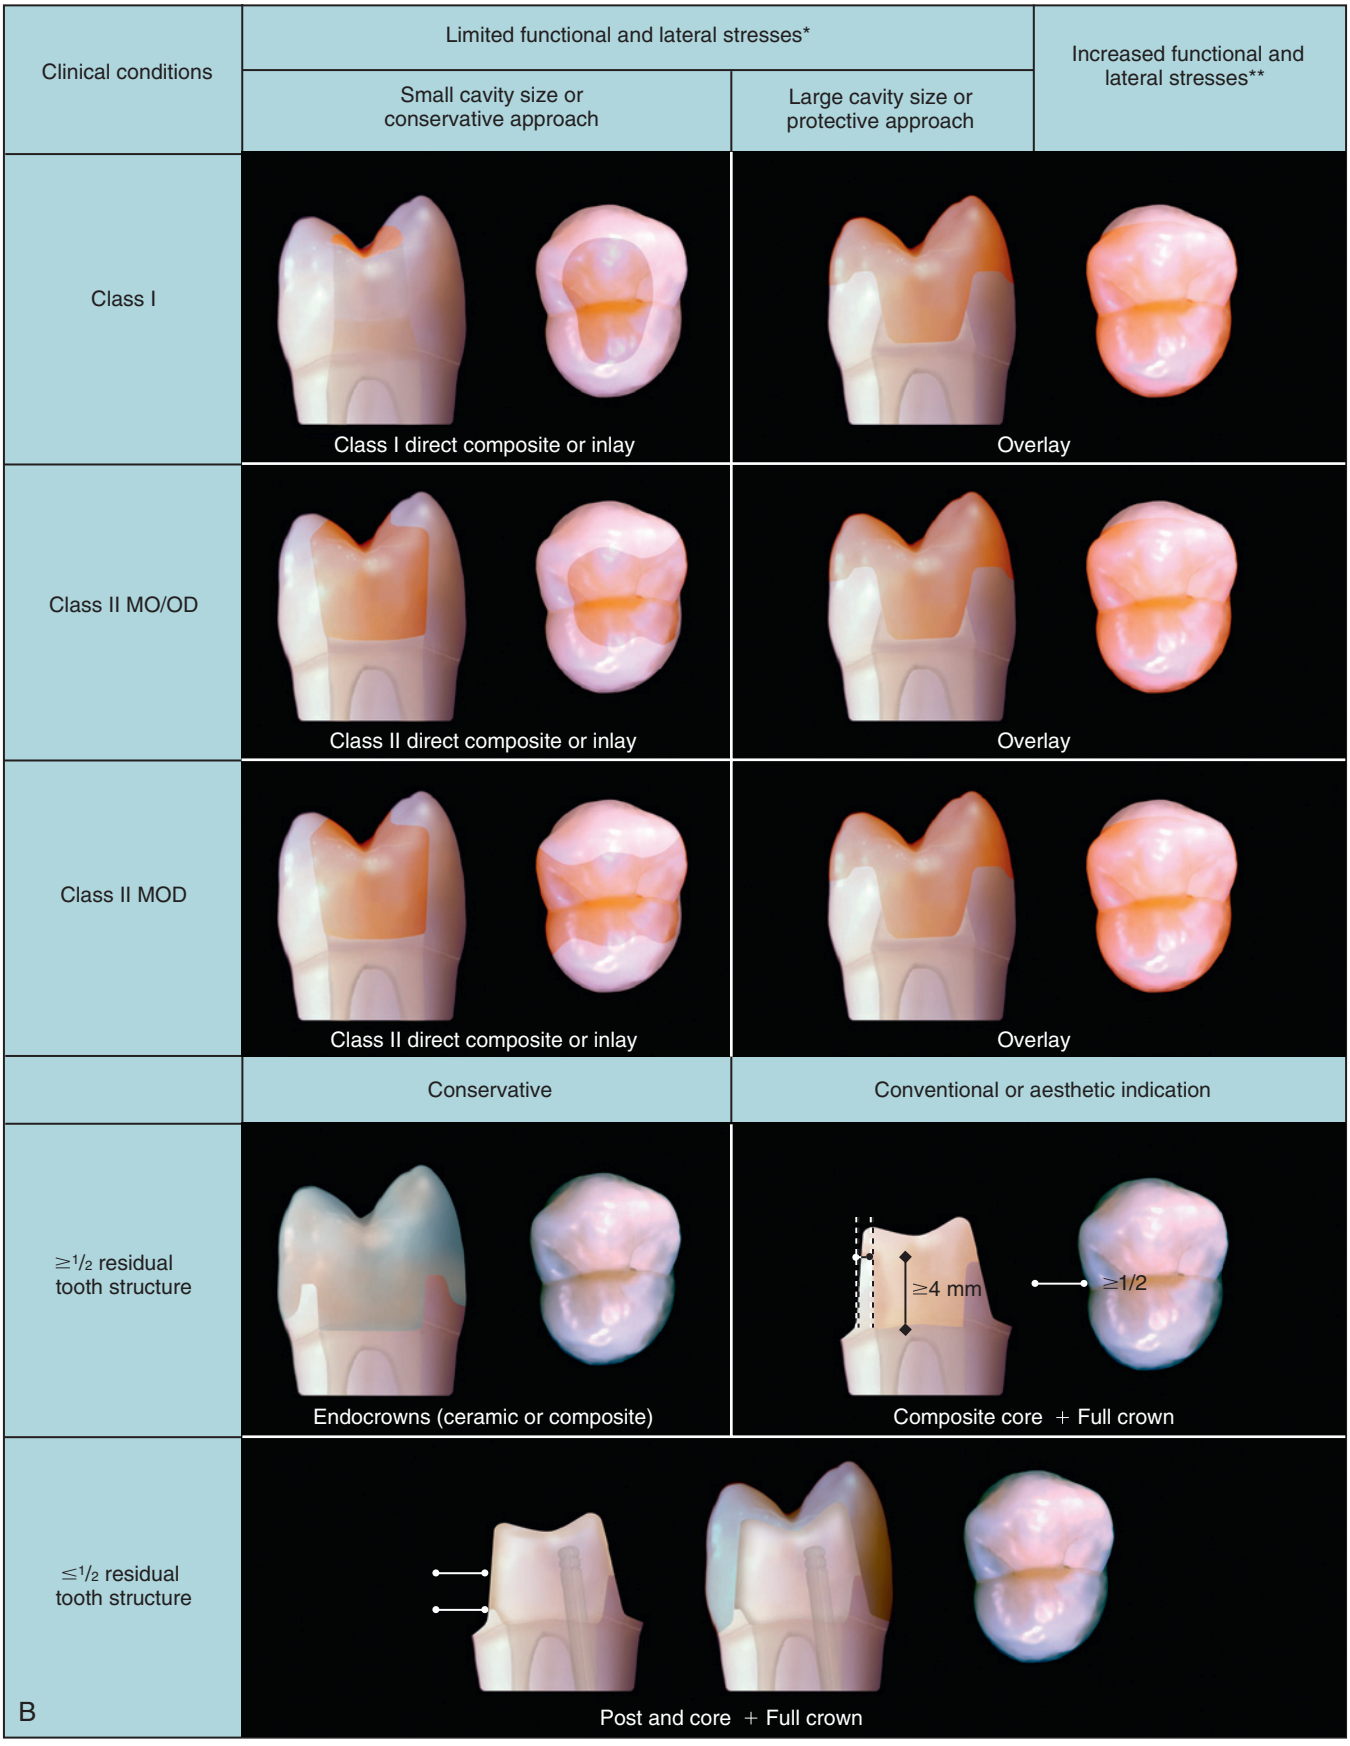

FIG. 22-5, cont'd B, Current recommendations for the treatment of nonvital posterior teeth. *Relatively flat anatomy and canine guidance, normal function; **group guidance, steep occlusal anatomy, parafunctions.

In less favorable biomechanical conditions (e.g.,) group guidance, steep occlusal anatomy, bruxism, clenching a protective approach with full occlusal coverage (onlay or overlay) is mandated to minimize the risk of fatigue failures (see Table 22-2).

Structurally Compromised Teeth

The decision for placing a post as well as the selection of a post system (rigid or nonrigid) depends once again on the amount and quality of remaining tooth structure and the anticipated forces sustained by this tooth (Table 22-3).

In general, rigid posts made of stiff materials (metal and ceramics) are indicated for teeth with minimal tooth structure that rely on the post to hold the core and crown. Because rigid posts flex and bend less than other types of posts, they are supposed to limit movement of the core and possible disruption of the crown margins and cement seal. But one must remember that stiff posts transmit more stresses to the root, next to the post apex, when conventionally cemented. An attempt to strengthen a weak root by adding a stiff post can instead make the root weaker as a result of the force concentration behavior of a stiff rod in a more flexible material. Adhesion therefore plays a crucial role, because a well-bonded post can help absorb stresses more evenly throughout the remaining tooth structure. Benefit and increased risk of fissure and

TABLE 22-3

Clinical Protocols for Restoring Nonvital Teeth with Full Prosthetic Restorations (Most Likely Procedures)

Treatment Approach	Indications	Tooth Preparation (Critical Guidelines)	Foundation		Restoration	
			Post	Core	Fabrication	Luting
Composite core	Reduced walls but > ½ crown height	Maintain all residual structures > 1 mm thickness (after core prep.)	—	DBA + composite Dual or LC, incremental	*In laboratory:* PFM or full ceramic restoration: slip-casting, pressed, or CAD-CAM	Coating, sandblasting, or etching + silane and Dual or SA cement
Composite core + ceramic post	More than ½ coronal structure lost, reduced wall height	Maintain all residual structures > 1 mm thickness (after core prep.)	Sandblasting or coating/silane + DBA + Dual cement or SA cement	DBA + composite Dual or LC, incremental	*In laboratory:* PFM or full ceramic restoration: slip-casting, pressed, or CAD-CAM	Coating, sandblasting, or etching + silane and Dual or SA cement
Composite core + in vitro fiber post	More than ½ coronal structure lost, reduced wall height	Maintain all residual structures > 1 mm thickness (after core prep.)	Sandblasting or coating/silane + DBA + Dual cement or SA cement	DBA + composite Dual or LC, incremental	*In laboratory:* PFM or full ceramic restoration: slip-casting, pressed, or CAD-CAM	Coating, sandblasting, or etching + silane and Dual or SA cement
Composite core + metal post	More than ⅔ coronal structure lost, reduced wall height	Maintain all residual structures > 1 mm thickness (after core prep.)	Sandblasting or coating/silane + DBA + Dual cement or SA cement	DBA + composite Dual or LC, incremental	*In laboratory:* PFM or full ceramic restoration: slip-casting, pressed, or CAD-CAM	Coating, sandblasting, or etching + silane and Dual or SA cement
Amalgam core (+/– metal post)	Alternative to composite core with metal post	Maintain all residual structures > 1 mm thickness (after core prep.)	No tt + nonadhesive cement or sandblasting/ coating/silane + DBA + Dual cement or SA cement	Amalgam placement in retentive cavity/ preparation	*In laboratory:* PFM restoration	Coating, sandblasting, or etching + silane and Dual or SA cement

fracture must then be appropriately weighed against adhesion potential inside the root and post type, composition, and surface treatment.

In structurally sound teeth, nonrigid posts flex with the tooth under functional forces, reducing the transfer of force to the root and reducing the risk of root fracture. Flexion is of course related to post diameter. In structurally compromised teeth, which lack cervical stiffness from dentin and ferrule effect, excessive post flexion can be detrimental to the marginal seal and prosthesis longevity, so fiber posts are generally contraindicated.

White or translucent fiber posts are generally preferred underneath full-ceramic restorations, whereas stronger black carbon fiber posts, which can reflect through gingiva, tooth structure, or ceramic restorations, are usually used in teeth to be restored with gold or porcelain fused to metal crowns, as well as in zirconia-based restorations. The literature has largely overemphasized the impact of post color on restoration aesthetics. Metal or carbon post color can be masked with resin opaquer and gold post and core ceramized to enhance aesthetic integration. Such procedures can help to approach a more ideal restoration biomechanical behavior through the fabrication of rigid but more aesthetic foundations. Upper lateral and lower incisors, together with extremely thin biotype, are probably the only real aesthetic contraindication for metal or carbon fiber posts.

In cases of extreme tooth fragility secondary to caries, fracture, previous overenlargement of the root canal system, or immaturity, residual root structure can be unified and reinforced with adhesive bonding and composite before placing a normal-diameter post, forming an altogether cohesive unit, as previously described.

In conclusion, in a damaged tooth that is to be restored with a nonrigid post, 2 to 3 mm of cervical tooth structure must ideally remain to allow creation of a restoration as a whole that is resistant to flexion. Teeth with minimal tooth structure and limited ferrule effect need additional cervical stiffness from a more rigid post to resist distortion. In this situation, adhesive cementation is preferred to conventional cementation.

Structurally Compromised Anterior Teeth

Restoration of endodontically treated teeth becomes more complex as teeth or supporting structures become increasingly affected. A nonvital anterior tooth that has lost significant tooth structure requires restoration with a crown, supported and retained by a core and possibly a post as well.

When less than half the core height is present, or when remaining walls are extremely thin (less than 1 mm on more than three fourths of the tooth circumference), a post is needed to increase retention and stabilize and reinforce the foundation. Many post options are available nowadays, including titanium, fiber-reinforced resin, and ceramics. Adhesion is now the preferred mode of post cementation unless a long-term contamination of root dentin is obvious (e.g., with eugenol), making adhesion highly questionable.

In the latter situation or in the presence of flared canals (possibly as well when a limited ferrule effect is present), cast gold post and core are still considered a feasible option. Actually, in this extremely unfavorable biomechanical environment, this traditional treatment approach provides a higher rigidity in the cervical area, which is mandatory for restoration stability. Here, a fiber-reinforced composite foundation having higher flexibility might present less favorable biomechanical behavior, such as suggested by FEM studies[42] (see Fig. 22-3 and Table 22-2). Tooth extraction and implant placement or bonded bridge (particularly for lateral incisors) are also to be considered in this situation.

In the aesthetic zone, the post should not detract from the aesthetics of the coronal tooth structure, ceramic crown, or gingiva. Current restorative procedures allow fabrication of highly aesthetic ceramic coronal restorations that have no metal substructure. When such restorations with remarkably lifelike color and vitality are selected, it usually implies the use of nonmetal aesthetic posts, either ceramic or resin fiber-reinforced ones.

Structurally Compromised Posterior Teeth

Slightly decayed posterior teeth in the context of parafunctions or significantly fragilized premolars and molars require cuspal protection afforded by onlay restoration, endocrown, or a full crown. The need for a post and core depends on the amount of remaining tooth structure. When remaining walls (buccal and lingual) provide more than 3 to 4 mm height (from the pulpal chamber floor) and 1.5 to 2 mm thickness, core and restoration stability are granted through macromechanical retention or adhesion; then, posts are not needed (see Fig. 22-5). With current treatment strategy, *the post has become the exception rather than the rule for the restoration of nonvital posterior teeth*.

Additional Procedures

Periodontal crown lengthening surgery or orthodontic extrusion can expose additional root structure to allow restoration of a severely damaged tooth. In the smile frame, crown lengthening might, however, be limited by aesthetically adverse consequences (proximal attachment reduction); basically, buccal crown lengthening only can be considered as a potential indication for this procedure. In the posterior region, crown lengthening is limited by tooth and furcation anatomy or by loss of bone structure, which complicates future implant placement. As regards to orthodontic extrusion, root length and anatomy are the limiting factors of this procedure; short roots or conical anatomy are contraindications to orthodontic extrusion. Once again, when a long-lasting, functional restoration cannot be predictably created, it might be better to extract the tooth than to pursue heroic efforts to restore an extremely weak tooth, using complex, expensive, and unpredictable procedures.

CLINICAL PROCEDURES

The restoration of a nonvital tooth may include several restorative components such as the post, the core, and the overlying restoration. Within the same tooth, several interfaces such as post to radicular dentin, core to coronal dentin, core to post, and core to overlying restoration will be created. According to the biomechanical status, some or all restorative components and interfaces will be present and need to be addressed.

General clinical guidelines for restoring endodontically treated teeth with either partial or full crown restorations are presented in Table 22-2, with specific procedures for tooth preparation and treatment of the different interfaces involved. Clinical steps for all recommended treatment options are presented in Figures 22-6 through 22-14.

FIG. 22-6 Direct composite restorations on front teeth (following bleaching). Nonvital anterior tooth with sufficient amount of residual tissue and intact, healthy neighboring teeth, usually in rather young patients. **A,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha were removed from the cavity to expose a clean dentin substrate. Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for the later placement of a post. **B,** Bleaching procedures. Two sessions of internal bleaching were needed to adapt the color of both traumatized anterior teeth (tooth #11), using a mixture of 3% hydrogen peroxide and sodium perborate powder. Each bleaching session extended over a 10-day period. Between sessions and until the given delay to proceed with final restoration (1 to 2 weeks up to 6 to 8 weeks), access cavity is closed with either a temporary filling material or flowable resin composite. **C, D,** Restorative procedures. A layer of adhesive is applied over all cavity surfaces. An etch-and-rinse system is frequently preferred when the dentinal tissue is highly sclerotic or was contaminated (e.g., by eugenol). A hard cement such as glass ionomer (not a resin-modified glass ionomer because of water uptake and further expansion) was used for dentin replacement, before adding enamel composite to close the lingual cavity. A full resin composite restoration can also be considered to fill in the lingual cavity (dentin + enamel masses) in consideration of the material's hydrophobic nature, which could presumably prevent or limit penetration of water-soluble pigments from the oral cavity. Two or three layers are usually used to replace the missing tissue, preferably following the "natural layering concept," which aims to build up the restoration with two basic masses, namely dentin and enamel, with the help of a silicone index. **E, F,** Postoperative views. The two conservative restorations are shown after finishing and polishing, with the rubber dam still in place **(E)** and after several weeks **(F)**. Note that aesthetic integration cannot be evaluated before full rehydration has occurred (4 to 6 hours at least).

FIG. 22-7 Direct composite restoration on posterior tooth. Nonvital posterior tooth with sufficient amount of residual tissue and mostly intact, rather healthy, neighboring teeth. No significant discoloration of buccal tooth substrate and absence of severe parafunctions or group guidance or other unfavorable occluso-functional condition. **A**, Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for a later placement of a post. **B**, Adhesive procedure. An etch-and-rinse adhesive system was used here owing to the presence of sclerotic and contaminated dentin. **C-E**, Restoration base and layering technique. Resins or glass ionomer cements can be used for dentin replacement, before adding enamel composite to close the lingual cavity. A full resin composite restoration can also be considered to fill in the lingual cavity (dentin + enamel masses) in consideration of the material's hydrophobic nature, which could presumably prevent or limit penetration of water-soluble pigments from the oral cavity. A dentin composite mass is used to replace missing dentinal tissue, and enamel composite is used to build up proximal walls and the occlusal anatomy. **F**, The postoperative view demonstrates the advantage of this conservative approach in the context of teeth with appropriate biomechanical status.

FIG. 22-8 Veneer. Nonvital anterior tooth with sufficient amount of residual tissue and rather healthy neighboring teeth. Discoloration resisted bleaching or relapsed, despite several retreatments. Preferably thick biotype to limit the risk of gingival recession and loss of aesthetic integration. **A,** Closing the lingual cavity. A hard cement such as glass ionomer (not resin-modified glass ionomer because of water uptake and possible expansion) can be used for dentin replacement, before adding enamel composite to close the lingual cavity. A full resin composite restoration can also be considered to fill in the lingual cavity (dentin + enamel masses) in consideration of the material's hydrophobic nature, which could presumably prevent or limit penetration of water-soluble pigments from the oral cavity. **B,** Preparation. A sufficient amount of buccal tooth structure must be removed to allow for a good aesthetic result (preparation depth is dictated by the discoloration severity). Cervical margins closely follow gingival contours, preventing soft-tissue impingement, but they assume complete coverage of discolored tooth structure. **C, D,** Adhesive procedure. Hydrophobic bonding systems are preferred to wet-etched enamel when no dentin is exposed. An etch-and-rinse adhesive system is preferred when dentin is exposed (here, in the presence of significant areas of sclerotic dentin). Restoration. Ceramic is etched and silanated. Just before cementation, a last layer of bonding resin is applied but not light-cured until placement. **E,** Luting technique. A light-curing, highly filled, translucent and fluorescent restorative material is preferably used for cementation. This allows better control of restoration placement and minimal wear and fatigue of the cement layer. **F,** Postoperative view. The postoperative view demonstrates satisfactory aesthetics. This approach is sometimes suitable to meet a patient's high aesthetic demands.

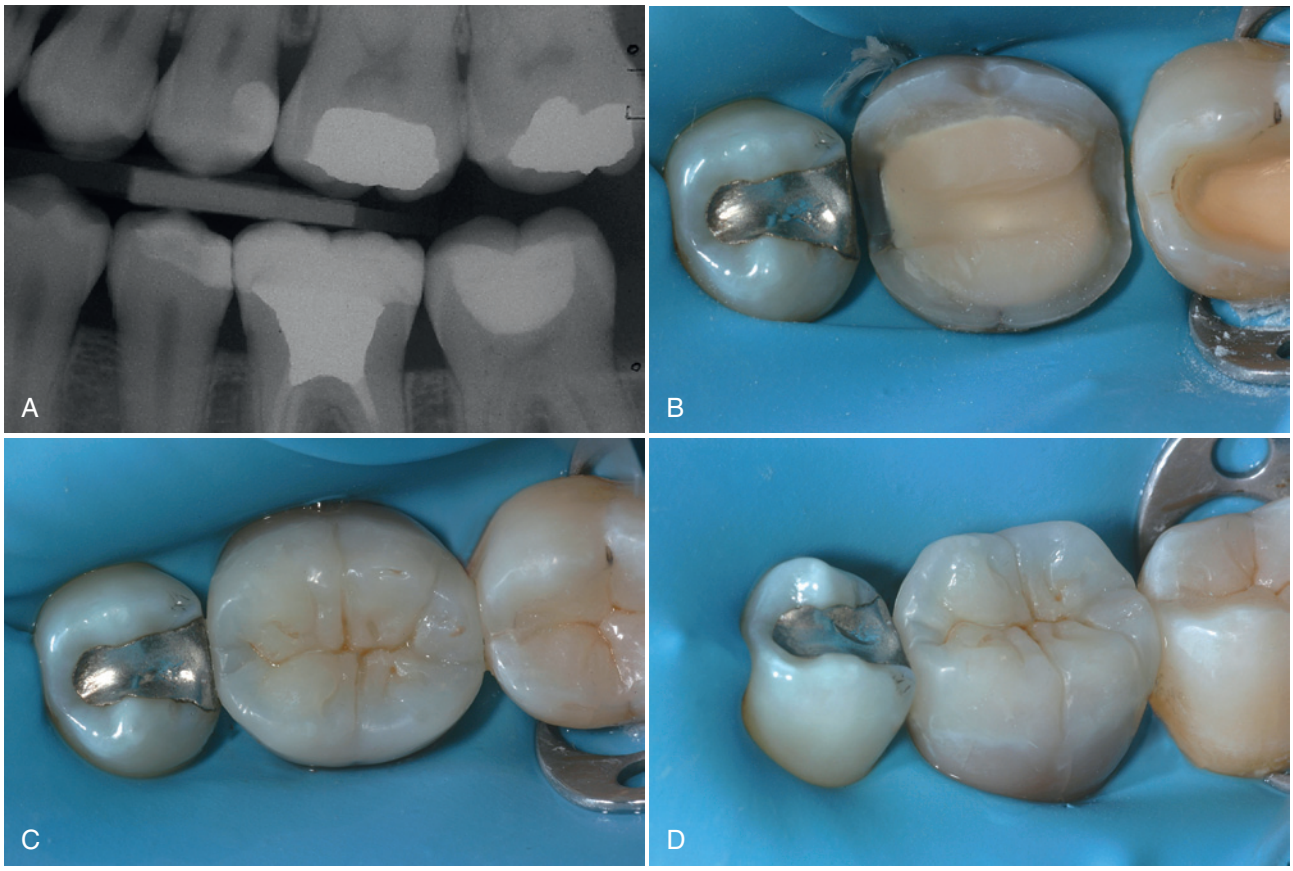

FIG. 22-9 Onlay/overlay. Nonvital posterior tooth with sufficient amount of residual tissue to justify partial restoration. Preparation involves both proximal surfaces or only two surfaces, but in a less favorable occluso-functional environment (thin walls). No significant discoloration of visible buccal tooth substrate. Option is favorable for short clinical crowns. **A, B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for the later placement of a post. Thin and weak occlusal walls are removed until reaching sufficient thickness for the restoration (1.5 to 2 mm in occlusal-free and occlusal areas, respectively). Adhesive procedure: an etch-and-rinse adhesive system is preferably used here owing to the presence of sclerotic and contaminated dentin (a self-etch adhesive system can also be used). A resin composite base is made with a restorative composite or preferably with flowable composite (for limited volume and thickness) to smooth internal angles, fill undercuts, and, when needed, relocate cervical margins occlusally. **C, D,** After impression and model fabrication, the restoration is generated in the laboratory to optimize restoration anatomy, function, and aesthetics. The restoration can be made of different tooth-colored materials: ceramics (fired, pressed, or CAD-CAM generated) or resin composite. This treatment option provides optimal tissue conservation, function, and aesthetics and is a good alternative to full crowns.

Tooth Preparation

The most important part of the restored tooth is the tooth itself. As described earlier, thickness and height of remaining dentin walls or cusps along with functional occlusal conditions are the determining factors in choosing the most appropriate restorative solution.

For partial intracoronal restorations, maximal tissue conservation is the only consideration for the clinician. In other situations, the selected restorative approach will usually necessitate some tooth preparation to comply with restoration design and thickness. Onlays, overlays, and endocrowns require about 1.5 to 2 mm occlusal space to guarantee restoration resistance to functional loads. For full crowns, a ferrule is needed to encircle the vertical walls of sound tooth structure above the restoration margin (1.5 to 3 mm), thus preventing a coincidence between core and restoration limits. Other preparation requirements presented in this chapter are to be respected to ensure treatment success. This means that a 4- to 5-mm height and 1-mm thickness of sound, suprabony tooth structure should be available to accommodate both the periodontal biologic width and the restorative ferrule.

Post Placement

The post is an extension of the foundation into the root of structurally damaged teeth, needed for core and coronal restoration stability and retention. The post is cemented or bonded into the root, according to tissue quality and post and core choice. The post performs both a mechanical and

FIG. 22-10 Endocrown. Nonvital posterior tooth with reduced amount of residual cervical tissue but sufficient tissue to provide supragingival restoration margins and good stabilization within former pulpal chamber. No or limited discoloration in visible buccal tooth substrate. Favorable option for short clinical crowns. **A, B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for the later placement of a post. Thin and weak walls are removed until reaching sufficient thickness (1.5 mm minimum); as much residual cervical structure as possible is then maintained to avoid restoration interference with periodontal tissues. **C,** Prosthetic restoration on working model. **D,** Restoration base. Adhesive procedures: An etch-and-rinse adhesive system is preferably used here owing to the presence of sclerotic and contaminated dentin (a self-etch adhesive system can also be used). Restoration base: A resin composite base is made with a restorative composite or preferably with flowable composite (for limited volume and thickness) to smooth internal angles, fill undercuts, and, when needed, relocate cervical margins occlusally. **E,** Impression and restoration fabrication. After impression and model fabrication, the restoration is generated in the laboratory to optimize restoration anatomy, function, and aesthetics. The restoration can be made of different tooth-colored materials: ceramics (fired, pressed, or CAD-CAM generated) or resin composite. **F,** Postoperative result. Despite their relatively rare application, endocrowns combine biomechanical advantages with facilitation of clinical procedures and minimal if any involvement of biologic width. It is an interesting alternative to full crowns. (From Rocca GT, Bouillaguet S: Alternative treatments for the restoration of nonvital teeth, *Rev Odont Stomat* 37:259, 2008.)

FIG. 22-11 Amalgam core. Nonvital posterior teeth with reduced tooth structure and wall height. Amalgam core stability is granted by extension of the restoration into the coronal portion of the canal (curved roots) and post (only if straight root anatomy) and remaining pulpal chamber undercuts. Today, this option is considered obsolete or historical because of the intrinsic staining of amalgam, the nonadhesive technique, and the less-than-ideal biomechanical behavior of amalgam. **A, B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Thin and weak walls are removed until reaching sufficient thickness (1.5 to 2 mm); existing retentions are used to stabilize the amalgam core, together with a post. The metal post (with passive and anatomic design, preferably made of titanium) extends into the root for about the same length as its coronal extension. **C-E,** Restoration fabrication. After placing a matrix or cupper ring to envelop the preparation, amalgam is compacted into the cavity, superior root canal portion, and around the post until the appropriate coronal volume is restored. Preparation of cores is made to manage optimal space for porcelain fused to metal (PFM) crowns. **F,** Posttreatment result. This treatment approach is feasible for teeth already restored with amalgam cores and when PFM restorations are mandated. Satisfactory aesthetics can be attained with intrasulcular restoration margins.

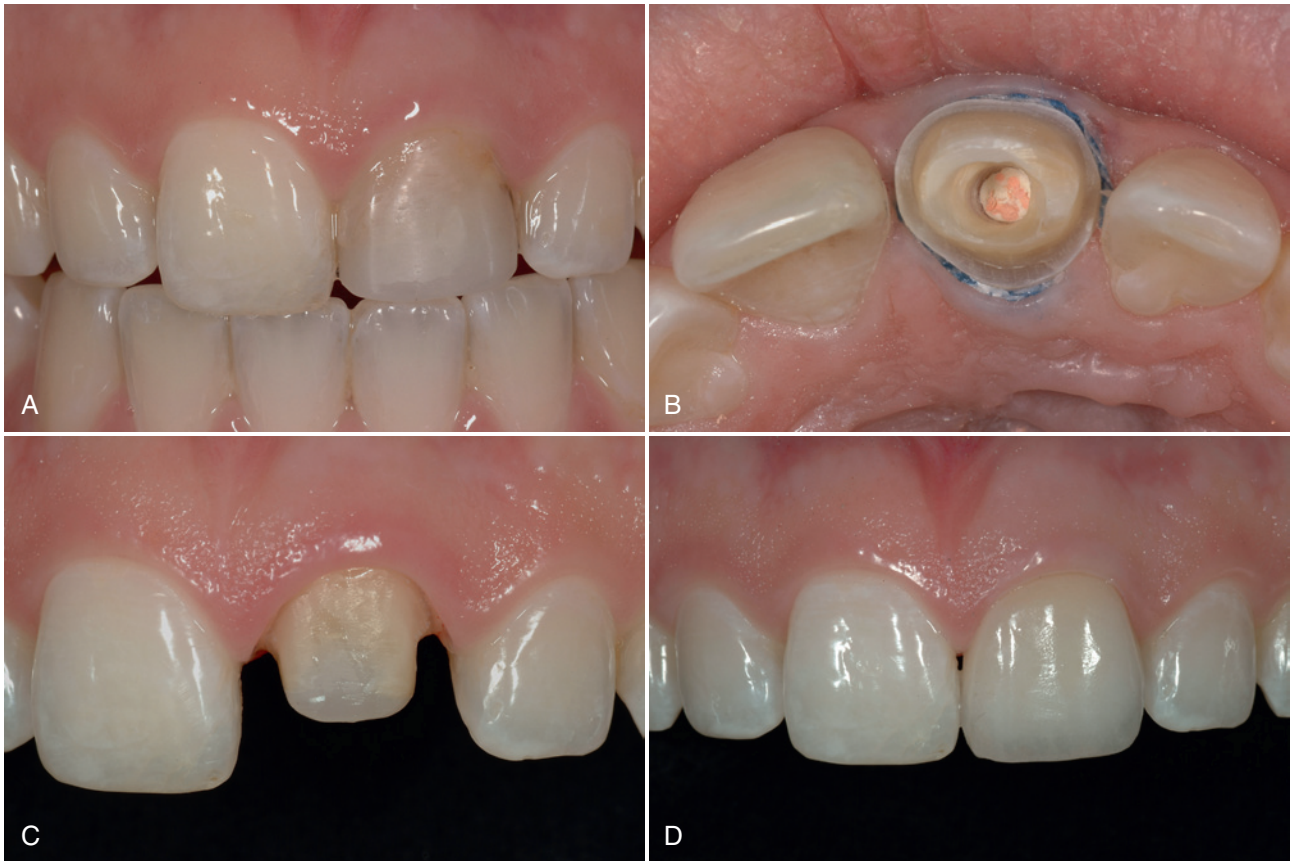

FIG. 22-12 Composite core (without post). Nonvital tooth with more than half the coronal structure left and sufficient wall thickness. Core stability is granted by adhesion, remaining pulpal chamber, and residual wall height. **A, B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. The tooth is prepared to evaluate precisely the height and thickness of residual tooth structure. Half of the abutment height and more than 1.5 mm wall thickness must be present to restore the tooth without a post. If aforementioned conditions are met, a thin layer of hard cement (calcium hydroxide, zinc phosphate, or glass ionomer; not resin-modified glass ionomer) is applied at the entrance of the root canal to enable possible retreatment in the future. **C,** Adhesive procedures and core fabrication. All walls are covered with the adhesive system (etch-and-rinse or self-etch) before applying in layers a direct light-curing restorative composite or a self-curing material, in case of limited restoration volume. **D,** Postoperative view. The advantage of this approach is the ease of application and excellent aesthetics. It is considered a good restorative solution for highly aesthetic ceramic crowns placed on teeth with limited tissue loss and discoloration.

biologic function by protecting the apical seal from bacterial contamination in case of coronal leakage. These functions should not be attained at the expense of tooth strength; post space preparation should be as conservative as possible to avoid an increased risk of root fracture. It is important to point out again that a post does not strengthen or reinforce a tooth. This elusive goal would only be achieved in a case of perfect cohesion between post and tooth substrate, nowadays only partially achievable. Therefore, the clinician must keep in mind that inherent strength of the tooth and its resistance to root fracture comes mostly from the remaining tooth structure and the surrounding alveolar bone. The tooth is weakened if dentin is sacrificed to place a larger-diameter post.

The post should be long enough to meet aforementioned biomechanical demands without jeopardizing root integrity. The standard parameters for post placement in a tooth with normal periodontal support are as follows:

1. In case of nonadhesive cementation (metal posts only)[60]:
   - Two thirds the length of the canal
   - A radicular extension at least equal to the coronal length of the core
   - One half the bone-supported length of the root
2. In case of adhesive cementation (fiber posts)[41,136]:
   - One third to one half the length of the canal, maximum
   - A radicular extension about the coronal length of the core

The first step for all types of post and core restorations is removal of gutta-percha and endodontic cement from the future post space. This procedure generally is best accomplished by the clinician providing the endodontic service, because that person has a clear knowledge of the size and form

FIG. 22-13 Composite core with white post (resin-reinforced fiber or zirconia post). Nonvital tooth with less than half the coronal structure left or insufficient wall thickness. Core stability is improved through adhesion and a tooth-colored post (resin-reinforced fiber or ceramic posts). **A,** Preoperative view. **B, C,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. The tooth is prepared to evaluate precisely the height and thickness of residual tooth structure. If less than half of the abutment height or 1.5-mm wall thickness remain, the abutment requires a post to increase core retention and foundation stability. **D, E,** Post-and-core fabrication. Post placement: The post space is prepared with ad hoc instruments until reaching a length equivalent to core height or slightly less depending on remaining wall height. Increased length is not needed, because retention is predominantly achieved through adhesion. Any tooth-colored post can be used, but fiber posts are usually preferred to limit stress buildup into the root structure, even though they provide less rigidity to the foundation. Post cementation: A self-curing adhesive system is applied on all cavity walls and into post preparation before luting the post with a dual-cured composite cement or, as a simple alternative, a self-adhesive cement (then, no adhesive is used). Core fabrication: The remaining core volume is built up in layers, using a direct light-curing restorative composite or with a single increment of a self-curing material when only limited volume is to be completed. **F,** Postoperative view. The primary advantage of this approach is the excellent aesthetic outcome. It is considered a good restorative solution for highly aesthetic ceramic crowns placed on teeth with more tissue loss but moderate discoloration.

FIG. 22-14 Composite core with prefabricated metal post. Nonvital tooth with reduced coronal structure and ferrule effect or insufficient wall thickness. Core stability is improved through adhesion and a metal (opacified) post (titanium posts are usually preferred). **A,** Preoperative view. **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose the remaining tooth structure and a clean dentin substrate. The absence of coronal tissue and ferrule effect mandates the use of a more rigid post (ceramic posts are considered too rigid and contraindicated in this situation). **C-F,** Post and core fabrication. Post space preparation: The post space is prepared with ad hoc instruments until reaching a length equivalent to about core height. More length is not needed, because retention is predominantly achieved through adhesion. Post preparation: The metal post (titanium here) is sandblasted (silicoating can be used to increase adhesion; i.e., Rocatec or CoJet systems, 3M), followed by silane application. An opaque resin or flowable composite can be used to mask metal dark color and improve aesthetics. Post cementation: A self-curing adhesive system is applied on all cavity walls and into post preparation before luting the post with a dual-cured composite cement or, as a simple alternative, a self-adhesive cement (then, no adhesive is used). Core fabrication: The remaining core volume is built up in layers, using a direct light-curing restorative composite or a single increment of a self-curing material when only limited volume is to be completed.

of the canal system. The initial post space preparation procedure is similar for most standardized post and core systems. The space, cleared of gutta-percha, has the form of the canal after cleaning and shaping. Proprietary systems are supplied with a series of drills to prepare the internal surface of the canal. The goal of post space formation is to remove little or no dentin from the root canal.

Adhesive Procedures

In general, both self-etch and etch-and-rinse adhesive systems can be used successfully on root dentin, both systems having a well-documented proof of efficacy. However, the use of etch-and-rinse adhesive systems may be advantageous in the presence of highly sclerotic or contaminated dentin, because phosphoric acids will etch dentin more deeply than self-etching primers. When treating the canal in the perspective of post cementation, a dual-curing adhesive system is preferably used to optimize polymerization. Self-adhesive cements have also demonstrated satisfactory performance for post cementation.

Partial Restorations

In the case of limited to moderate coronal substance loss, the restorative strategy for endodontically treated front teeth varies, from direct composite restoration using the same layering or application techniques as for vital teeth (possibly with the contribution of intracoronal or extracoronal bleaching) to full veneers, when discoloration is not fully treatable or tends to relapse. From a restorative standpoint, it is only necessary to mention that a 1- to 2-week delay is mandatory prior to adhesively restoring a bleached tooth. For more extensive restoration, it is even advised to wait up to 6 weeks or more (depending on the extent and duration of bleaching treatment) to allow for tooth final color stabilization and to proceed with shade selection.[39] Figures 22-6 and 22-7 describe the clinical steps involved in the restoration of moderately decayed front teeth using direct composite and bleaching or veneers.

In posterior teeth exhibiting limited to moderate tissue loss, direct to indirect partial or full occlusal restorations are proposed. Their benefit is to take advantage of residual tooth structure to stabilize the restoration and minimize the potential impact of a prosthetic rehabilitation on periodontal tissues. For instance, second molars definitely profit from a conservative approach using adhesively luted intracoronal and full occlusal coverage restorations. An endocrown is a modification of the aforementioned concept, with extension of the restoration into the pulpal chamber as an additional retentive and stabilization structure. Figures 22-8, 22-9, and 22-10 describe the clinical steps involved in the restoration of moderately decayed posterior teeth using onlays, overlays, and endocrowns.

Foundation Restoration Underneath Full Crowns

If significant coronal substance loss justifies a full-tooth coverage, the strategy for foundation fabrication varies as follows:

- Amalgam core with/without metal post
- Composite core without post
- Composite post with fiber or ceramic post
- Composite with prefabricated metal post
- Cast gold post and core

Amalgam Core

A coronal-radicular amalgam foundation may be realized with or without a post (Figs. 22-11 through 22-14). The amalgam coronal-radicular core without a post is indicated for posterior teeth that have a large pulp chamber and lateral walls at least 4 mm high. This restoration extends slightly into the coronal portion of the canals (1 to 1.5 mm). The core is then retained by a combination of the divergence of the canals and natural undercuts in the pulp chamber. A single, homogeneous material is used for the entire restoration, rather than the dual phases of a conventional preformed post and core.

When shorter lateral walls are present, a post is mandatory to improve core stability and retention. The preferred roots for post placement for molars are the palatal root in the upper jaw and the distal root in the lower jaw. Other roots, thinner and presenting more pronounced curvatures, are normally not indicated for post placement. Coronal-radicular amalgam foundations are not indicated for premolars owing to their smaller dimensions; adhesive foundations or cast gold post and core are preferred.

Cast Gold Post and Core

Cast gold post and core restorations can be fabricated with either direct or indirect techniques.

Direct Technique

In the direct technique, a castable post and core pattern is fabricated in the mouth on the prepared tooth. A preformed plastic post pattern is seated in the post space. To gain a path of withdrawal, undercuts are blocked out with resin composite rather than by removing healthy dentin structure. Acrylic resin is added to create a core directly attached to the post pattern. The finished pattern is removed from the tooth and cast in the laboratory.

Indirect Technique

With the indirect technique, a final impression of the prepared tooth and post space is made (Fig. 22-15). As with the direct technique, the path of withdrawal is made by undercut blockout, not by dentin removal. The castable final post and core pattern are fabricated on a die from this impression. The crown margins need not be accurately reproduced at this stage. Proprietary systems provide matched drills, impression posts, and laboratory casting patterns of various diameters. An impression post (preferably a repositionable one) is fitted to the post space, and a final impression is made that captures the form of the remaining coronal tooth structure and picks up the impression post. In the laboratory, a die reproduces the post space and the residual coronal tooth structure for fabrication of the post and core pattern.

With both techniques, the fabrication of a temporary crown with intraradicular retention is needed. This provisional restoration must stay in the mouth only for a limited time to prevent decementation or canal reinfection. This is why this approach is less popular today and replaced by direct techniques in most cases.

The cast post and core is cemented at the second appointment. The cementation process must be passive in nature and an evacuation groove made on post side to facilitate cement expulsion and limit seating pressure. Rapid seating, excessive cement, and heavy seating pressure (e.g., occlusal force) can

FIG. 22-15 Nonvital teeth with limited coronal structure or numerous abutments. Indirect post and core fabrication helps to achieve proper parallelism and core anatomy. Core retention is assumed by a conventional or adhesive cement. Today, this solution is considered mostly for extended metal-ceramic restorations or sometimes for multiple full-ceramic restorations. **A,** Preoperative view. **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose the remaining tooth structure and a clean dentin substrate. Despite the indirect approach, all healthy coronal structures must be maintained to improve foundation stability. Access cavity and coronal walls are prepared with minimal convergence (6 to 10 degrees) to allow for easy insertion. **C, D,** Cast gold post and core fabrication and luting. Post space preparation: The post space is prepared with ad hoc instruments until reaching a length equivalent to about core height or more. More length is needed here, as retention cannot always be achieved through adhesion (endodontic retreatment or highly sclerotic contaminated dentin). Then a conventional glass ionomer or zinc phosphate cement is used. Post and core preparation: The gold post is sandblasted (or eventually sandblasted and coated if adhesive procedures are possible) using Rocatec or CoJet systems, 3M + silane. Post cementation: The post and core is luted with the aforementioned conventional cements or adhesive technique. Next, a self-curing adhesive system is applied on all cavity walls and into post preparation (before the insertion of the post and core) and covered with a dual-cured composite cement or, as a simple alternative, a self-adhesive cement (then, no adhesive is used). **E, F,** Restoration fabrication and placement. A second impression is needed for the final prosthetic work to optimize restoration precision and quality. Lab-made PFM or full ceramic crowns are made with optimal foundation design and alignment.

produce high hydraulic pressures inside the root that may be great enough to crack the root.

Crown Preparation and Temporary Restoration

When a coronal restoration is indicated, the amount of tooth structure remaining after final preparation is the most important determinant of the design of the post and core. In addition, the underlying sound tooth structure provides greater resistance to fracture than any post and core type, design, or material. Natural tooth structure should always be carefully preserved during all phases of post space and crown preparation. Otherwise, preparation of endodontically treated teeth is not different from that for vital teeth, with the exception of severely discolored teeth, which require a slightly deeper chamfer to hide discoloration with the prosthetic structure and intrasulcular margins to reduce the visibility of a dark cervical tooth structure.

Provisional crowns for endodontically treated teeth must be used only for short periods of time because the loss of cement seal—which is, of course, symptom free—can lead to leakage, canal reinfection, and even serious carious invasion, thereby jeopardizing the success of endodontic treatment and even resulting in tooth loss.

SUMMARY

Endodontically treated teeth represent a singular situation because of the attendant qualitative and quantitative alterations of the dental substrate. Current literature indicates that treatment success relies on an effective coronal seal that will prevent canal reinfection and an adequate restoration that will resist functional stresses applied to the remaining tooth structure. The purpose of this chapter is to help the clinician make treatment planning decisions concerning the restorative options available for endodontically treated teeth.

Postoperative Follow-Up and Recall

"There is nothing permanent except change."

—Heraclitus

Vital pulp therapy is designed to preserve and maintain pulpal health in teeth that have been exposed to trauma, caries, restorative procedures, and anatomic anomalies. The treatment can be completed for permanent teeth that show reversible pulpal injuries, and the outcomes depend on a variety of factors.[63,162,215] The prime objective in vital pulp therapy is to initiate the formation of tertiary reparative dentin or calcific bridge formation. This procedure is essential for the preservation of involved immature permanent teeth where root development may be incomplete and preservation of arch integrity is critical during maxillofacial development.[288]

Recent advances in pulp biology and dental materials have provided alternative treatment strategies for healthy and partially inflamed pulps. Vital pulps can be successfully treated if the clinician has an improved understanding of diagnosis and case selection, hemostasis, caries removal, magnification systems, bioactive capping materials, bonded composites, and other restorative materials. The treatment is particularly valuable in young permanent teeth that have not attained their complete adult length and exhibit thin-walled roots and wide-open apices.[52,219,350]

Immature teeth may require up to 5 years or more to gain apical closure after emergence into the oral cavity. They are characterized by large dentinal tubules that allow increased permeability for microbial penetration.[53] The vulnerability and perceived poor prognosis of vital pulp treatment for immature permanent teeth have prompted aggressive treatment recommendations that include extraction.[350] Alternately, with an accurate diagnosis and early intervention, new strategies for pulp preservation promote a domain for continued hard tissue formation that encourages apexogenesis. Maintaining pulp vitality in these teeth reduces the probability of fracture, through continued growth and natural strengthening of the tooth structures.[78,94]

The introduction of mineral trioxide aggregate (MTA) and other bioceramic or calcium silicate-based cements (CSCs), along with advanced treatment strategies, has markedly changed the long-held concept that pulp capping after carious pulp exposure should be avoided. According to Seltzer and Bender,[289,290] "Pulp capping is a questionable procedure even under ideal circumstances." They further stated that "pulp capping should be discouraged for carious pulp exposures, since microorganisms and inflammation are invariably associated." The perception that outcomes for direct pulp capping in a carious field are inconsistent and problematic is based on traditional protocols and materials that did not generate a favorable milieu for hard tissue formation.[139,197,235,334] This perspective has encouraged clinicians to deliver alternative treatments, such as pulpotomy or pulpectomy, particularly in immature permanent teeth.[53,350] This rigid approach is further complicated by the difficulty in

FIG. 23-1 **Radiographs of carious molars in patients aged 12 to 38 years. A,** Mandibular left first molar in a 23-year-old with minor symptoms. **B,** Asymptomatic maxillary right molar in a 16-year-old. **C,** Asymptomatic maxillary left first molar in a 38-year-old. **D,** Deep caries in the mandibular right first molar of a 12-year-old. All patients were referred to the endodontist for root canal treatment based on radiographic observation. They exhibited normal vitality with cold testing, and all were treated successfully with vital pulp therapy. (© Dr. George Bogen.)

establishing the appropriate diagnosis because clinical signs, symptoms, and radiographic evidence may not accurately reflect the histologic condition of the involved pulp tissue (Fig. 23-1).[165] However, based on a better understanding of pulp physiology, caries microbiology, and the inflammatory mechanisms responsible for irreversible changes in pulp tissue, teeth with the potential for repair and continued vitality can now be more readily identified and predictably treated.[335]

Advances in our knowledge of pulpal physiology and immunology, together with recently introduced dental materials, have markedly changed the treatment approaches for teeth with involved pulps. Bioactive CSCs, such as MTA, have changed the perception that treating direct carious pulp exposures is unpredictable and therefore contraindicated. From the introduction of indirect pulp capping by Pierre Fauchard in the eighteenth century, dentistry has recognized the innate reparability of the dental pulp when exposed to injury.[99] Subsequent advances have been complemented by newly developed dental materials that provide superior sealing properties and protect the pulp from microorganisms and their toxic by-products.

A goal in vital pulp therapy has been to identify bioactive pulp capping and pulpotomy agents and implement a consistent treatment regimen that favors pulp preservation. It is recognized that outcomes for vital pulp therapy can vary, depending on the age of the patient, extent of bacterial contamination, and degree of pulp inflammation. Perhaps of greater importance may be the choice of pulp capping material and the quality of the permanent restoration.[63] Appropriate case selection, through a detailed differential diagnosis using multiple tests paired with a careful radiographic interpretation, is paramount for establishing the best treatment for the problem tooth. In its guidelines, the American Academy of Pediatric Dentistry (AAPD) states, "Teeth exhibiting provoked pain of short duration relieved with over-the-counter analgesics, by brushing, or upon the removal of the stimulus without signs and symptoms of irreversible pulpitis, have a clinical diagnosis of reversible pulpitis and are candidates for vital pulp therapy."[13]

In young patients, assessment of pulpal status before treatment is often difficult, but the probability of favorable outcomes increases with a diagnosis of reversible pulpitis or normal pulp (AAPD). Furthermore, subjective and sometimes negative patient reports or pain associated with cold testing does not absolutely signify that the pulp capping or pulpotomy procedure will be unsuccessful. Because pulpal disease is microbial in nature,[179] this chapter describes the microbiology of caries and the associated physiologic reactivity of pulp tissue. Based on the understanding that pulp tissue has an innate potential for repair in the absence of bacterial contamination, the chapter reviews new treatment concepts in vital pulp therapy intended for the ultimate preservation of the pulpally involved permanent tooth.[72,172]

THE LIVING PULP

As reviewed in Chapter 12, the dental pulp is a highly vascular and innervated loose connective tissue that has the unusual distinction of being enclosed within a rigid envelope composed of enamel, dentin, and cementum.[321,362] These hard tissues impart mechanical support and offer protection from the oral microbiota.[200] When these tissues are examined together embryologically and histologically, they may be referred to as

the *dentin-pulp complex*.[68,339] The pulp tissue accomplishes several important functions, including immune cell defense and surveillance, nutrition, dentinogenesis, and proprioreceptor recognition.[309] Healthy pulp tissue can generate reparative hard tissue, secondary, and peritubular dentin in response to assorted biologic and pathologic stimuli.[309] The maintenance of dental pulp vitality, therefore, is essential to the long-term retention and normal functioning of the tooth.

The dental pulp encompasses four distinct structural zones: a cell-rich zone, and core, composed of major vessels and nerves; a cell-free zone; and the odontoblastic layer that lines the entire pulp periphery.[321] The cell-rich zone demonstrates a greater density of undifferentiated mesenchymal cells and fibroblasts than is present in the pulp proper. The central pulp core consists of nerve fibers, blood vessels, fibroblasts, undifferentiated mesenchymal stem cells, immunocompetent cells, ground substance, and collagen fibers. The cell-free zone of Weil is subjacent to the odontoblast layer and is linked by capillaries, fibroblastic processes, and an extensive network of unmyelinated nerve fibers. The odontoblastic zone lines the pulp circumference as an epithelioid layer and includes the large, columnar-shaped odontoblasts, nerve fibers, capillaries, and dendritic cells.[186]

Vital pulp tissue comprises various cell populations that include fibroblasts or pulpoblasts, undifferentiated mesenchymal cells, odontoblasts, macrophages, dendritic cells, and other immunocompetent cells. The cells of the subodontoblastic layer and odontoblasts form a thin border between the inside margin of the dentin and the periphery of the pulp; this border is known as the *Höehl cell layer*.[130] The odontoblasts are tall, columnar-shaped cells separated from the mineralized dentin by predentin and characterized by processes that extend into the dentin and possibly to the dentinoenamel junction.[137,298,321,354] Odontoblasts are credited with formation of the mineralized predentin-dentin matrix, which is composed of an assortment of molecules, including phosphoproteins, glycoproteins, proteoglycans, and sialoproteins.[186] Repair mechanisms in the dental pulp are similar to those observed in normal connective tissue injured by trauma. When the enamel and dentin are challenged and the pulp exposed to advancing microorganisms, inflammatory changes can induce pulp necrosis, which precedes progressive pathologic changes that can include infection and its complications.[35,44]

Pressoreceptors and proprioreceptors protect the dentin-pulp complex against excessive occlusal loading while circulating immune competent cells confront bacterial challenges. Pulpless teeth with minimal remaining tooth structure that undergo root-filling procedures and are restored with post and core systems combined with cuspal coverage restorations are more vulnerable to irreparable fracture because of the loss of any protective proprioceptive mechanisms.[225,273,307] Investigations have shown that moisture depletion from dentin and the relative reduction of tooth stiffness are minimal after root canal treatment.[154,175,206] Although root canal treatment can prolong tooth survival, the cumulative loss of tooth structure from it and restorative care may precipitate tooth loss.[54,89,346] Root-filled teeth also demonstrate an increased susceptibility to recurrent caries, either because of poor marginal integrity of the permanent restoration or as a result of the modification of the biologic environment in these teeth.[226]

The pulp undergoes physiologic, pathologic, and defensive changes during its life.[240,333] These age-related transitions include continued dentin apposition, causing gradual narrowing of pulp volume and circumference.[96,241] The atrophy results in fibrosis, dystrophic calcification, degeneration of odontoblasts, and increased cellular apoptosis.[33,96] The aging of human dental pulp cells is primarily characterized by the formation of reactive oxygen species and senescence-related beta-galactosidase activity.[199] In addition, sensitivity to dental pain is reduced due to a decrease in fast-conducting A-delta fibers and diminished pulp repair, partly attributed to decreases in the levels of substances such as alkaline phosphatase.[217,295] An array of extracellular matrix macromolecules regulated by pulp cell activity contributes to tissue differentiation and growth, defense mechanisms, reactions to inflammatory stimuli, and the formation of calcified tissues.[333]

A comparison analysis of gene expression levels that reflect the activity of biologic cell function, proliferation, differentiation, and development found them markedly higher in young pulps compared to older dental pulps.[333] Analyses of young dental pulps indicated a greater expression level in cell and tissue differentiation, proliferation, and development of the lymphatic, hematologic, and immune systems compared to older dental pulps where the apoptosis pathway is highly expressed.[333] Although A-beta fiber function remains constant with aging, a decrease in A-delta fibers with age may reduce the perception of dental pain transmitted by these faster-conducting fibers.[217] Pulp volume and root canal lumen dimensions also diminish with advancing age as a result of continual deposition of dentin.[96,241] These age-related changes in tissue differentiation and organization, growth regulation, defense mechanisms, responses to inflammatory stimuli, and the deposition of calcified tissue are regulated by pulp cell activity and an assortment of extracellular matrix molecules.[333]

PULPAL RESPONSE TO CARIES*

The advance of invading microorganisms in carious lesions is the essential cause of pulpal inflammation and potential tissue necrosis. Acidogenic gram-positive bacteria, predominantly oral streptococci and lactobacilli, produce metabolic by-products during active caries that demineralize enamel and dentin.[147] Immune responses and pulpal inflammation occur when the caries front advances to within 1.5 mm of the pulp and bacterial antigens and metabolites diffuse through the dentinal tubules.[32,174,255] The main by-product in active carious lesions is lactic acid, which contributes to the demineralization of tooth structure. If the bacterial challenge continues, immune cell responses lead to increased inflammation and edema, initially characterized clinically by pulpal pain. Inflammation is a complex protective biologic response designed to remove injurious stimuli produced by pathogens and reestablish pulpal equilibrium. Prolonged inflammation in the low-compliance environment of the pulp space eventually leads to pulp disintegration and apical pathosis.[147,328]

The caries invasion is initially blocked by protective innate immune responses; it progresses to an adaptive immune response when bacteria directly approach the pulp.[146] The pioneer microbes during caries progression first encounter a positive outward flow of dentinal fluid, characterized by the deposition of immunoglobulins and serum proteins that slow

*Adapted from Hahn and Liewehr.[146-148]

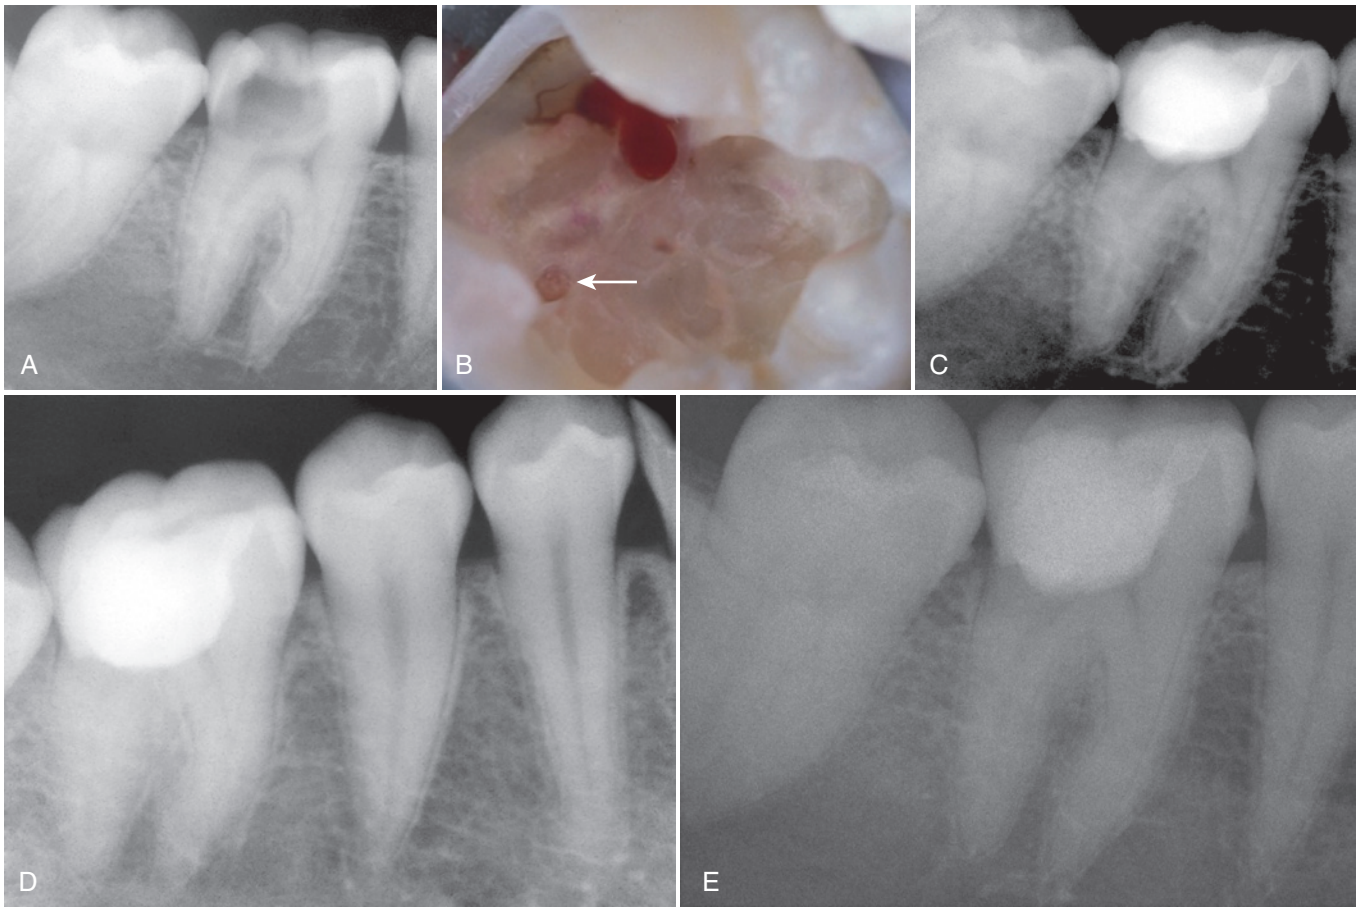

FIG. 23-2 Eighteen-year-old patient who presented with a carious mandibular right first molar that was sensitive to chewing. Cold testing elicited a short, nonlingering but painful response. **A,** Preoperative radiograph showing deep caries near the pulpal roof. **B,** Photograph after caries excavation using caries detector dye and 5-minute sodium hypochlorite hemostasis. Patient was asymptomatic and had normal responses on cold testing. **E,** Thirteen-year, 6 month radiographic review. Patient was asymptomatic and responded to vitality testing. The bonded composite restoration was intact and had no marginal degradation. (© Dr. George Bogen.)

the diffusion of bacterial antigens.[147] Potent microbial metabolites, such as lipoteichoic acid and lipopolysaccharide, also activate the innate immune system. The bacterial by-products stimulate signaling by Toll-like receptors in odontoblasts when the odontoblasts first encounter the carious front. They also stimulate proinflammatory cytokines, including interleukin-1, interleukin-8, interleukin-12, tumor necrosis factor alpha, vascular endothelial growth factor, and transforming growth factor beta (TGF-β).[108,156,361] Vascular endothelial growth factor promotes vascular permeability and angiogenesis. Dentin mineralization and matrix metalloproteinase secretion are also induced by the increased expression of TGF-β. Caries bacteria also activate complement pathways and induce the proinflammatory cytokine interferon gamma, which is responsible for killing phagocytosed bacteria by activated macrophages.[160] Odontoblasts also participate in the adaptive response to microbial invasion of dentin by the synthesis of a modified mineralized matrix known as *reactionary dentin,* a structurally altered hard tissue characterized by diminished tubularity.[62] As microorganisms advance toward the pulp, the modified helical structure in reparative dentin effectively constricts tubular lumen diameter and forms an active barrier against advancing pathogens (Fig. 23-2).[61]

As pulpitis progresses, vasoactive neuropeptides contribute to increased vascular permeability and intrapulpal blood flow. Increases in neuropeptide concentration and nerve sprouting characterize neurogenic inflammation, which can cause a transient increase in interstitial tissue pressure and contribute to painful pulpitis.[47,277] Immune cells attempt to control neurogenic inflammation with the secretion of peptides such as somatostatin and β-endorphin.[243] The primary effector cells in innate responses include natural killer cells, neutrophils, monocytes, and macrophages. Immature dendritic cells and T cells contribute to immunosurveillance during the progression of caries. Macrophages participate in the innate and adaptive immune responses by eliminating both pathogens and senescent cells while contributing to tissue homeostasis by repairing and remodeling tissue after inflammation.[146]

Cytokines are small, cell-signaling proteins secreted by innate immune cells that induce phagocyte extravasation during inflammation. Chemokines secreted by odontoblasts, fibroblasts, immature dendritic cells, and macrophages stimulate leukocyte recruitment by directing monocyte and neutrophil migration extravascularly to sites of infection.[146] Persistent infection engages the adaptive immune system, which can lead to edema and increased intrapulpal pressure, causing tissue destruction, acute phase protein production, and cell death, leading to tissue necrosis.[148] As the caries front progresses to the pulp, prompt clinical intervention, through removal of decay and bacterial antigens before irreversible pulpitis commences, can resolve pulpal inflammation and promote recovery.

REPARATIVE BRIDGE FORMATION

The foremost objective in vital pulp therapy is to encourage protective hard tissue barrier formation after injury. The process is initiated when regenerated odontoblast-like cells recruited from the cell-rich zone and subodontoblastic layer advance the repair of pulpodental defects after migration of highly vascularized tissue to the site. The repair process after pulp capping is characterized by four steps: (1) moderate inflammation, (2) recruitment and advance of dedicated adult reserve stem (progenitor) cells, (3) proliferation of the progenitor cells, and (4) terminal differentiation.[132] Strong evidence supports the role of inflammation as a prerequisite for tissue repair to proceed.[104]

The osteoblast/odontoblast-like progenitors responsible for reparative calcific bridge formation are either fibroblasts, inflammatory cells that undergo phenotypic conversion, or potentially resident stem cells activated by cytokines released during the inflammatory process.[130] Progenitor cell differentiation may also be modulated during inflammation by activation of antigen-presenting dendritic cells or triggered by specific odontoblast and fibroblast membrane receptors.[130] Currently, the origin of the differentiated odontoblast-like cells remains controversial. Fibroblasts, perivascular cells, bone marrow stem cells, and undifferentiated mesenchymal stem cells have all been proposed as potential progenitors.[338] A recent histologic study, however, suggests that the amorphous, atubular calcified repair tissue formed subjacent to the calcium hydroxide (CH) placed on the pulp wound in the absence of odontoblasts is produced by pulpal fibroblasts.[276a] Therefore, such mineralized hard tissue is not genuine dentin, but repair tissue that has been called "reparative dentin," for lack of a better term.

Odontoblast replacement in nonhuman primates directly after pulp exposures capped with CH has been examined during the cell migration and replication stages.[111] Newly differentiating odontoblast-type cells showing initial matrix formation were demonstrated as early as day 8 at the CH-pulp interface. The continual influx of labeled differentiating cells indicated that the original derivation was from the deeper, central pulp tissue that required two DNA replications before terminal differentiation.[111] Investigations have also indicated that reparative bridge mineralization may be more dependent on the extracellular matrix than on the capping material selected.[171,189,259]

During healing, initial calcification immediately after pulp amputation is characterized by a proliferation of extracellular matrix vesicles situated between the forming cells and the injured pulp surface.[152,264] The formation of needle-like crystals and osmophilic material within vesicles proceeds with an accumulation of crystals and aggregate at the calcified fronts, along with the disappearance of the vesicular membrane. The crystals produced during the calcification process are associated with phosphate and calcium ions, similar to fundamental calcification processes shown by other normal and pathologic calcified tissues.[152] Defects in pulpal healing and dentinal bridge formation are associated with different pulp capping materials and include pulpal inflammation, bacterial microleakage, operative debris, and tunnel defects.[188]

PROCEDURES FOR GENERATING HARD TISSUE BARRIERS

Direct Pulp Capping

The treatment options for permanent teeth that encourage pulp preservation include direct and indirect pulp capping and partial or complete pulpotomy. *Direct pulp capping* is defined as "placing a dental material directly on a mechanical or traumatic vital pulp exposure" and "sealing the pulpal wound to facilitate the formation of reparative dentin and maintenance of the vital pulp."[12] The procedure is indicated for pulp exposures incurred as a result of caries removal, trauma, or tooth preparation. When mechanical exposures occur during tooth preparation, the exposed tissue is generally not inflamed. However, in cases of trauma or carious exposure, the degree of inflammation is the key predetermining prognostic factor. According to the American Association of Endodontists, "In a carious pulp exposure, underlying pulp is inflamed to a varying or unknown extent."[12] The major challenge in direct pulp capping is the proper identification and removal of the acutely inflamed or necrotic tissue compromised by longstanding exposure to oral microorganisms.[210]

Pulpotomy

Pulpotomy, or *pulp amputation,* is a more intrusive procedure defined as "the removal of the coronal portion of the vital pulp as a means of preserving the vitality of the remaining radicular portion: may be performed as emergency procedure for temporary relief of symptoms or therapeutic measure, as in the instance of a Cvek pulpotomy."[12] After complete amputation of the coronal pulp, a capping material is placed over the pulp floor and the remaining exposed tissue in the canal orifices. Dressing materials of varying toxicity have been used for this purpose, including ferric sulfate, creosote, phenol, zinc oxide eugenol, polycarboxylate cement, glutaraldehyde, CH, and formaldehyde; some of these dressing materials embalm any remaining tissue.[265]

The procedure is recommended for primary teeth for which short-term outcomes are generally favorable. Formocresol has been the accepted "standard" universal pulpotomy agent in primary teeth and is recommended for young adult teeth; however, it has considerable drawbacks that put into question its continued use in humans.[195,196,281,318] It has been identified as carcinogenic and genotoxic, and experiments have shown a high incidence of internal resorption in nonhuman primate models.[120,203,207] Changes in the root canal system apical to formocresol placement can also create challenges when orthograde root canal treatment is attempted.[278] Comparative studies have demonstrated MTA to be an appropriate replacement for formocresol for primary molar pulpotomy.[48,164,306] Recent

investigations also support the use of MTA and other CSCs for application in pulpotomy procedures in permanent teeth.[17,300]

Partial Pulpotomy

Partial pulpotomy (shallow pulpotomy, or Cvek pulpotomy) is defined as the removal of a small portion of the vital coronal pulp as a means of preserving the remaining coronal and radicular pulp tissues.[12] After the pulp has been exposed and is visualized after hemostasis, inflamed or necrotic tissue is removed to uncover deeper, healthy pulp tissue in the pulp chamber.[77,257] Partial pulpotomy and direct pulp capping can be viewed as similar procedures, but they differ in the amount of vital pulp tissue remaining after treatment. Partial pulpotomy is the preferred option in elective treatment procedures for teeth diagnosed with anatomic anomalies, such as dens invaginatus.

Indirect Pulp Capping

Indirect pulp capping is defined by the AAPD as "a procedure performed in a tooth with a deep carious lesion approximating the pulp but without signs or symptoms of pulp degeneration. Indirect pulp treatment is indicated in a permanent tooth diagnosed with a normal pulp with no signs or symptoms of pulpitis or with a diagnosis of reversible pulpitis."[13] The treatment can be completed as a one-step or two-step procedure (stepwise technique) with the objective of arresting the active carious lesion.[37] Indirect pulp capping has been shown to be an effective technique for caries and patient management in the primary dentition, but it remains controversial in permanent teeth.[46,107,116,210,212] The technique is similar for both primary and permanent teeth, except that permanent teeth require reentry for the removal of residual carious tissue; reentry also is considered necessary to confirm reactionary dentin formation.[53,178] However, data from a recent investigation have questioned the need to reopen cavities to remove residual infected dentin in a subsequent visit.[209]

The treatment requires prudent case selection, including identification of asymptomatic patients with no suspicion of irreversible pulpitis. Pulp exposures are avoided during caries excavation by removal of the superficial demineralized necrotic dentin and then the removal of the peripheral dentin.[119] After excavation, the remaining carious dentin is lined with CH and sealed with a provisional material, such as intermediate restorative material (IRM) or a resin-modified glass ionomer (RMGI). The patient returns in 8 to 12 weeks for placement of a permanent coronal restoration. Advocates of indirect pulp capping argue that pulp healing can be compromised if the carious dentin barrier is removed during excavation and that the prognosis of vital pulp therapy (direct exposure) is unfavorable.[36] A challenging aspect of indirect pulp capping is determining the exact boundary point where caries excavation is terminated. Therefore, the technique is based primarily on subjective criteria and the operator's skill.[201] Further complicating the process is the presence of potential voids under the provisional restoration; during the mineralization process, these can permit dentin to lose volume during desiccation. Another drawback is the rapid reactivation of dormant lesions after restoration failure.[36] However, in younger patients with management issues, indirect pulp capping has shown promising results for immature permanent teeth in which the apical foramina are large, the canal walls are thin, and pulp vascularization is pronounced.[88,138,201,323]

INDICATIONS FOR VITAL PULP THERAPY

Vital pulp therapy is recommended for all teeth diagnosed with reversible pulpitis or partially inflamed pulps in which the remaining healthy tissue can be conserved to generate a hard tissue barrier that seals and protects the pulp from future microbial insult. The introduction of new bioactive materials, along with modified protocols, make more teeth with deep caries, traumatic injuries, and mechanical exposures viable candidates for innovative pulp therapies designed to potentiate and maintain pulpal survival. Treatment outcomes for direct pulp capping and pulpotomy procedures depend on multiple factors, beginning with a differential diagnosis that takes into account pulp testing, radiographic evaluation, clinical evaluation, and the patient history to determine a rational prognosis. Outcomes also depend on case selection, hemostatic agents, choice of pulp capping material, and the integrity of the sealed permanent restoration. The underlying purpose in vital pulp therapy is to avoid or delay root canal therapy and advanced restorative care because these, together, may reduce long-term tooth survival compared to teeth with vital pulps.*

MATERIALS FOR VITAL PULP THERAPY

A variety of pulp dressing materials have been investigated and used over the past century to encourage bridge formation and pulp preservation. A short list of compounds includes CH products, calcium phosphate, zinc oxide, calcium-tetracycline chelate, zinc phosphate and polycarboxylate cements, Bioglass, Emdogain, antibiotic and growth factor combinations, Ledermix, calcium phosphate ceramics, cyanoacrylate, hydrophilic resins, RMGI cements, hydroxyapatite compounds and, recently, MTA and other CSCs.† Other strategies designed to arrest invasive caries and promote repair of underlying tissues include the use of lasers, ozone technology, silver diamine fluoride, and bioactive agents that stimulate pulpal defense mechanisms.‡ Retrospective investigations have shown varying success rates of 30% to 85% for direct pulp capping in humans, depending on the method, hemostatic agent, and dressing material used.§ The search to identify and produce the ideal pulp capping material continues, and remarkable progress has been made in pulp preservation research in the past decade.

Calcium Hydroxide

Calcium hydroxide has long been considered the universal standard for vital pulp therapy materials. The introduction of CH into dentistry is credited to Hermann in the 1920s.[158] Although the material demonstrates many advantageous properties, long-term study outcomes in vital pulp therapy have been inconsistent.[21,28,30,165] Desirable characteristics of CH include an initial high alkaline pH, which is responsible for stimulating fibroblasts and enzyme systems. It neutralizes the low pH of acids, shows antibacterial properties, and promotes pulp tissue defense mechanisms and repair. The drawbacks of CH include weak marginal adaptation to dentin, degradation and dissolution over time, and primary tooth resorption.

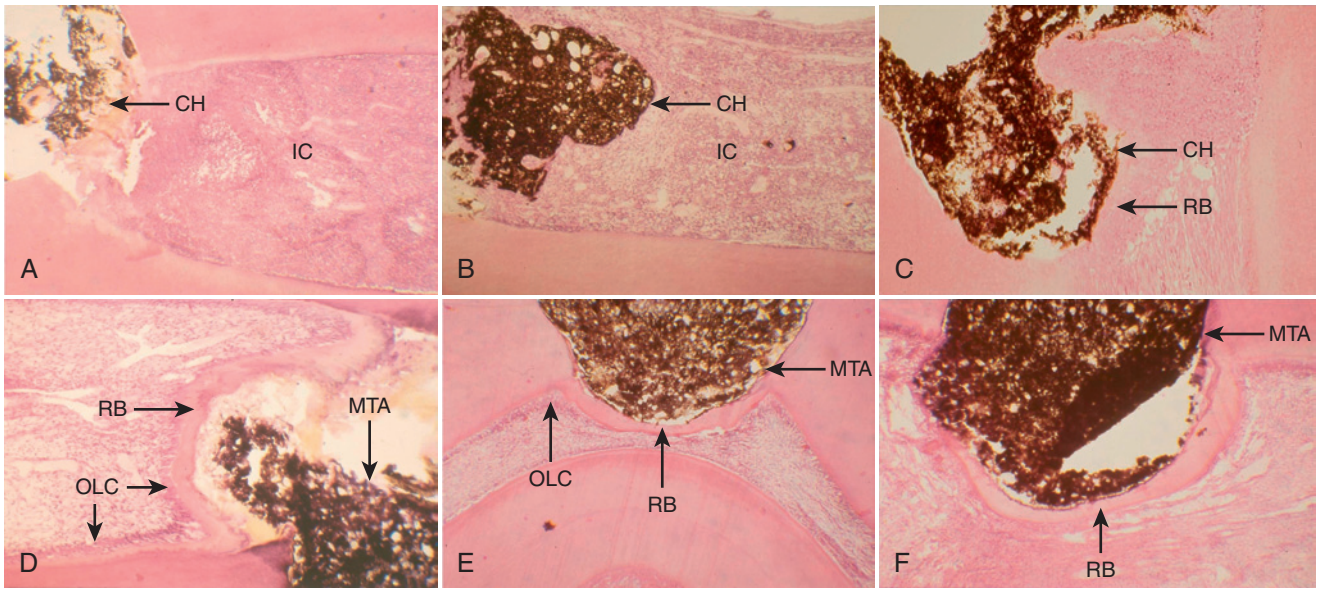

FIG. 23-3 Reparative bridge formation compared in dog pulps using mineral trioxide aggregate *(MTA)* and calcium hydroxide *(CH)*. **A,** Two-week pulp response to CH showing inflammatory cells *(IC)*. **B,** Tissue specimen showing lack of bridge formation and disorganized tissue proximal to CH. **C,** An 8-week specimen with partial reparative bridge (RB) formation subjacent to CH. **D,** Two-week pulpal response to MTA showing notable barrier formation and layer of organized odontoblast-like cells *(OLC)*. **E,** Pulp tissue section demonstrating complete calcificbridge formation proximal to MTA at 4 weeks. **F,** Sample section pulp capped with MTA at the 8-week period showing organized hard tissue formation with no inflammatory cell infiltrate. (Loma Linda University, Loma Linda, California.)

Reparative bridge formation subjacent to CH can also be characterized by tunnel defects.* Histologically, CH demonstrates cytotoxicity in cell cultures and has been shown to induce pulp cell apoptosis.[14,131,287]

Tunnel defects have been demonstrated in reparative hard tissue bridges associated with both CH and CSCs.[10] However, the primary difference between the two pulp therapy agents is that CH products are absorbable over time and dimensionally unstable. The slow disintegration of the CH after hard tissue barrier formation can allow microleakage, thus permitting a slow ingress of microorganisms through calcific bridge defects. This can induce subsequent pulpal degeneration, further leading to potential dystrophic calcification and pulpal necrosis. Over extended periods, this problematic outcome of CH pulp capping can complicate nonsurgical root canal treatment if required.[237]

Clinical retrospective investigations have shown variable success rates over 2- to 10-year recall periods for direct CH pulp capping in humans.[21,28,30,165] Two current studies have examined the efficacy of CH as a direct pulp capping agent. One study examined the survival rate of 248 pulp-capped teeth that were diagnosed either as having normal pulps or as exhibiting spontaneous pain; the researchers found an overall survival rate of 76.3% with an average recall period of 6.1 years.[81] Treatment outcomes were less favorable for teeth showing spontaneous pain, in older compared to younger patients, and in teeth restored with glass ionomer cements. The probability of pulps becoming nonvital after CH pulp capping was greater within the first 5 years of treatment.

*References 14, 25, 73, 74, 131, 134, 238, and 286.

The second study observed 1,075 teeth directly pulp capped with a CH-based agent; these teeth had either healthy pulps or showed signs of reversible pulpitis.[349] Inclusion criteria limited pulp chamber roof exposures to no larger than 2 mm in diameter. Successful outcomes were 80.1% after 1 year and 68% after 5 years; this diminished to 58.7% after a 9-year observation period.

The results of the two studies indicate increasing failure rates over time, attributable to absorption of the material under permanent restorations proximal to mineralized bridges with tunnel defects. Another investigation has confirmed decreasing success rates with CH pulp capping with extended recall periods.[222] Calcium hydroxide clearly has many favorable characteristics as a vital pulp therapy agent. However, the material also demonstrates inherent physical weaknesses and can no longer be considered the preferred universal agent in vital pulp therapy (Fig. 23-3).[105,162a,222,224a,247]

Resin-Modified Glass Ionomer Cements and Hydrophilic Resins

Adhesive systems were introduced in the early 1980s as potential agents for direct pulp capping of cariously and mechanically exposed pulps.[170,216,355] These materials include RMGI cements, composite resins, and hydrophilic resins. Hydrophilic resins and RMGI cements initially showed favorable outcomes in preliminary pulp capping investigations with nonhuman primates based on standards set by the International Organization for Standardization (ISO).[71,315-317] However, the transitional use of these materials in human subjects did not demonstrate the corresponding biocompatibility or consistent reparative bridge formation.[2,90,131,153,166,235] Investigations that

have examined responses of resin-based materials in human teeth have demonstrated unfavorable histologic reactions when the material is placed directly or in close proximity to pulp tissue.[2,95,143,236,274] Histologic sections from these studies typically demonstrate the presence of inflammatory cell infiltrates consistent with pulp cell cytotoxicity, subclinical adhesive failures at the pulp interface, and a profound absence of biocompatibility.*

Research data have shown that increasing concentrations of triethylene glycol dimethacrylate (TEGDMA), a common dentin bonding compound, differentially increase the levels of apoptotic and necrotic cell populations after direct exposure.[305] Moreover, even low levels of TEGDMA diminish alkaline phosphatase activity and calcium deposition, thus inhibiting pulp cell mineralization and potential reparative bridge formation.[127] Alternatively, adhesive resins have shown some promise when combined with additives or growth factors, such as hydroxyapatite powder, dental matrix protein-derived synthetic peptides, calcium chloride ($CaCl_2$), calcium phosphate, and antibacterial agents, including 12-methacryloyloxydodecylpyridinium bromide (MDPB).[76,183,312] It is evident that bonding agents used for direct pulp capping do not predictably generate a favorable environment for pulp healing and hard tissue formation.[299] However, hydrophilic resins and RMGI cements provide excellent seals when they are combined with light-cured composites in permanent restorations and then placed directly over pulp capping materials such as MTA.[20,101,249]

Mineral Trioxide Aggregate (MTA)

Mineral trioxide aggregate was introduced as a pulp capping material by Torabinejad and associates in the mid-1990s.[113] Most preliminary experimental and current clinical data in vital pulp therapy are based on the proprietary material ProRoot MTA (Tulsa/Dentsply, Tulsa, Oklahoma). The cement consists of hydraulic calcium silicate powder containing various oxide compounds, including calcium oxide, ferric oxide, silicon oxide, sodium and potassium oxides, magnesium oxide, and aluminum oxide.[51] The material exhibits favorable physiochemical characteristics that stimulate reparative dentinogenesis by recruitment and activation of hard tissue–forming cells, contributing to matrix formation and mineralization.[260] Soluble cytokines and growth factors that mediate wound repair of the dentin-pulp complex are nested in the extracellular matrix, and MTA stimulates reparative hard tissue formation by sequestering these growth factors and cytokines embedded in the surrounding dentin matrix.[190,191,327,340] Calcium hydroxide and calcium silicate hydrate, the principal by-products formed during hydration of mixed MTA, contribute to a sustained alkaline pH.[50,117] The setting properties of the hydroscopic silicate cements are not affected by the presence of tissue fluids or blood.[329]

During the setting process, the gradual release of calcium ions encourages reparative barrier formation by promoting signaling molecules, such as vascular endothelial growth factor (VEGF), macrophage colony-stimulating factor (MCSF), TGF-β, and interleukins IL-1β and IL-1α.[214,267] MTA demonstrates superior marginal adaptation to dentin compared to CH-based agents; MTA forms an adherent interfacial layer during mineral nucleation at the dentin surface that appears similar in composition to hydroxyapatite when examined with X-ray diffraction, energy-dispersive X-ray analysis, and scanning electron microscopy (SEM).[260,283,330]

If the pulp is injured, wound healing and the repair process can advance only after the initiation of the inflammatory reaction.[130,205] Similar to CH, MTA induces an inflammatory cascade that results from calcium ion release and the creation of an alkaline environment, producing tissue necrosis. Both MTA and CH have been shown to stimulate and increase the Höehl cell mitosis index in rodent models.[82,83] MTA activates the migration of progenitor cells from the central pulp to the injury site and promotes their proliferation and differentiation into odontoblast-like cells without inducing pulp cell apoptosis.[260] MTA also stimulates in vitro the production of messenger ribonucleic acid (mRNA) and increases protein expression of the mineralized matrix genes and cellular markers crucial for mineralization after matrix formation.[260]

Gray MTA has been shown to enhance cell proliferation and survival of cultured human dental pulp stromal cells.[267] The biocompatibility of set MTA up-regulates the expression of transcription factors, angiogenic factors, and gene products, such as dentin sialoprotein, osteocalcin, and alkaline phosphatase.[266] Odontoblast signaling proteins are essential in the differentiation of progenitor cells into the odontoblast-like cells responsible for repair and hard tissue deposition.[266,267] After MTA pulp capping, both sialoprotein and osteopontin have been observed in the fibrodentin matrix at the exposure site during the process of reparative hard tissue formation.[194]

Dental pulp cells differentiate into the odontoblastic cell line in the presence of the signaling molecules, such as TGF-β, heme oxygenase-1 enzyme, and bone morphogenetic proteins BMP-2, BMP-4, and BMP-7.[141] MTA most likely up-regulates fibroblast secretion of BMP-2 and TGF-β1 and therefore stimulates and promotes mineralization and hard tissue regeneration.* MTA induces a time-dependent environment that is proinflammatory and promotes wound regeneration through up-regulation of cytokines.[275] Immunohistochemical analyses show that cytokines, including myeloperoxidase, inducible nitric oxide synthase, VEGF, nuclear factor-kappa B (NF-κB), activating protein-1, and cyclooxygenase-2, show increased expression in the presence of MTA. Cytokine up-regulation is responsible for inducing biomineralization by producing apatite-like clusters on collagen fibrils at the MTA-dentin interface. MTA does not affect the generation of reactive oxygen species, thereby positively influencing cell survival. MTA also has been shown to improve the secretion of IL-1β , Il-6, and IL-8.[49,57,66] However, an inhibitory effect on dental pulp cells has been demonstrated in the presence of MTA, which may be attributed to the release of aluminum ions.[231] The data indicate that MTA promotes a biocompatible, noncytotoxic, antibacterial environment and surface morphology that are favorable for reparative calcific bridge formation. MTA stimulates the release of the dentin matrix components necessary for hard tissue repair and regeneration in mechanically exposed healthy and partially inflamed pulps (Figs. 23-4 to 23-6).†

Calcium Silicate–Based Cements (CSCs)

A variety of new bioactive CSCs or bioceramic materials have been developed since the introduction of MTA.[85,128,198]

Preliminary investigations with CSCs have demonstrated physiochemical and bioinductive properties comparable to those of MTA, indicating the potential future application of these materials in vital pulp therapy.[42,98] Some of these tricalcium-based materials include BioAggregate (Innovative Bioceramix, Vancouver, British Columbia), Biodentine (Septodont, Cambridge, Ontario, Canada), MTA-Angelus, MTA Bio, and MTA Branco (MTA-Angelus, Londrina PR, Brazil).[133,202] Other formulations include EndocemMTA (Maruchi, Wonju-si, Gangwon-do, South Korea) and Endosequence root repair material (Brasseler USA, Savannah, Georgia). Additional compounds are currently undergoing clinical investigations to establish their safety and efficacy.[16,242]

The main components of MTA and the new CSCs are tricalcium silicate and dicalcium silicate, major components of Portland cement. Hydraulic tricalcium silicates promote reparative barrier formation by up-regulation of transcription factors after gaining immediate strength on hydration. However, research data are limited on direct pulp capping and pulpotomy treatments in humans using these new bioceramic products.

BioAggregate is a bioinductive tricalcium cement that can induce mineralization in osteoblast cells by increasing levels of osteocalcin, collagen type 1, and osteopontin gene expression.[363] Hydration of the cement results in the formation of calcium silicate hydrate and CH, showing high concentrations of silica and calcium phosphate.[136] This characteristic is consistent with materials used in vital pulp therapy to promote hard tissue formation. Investigations using X-ray diffraction show the material to have a composition similar to that of MTA, but BioAggregate contains tantalum rather than bismuth oxide to provide radiopacity.[268] BioAggregate demonstrates remarkable biocompatibility compared to MTA, inducing cell differentiation in both human periodontal ligament and gingival fibroblasts.[356] Both fresh and set mixtures of MTA and BioAggregate have shown antimicrobial properties effective against *Enterococcus faecalis* in vitro when combined with equal amounts of human dentin powder.[366] The material also shows a greater resistance to dislodgement in an acidic environment compared to MTA, in addition to higher fracture resistance when used as a filling material.[150,336]

Biodentine is a tricalcium silicate–based cement that also demonstrates exceptional bioactive properties with potential for both direct and indirect pulp capping procedures. The cement has a short setting time of 10 minutes and does not induce genotoxic or cytotoxic effects when measured with the Ames mutagenicity test. It is considered a biocompatible dentin replacement material for use under various restorative materials as a base or liner, and it does not alter human pulp fibroblast cytodifferentiation.[198] SEM analysis demonstrates the sealing ability of Biodentine to be similar to that of MTA; Biodentine forms needle-like crystals resembling apatite at the dentin interface.[91] The material induces odontoblast-like cell differentiation, stimulates biomineralization, and promotes hard tissue formation when used as a pulp capping material.[293,365]

Another promising material for vital pulp therapy is MTA-Angelus, which has a basic formulation of 25% bismuth oxide and 75% Portland cement. The composition eliminates calcium sulfate, providing a short setting time of 10 minutes, which is preferable for one-visit pulp capping or pulpotomy procedures (Fig. 23-7).[42] Variations in bismuth oxide and the presence of iron characterize the chemical composition of MTA-Angelus, and the crystalline structures formed on hydration are similar to gray and white ProRoot MTA.[302] MTA-Angelus and ProRoot MTA have been compared experimentally as pulp capping agents in intact, caries-free human teeth.[5] Histomorphologic examination of extracted teeth revealed that the two materials produced similar responses with regard to inflammation and hard tissue formation.[5,193] MTA-Angelus also demonstrates antifungal properties and a lower compressive strength than ProRoot MTA.[29,180]

Endosequence root repair material shows low cytotoxicity, antibacterial activity against *E. faecalis,* and strong potential as a pulp capping material.[80,370] Another material, calcium-enriched mixture (CEM) cement, has also demonstrated excellent physical and biologic properties in vital pulp therapy investigations.[17-19,256]

This new generation of CSCs appears promising when used as vital pulp therapeutic agents and current investigations appear to support these materials' future potential.

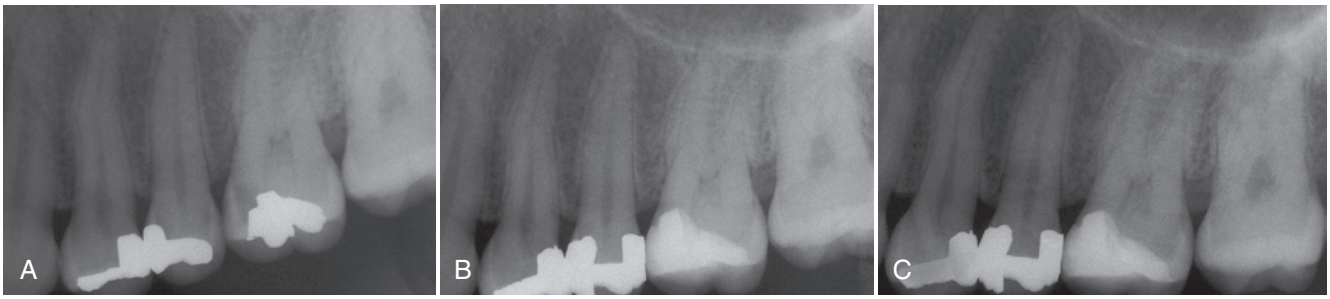

FIG. 23-7 Thirty-four-year old patient who presented with sensitivity to hot, cold, and sweet foods. **A,** Preoperative radiograph of maxillary left first molar showing mesial caries and an occlusal amalgam restoration. **B,** Posttreatment radiograph after 1.5-mm wide pulp exposure, direct "fast set" mineral trioxide aggregate (MTA-Angelus) pulp cap, and bonded composite restoration. MTA APPLICATIONS IN VITAL PULP THERAPY

Direct Pulp Capping with MTA

Controlled prospective investigations on direct pulp capping in humans using MTA against cariously exposed pulps are limited. Collectively, most studies are inconsistent with regard to case selection, treatment strategies, and clinical protocols.[232] The subsequent spectrum of outcomes is reflected by the absence of standardized guidelines for caries removal, hemostatic agents, single- versus two-visit delivery sequences, and the choice and placement of a capping material.

Unsatisfactory outcomes for direct capping due to variations in treatment delivery and protocols were clearly demonstrated in a cohort investigation completed by predoctoral dental students.[229] Fifty-one direct MTA pulp caps completed in a carious field were radiographically and clinically evaluated for a 12- to 27-month period. The overall success rates using Kaplan-Meier analysis were 67.7% at 1 year and 56.2% at 2 years. The poor outcome can be attributed to an absence of strict control protocols with regard to caries removal, selection of hemostatic agents, and appropriate magnification, illumination, and thickness combined with area coverage of MTA. As a result, the investigation concluded that the amount of hemorrhaging after pulp exposure was not a determining factor in the clinical outcome, contrary to other findings.[63,215]

More impressive results for pulp maintenance and continued vitality after direct pulp capping procedures have been demonstrated in several other contemporary studies.[4,6,204,222] An investigation examined 30 immature permanent teeth exhibiting wide-open apices directly pulp capped with MTA and restored temporarily with IRM.[109] Definitive permanent composite restorations were placed 2 weeks later, after confirmation of pulp vitality. In these cariously exposed immature permanent teeth, the success rate at a 2-year review was 93%.

Another observational investigation examined direct pulp capping after carious exposures of mature and immature permanent teeth completed using MTA in a two-visit sequence.[40] Forty-nine teeth were examined in patients aged 7 to 45 years over a 1- to 9-year period, with an average 3.94-year observation time. The study incorporated a strict protocol that included detector dye–aided caries excavation using the dental operating microscope, 5.25% to 6% sodium hypochlorite (NaOCl) hemostasis, thick MTA placement on pulp exposures and surrounding dentin, coupled with adhesion-based permanent restorations placed at a subsequent visit to compensate for the delayed setting properties of ProRoot MTA. Based on subjective symptomatology, cold testing, and radiographic evaluation, 97.96% of teeth showed a favorable outcome. All 15 patients with immature apices showed continued root formation, with apical closure over a 6- to 10-year period; five patients with large or multiple exposures exhibited pulpal calcification (Fig. 23-8).

The improved survival outcomes seen in this MTA pulp capping study can be credited to changes in established treatment protocols and the incorporation of improved pulp capping materials. Progress in the caries removal process, magnification systems, NaOCl hemostasis, MTA selection, and adhesion technology take advantage of advances in vital pulp therapy to surpass the outcomes seen with accepted traditional methods (Figs. 23-9 and 23-10).

The unique physiochemical properties of MTA also promote a superior environment for pulpal repair and bridge formation, compared to CH products.[162a,204,222,224a,247] MTA is a hygroscopic cement that sets in the presence of blood and serum, produces a gap-free interface with dentin, and generates a sustained alkaline pH; in addition, the surface morphology of the hardened cement allows for predictable bonding with current adhesion systems. Growth factors necessary for hard tissue formation are activated by MTA through the gradual release of calcium ions during cement curing.[190] The small particle size and alkaline pH contribute to the entombment of remaining cariogenic bacteria at the dentin-MTA interface, impeding bacterial ingression and caries progression and discouraging continued pulpal injury.[250,359a]

Pulpotomy with MTA

The decision to remove a small or large portion of the coronal pulp is based on visual inspection of the pulp tissue and the ability to achieve hemostasis after pulp exposure during either caries excavation or exposure as a result of trauma (partial or shallow pulpotomy). The coronal pulp tissue can also be removed completely to the pulp floor or cervical area (pulpotomy) in the case of molars and some premolars.[118,122] The AAPD guidelines state, "A pulpotomy is performed in a tooth with extensive caries but without evidence of radicular pathology when caries removal results in a carious or mechanical

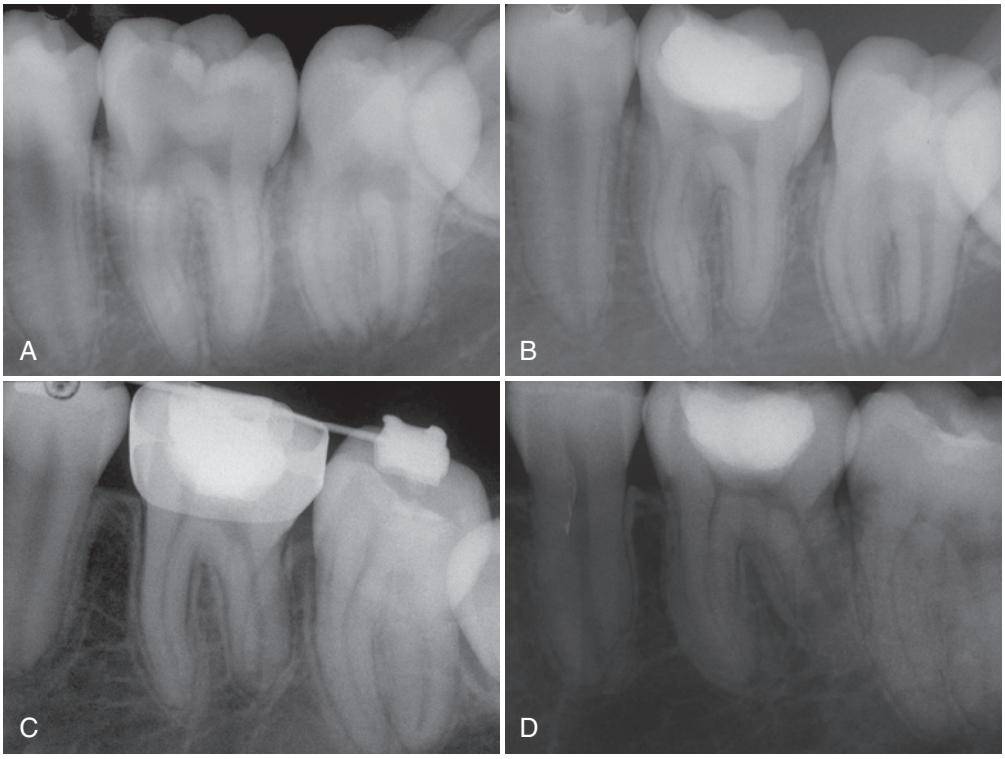

FIG. 23-8 An 11-year-old who presented with deep occlusal caries in a mandibular left first molar. Responses to cold testing were normal, although the patient complained of a sleepless night. **A,** Preoperative radiograph. **B,** Radiograph after direct mineral trioxide aggregate (MTA) pulp caps were applied, followed by composite restoration placement on the second visit. (© Dr. George Bogen.)

pulp exposure."[13] If bleeding cannot be controlled after 10 minutes of direct exposure to NaOCl after removal of unhealthy tissue, complete removal of the coronal pulp to the pulp floor is the preferred option.

Sodium hypochlorite serves as an excellent diagnostic tool to differentiate irreversible from reversible pulpitis and to help determine whether to proceed with partial pulpotomy, complete pulpotomy, or pulpectomy. This decision can be of paramount importance in young permanent teeth with open apices, in which removal of tissue contaminated by microorganisms can reverse symptoms and stabilize inflamed tissue.[64,100] Investigations have shown that the proliferative response of pulp tissue after exposure progresses several millimeters into the pulp from the injury site.[77] The removal of 1 to 3 mm of peripheral tissue to access the deeper, healthy tissue, in cases of trauma or when carious exposures reveal inflamed tissue, ensures pulp survival (Fig. 23-11).

Partial pulpotomy for treating direct pulp exposures in immature permanent teeth using CH products has been shown to be a reliable treatment option with proper case selection.* However, improved success rates ranging from 93% to 100% have been demonstrated using MTA for pulpotomies in permanent teeth.[28,272,352] Moreover, pulpotomies completed with MTA in primary molar teeth do not show pathologic complications such as internal resorption, which typically are seen with CH, formocresol, and ferric sulfate.[97]

It has been recommended that pulpectomy be avoided in immature permanent teeth with vital canal tissue so as to protect the remaining radicular pulp tissue and thus encourage continued root development and apexogenesis.[112,287,303] However, with the introduction of MTA, predictable root-end closure and maturogenesis can be achieved with new approaches using regenerative, revascularization, and apexogenesis procedures (Fig. 23-12).† Although controversy remains regarding the type and quality of tissue produced in regenerative procedures for nonvital teeth, current treatment options for immature teeth strengthen roots by increasing wall thickness and root length.[177,211]

Complete pulpotomy for mature irreversibly inflamed permanent molars represents a novel approach in treating symptomatic teeth while preserving pulp canal tissue.[17] A current randomized clinical trial compared full pulpotomies completed with MTA and CEM; the study examined postoperative pain, along with radiographic and clinical outcomes in patients diagnosed with irreversible pulpitis.[18] At a 1-year follow-up for 413 pulpotomized teeth, the clinical success rates were 98% for MTA and 97% for CEM. Similarly, the radiographic success rates were 95% for MTA and 92% for CEM. Most patients experienced a significant reduction in pain intensity postoperatively over a 7-day period. This conservative strategy for irreversibly inflamed teeth may be beneficial for patients in underserved areas globally.

VITAL PULP THERAPY TECHNIQUES

Diagnosis

A differential diagnosis based on symptoms and clinical findings is the goal in the assessment of pulp vitality. However, an accurate determination of the pulpal condition before treatment initiation can be more challenging in younger patients.[304] Establishing a diagnosis of reversible versus irreversible pulpitis in immature teeth can be complicated by subjective symptoms and testing responses that may not accurately reflect the histopathologic condition of the involved pulp.[52] However, efforts should be directed toward the ultimate goal of pulpal preservation and continued apexogenesis in immature permanent teeth.[38,39] A diagnosis of irreversible pulpitis, based on signs and symptoms, along with clinical testing procedures, does not preclude vital pulp therapy options. Regardless of the treatment choice of pulp capping or partial or complete pulpotomy, preservation of the radicular pulp and apical papilla allows for root maturation in cases of trauma or deep caries.[121,122,140,292]

Acceptable diagnostic quality intraoral radiographs of the involved tooth must be taken to evaluate accurately the extent

of root formation and periradicular or furcation changes associated with the periodontal ligament and supporting bone.[219] In young permanent teeth, the stage of root development directly influences the diagnosis and treatment options.[53] Because the faciolingual dimension of most immature roots is greater than the mesiodistal dimension, apical closure may be difficult to determine radiographically.[53,187] Teeth that demonstrate radiographic evidence of deep caries should not be planned for aggressive procedures, such as pulpectomy, without the benefit of thermal (cold) testing (see Fig. 23-1).

Before arriving at treatment decisions, the clinician should carefully assess all available information; the medical history, patient report, radiographic evidence, clinical evaluation, and vitality (cold) testing are recommended. Periodontal probing, mobility assessment, and the presence of any localized swelling or sinus tracts should be recorded during the evaluation. Radiographs, including bite wings and periapical views, should be evaluated for periapical and furcation pathosis, resorptive defects, and pulpal calcification resulting from trauma or previous restorations.

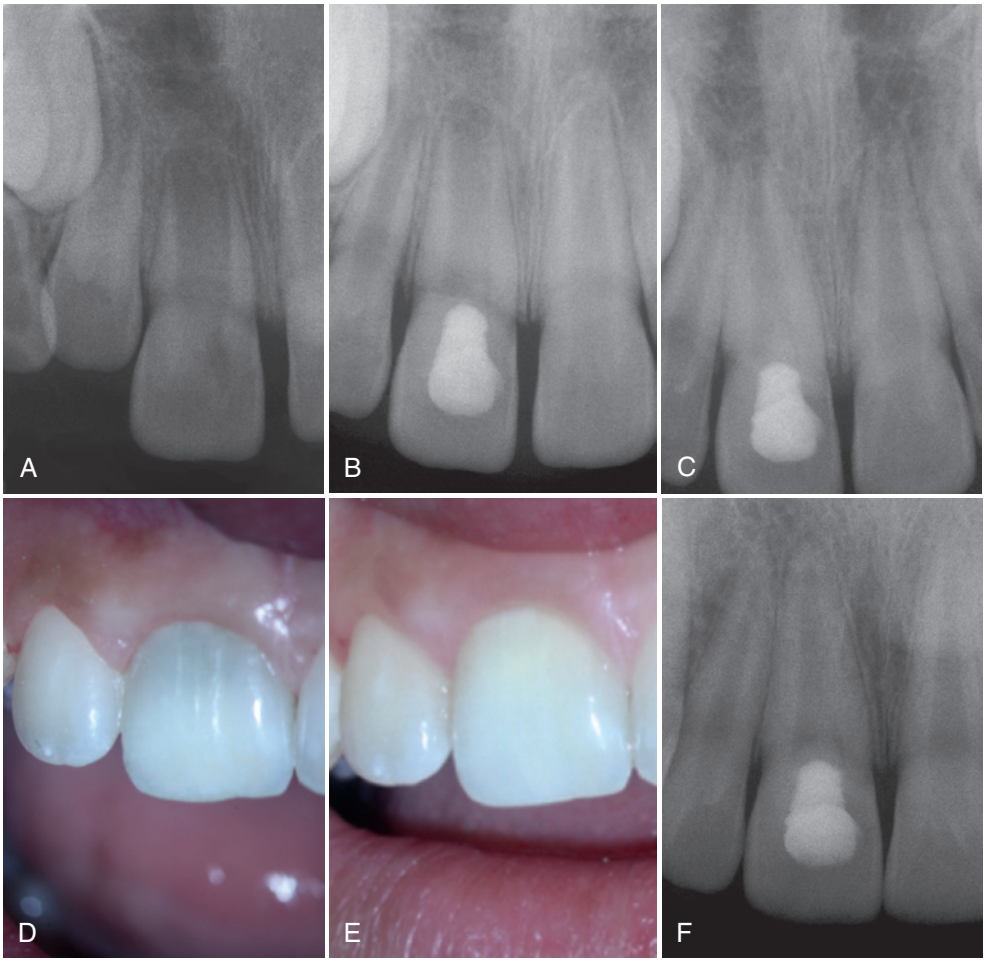

FIG. 23-12 Eight-year-old patient who presented with pulp exposure after traumatic injury. **A,** Periapical radiograph of maxillary right central incisor showing wide-open, immature apex. **B,** Radiograph 6 months after pulp amputation with a high speed diamond bur, saline irrigation, white mineral trioxide aggregate (MTA) partial pulpotomy, and placement of adhesive composite restoration. **C,** Two-year radiographic review; note apical maturation. **D,** Photograph showing coronal staining at 4-year recall. **E,** Photograph after MTA removal, reparative bridge confirmation, and internal bleaching with sodium perborate for 6 days. The hard tissue bridge was covered with a thin layer of phosphate cement before bleaching. **F,** Four-year radiographic review after MTA removal and bonded composite placement. Note presence of thick reparative calcific bridge and complete apical closure. The incisor remained asymptomatic and responded normally to cold testing at all time periods. (Courtesy Dr. Michael Hülsmann, Göttingen, Germany.)

Subjective symptomatology can be reviewed after clinical and radiographic assessments preclude the presence of unconditional irreversible pulpal disease. Patients with deep carious lesions often experience sensitivity to cold, heat, or sweet or acidic foods, and cold tests may evoke a short lingering response of 1 to 2 seconds. This may not be a definitive indicator that the pulp is irreversibly damaged. Determination of the pulpal condition with the aid of contemporary testing methods can be challenging, even for veteran clinicians, because of possible excessive responses to pulp percussion and palpation testing in children.[123,181,350] Clinical evidence indicates that cold testing with carbon dioxide ice is a more reliable prognosticator of pulp status in immature permanent teeth than electronic testing devices.[53] However, a diagnosis of irreversible pulpitis or pulp necrosis should be considered for teeth that generate pain on percussion.

Recent clinical investigations have demonstrated that a diagnosis of symptomatic irreversible pulpitis and acute apical periodontitis may not proscribe pulp capping and pulpotomy procedures when MTA or other CSCs that have been shown to reverse the inflammatory process are used.[64,100] Clinically, the difference between reversible and irreversible pulpitis is often determined on the basis of the duration and intensity of pain.[122] Unprovoked spontaneous pain of long duration or unrelenting symptoms forcing sleep deprivation are consistent with irreversible pulp inflammation or an acute periapical abscess.[350]

Another important consideration in the differential diagnosis is a patient with displacement trauma, which can display a transient apical breakdown radiographically that mimics periapical radiolucencies.[15] Teeth that experience luxation-type injuries can discolor and may not respond to cold testing for up to 4 months before they recover normal color and vitality. Also, biologically or pharmacokinetically immunosuppressed patients may not respond to conventional treatments because of abnormal function of related repair mechanisms.[208,343] Most clinical investigations clearly indicate that successful outcomes

for vital pulp therapy decrease as the patient's age increases. Although aging of the pulp diminishes pulpal volume, vascularity, and host immune responses, functional repair mechanisms can still provide favorable treatment outcomes in older patients (Fig. 23-13).[1,234]

The initial pulpal diagnosis can be confirmed after visualization of the exposed pulp and during hemostasis assessment. If no hemorrhaging is seen, this area of the tissue is most likely necrotic, and the tissue must be removed with a high-speed round diamond bur until bleeding is evident (Fig. 23-14). After hemostasis with NaOCl, a large bulk of MTA can be placed directly against the remaining tissue. Alternatively, if hemorrhage control cannot be achieved after 10 minutes of direct contact with 3% to 6% NaOCl, the pulp is likely to be irreversibly involved, and a full pulpotomy or pulpectomy is recommended.

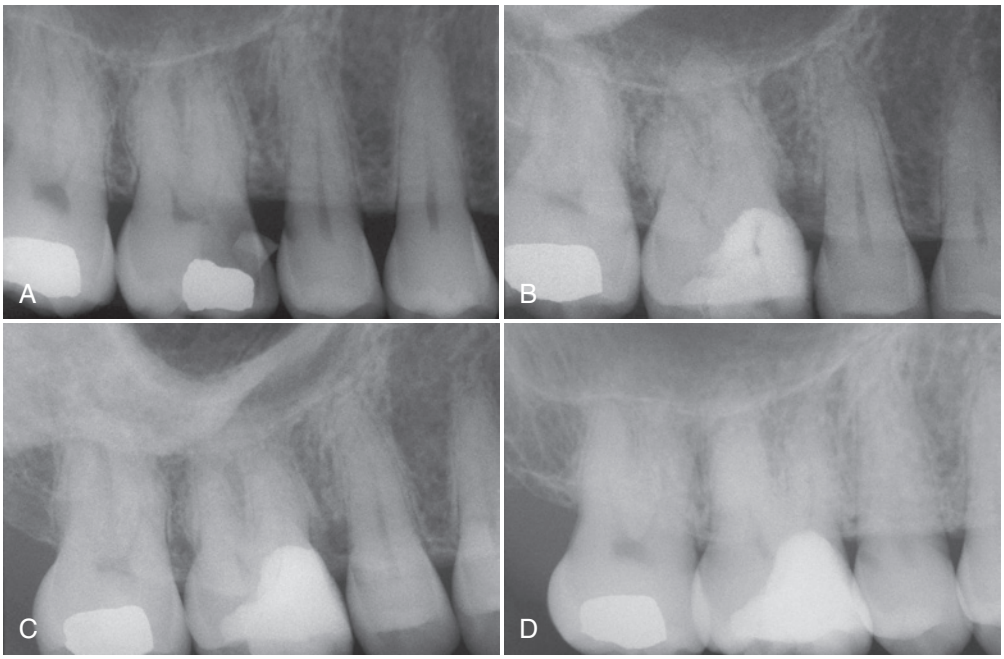

FIG. 23-13 Fifty-one-year-old patient who presented with a deeply carious but asymptomatic maxillary right first molar. **A,** Preoperative radiograph reveals extensive mesial caries and an occlusal amalgam. **B,** Postoperative radiograph after 1.5-mm pulpal exposure, sodium hypochlorite hemostasis, mineral trioxide aggregate (MTA) direct pulp cap, wet cotton pellet placement, and Photocore® provisionalization. **C,** Radiograph 1 week after pulp capping and placement of a permanent bonded composite restoration. The patient was asymptomatic and showed a positive response to cold testing. **D,** One-year radiographic recall; cold testing revealed normal vitality. (© Dr. George Bogen.)

Note necrotic pulp tissue *(arrow)* that was subsequently removed with the remaining coronal pulp during a complete pulpotomy procedure. **B,** Clinical presentation of mandibular right molar in a 7-year-old patient after pulp exposure during caries excavation using a caries detector dye. Note the extruded seminecrotic, nonhemorrhagic tissue *(arrow).* The tooth later underwent mineral trioxide aggregate (MTA) partial pulpotomy and permanent restoration. (© Dr. George Bogen.)

Although the size of the pulp exposure has no significant bearing on the final outcome, some clinicians falsely assume that larger exposures have an unfavorable prognosis.[215] Pulp sizes are underestimated on radiographs.[58-60] The size of the pulp exposures may also be overestimated, which could affect the decision-making process, leading clinicians to abandon more conservative vital pulp options.[135] Pulp dimensions may also vary with various racial groups and between genders.[59,296,345]

Teeth that have a history of trauma or previous restorations or that display pulpal calcification have a poorer prognosis than teeth showing only initial caries. In the selection of a specific vital pulp treatment, it is important to consider the remaining tooth structure and future restorative plan. In patients with uncontrolled caries or extensive loss of coronal structure, in which full coverage is indicated, pulpotomy rather than pulp capping is recommended.[43,52,324]

Caries Removal

The main objective in caries removal is the identification and complete removal of the infected tissue while preserving sound tooth structure; this contributes to pulpal protection and continued vitality. Caries removal is enhanced with the aid of a caries detector dye and optical magnification; however, some studies have indicated that dyes can cause excessive and unnecessary removal of healthy tooth structure.[24,218,359]

Caries removal has traditionally been completed somewhat subjectively using hand instruments and slow-speed burs. The procedure is performed using an explorer and tactile sense to differentiate soft from hard dentin to determine infected from noninfected dental tissue. However, this method can have shortcomings because clinicians may leave decay at the dentinoenamel junction and unnecessarily remove dentin that still has the potential to remineralize under a sealed restoration.[124] Furthermore, it has been found that the ability to remove caries varies among operators and during different time periods for the same operator.[124,125]

Investigators in the early 1970s used SEM to identify two different layers of carious dentin.[125] Teeth show two distinct layers of carious dentin as the result of gram-positive bacteria releasing lactic acid as their main by-product. The outside carious layer subjacent to the dentinoenamel junction exhibited demineralized hydroxyapatite crystals that were dissolved by acidic bacterial byproducts; this layer also featured unbound and altered collagen denatured by microbial proteolytic enzymes.[271] A fuchsin dye suspended in propylene glycol was used to reveal that this necrotic and infected layer could be selectively stained, identified, and removed objectively, thus preserving the inner carious layer that remained capable of remineralization. A highly significant difference in the total colony-forming units in stained and unstained dentin has been demonstrated.[364]

The second demineralized carious layer proximal to the pulp featured degraded hydroxyapatite crystals but contained collagen with intact intermolecular cross-links unaffected by cariogenic acids and not stainable with caries detector dyes.[125,126,285] If the second inner layer can be identified and preserved during caries excavation, the remaining pulp tissue and odontoblasts subjacent to the carious zone will be subjected to less trauma, which contributes to pulpal protection and survival.[245,280] The second layer proximal to the pulp has a stronger capacity to remineralize when paired with bonded composite restorations to prevent bacterial microleakage.[233,245]

The two carious layers have been further classified into four zones (pink, light pink, transparent, and apparently normal) when analyzed by atomic force microscopy and transverse digital microradiography.[271] Consistent with previous investigations, the four zones reinforce the concept that increasing levels of demineralization decrease the peritubular dentin rating and mechanical properties of dentin.[271]

Caries detector dyes can be considered a valuable tool in caries excavation when attempts are made to preserve remineralizable dentin and to minimize trauma to the pulp.[87,168,173] Investigations in human, dog, and nonhuman primate models have demonstrated this regenerative characteristic in caries-affected dentin.[178,184,233,319,320] Several studies have questioned the efficacy of caries removal using a caries detector dye. Not all stainable dentin can be classified as infected, and the absence of staining does not eliminate the potential for residual cariogenic bacteria.[185,271] However, dyes allow the operator to visually inspect, under magnification, infected dentin that may have been overlooked, particularly at the dentinoenamel junction, a situation that may compromise the outcome for vital pulp therapy.[185,358] Although a compromise, it may be preferable clinically to inadvertently remove a small excess amount of dentin than to leave infected tissue with active caries.

Hemostatic Agents

A wide range of hemostatic solutions and methods have been recommended to control a bleeding pulp exposure. These include various concentrations of NaOCl; 2% chlorhexidine; MTAD (DENTSPLY Tulsa Dental Specialties, Tulsa, Oklahoma); 30% hydrogen peroxide (Superoxol); ferric sulfate; disinfectants, such as Tubulicid (Global Dental Products, North Bellmore, New York); epinephrine; direct pressure with cotton pellets soaked in sterile water or saline; and the use of lasers.[8] Sodium hypochlorite in concentrations of 1.5% to 6% is currently regarded as the most effective, safe, and inexpensive hemostatic solution for pulp capping and partial and complete pulpotomy procedures.[145,351] First used as a wound antiseptic during World War I and referred to as Dakin's solution, NaOCl became a valuable hemostatic agent in dentistry for direct pulp exposures in the late 1950s.[144,163,310] The antimicrobial solution provides hemostasis and disinfection of the dentin-pulp interface, chemical amputation of the blood clot and fibrin, biofilm removal, clearance of dentinal chips, and removal of damaged cells at the mechanical exposure site.[27,97,144,212] Concentrations of 1.5% to 6% in direct contact with pulp tissue do not appear to adversely alter pulp cell recruitment, cytodifferentiation, and hard tissue deposition.[92] Sodium hypochlorite also shows excellent efficacy as a hemostatic agent at lower dilutions (0.5%).[337]

When direct pulp exposures occur in a carious field, the ability to attain hemostasis remains the most crucial factor in the success of vital pulp therapy. This was demonstrated in an innovative study that examined outcomes of teeth directly pulp capped with a hard-setting CH after pulp exposures were generated during caries excavation.[215] Caries removal during the investigation was aided by a caries detector dye, and 10% NaOCl was used for hemostasis. The 2-year success rate was 81.8%. A statistical analysis of key factors revealed that preoperative thermal responses, percussion sensitivity, the diameter of the exposure, the age of the patient, and the tooth type and location had no significant influence on the outcome. The degree of bleeding and its control at the time of exposure constituted the most critical predictor for outcome assessment.

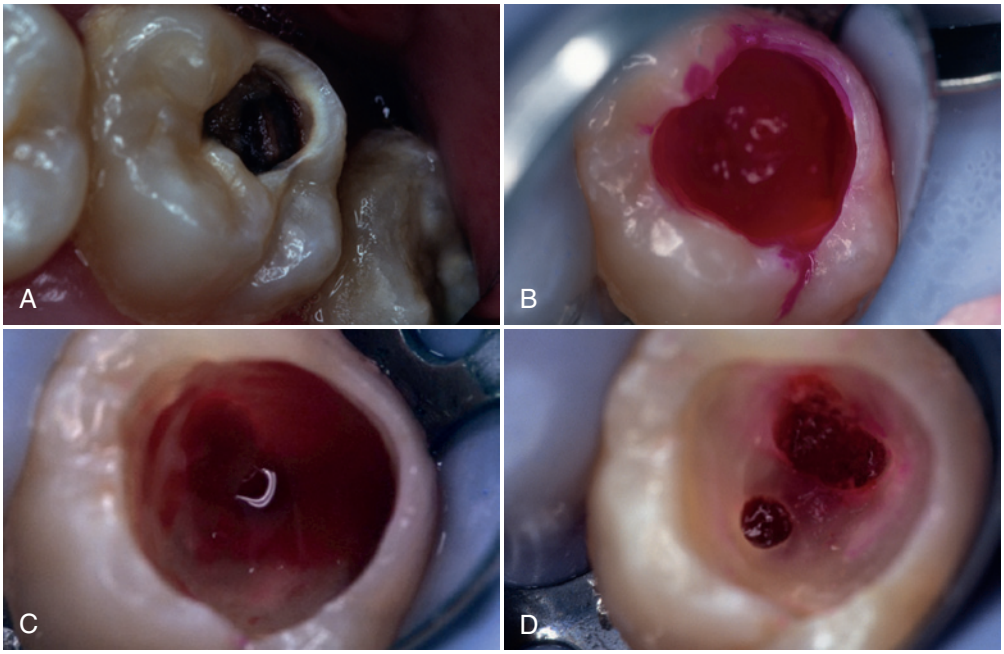

FIG. 23-15 Clinical sequence showing a cariously involved maxillary right first molar in an asymptomatic 20-year-old patient. **A,** Large occlusal-buccal carious lesion. **B,** Caries detector dye staining after initial removal of debris and infected dentin. **C,** Occlusal view of pulp roof exposure with 6% sodium hypochlorite hemostatic solution. **D,** Two large pulp exposures (2 mm and 2 · 4 mm) after caries removal and sodium hypochlorite hemostasis. Note that bleeding is absent and there is no evidence of necrotic tissue. (© Dr. George Bogen.)

When hemostasis can be attained, pulpal repair and reparative dentin formation can proceed normally, in the absence of microbial challenges, when MTA is used as the pulp dressing.[63,179]

Sodium hypochlorite is not only an effective hemostatic agent, it can also be considered an invaluable diagnostic tool for assessing the difference between irreversibly and reversibly inflamed pulps (Fig. 23-15). During the inflammatory process, as cariogenic bacteria approach the pulp, higher levels of immunoglobulins (e.g., IgA, IgG, IgM) and inflammatory markers have been detected, including elastase and prostaglandin E_2.[248] The presence of these mediators can contribute to increased intrapulpal pressure and may play a critical role in the pathogenesis of the irreversibly inflamed pulp.[248,325]

The coronal pulp must be considered irreversibly inflamed when hemorrhage cannot be arrested after 5 to 10 minutes of direct exposure to NaOCl. If bleeding continues, partial or complete removal of the coronal pulp is indicated, with the goal of gaining hemostasis before MTA placement (Figs. 23-16 and 23-17). Sodium hypochlorite has demonstrated effective hemostatic and antiseptic properties in humans without adversely affecting pulp repair, healing, and tertiary dentinogenesis.[92] An investigation into pulp-capped human third molars treated with either CH or a self-etching adhesive system histologically examined pulps at 30 and 60 days after the use of 2.5% NaOCl for hemostasis.[102] Histologic evidence demonstrated no impairment of the repair process after the use of NaOCl, although CH appeared to outperform the resin-based pulp capping agent. Current data clearly support the use of 1.25% to 6% NaOCl solutions in humans as a safe and appropriate hemostatic agent for direct pulp capping and pulpotomies.*

Treatment Considerations

An important and often unrecognized aspect of direct pulp capping in a carious field is the potential survival of undetected cariogenic bacteria, in dentinal tubules of the dentin adjacent to the exposure site, after caries removal. These microorganisms can compromise treatment even after meticulous caries excavation and NaOCl disinfection. Unfortunately, traditional pulp capping protocols have directed clinicians to place pulp dressings only at the exposure site, without considering the adjacent dentin. Therefore, it is recommended that MTA or CSC be placed over the exposure sites and most of the surrounding dentin with the goal of entombing residual microorganisms.[359a] This notable change in pulp capping strategy can improve treatment outcomes in symptomatic and asymptomatic teeth featuring extensive caries and multiple exposures after caries excavation.[39] Together with an extensive application of MTA or CSC, a cement thickness of 1.5 mm or greater increases the likelihood of bacterial neutralization and minimizes further microbial challenges.

This concept in pulp capping with MTA becomes more critical in one-step pulp capping protocols that use slow-set CSCs covered with RMGI cements. These cements are water-based bonding agents and are not affected by small amounts of water on the dentin or MTA/CSC surface.[86] Unset RMGI cement has an initial pH of about 1.5 and demonstrates no polymerization shrinkage stress, and the material acts as a self-etching primer. Although the bond strength reaches only 25% of comparable resin bonding systems (approximately 10 MPa), the bond is reliable and resistant to disintegration.[86] Although the active chemical constituents are inflammatory and toxic when used for pulp capping and placed directly on exposed pulp tissue, RMGI cements produce only mild inflammatory

changes to vital pulp tissue when indirectly placed on the remaining dentin.[70,95,159,192]

Resin Modified Glass Ionomer cements have substantial antimicrobial properties, and there are no known physiochemical properties of unset MTA that would adversely affect the set of RMGI materials. However, the challenge during one-step pulp capping procedures with RMGI cements in conjunction with a larger volume of unset MTA is adequate adhesion of the RMGI to the remaining dentin and wet MTA during composite placement.[26] This situation creates great difficulty when contemporary bonding protocols require air blasting during primer and resin placement because the RMGI can be easily dislodged from the unset MTA. In this instance, it may be advisable to place an unbonded amalgam restoration over the RMGI/MTA/dentin interface, if feasible.[250] A reduction in MTA coverage and probable thickness to accommodate RMGI adhesion can compromise favorable outcomes in vital pulp therapy, and either a two-step treatment sequence or fast-set CSCs should be considered.

TREATMENT RECOMMENDATIONS*

Two-Visit MTA Pulp Capping

1. After differential diagnosis, it is determined that the tooth demonstrates either a normal pulp or reversible pulpitis. The tooth should have a normal radiographic appearance and be restorable without crown lengthening procedures. After profound local anesthesia has been obtained, the tooth is isolated with a dental dam and additionally sealed with an agent, such as Oraseal (Ultradent Products, South Jordan, Utah) or a similar product, if saliva leakage is present. The clinical crown is then disinfected with NaOCl or chlorhexidine. Optical magnification and illumination are highly recommended. A high-speed diamond or carbide bur is used to remove undermined enamel, and soft debris is removed with a spoon excavator.
2. After the carious dentin has been exposed and air-dried, a caries detector dye is applied for 10 seconds, and the tooth is washed and dried with a two-way syringe. Caries removal is completed with spoon excavators and/or slow-speed #6-2 carbide round burs until minimal (light pink) or no deeply stained dentin is evident. The dentin is washed and dried again, and the caries detector is reapplied on the dentin for 10 seconds. The process is repeated meticulously until no or only light pink staining is evident (usually 5 to 7 applications).
3. Bleeding can be controlled by the placement of a cotton pellet moistened with 3% to 6% NaOCl for 20 to 60 seconds if pulp exposure occurs during the caries removal process. The staining and caries removal are continued carefully around the exposure site(s) until minimal or no staining is visible. Areas of reparative dentin should be left intact.
4. Direct pulp exposures that occur during caries removal should be hemorrhaging to some degree. A 3% to 6% NaOCl solution, with or without a cotton pellet, is placed directly against the exposure or exposures for a contact time of 1 to 10 minutes. If the tissue appears normal while hemorrhaging, no tissue amputation is indicated. The diagnosis is changed to irreversible pulpitis when hemostasis cannot be obtained within 10 minutes; more aggressive treatment should then be initiated. If bleeding is not evident after pulpal exposure, a high-speed round diamond bur is used to remove tissue until bleeding and healthy tissue are evident. A second application of NaOCl after tissue removal should stop any hemorrhaging. A pulpotomy or pulpectomy must also be considered if the entire axial wall or pulpal roof is removed during caries excavation (Fig. 23-18).
5. The dentin should be gently washed with water and dried to remove excess NaOCl before MTA is applied. The material is mixed according to the manufacturer's instructions (3:1, MTA:H_2O) to a consistency similar to wet sand. An MTA carrier gun or a hand instrument (spoon excavator or Glick) is used to bring the cement to the site in bulk. The MTA should be placed directly over the exposed pulp tissue, including all surrounding dentin. The material is gently patted down with a small moist cotton pellet or a dry pellet if the mixture is too wet. The cement placed should have a minimum thickness of 1.5 mm. MTA inadvertently forced into the pulp chamber will not affect the outcome adversely. For the final bonded restoration to provide an effective seal, a region of dentin and enamel measuring approximately 1.5 to 2 mm should be cleared circumferentially around the MTA with a small (2 mm) moist cotton pellet or sponge brush.
6. A custom-fabricated, flat (1 to 2 mm), moist cotton pellet or gauze is placed over the entire mass of the MTA. The moist pellet or gauze may require placement in two sections if the cavity involves a proximal preparation with an exposure on the axial wall. If the decision is made to complete the restorative treatment on the same day, a large moist cotton pellet can be placed; the patient is instructed not to eat or chew because this may disrupt the unset MTA. A bonded restoration can be placed after a 4-hour waiting period.
7. After placement of MTA and coverage with a wet, flat cotton pellet or gauze, a durable and removable provisional material is used. Unbonded Photocore® (Kuraray America, Inc., New York, New York) is recommended as a reliable option because of its ease of handling and unique polymerization characteristics. Teeth should be conservatively removed from occlusion if thin cusps are present as a result of extensive caries removal. Unless amalgam is the designated restorative material, restorations such as IRM or zinc oxide eugenol (ZOE) (eugenol based) may reduce the bond strengths of adhesive resins and their use with bonding materials remains controversial.[56a,269a]
8. The return appointment can be scheduled 1 to 10 days after MTA placement. The patient is asked about sensitivity, mastication comfort, and pain before the local anesthetic is given. To confirm continued normal vitality before anesthesia, the tooth is cold tested with carbon dioxide (CO_2) ice or Hygienic Endo-Ice (Coltène/Whaledent, Cuyahoga Falls, Ohio). After profound anesthesia is obtained, the tooth is isolated with a dental dam. The provisional material is removed with a high-speed diamond or carbide bur using water coolant. The cotton pellet or gauze is removed, and the embedded cotton fibers are removed with a spoon excavator or similar hand instrument. Magnification and

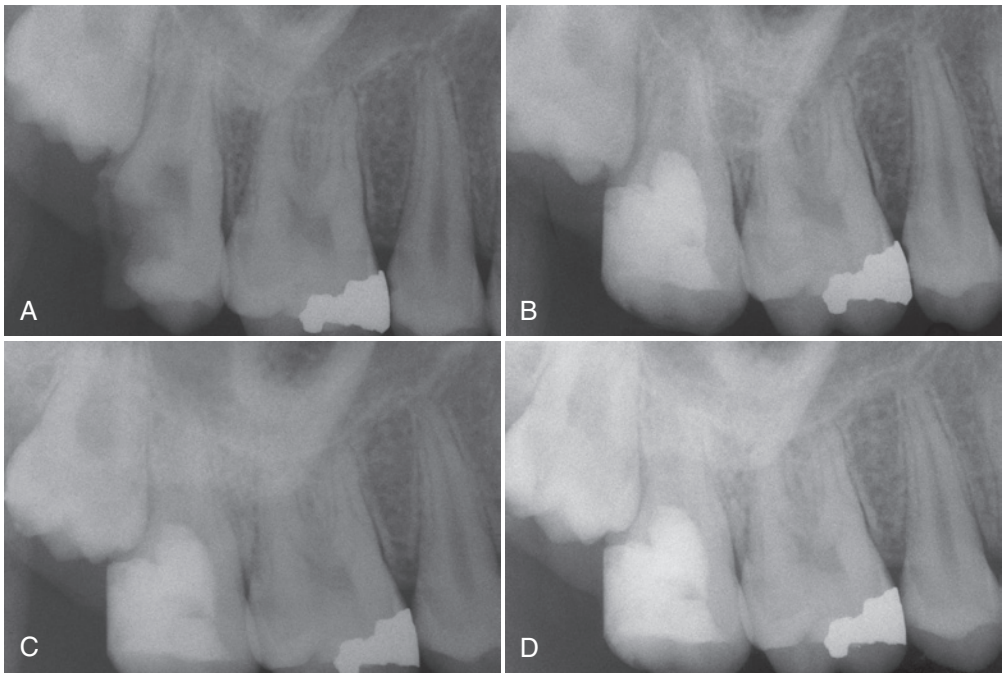

FIG. 23-18 Radiographic sequence of treatment of a maxillary right second molar in a 14-year-old patient, previously recommended for extraction because of advanced caries. **A,** Preoperative radiograph showing extensive caries at the occlusal level of the erupting third molar. The patient was asymptomatic but had pain on cold testing. **B,** Postoperative radiograph after complete exposure of axial wall during caries excavation, mineral trioxide aggregate (MTA) pulpotomy, and placement of flowable resin-modified glass ionomer cement over wet MTA with bonded composite placement. **C,** One-year radiographic recall. **D,** Two-year radiographic control showing absence of apical disease. The molar was functioning normally and without symptoms. (© Dr. George Bogen.)

illumination are strongly recommended to guide the operator. A bonded composite restoration is placed, following the manufacturer's recommendations, after the MTA has been checked to ensure proper curing.

9. After completion of the permanent bonded restoration, the occlusion is checked and adjusted as required. Subjective symptomatology and cold testing should be evaluated at 6 weeks. Radiographic follow-up, cold testing, and subjective symptomatology can be reevaluated at 6 and 12 months if the initial follow-up appears favorable. Yearly or biannual recalls are recommended.

One-Step Pulp Capping

The manufacturer of MTA (ProRoot MTA, DENTSPLY Tulsa Dental Specialties) recommends that pulp capping be completed in one visit. In some instances, treatment of the immature permanent tooth can be difficult, particularly in young patients with challenging medical or behavioral problems that require treatment under sedation. The manufacturer of MTA recommends the following protocol when one-step treatment is indicated.

1. With dental dam isolation, complete a cavity preparation outline using high-speed burs under constant water cooling.
2. If caries is present, excavate using a round bur in a handpiece at low speed or use hand instruments.
3. Rinse the cavity and exposure site (or sites) with 2.6% to 5% NaOCl. Heavy bleeding may be controlled with a cotton pellet moistened with NaOCl.
4. Prepare ProRoot MTA according to mixing instructions.
5. Using a small ball applicator or similar device, apply a small amount of ProRoot MTA over the exposure.
6. Remove excess moisture at the site with a dry cotton pellet.
7. Apply a small amount of Dyract flow flowable compomer (Dentsply International, York, Pennsylvania) (or an equivalent light-cured resin–glass ionomer liner) to cover the ProRoot MTA and light cure according to the material's instructions.
8. Etch the remaining cavity walls with 34% to 37% phosphoric acid gel for 15 seconds. Rinse thoroughly.
9. Dry the cavity gently, leaving the dentin moist but not wet. Apply Prime and Bond NT material or an equivalent bonding material. Cure according to its instructions.
10. Place TPH Spectrum (Dentsply Caulk, Milford, Delaware) composite material or an equivalent composite resin to complete the restoration. Cure according to its instructions.
11. At the next appointment, assess the pulp vitality. Pulp vitality and status should be assessed radiographically every 3 to 6 months or as needed.

The authors recommend the following modifications: Caries removal can be completed under magnification and illumination with the aid of a caries detector dye (step 2). During MTA placement against the exposure site (step 5), a larger bulk of MTA be placed that includes most of the surrounding dentin at a thickness of at least 1.5 mm. One-step pulp capping and pulpotomy procedures can also be completed with the faster-setting hydraulic tricalcium silicate materials.

THE PERMANENT RESTORATION

The placement and quality of the permanent restoration can be crucial to the long-term maintenance of pulp vitality and may be more significant than the actual pulp treatment.[11,114,157,221,227] The aim of the final restoration is to complement the sealing ability of the pulp capping/pulpotomy material and effectively defend the pulp from further microbial challenges. The selection of the restorative material, procedure execution, and adherence to proper restorative protocols can all contribute to minimizing potential restorative microleakage. It has been proposed that microleakage around restorations may be more detrimental to vital pulp tissue than unfilled cavity preparations directly exposed to the oral environment.[284] An important consideration in both mature and immature permanent teeth is the conservation of the remaining tooth structure, which ultimately contributes to favorable long-term retention and function.[69,93,167,301] The incorporation of adhesive restorative materials as definitive final restorations minimizes tooth reduction, encourages anatomic preservation, and thus provides better pulpal protection and repair potential.[124,143]

Technologic advances in dental materials have increased treatment options in the restoration of teeth that have undergone vital pulp procedures. Permanent restorations for pulp capped or pulpotomized permanent teeth can include composite resins, bonded or unbonded amalgam restorations, and cuspal coverage restorations. However, the more conservative the restorative treatment, the greater the probability of pulp survival.[124] Vital pulp therapy must be considered an injury to an already challenged connective tissue, and every effort should be directed toward minimizing further injurious procedures.[1] Factors that affect the repair mechanisms in pulp tissue can include the age of the patient, the depth and size of the cavity preparation, and the choice of restorative material.[246]

Amalgam remains the most widely used restorative material because of its ease of placement, proven durability, and low cost. However, drawbacks include potential health risks to dental personnel, esthetic limitations, and a high modulus of elasticity that can increase the incidence of cuspal fracture or coronal infractions.[9,114] This is a major concern in immature permanent teeth, in which cusps are unprotected, requiring further tooth reduction by placement of stainless steel crowns.[75,106,297,348,350] The implementation of bonding resins or RMGI liners in conjunction with amalgam placement can improve sealing ability and reduce potential microleakage. Even though amalgam restorations remain a safe and predictable long-term restorative option, the technology driving adhesion dentistry continues to improve as new composites and bonding resins evolve.[115,263]

Total-etch and self-etching systems produce excellent bond strength to enamel, dentin, and cured tricalcium silicate cements.[20,249] The most durable bond strengths generated with contemporary materials are achieved using selective etching of the enamel with 40% phosphoric acid, followed by two-step self-etching adhesive systems.[56,253,341] Current advances in adhesive technology have also shown that beneath the resin-interfused hybrid layer, an acid-base–resistant zone is formed that enhances the resistance of normal dentin to recurrent caries. This reinforced layer (termed "super dentin") forms when monomer penetration and polymerization occur, and it demonstrates an ability to restrict (inhibit) primary and secondary caries.[252] As a result of their simplifications and improved bonding strengths, modern adhesives have proved to be a predictable partner that complements vital pulp therapy. It is imperative that all bonding procedures strictly follow the manufacturer's recommendations and include dental dam placement.[56]

POSTOPERATIVE FOLLOW-UP AND RECALL

After treatment completion, the pulp status must be assessed periodically to ensure continued pulp vitality, normal function, and apical closure in immature teeth. Radiographic evaluation and cold testing most accurately assess continued pulp health and are excellent predicators for measuring survival rates. Recalls can address postoperative sensitivity, pulpal degeneration or necrosis, and indications for more extensive endodontic care, such as pulpectomy and root canal treatment Radiographic and clinical review also allows detection of emerging complications, including recurrent caries, poor hygiene, restoration failures, cuspal fractures, and other potentially adverse conditions.

Patient compliance for recall in asymptomatic cases can be challenging compared to patients who had unsuccessful pulp treatments that became irreversibly inflamed or advanced to symptomatic apical periodontitis. Because some parents do not practice regular preventive care and may not have a strong background in basic oral health care, recall compliance rates for children can be unpredictable.[176,270] Although recall intervals have traditionally been based on the conventional 6-month checkup and oral prophylaxis period, this generally accepted practice has come into question for accurate follow-up assessment.[228] It may be preferable to establish recall rates individually, based on patient need, symptomatology, the caries index, periodontal status, and craniofacial development assessment in younger patients.[254,344]

A tentative diagnosis of tooth survivability can be made at the 3-month recall.[215] One study demonstrated that the prognosis for long-term pulp survival can be established at an observation period of 21 to 24 months.[215] A 5- to 10-day review period can be beneficial diagnostically when the patient returns for the final restoration in the two-visit MTA pulp capping protocol. Thereafter, if cold testing reveals normal vitality, recall reviews can be scheduled, if possible, at 6 weeks and at 6 and 12 months depending on patient compliance.[40]

The paramount objective in vital pulp therapy is to promote the physiologic formation and maturation of the root end (apexogenesis). Radiographic evidence of root-end closure in immature adult teeth is a reliable prognostic marker of continued pulp vitality (Fig. 23-19).[23] Apexogenesis after direct pulp capping or pulpotomy procedures using MTA should proceed normally in healthy patients at a progressive rate.[27,269,347,353] The observed root maturation should also follow a predictable pattern of tooth development that coincides with the contralateral teeth in the same patient when the teeth are compared radiographically and viewed chronologically.[23]

Observation of contralateral tooth development can be an invaluable method of measuring the success of vital pulp therapy when using MTA. Alternatively, in traumatized teeth that exhibit necrotic pulps and periradicular pathosis, MTA and CH can be used as an apical plug to stimulate the apical papilla to promote barrier formation, which may otherwise require 5 to 20 months for completion (apexification).[7,65,294]

FIG. 23-19 **A,** Radiograph of a symptomatic mandibular first molar with deep caries in a 7-year-old patient who presented with an open distal root apex *(arrow).* **B,** The patient received a mineral trioxide aggregate (MTA) direct pulp cap and bonded restoration in a two-visit sequence. **C,** Radiographic recall after 14 months showing maturation and apical closure. The tooth showed a positive response to carbon dioxide (CO_2) ice testing. (© Dr. George Bogen.)

If MTA is substituted for CH in vital pulp therapy procedures, similar time periods for apical maturation can be anticipated.[103,223,224]

In the absence of microbial challenges, the human dental pulp demonstrates an exceptional regenerative capacity when treated with MTA and similar bioactive substances. Together with our advances in pulp biology and dental materials, changes in treatment protocols and delivery that encourage dental pulp preservation and survival will ultimately contribute to improved dental health for all patients needing vital pulp therapy.

ACKNOWLEDGEMENT

We wish to thank Dr. Leif K. Bakland for his contributions to this chapter.

CHAPTER 24

Pediatric Endodontics: Endodontic Treatment for the Primary and Young Permanent Dentition

PAULA J. WATERHOUSE | JOHN M. WHITWORTH

CHAPTER OUTLINE

The Pulp-Dentin Complex in Primary and Young Permanent Teeth
Differences in Primary and Permanent Tooth Morphology
Root Formation
Primary Root Canal Anatomy
Primary Anterior Teeth
Primary Molars
Clinical Pulpal Diagnosis in Children
History and Characteristics of Pain
Clinical Examination
Palpation, Percussion, and Mobility
Pulp Tests
Radiographic Examination
Restorative Diagnosis: Pulpal Exposures and Hemorrhage
Diagnosis After Traumatic Injuries in Children
Pulp Diagnosis and Treatment Planning After Trauma
Principles of Endodontic Treatment in Children
Pulp Therapy for the Primary Dentition
Indirect Pulp Therapy in Primary Teeth
Direct Pulp Capping in Primary Teeth
Pulpotomy in Primary Teeth
Formocresol Pulpotomy
Alternatives to Formocresol Pulpotomy
Glutaraldehyde Pulpotomy
Ferric Sulfate Pulpotomy
Mineral Trioxide Aggregate Pulpotomy
Electrosurgical Pulpotomy
Laser Pulpotomy
Nonvital Pulp Therapy on Primary Teeth
Pulpectomy in Primary Teeth
Access Openings for Pulpectomy
Root-Filling Materials for the Primary Root Canals
Follow-Up After Pulpectomy in the Primary Dentition
Pulpal Therapy for the Young Permanent Dentition
Indirect Pulp Therapy: Avoiding Pulp Exposure
Managing Pulp Exposure
Pulpotomy
The Cvek Pulpotomy on Immature Permanent Teeth
Partial Pulpotomy on Asymptomatic Young Permanent Posterior Teeth
Pulpotomy on Symptomatic Young Permanent Teeth
Follow-Up After Pulp Capping and Pulpotomy
Formocresol Pulpotomy on Young Permanent Teeth
Apexogenesis
Apexification
Apexification Technique
Artificial Apical Barrier Techniques
Restoration After Apexification
New Horizons for Pulp Regeneration

Despite the dental profession's emphasis on prevention, threats to pulp survival, such as caries, restorative dental treatment, and traumatic injuries, have not been eliminated. As a consequence, children continue to lose teeth prematurely, and procedures aimed at preventing and treating pulp disease in the primary and immature permanent dentitions remain an integral part of contemporary dental practice.

Some may question why efforts to preserve pulpally involved primary teeth are important. These practitioners maintain that such efforts may present a risk to developing permanent successors and, in any case, the primary teeth will be lost before long. Preservation of arch space is one of the principal objectives of pediatric dentistry. Premature loss of primary teeth may cause aberration of the arch length, resulting in mesial drift of the permanent teeth and consequent malocclusion. Whenever possible, the tooth with pulp involvement should be maintained within the dental arch in a functional and disease-free condition.

Other objectives of preserving the primary teeth are to safeguard aesthetics and mastication, prevent aberrant tongue

habits, aid in speech, and prevent the psychological effects that may be associated with tooth loss. Premature loss of the maxillary incisors before 3 years of age has been shown to cause speech impairment that may persist in later years.[229]

It is equally undesirable for children to suffer the unplanned loss of permanent teeth, and it should be noted that the prognosis for lifelong retention of an immature tooth with a short root and fragile dentinal walls is far worse than for a mature permanent tooth. Special treatments for the immature permanent tooth, therefore, focus on preserving vital pulp functions, at least until dental development is complete (see also Chapter 10).

This chapter attempts to provide a review of current therapies for the prevention and treatment of pulpal disease in primary and young permanent teeth. The biologic basis of these procedures is emphasized and supported with clinically relevant evidence to help clinicians preserve functional and disease-free teeth in children.

THE PULP-DENTIN COMPLEX IN PRIMARY AND YOUNG PERMANENT TEETH

Pulp therapies should be based on an understanding of dental tissues and their innate reaction patterns. Some fundamentals of tissue structure and behavior merit review, and the reader is encouraged to see Chapter 12.

DIFFERENCES IN PRIMARY AND PERMANENT TOOTH MORPHOLOGY

Successful pulpal therapy in the primary dentition requires a thorough understanding of primary pulp morphology, root formation, and the special features associated with physiologic resorption of primary tooth roots. These factors are considered in the following sections.

According to Finn[74] and Nelson and Ash,[196] there are 12 basic differences between primary and permanent teeth (Fig. 24-1):

1. Primary teeth are smaller in all dimensions than corresponding permanent teeth.
2. Primary crowns are wider in the mesial-to-distal dimension compared with crown length than are permanent crowns.
3. Primary teeth have narrower and longer roots compared to crown length and width in permanent teeth.
4. The facial and lingual cervical thirds of the crowns of anterior primary teeth are much more prominent than those of permanent teeth.
5. Primary teeth are markedly more constricted at the dentinoenamel junction (DEJ) than are permanent teeth.
6. The facial and lingual surfaces of primary molars converge occlusally; therefore, the occlusal surface is much narrower in the faciolingual dimension than the cervical width.
7. The roots of primary molars are comparatively more slender and longer than the roots of permanent molars.
8. The roots of primary molars flare out from the cervical area, and more at the apex, than do the roots of permanent molars.
9. The enamel is thinner (approximately 1 mm) on primary teeth than on permanent teeth, and has a more consistent depth.
10. The thickness of the dentin between the pulp chamber and enamel in primary teeth is less than in permanent teeth.
11. The pulp chambers in primary teeth are comparatively larger than those in permanent teeth.
12. The pulp horns, especially the mesial horns, are higher in primary molars than in permanent molars.

FIG. 24-1 Cross section of a primary and permanent molar for comparison. Divergence of the primary molar roots allows space for the developing permanent premolar.

Root Formation

According to Orban,[205] development of the roots begins after enamel and dentin formation has reached the future cementoenamel junction (CEJ). The epithelial dental organ forms Hertwig's epithelial root sheath, which initiates formation and molds the shape of the roots. Hertwig's sheath takes the form of one or more epithelial tubes (depending on the number of roots of the tooth, one tube for each root). During root formation, the apical foramen of each root has a wide opening limited by the epithelial diaphragm. The dentinal walls diverge apically, and the shape of the pulp canal is like a wide-open tube. Each root contains one canal at this time, and the number of canals is the same as the number of roots (Fig. 24-2, *A*). When root length is established, the sheath disappears, but dentin deposition continues internally within the roots.

Differentiation of a root into separate canals, as in the mesial root of the mandibular molars, occurs by continued deposition of dentin. This narrows the isthmus between the walls of the canals and continues until the formation of dentin islands in the root canal and eventual division of the root into separate canals. During the process, communications exist between the canals as an isthmus and then as fins connecting the canals (Fig. 24-2, *B*). (See Chapter 12 for a complete description of pulp and dentin formation.)

As growth proceeds, the root canal is narrowed by continued deposition of dentin, and the pulp tissue is compressed. Additional deposition of dentin and cementum closes the apex of the tooth and creates the apical convergence of the root canals common to the completely formed tooth (Fig. 24-2, *C*).

Root length is not completed until 1 to 4 years after a tooth erupts into the oral cavity. In the primary dentition, root length is completed in a shorter period than in the permanent tooth because of the shorter length of the primary roots.

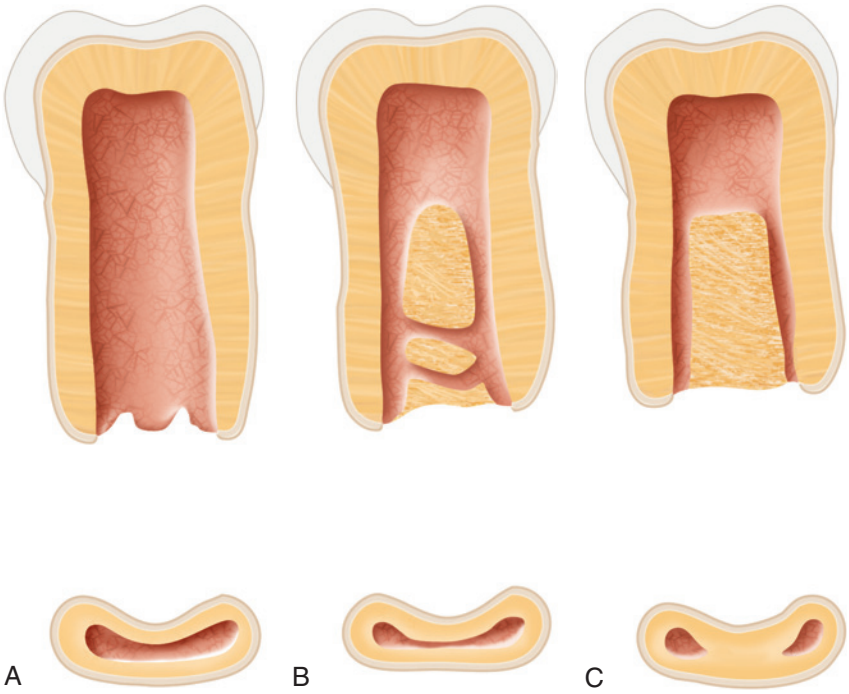

FIG. 24-2 **Faciolingual cross section of the mesial root of a mandibular primary molar. A,** Formation of the root at the time the root length is completed; only one canal is present. **B,** Differentiation of the root into separate canals by the continued, but incomplete deposition of dentin in central areas. Small fins and branches are present between the two canals. **C,** Canals are completely divided; root resorption has begun.

The root-to-crown ratio of the primary teeth is greater than that of the permanent teeth. The primary roots are narrower than the permanent roots. The roots of the primary molars diverge more than those of the permanent teeth; this feature allows more room for the development of the crown of the succeeding premolar (see Fig. 24-1).[194]

The primary tooth is unique insofar as resorption of the roots begins soon after formation of the root length has been completed. At this time, the morphology of the root canals roughly corresponds to the form and shape of the external anatomy of the teeth. Root resorption and the deposition of additional dentin within the root canal system, however, significantly change the number, size, and shape of the root canals within the primary tooth. A more detailed description of how this affects the primary teeth is presented later in this section.

It should be noted that most variations within the root canals of primary and permanent teeth are in the faciolingual plane; dental radiographs do not visualize this plane but show the mesiodistal plane. Therefore, when reviewing clinical radiographs, many of the variations that may be present are not visible. Figures 24-3 and 24-4 show silicone models of root canals, and Figure 24-5 shows a reconstructed digital image to illustrate morphology not visible with plain radiographs. The increasing availability of three-dimensional imaging techniques, such as cone beam computed tomography,[211] is bringing greater understanding of such anatomic features to practicing clinicians.

Primary Root Canal Anatomy

To treat the pulps of primary teeth successfully, the clinician must have a thorough knowledge of the anatomy of the primary root canal systems and the variations that exist within them.[196]

BOX 24-1

Root Canal Anatomy Considerations in Primary Teeth

- After root-length completion, dentin deposition continues in the root canal.
- After root-length completion, dentin deposited in a root canal may change the number, size, and shape of the root canals.
- Often root canal variations are not visible on clinical radiographic images.
- In anterior teeth, one root canal is usually present, although mandibular incisors occasionally have two.
- In anterior teeth, accessory and lateral canals and apical ramifications are rare.

Understanding some of the variations in the primary root canal systems requires an understanding of root formation (see previous discussion and Box 24-1).

Primary Anterior Teeth

The morphology of root canals in primary anterior teeth resembles the form and shape of the roots of the teeth themselves (see Figs. 24-3 and 24-4). The permanent tooth bud lies lingual and apical to the primary anterior tooth, so physiologic root resorption of primary incisors and canines begins on the lingual aspect of the apical third of the roots (see Fig. 24-3, *A*).

Maxillary Incisors

The root canals of maxillary primary incisors are almost round in cross section but somewhat compressed in a faciolingual

FIG. 24-3 Primary central incisors and silicone models of pulp canals. **A,** Facial surfaces. **B,** Beginning resorption of roots on apical third of lingual surfaces. **C,** Models. Pulp canals were injected with silicone, and the tooth structure decalcified away, leaving a model of the root canal systems. Note the division of the canal in the model on the left.

direction. Commonly these teeth have one canal without bifurcations. Apical ramifications and accessory and lateral canals are rare but may occur (see Fig. 24-3).[309]

Mandibular Incisors

The root canals of primary mandibular incisors are flattened on the mesial and distal surfaces and are sometimes grooved, progressing in an apical direction to an eventual division into two canals (facial and lingual). The presence of two canals is seen less than 10% of the time. Occasionally, lateral or accessory canals are observed.[309]

Maxillary and Mandibular Canines

The root canals of primary maxillary and mandibular canines correspond to the exterior root shape: a rounded, triangular shape with the base toward the facial surface. Sometimes the lumen of the root canal is compressed in the mesiodistal dimension. The canines have the simplest root canal systems of all the primary teeth and offer few challenges during endodontic treatment. Bifurcation of the canal does not normally occur. Lateral canals and accessory canals are rare (see Fig. 24-4).[309]

Primary Molars

Often, primary molars have the same number and position of roots as the corresponding permanent molars (see Fig. 24-5). Maxillary molars have three roots, two facial and one palatal; mandibular molars have two roots, mesial and distal. The roots of the primary molars are long and slender compared with crown length and width, and they diverge to allow for permanent tooth bud formation.

When full-length root formation has just been completed in the primary molars, only one root canal is present in each of the roots. The continued deposition of dentin internally may divide the root into two or more canals. During this process, communications exist between the canals and may remain in the fully developed primary tooth as isthmi or fins connecting the canals (see Fig. 24-2, *B*, and Fig. 24-5).

In primary teeth, the deposition of secondary dentin has been reported to occur after root-length completion.[21,111,127] This may result in changes to the basic root canal morphology, producing variations and alterations in the number and size of the root canals. This deposition begins at about the time root resorption begins. Variations in form are more pronounced in teeth that show evidence of root resorption.[111]

The greatest variation in morphology of the root canals occurs in the mesial roots of maxillary and mandibular primary molars. This variation originates in the apical region as a thinning of the narrow isthmus between the facial and lingual extremities of the apical pulp canals. Subsequent deposition of secondary dentin may produce complete separation of the root canal into two or more individual canals. Many fine connecting branches or lateral fibrils form a connecting network between the facial and lingual aspects of the root canals (see Fig. 24-5).

The variations found in the mesial roots of the primary molars are also found in the distal and lingual roots but to a lesser degree. Accessory canals, lateral canals, and apical ramifications of the pulp are common in primary molars, occurring in 10% to 20%.[111,309]

In the primary molars, resorption usually begins on the inner surfaces of the roots next to the interradicular septum. The effects of resorption on canal anatomy and root canal filling on the primary teeth are discussed in detail later in this chapter.

Maxillary First Primary Molar

The maxillary first primary molar has two to four canals that correspond approximately to the exterior root form, with much variation. Usually, the palatal root is round and often longer than the two facial roots. Bifurcation of the mesiofacial root into two canals is common and occurs in approximately 75% of maxillary first primary molars.[194,309]

Fusion of the palatal and distofacial roots occurs in approximately one third of maxillary first primary molars. In most of these teeth, two separate canals are present, with a very narrow isthmus connecting them. Islands of dentin may exist between the canals, with many connecting branches and fibrils.

Maxillary Second Primary Molar

The maxillary second primary molar has two to five canals roughly corresponding to the exterior root shape. The mesiofacial root usually bifurcates or contains two distinct canals. This occurs in approximately 85% to 95% of maxillary second primary molars.[111,309]

Fusion of the palatal and distofacial roots may occur. These fused roots may have a common canal, two distinct canals, or two canals with a narrow connecting isthmus of dentin islands between them and many connecting branches or fibrils.

Mandibular First Primary Molar

The mandibular first primary molar usually has three canals, again corresponding approximately to the external root

anatomy, but it may have two to four canals. It is reported that approximately 75% of the mesial roots contain two canals, whereas only 25% of the distal roots contain more than one canal.[111,309]

Mandibular Second Primary Molar

The mandibular second primary molar may have two to five canals, but it usually has three. The mesial root has two canals approximately 85% of the time, whereas the distal root contains more than one canal only 25% of the time.[111,309]

CLINICAL PULPAL DIAGNOSIS IN CHILDREN

Restorative dental treatment should never commence without a working diagnosis and treatment plan. Chapter 1 provides a comprehensive account of diagnostic procedures, but certain points should be emphasized for examination of the child patient. As always, the diagnostic process should follow an orderly pattern, with attention to the medical and dental history, clinical examination, and special tests, including radiographs where appropriate. Parents or caregivers may be helpful in clarifying the case history and may need to be involved if any systemic condition is likely to influence clinical management. The medicolegal dimensions of careful history taking, diagnostic procedures, and case documentation should also be recognized.

Every effort should be made to establish a working pulp diagnosis before anesthetizing the suspect tooth and isolating it with a rubber dam. These conditions are rarely conducive to accurate history taking or diagnostic reliability, especially in young children. The opportunity should also be taken before treatment to discuss contingent alternatives that may become necessary as a result of an unexpected event, such as the exposure of a pulp during deep caries excavation.

Established tests to determine the extent of pulpal inflammation are crude at the best of times and may be of little or no value in young and anxious children and on primary or immature permanent teeth. The literature on pulp diagnosis in children is mostly outcome reports based on empiric treatment and anecdotal case reports. Assumptions about pulpal status before treatment have often been based on retrospective findings rather than histologic or microbiologic data to support the prerestorative diagnosis. Histologic investigation remains the only true method of determining the nature and extent of pulp inflammation, and any correlation with clinical signs and symptoms is limited.[53,172,264]

Although every effort should be made to discern the condition of the pulp before treatment, exhaustive pulp provocation tests may not be helpful in children. From a clinical standpoint, the characteristics of the presenting pain are often critical to the working diagnosis, especially when summated with additional information from the clinical and radiographic examination. Further evidence can be provided by clinical observations during the procedure, such as the nature, volume and ability to control hemorrhage from an exposed pulp. It should be recognized that pulp diagnosis in children is as much an art as a science.

History and Characteristics of Pain

The character of any presenting pain is first identified in the history. Wherever possible, the distinction should be made between provoked and spontaneous pain.

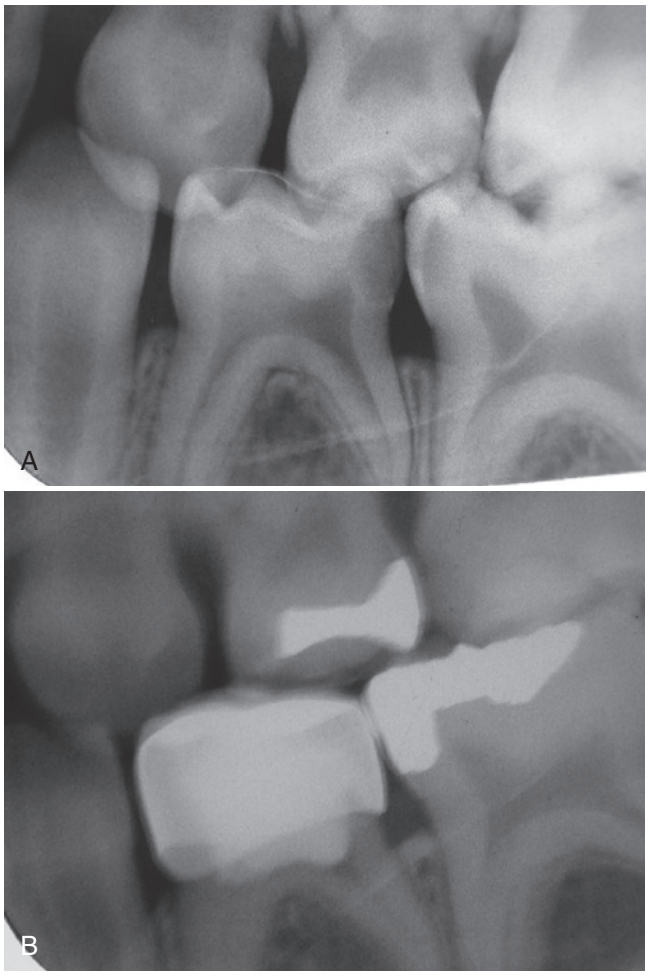

FIG. 24-6 Bone loss (and pain) caused by food impaction in interproximal space between primary molars. **A**, First and second mandibular primary molars with caries and marginal bone loss caused by food impaction. **B**, Healthy bone after restoration of teeth.

Provoked pain is usually triggered by a thermal or an osmotic stimulus (e.g., cold drinks, eating candy) and usually ceases when the stimulus is removed. This history is indicative of minor, reversible pulp inflammation. Provoked pain may sometimes be confused with that caused by interproximal impaction of food (Fig. 24-6), soreness associated with tooth exfoliation, or eruption of permanent teeth.

By contrast, spontaneous pain is not consistently associated with an external stimulus, may arise at any time of the day, or may wake the child from sleep. In both primary and young permanent teeth, spontaneous pain and provoked pain that continues long after the causative factor has been withdrawn are usually associated with extensive, irreversible pulpal inflammation that extends into the root canals.[101] Primary teeth with a history of spontaneous toothache are unreliable candidates for vital pulp therapy and should not be considered for any form of treatment short of pulpectomy or extraction. The situation is quite different for immature permanent teeth. Because the consequences of losing vital pulp functions are so serious, immature permanent teeth with a similar pain history should always be considered for pulpotomy, apexogenesis, or even regenerative techniques in an effort to safeguard tooth development (see later sections on immature permanent teeth).

Clinicians faced with an apparently graphic pain history should not neglect to conduct a proper clinical examination because other conditions, such as papillitis caused by interproximal food impaction, can mimic pulpal pain.

Equally, the absence of pain should not encourage clinical complacency because varying degrees of pulp degeneration or even complete necrosis can be encountered without any report of pain. Consequently, children may present without any complaint, despite extensive carious lesions and a draining sinus tract. Those who have developed early childhood caries (e.g., nursing bottle caries) may have no experience of their teeth feeling any other way and thus no special pain history to report.[214]

Clinical Examination

A careful extraoral and intraoral examination is of great importance in identifying teeth with pulpal involvement. Signs such as tooth discoloration, gross caries, redness and swelling of the vestibulum, or a draining sinus tract may strongly suggest pulpal pathoses. In addition, attention should be paid to teeth with extensive fractured or missing restorations or restorations with recurrent caries. All may indicate involvement of the pulp through the relatively thin and porous dentin of the cavity floor.

Palpation, Percussion, and Mobility

Fluctuation, felt by palpating a swollen mucobuccal fold, may be the expression of an acute dentoalveolar abscess that may not be visualized yet externally. Bone destruction associated with a chronic dentoalveolar abscess may also be detected by palpation.

Although significant inflammatory bone loss can make primary teeth mobile, this is not a reliable, objective test of pulpal status. Teeth with varying degrees of pulpal inflammation may have very little mobility, whereas mobility can be significant during phases of active physiologic root resorption in primary teeth with healthy pulps.

Comparing the mobility of a suspicious tooth with its contralateral equivalent can be especially helpful in clarifying such quandaries. If a significant difference in mobility is noted, this, along with other diagnostic information, may suggest pulpal inflammation or necrosis.

Sensitivity to percussion may reveal a painful tooth in which pulpal breakdown has resulted in acute periradicular periodontitis. Exceptions include recently traumatized teeth. Care should be taken in percussing the teeth of children; Pinkham et al.[214] recommend gentle use of a fingertip rather than the end of a dental mirror.

Pulp Tests

Standard electrical and thermal pulp provocation tests are of limited value in the primary dentition and in young permanent teeth with incompletely developed apices.[7] Although these tests may indicate the presence of some vital responsive tissue, they do not give reliable data on the extent of pulpal inflammation. Many children with perfectly normal teeth do not respond to the electrical pulp tester, even at the higher settings. In addition, young patients may give unreliable responses to such provocation tests because of apprehension, fear, or general management problems.

The unreliability of electrical pulp testing in immature permanent teeth has been reported in several studies.[86,87,89,139] Klein[139] showed responses ranging from 11% in 6- to 11-year-olds with completely open apices to 79% in older children with complete root formation.

Thermal tests may be more reliable than electrical methods for determining the presence of vital responsive tissue in immature permanent teeth, and carbon dioxide snow has been shown to be more effective than ice and ethyl chloride.[86,87,89,139] Heat is unreliable as a diagnostic test in young children.[87]

Laser Doppler flowmetry has been reported to be reliable for diagnosing pulpal vitality in immature permanent teeth,[66,256,306] but the equipment has not been perfected for clinical use[66] and is cost prohibitive. It is also affected by blood pigmentation of the crown, or by the presence of large or full-coverage coronal restorations.

Radiographic Examination

The clinical examination should be supplemented where appropriate with high-quality radiographs. Interradicular (furcal) radiolucencies, a common finding in primary posterior teeth with pulpal pathoses, are best observed in bite wing radiographs. If the apical area cannot be clearly observed, a periapical view should be obtained. The integrity of the lamina dura of the affected tooth should be compared with that of adjacent or contralateral teeth.[214]

Current radiographs are essential in examining for caries, restoration integrity, previous endodontic treatments, and resorptive and periapical changes in primary and young permanent teeth. In children, interpretation of radiographs is complicated by physiologic root resorption of primary teeth and incompletely formed roots of permanent teeth. If the clinician is not familiar with interpreting radiographs of children or does not have radiographs of good quality, these normal conditions can easily be misinterpreted as pathologic changes in need of treatment. In the case of immature permanent teeth, comparison of root formation with the contralateral tooth should always be considered.

The radiograph does not always demonstrate periapical pathosis, nor can the proximity of caries to the pulp always be accurately determined (see also Chapter 2). What may appear as an intact barrier of secondary or tertiary dentin overlying the pulp may actually be a perforated mass of irregularly mineralized and/or carious dentin overlying a pulp with extensive inflammation.[53]

The presence of calcified masses within the pulp is an important diagnostic sign (Fig. 24-7). Mild, chronic irritation to the pulp stimulates tertiary reactionary dentin formation. When the irritation is acute and rapid in onset, the defense mechanism may not have a chance to lay down reactionary dentin. When the disease process reaches the pulp, the pulp may form calcified masses away from the exposure site. These calcified masses can be associated with degeneration of the coronal pulp and inflammation of the radicular pulp in primary teeth.[53] In the absence of other clinical evidence, it is unclear whether this warrants invasive treatment in all cases. Certainly for immature permanent teeth, the presence of calcific metamorphosis within the coronal pulp chamber would not in isolation warrant pulpectomy and root canal treatment.

Pathologic changes in the periapical tissues surrounding primary molars are most often apparent in the bifurcation or trifurcation areas rather than at the apices (as generally seen in permanent teeth) (see Fig. 24-7). Pathologic bone and root resorption indicates advanced pulpal degeneration that has

FIG. 24-7 Calcified mass in the pulp chamber. Internal and external root resorption has occurred. The calcified mass *(arrow)* is an attempt to block a massive carious lesion. Because of the root resorption, this tooth should be extracted. Note the bone loss in the bifurcation area.

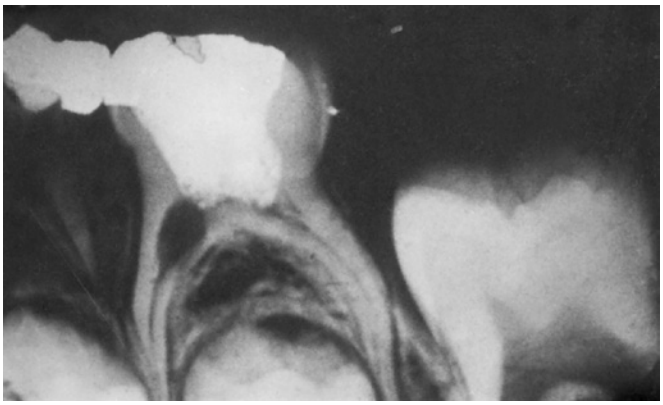

FIG. 24-8 Pulpotomy failure. Note the internal resorption, which has perforated the pulp chamber floor and resulted in a furcal radiolucency.

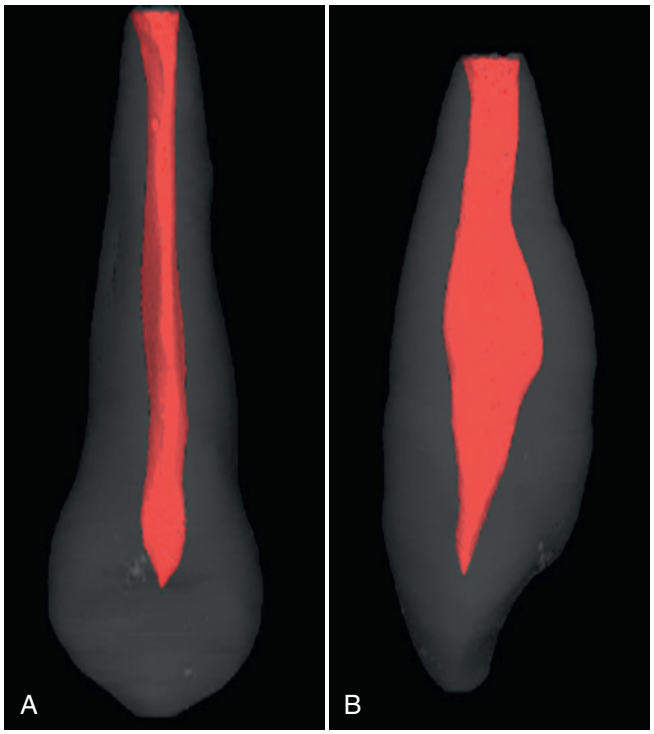

FIG. 24-9 Three-dimensional tomographic images of an immature maxillary canine. A, Faciolingual view. **B,** Mesiodistal view. Such imaging techniques are bringing new anatomic awareness to both the research laboratory and the clinic. (Courtesy Paul Dummer and Sue Bryant, Cardiff University, Wales, UK.)

spread into the periapical tissues. The pulpal tissue may remain vital even with such advanced degenerative changes. Periapical radiolucencies of primary anterior teeth, like those in permanent teeth, are usually at the apices.

Internal resorption occurs frequently in the primary dentition after pulpal involvement. It is always associated with extensive inflammation,[101] and it usually occurs in the molar root canals adjacent to the bifurcation or trifurcation area. Because of the thinness of primary molar roots, once the internal resorption becomes visible on radiographs, it has usually advanced to root perforation (Fig. 24-8). In some instances, however, the process is reversible and self-correcting, and the resorbed area becomes filled with mineralized tissue.[105,208] If a perforation of the root occurs in a primary tooth because of internal resorption, all forms of pulp therapy are contraindicated. The treatment of choice is observation (if the area of the resorption is confined to the tooth) or extraction (if the process has reached the bone).[105,208]

In immature permanent teeth, it is often difficult to assess the extent of apical closure. Plain-film images are frequently misleading because under normal conditions, they show the mesiodistal plane of the tooth but give little information about the faciolingual dimension. Except for the maxillary central and lateral incisor, all other root canals of the permanent teeth are wider in the faciolingual plane than in the mesiodistal plane. The faciolingual aspect of the root canal is two to three times as wide as the mesiodistal width and is the last to become convergent apically as the root develops. Therefore, it is possible to have a dental radiograph showing an apically convergent root canal, whereas in the faciolingual plane, the root canal is divergent. Equally, canals that are apically diverging in the faciolingual view may be parallel or converging in the mesiodistal view. As mentioned, contemporary three-dimensional imaging techniques are beginning to improve understanding, both in the research laboratory (Fig. 24-9) and in the clinic.[211]

In summary, radiographs add to the diagnostic process by visualizing the presence or absence of the following:

1. Deep caries with possible or definite pulp involvement
2. Deep restorations close to a pulp horn
3. A successful or failing pulp cap, pulpotomy, or pulpectomy
4. Changes within the pulp, such as calcific barrier formation, calcific metamorphosis, and pulp stones (denticles)
5. Pathologic root resorption, which may be internal (within the root canal) or external (affecting the root or the surrounding bone). Internal inflammatory resorption indicates inflammation of a vital pulp, whereas external inflammatory resorption demonstrates a nonvital pulp

with extensive inflammation, including resorption of the adjacent bone. External, replacement resorption usually follows trauma and is discussed more fully in Chapters 16 and 20.

6. Periapical and interradicular radiolucencies of bone. In primary molar teeth, any radiolucency associated with a nonvital tooth is usually located in the furcation area, not at the apices. This is because of the presence of accessory canals on the pulpal floor area. A bite wing film is frequently a useful diagnostic aid, particularly in maxillary molars where the developing premolar obscures the furca in a periapical radiograph.
7. The degree of root formation in young permanent teeth

It is important to emphasize once again that the clinician should be familiar with the normal factors that complicate interpretation of radiographs in children: larger bone marrow spaces, superimposition of developing tooth buds, normal resorption patterns of the teeth, and immature root apices.[214]

Restorative Diagnosis: Pulpal Exposures and Hemorrhage

It has been reported that the size of the exposure, the appearance of the pulp, and the color and amount of hemorrhage are important factors in diagnosing the extent of inflammation in a pulp exposed by caries. The presence of excessive[53,214,264] or deep purple[214] hemorrhage from an exposed or amputated pulp is evidence of extensive inflammation in both primary and young permanent teeth. A true carious exposure is always accompanied by pulpal inflammation (see Chapter 13),[53,264] and even a pinpoint carious exposure can be associated with pulpal inflammation ranging from minimal to extensive or even complete necrosis. However, massive exposure in primary teeth is always associated with widespread inflammation or necrosis and makes the tooth a poor candidate for any form of vital pulp therapy. As discussed previously, this rule does not apply for young permanent teeth with incomplete root development, where the premature loss of vital pulp functions is so catastrophic that every effort should be made to safeguard tooth development (see later section on the management of pulpal exposure in immature permanent teeth).

Sometimes a final working diagnosis can be reached only by direct evaluation of the pulp tissue, and a decision about treatment is made accordingly. For example, if a pulpotomy is planned in a primary molar, the bleeding from the amputation site should be normal, and hemostasis should be evident after 2 to 3 minutes of light pressure with a moistened cotton pellet. Significant bleeding beyond this point indicates inflammation of the radicular pulp, and a more radical treatment, such as pulpectomy or extraction, should be considered. Conversely, if a pulp polyp is present and bleeding stops normally after coronal pulp amputation, a pulpotomy may be performed instead of a more radical procedure.[214]

In the case of an immature permanent tooth, persistent hemorrhage after several minutes of sodium hypochlorite application is an indication of serious pulp inflammation, and a tooth initially scheduled for a direct mineral trioxide aggregate (MTA) pulp cap may be a better candidate for a pulpotomy, apexification, or pulp regeneration (see later section on immature permanent teeth).

Guthrie et al.[101] attempted to use the first drop of hemorrhage from an exposed pulp site as a diagnostic aid for determining the extent of degeneration within the pulp. A white blood cell differential count (i.e., hemogram) was made for each of 53 teeth included in the study. A detailed history was obtained, including percussion, electrical pulp testing, thermal tests, mobility, and history of pain. The teeth were extracted and histologically examined. On correlation of the histologic findings with the hemogram and history, it was determined that percussion, electrical and thermal pulp tests, and mobility were *unreliable* in establishing the degree of pulpal inflammation. The hemogram did not give reliable evidence of pulpal degeneration, although teeth with advanced degeneration of the pulp involving the root canals did have an elevated neutrophil count. A consistent finding of the study, however, was advanced degeneration of pulpal tissue in teeth with a history of spontaneous toothache.

The outward clinical signs of inflammation represent a succession of cellular, vascular, and immunologic processes involving many endogenous mediators. Inflammatory mediators (vascular mediated and cell released) and their role in pulpal inflammation have been the subject of much research. The relationship between the concentration of a known cell-released inflammatory mediator (prostaglandin E_2 [PGE_2]) in pulpal blood samples and treatment outcome after vital pulpotomy in extensively carious primary molars has been reported.[297] Thirty-nine primary molars with no history of spontaneous pain had blood samples harvested from the radicular pulp stumps immediately after coronal pulp amputation. Enzyme immunoassay of the samples for PGE_2 detected the inflammatory mediator in all samples. A wide range of concentrations was detected, and it was shown that the concentration of PGE_2 detected correlated positively with radiologic signs of failure after treatment. The authors tempered their findings by describing the dependence upon a single inflammatory mediator to predict prognosis as oversimplistic and suggested the "trauma" of pulp amputation would stimulate prostaglandin production irrespective of the underlying inflammatory status of the tissue. Similarly, a rapid and low-cost, chairside diagnostic kit to assess the extent of pulp inflammation does not yet exist. Therefore, despite research in this area, clinicians still rely upon empiric clinical findings to diagnose the inflammatory status of the pulp.

Diagnosis After Traumatic Injuries in Children

The details of trauma management are considered in Chapter 20. Injuries to the primary dentition are common, occurring in 1 in 3 children by the age of 5 years.[9,94] Diagnosis after traumatic injuries requires consideration of other factors in addition to those previously discussed. The most frequent injury in the primary dentition is tooth displacement that occurs because the bone is less dense and the roots are shorter. Healing varies from normal without sequelae to canal calcification or pulpal necrosis. Canal calcification may vary from an amorphous material resembling osteodentin to partial or complete closure of the canal.[115,234]

Pulp Diagnosis and Treatment Planning After Trauma

Treatment guidelines are almost nonexistent concerning healing and complications after trauma in primary teeth. The

literature is devoid of histologic or microbiologic studies in this area. In a study of 545 traumatized primary maxillary incisors, Borum and Andreasen[27] found that 53% developed pulpal necrosis, and 25% developed canal obliteration. The age of the patient, degree of tooth displacement, concurrent crown fracture, and amount of root resorption were factors influencing pulpal necrosis and calcification. Teeth with a coronal fracture were less likely to suffer mineralized obliteration of the root canal than those that had been luxated.

In deciding on the appropriate treatment, the proximity of the primary tooth to the permanent successor is an important consideration. The treatment least likely to damage the permanent tooth should be chosen.[7,27] Studies present conflicting data on the merits of treating or extracting traumatized primary teeth. Some have suggested no relationship,[8,9] whereas others have shown more extensive developmental disturbances if the primary tooth is treated and preserved.[250]

Transient or permanent discoloration of the crown occurs in approximately 50% of traumatized primary incisors, varying from yellow to dark gray and usually becoming evident in 1 to 3 weeks. The yellow discolorations are frequently associated with canal calcification but are not commonly associated with pulp necrosis.[27,114]

Pulpal necrosis ranging from 50% to 82% has been reported in traumatized primary incisors with dark gray discoloration, compared to 25% in those with no discoloration.[27,114,116,247] Croll et al.[43] pointed out that color change in the absence of other clinical findings is unreliable. The diagnosis of pulpal necrosis is usually based on dark gray color and radiographic evidence of periapical pathology or cessation of root development.

In immature permanent teeth, discoloration of the crown is also one of the best diagnostic indicators after traumatic injuries.[124,129] Yellow or brown-tinted discoloration usually indicates calcification of the pulp space; a gray color is usually associated with pulpal necrosis. A return to normal after transient coronal discoloration[6,38] and transient apical breakdown up to 4 months' duration[38] has also been reported.

PRINCIPLES OF ENDODONTIC TREATMENT IN CHILDREN

Endodontic procedures are undertaken to preserve teeth in a comfortable, functional, and ideally disease-free condition. The following sections describe a range of clinical procedures that aim to achieve these goals in the primary and young permanent dentitions, but they should not be seen merely as technical exercises. Readers should bear in mind that clinical management goes beyond the simple restorative procedure. The general care of anything from a preschool child requiring pulp therapy on a carious primary molar to an 8-year-old who has sustained trauma to an immature maxillary incisor requires special skills. In purely dental terms, the principle adopted is that the best root filling is a healthy pulp, and emphasis is given to methods of pulp preservation in both the primary and young permanent dentitions. Pulpotomy techniques for the partial preservation of pulp tissue are also presented as legitimate therapies—in primary teeth where young and well-perfused tissues combine with the relatively transient nature of the dentition to win success, and in young permanent teeth where therapies strive to maintain the well-perfused and resilient apical pulp, at least until root formation is complete. None of this diminishes the potential for pulpectomy and root canal treatment, should this become necessary, but as new opportunities open for regenerative therapies, traditional approaches to the root canal treatment of pulpless immature teeth may be coming into question.

PULP THERAPY FOR THE PRIMARY DENTITION

Indirect Pulp Therapy in Primary Teeth

Indirect pulp treatment (IPT) in the primary dentition is considered a contemporary, effective approach to the management of a deep carious lesion in the absence of signs or symptoms of irreversible pulp pathosis.[249] It involves the removal of caries to leave a layer of stained dentin at the cavity floor in areas where its removal would result in exposure of pulp tissue. A decision to use this treatment is derived from a thorough pain history, clinical and radiographic examination, direct evaluation of the cavity preparation, and a good knowledge of tooth anatomy and the caries process.[11]

The aims of IPT are to arrest the carious process, provide conditions conducive to the formation of reactionary dentin, and promote remineralization of the altered dentin remaining.[235] This in turn is expected to promote pulpal healing and preserve the vitality of the pulp.

Technique

The clinical steps in IPT may be divided into stages involving partial caries removal, placement of an antibacterial agent, and restoration of the crown in a way that provides the optimum coronal seal.

Some studies of IPT in primary teeth have advocated a two-stage approach.[67,284] After initial partial caries removal without local anesthetic, the cavity was restored for 1 to 3 months, using a reinforced zinc oxide–eugenol (ZOE) cement or glass ionomer restoration. After this, further caries removal and definitive restoration were undertaken under local anesthesia. It has been suggested that this approach may have a use in the very young or very anxious child, but it may be argued that a single-visit approach is more appropriate and successful.[68] Thinner dentin in the primary tooth compared with the permanent tooth may result in a higher risk of pulp exposure if a primary tooth is reentered to remove residual caries.[262]

The following technique is based on a recommended approach[235]:

1. Local anesthetic
2. Isolation with a rubber dam
3. Removal of all caries at the enamel-dentin junction of the cavity, ensuring caries-free walls
4. Judicious removal of soft, deep carious dentin, using large, round steel burs (#6 to #8). Hand excavators should be used only to remove caries at the dentinoenamel junction and should be angled outward at the DEJ, with care taken not to produce a pulp exposure.
5. Placement of an appropriate lining material, such as glass ionomer cement, hard-setting calcium hydroxide ($Ca(OH)_2$). ZOE, or a directly bonded restoration
6. Definitive restoration providing the optimal coronal seal, such as an adhesive restoration or preformed metal (stainless steel) crown

Unfortunately, the evidence currently is insufficient to promote a definitive choice for the lining material placed over the residual stained dentin.[235] Studies show good success rates for resin-modified glass ionomer lining/restoration, self-etching adhesive systems, and $Ca(OH)_2$ linings.[35,36,142]

Although additional prospective clinical evaluation of IPT is required, studies involving the primary dentition show good success rates (over 90% at 3 years).[4,67,68,295] However, it has been suggested that a successful outcome is highly dependent upon obtaining the optimal coronal seal to eradicate the nutrient supply to residual cariogenic microorganisms. When intracoronal amalgam restorations were compared with extracoronal preformed metal (stainless steel) crowns after IPT, failure was 7.7 times more likely with the amalgam restorations. Adhesive restorations also were reported to provide the optimal coronal seal after pulp therapy.[103] Therefore, to secure the best possible outcome after IPT, or indeed after any pulp therapy for the primary tooth, definitive restoration should involve a bonded restoration and/or preformed metal (stainless steel) crown.

The Hall Technique

The Hall technique, an emerging method of managing dental caries in primary molars, is noteworthy in this section on indirect pulp therapy. The technique was introduced by Dr. Norna Hall, a primary care clinician in Scotland, who was overwhelmed by the number of children with dental caries. In Scotland, by the age of just 5 years, 55% of children had visible decay into dentin, and 16% had experienced tooth extraction. In response, this clinician decided to manage lesions in primary molars (that were symptom free and free of radiographic signs of periradicular pathology) by cementing a preformed metal (stainless steel) crown in place without local anesthesia, tooth preparation, or any attempt at caries removal. This is viewed in the United Kingdom as an undoubtedly novel approach to caries management and caught the attention of clinical academics in Scotland. Audit data from Hall's records indicate that her technique may have results similar to those for more conventional approaches in the primary care setting.[126]

Subsequently, a randomized, controlled clinical trial was undertaken comparing the Hall technique with conventional restorations in carious primary molars in primary care.[125] Interestingly, the Hall technique was preferred to conventional restorations by most children, guardians, and clinicians. After a review period of 2 years, in which the teeth managed using Hall preformed metal (stainless steel) crowns were compared with conventional restorations, the "Hall crowns" showed better treatment outcomes for both pulpal health and restoration longevity. In the United Kingdom, this has further stimulated an ongoing debate over whether restorative treatment provided by general clinicians in primary care is an effective way of managing caries in the primary dentition.[70,179]

Certainly this new and novel approach would appear to encompass present-day theory. Potentially cariogenic microorganisms require a very specific environment to start or progress a carious lesion. By sealing the lesion within the tooth, this removes the nutrient supply and stops or slows the lesion's progress.[168] Nevertheless, obtaining an effective and complete coronal seal should be of utmost concern.

Direct Pulp Capping in Primary Teeth

The life span of the average primary tooth from initial development to exfoliation is significantly shorter than that of a permanent tooth. Primary teeth undergo dramatic physiologic and physical changes over a relatively short period. Clinicians should keep in mind that pulp tissue is not static in nature, and outcomes for the same procedure may differ, depending on the age of the patient. Furthermore, because of the aging process within dental pulp, the likelihood of successful pulp capping diminishes with age. This may be explained by the increase in intrapulpal fibrous and calcific deposits seen with aging, together with a reduction in both pulpal volume and pulp fibroblast proliferation.[105]

Direct pulp capping should not be performed on carious pulpal exposures in primary teeth. *Guidelines developed by both the American Academy of Pediatric Dentistry (AAPD) and the British Society of Paediatric Dentistry (BSPD) recommend that direct pulp capping should be reserved only for small mechanical or traumatic exposures in primary teeth.*[54,235] Under these circumstances, it is presumed that the conditions for a favorable pulpal response are optimal.

Pulpotomy in Primary Teeth

The AAPD guidelines for pulp therapy for primary and young permanent teeth describe the pulpotomy procedure in primary teeth as the amputation of the affected or infected coronal portion of the dental pulp, preserving the vitality and function of all or part of the remaining radicular pulp.[54] Evidence of successful pulp therapy includes the features listed in Box 24-2.

Complete amputation of the coronal pulp is the norm for pulpotomy procedures performed on the cariously exposed vital pulps of primary teeth. After this, and once hemostasis has been achieved, a decision is made on the wound dressing or technique to apply to the pulp stumps.

The following are some of the available options. The success of all procedures depends upon ensuring that the residual pulp tissue is correctly diagnosed as healthy or reversibly inflamed.

- Hemostasis and maintenance of vital tissue (e.g., ferric sulfate solution, electrosurgery, laser)
- Dentin bridge formation and maintenance of vital tissue (e.g., MTA)
- Superficial (partial) pulp tissue fixation and maintenance of vital tissue (e.g., dilute formocresol solution, glutaraldehyde solution)

Many pharmacotherapeutic agents have been used for pulp therapy in the past. Formocresol has been the most popular agent, mainly because of its ease of use and good clinical success. Nonetheless, formocresol, and in particular one of its constituents, formaldehyde (FAD), has come under close

BOX 24-2

Evidence of Successful Pulp Therapy

- Vitality of most of the radicular pulp
- No prolonged adverse clinical signs or symptoms (e.g., sensitivity, pain, or swelling)
- No radiographic evidence of internal resorption reaching the alveolar bone
- No breakdown of periradicular tissue
- No harm to permanent successor teeth
- Pulp canal obliteration (abnormal calcification)—not considered a failure

scrutiny because of reported concerns related to the systemic distribution of FAD and its potential for toxicity, allergenicity, carcinogenicity, and mutagenicity. Other medicaments (e.g., glutaraldehyde, $Ca(OH)_2$, collagen, ferric sulfate, MTA) have been suggested as possible replacements. However, varying success rates and questions about the safety of these materials make it clear that additional research is required on the use of these and other pharmacotherapeutic agents.

Nonpharmacologic hemostatic techniques have been recommended, including electrosurgery[163,197,237,253,254] and laser therapy.[62] Research involving human clinical trials on both these techniques is sparse; nevertheless, electrosurgical pulpotomy currently is taught in several dental schools. Comprehensive reviews of the techniques and agents used in vital pulp therapy and discussion of possible new modalities are available in the literature.[223,262,296]

Indications and Contraindications for Pulpotomy

Pulpotomy is indicated for *pulp exposure on primary teeth in which the inflammation or infection is judged to be confined to the coronal pulp.*[137,278] If inflammation has spread into the tissues within the root canals, the tooth should be considered a candidate for pulpectomy and root canal filling or extraction. The contraindications to pulpotomy on a primary tooth are outlined in Box 24-3.

Technique

Pulpotomy is used for primary teeth with radicular pulp tissue judged to be free of inflammation and infection. Compromise on this principle leads to a diminished success rate. If inflamed vital (coronal) pulp tissue is amputated to leave residual healthy pulp tissue (radicular), the tissue remaining has the capacity to remain healthy if managed correctly. The overall success of vital pulp therapy in the primary dentition depends upon several factors:

- Effective control of infection
- Complete removal of inflamed coronal pulp tissue
- Appropriate wound dressing
- An effective coronal seal during and after treatment

An accurate diagnosis of pulp status is very important in aiding appropriate pulpal management. However, this can be challenging, particularly in young children. The following points highlight the diagnostic aids available.

- An accurate pain history is helpful for determining the possible stage or extent of pulpal inflammation, but it may be difficult to elicit such information from a child.
- Radiographic findings can guide treatment decisions. Pretreatment radiographs are essential to assess the extent of the carious lesion and its proximity to the pulp horns or chamber. They also provide information about periradicular pathosis.
- Clinically, pulpal involvement can be assessed immediately after caries removal by a very careful search for evidence of a pulp exposure.

BOX 24-3

Contraindications to Pulpotomy in a Primary Tooth

- History of spontaneous toothache (not caused by papillitis resulting from food impaction)
- Nonrestorable tooth where a postpulpotomy coronal seal would be inadequate
- Tooth near exfoliation; or, no bone overlies crown of the permanent successor tooth
- Evidence of periapical or furcal pathosis
- Evidence of pathologic root resorption
- Pulp that does not bleed (necrotic)
- Inability to control radicular pulp hemorrhage after coronal pulp amputation
- Pulp with serous or purulent drainage
- Presence of a sinus tract

Technique for Coronal Pulp Amputation

Removal of the coronal pulp tissue is a process common to whichever pulpotomy procedure is chosen for the cariously exposed vital primary tooth. After successful coronal amputation and hemostasis (Fig. 24-10, *A* and *B*), the subsequent management of the radicular pulp stumps is defined by which pulpotomy technique the clinician chooses. For example, once hemostasis has been achieved, a wound dressing may be applied to the pulp wounds or, alternatively, the exposed tissue might be subjected to electrosurgery or laser application. Figure 24-10, *C* to *H* provides a schematic overview of the options and expected outcomes.

Stages of the Technique for Coronal Pulp Amputation

1. After the initial diagnosis of probable vital pulpal involvement, the primary tooth is anesthetized and isolated with a rubber dam.
2. All caries is removed, and the observation of bleeding from exposure sites indicates vital (if inflamed) coronal pulp tissue (Fig. 24-11, *A* and *B*).
3. The entire roof of the pulp chamber is removed using a high-speed non–end cutting bur and copious water spray.
4. All the coronal pulp is amputated with a slow-speed #6 or #8 round bur or spoon excavator. Care must be exercised to fully unroof the chamber and extirpate all filaments of the coronal pulp (Fig. 24-11, *C* and *D*). If any filaments remain in the pulp chamber, hemorrhage will be impossible to control.
5. The pulp chamber is thoroughly washed with sterile water or saline to remove all debris, and the site is dried by vacuum and sterile cotton pellets.
6. Hemorrhage is controlled by slightly moistened cotton pellets (wetted and blotted almost dry) placed against the stumps of the pulp at the openings of the root canals. Completely dry cotton pellets should *not* be used; fibers of the cotton will be incorporated into the clot, and when the pellet is removed, hemorrhage will result. Dry cotton pellets are placed over the moist pellets, and pressure is exerted on the mass. Hemorrhage should be controlled in this manner within 3 minutes. It may be necessary to change the pellets to control all hemorrhage.
7. If bleeding persists, the clinician should carefully check that all tissues of the pulp were removed from the pulp chamber and that the amputation site is clean. If the bleeding persists from one of the canals, that canal can be reentered with a small round bur to amputate the suspected inflamed tissue; the canal then is rinsed again, and cotton pellet pressure is applied.

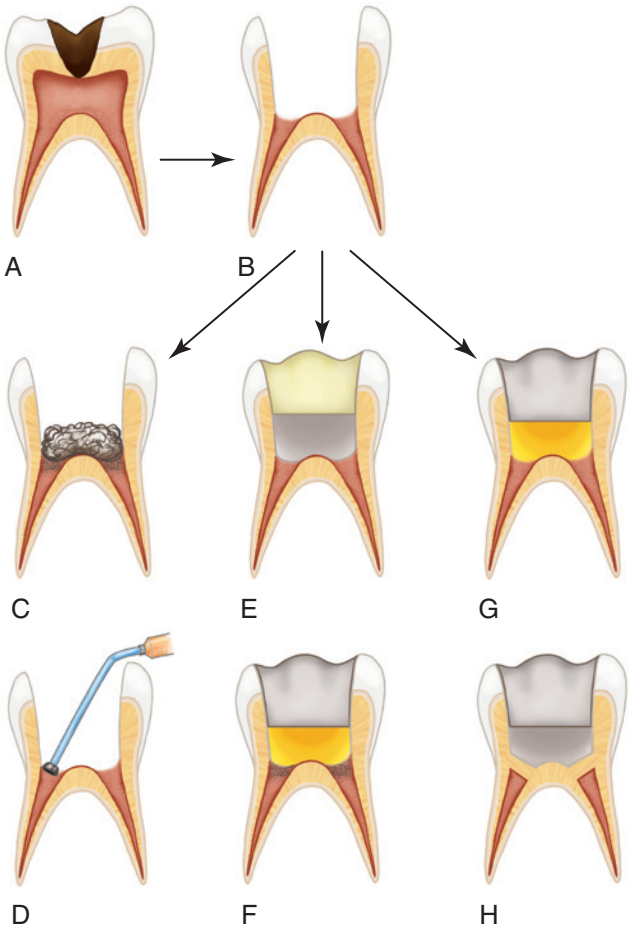

FIG. 24-10 Three different approaches to the radicular pulp after coronal pulp amputation during pulpotomy in an extensively carious primary molar. **A,** Primary molar with caries extending to the pulp. Note the inflammatory response in the coronal pulp. **B,** The tooth has undergone removal of the coronal pulp. The radicular pulp tissue is healthy and has stopped bleeding. **C,** A 1:5 dilute solution of formocresol may be applied to the pulp stumps for 5 minutes. This produces partial tissue fixation, which is greatest near the point of application. **D,** Intracoronal restoration: zinc oxide eugenol (ZOE) is placed directly over the pulp stumps, and an intracoronal restoration is placed. Vital radicular pulp may remain apically. **E,** A 15.5% ferric sulfate solution is applied to the pulp stumps for 15 seconds. This produces mechanical blockage of open capillaries by a protein-iron complex. **F,** Intracoronal restoration has been provided as in **D.** Healthy, vital pulp tissue remains in the root canals. **G,** Mineral trioxide aggregate (MTA) is placed directly over the radicular pulp stumps, and an intracoronal restoration is provided as before. **H,** The radicular pulp tissue remains vital beneath the MTA; a calcific bridge may form over time beneath the MTA.

8. If hemostasis is not achieved within 2 to 3 minutes, the pulp tissue within the canals is probably inflamed, and the tooth is not a candidate for a pulpotomy. The clinician should then proceed with pulpectomy, or the tooth should be extracted.

Once bleeding has stopped at the radicular pulp stumps, the wounds are managed according to one of the following pulpotomy techniques (see Fig. 24-10):

- Application of dilute formocresol solution for 5 minutes
- Application of 15.5% ferric sulfate solution for 15 seconds (Fig. 24-11, *E* and *F*)

BOX 24-4

Formulation of a One-Fifth Dilution of Formocresol Solution

Mix 1 part Buckley's formocresol solution with:

- 1 part distilled water
- 3 parts glycerin

- Permanent placement of MTA
- Electrosurgical manipulation of the wound surfaces
- Laser manipulation of the wound surfaces

Figure 24-11, *G* shows the treated tooth restored with a preformed metal crown.

Formocresol Pulpotomy

Technique (See Fig. 24-10, *C* and *D*)

1. After coronal pulp amputation and once hemostasis has been achieved, a cotton pellet moistened with *one-fifth dilution formocresol solution* (Box 24-4) is blotted to remove excess formocresol and then placed in direct contact with the pulp stumps for 5 minutes. Formocresol is caustic and creates a severe tissue burn if allowed to touch the gingiva.
2. When the pellet is removed, the tissue appears brown, and no hemorrhage should be evident.
3. If an area of the pulp was not in contact with the medication, the procedure must be repeated for that tissue. Small cotton pellets for applying the medication usually work best because they allow closer approximation of the material to the pulp.
4. A cement base of ZOE is placed over the pulp stumps and allowed to set. The tooth may then be restored permanently.
5. The restoration of choice is a preformed metal (stainless steel) crown for primary molars. On anterior primary teeth, a composite tooth-colored restoration is the treatment of choice unless the tooth is so badly broken down that it requires a crown.

The use of formocresol in dentistry remains controversial. Formaldehyde, a volatile organic compound, is toxic and corrosive, especially at the point of contact. Formocresol's other active constituent, cresol, is also an irritant and corrosive in nature.[144]

Local and Systemic Accumulation of Formaldehyde

Localized accumulation of formocresol or FAD has been demonstrated in pulp, dentin, periodontal ligament, and bone surrounding the apices of pulpotomized teeth.[88,190]

Although animal studies have identified radioisotope-labeled formocresol or FAD in major organs after systemic injection or multiple pulpotomies, researchers concluded that the doses of formocresol were far in excess of those used in normal clinical practice. Therefore, it has been suggested that the findings should not be extrapolated to clinical use in humans.[187-189] More recently, a review of the safety of formocresol, including FAD metabolism, suggested that FAD is rapidly metabolized, so the findings of previous studies may have been identifying FAD metabolites systemically and not FAD itself.[178] Notwithstanding this, the amount of formocresol

FIG. 24-11 Clinical stages of a vital pulpotomy using ferric sulfate solution. A, Extensive dental caries affecting a mandibular first primary molar. Note the proximity of the radiographic lesion to the mesial pulp horn. **B,** Caries removal, showing a carious pulpal exposure; bleeding is evident. **C,** Partial unroofing of the pulp chamber; note the bleeding coronal pulp before amputation. **D,** Roof of pulp chamber removed completely. **E,** A 15.5% solution of ferric sulfate is applied to the radicular pulp stumps with a dento-infuser tip supplied by the manufacturer. **F,** Hemostasis is evident at the radicular pulp stumps. **G,** Definitive restoration involves placement of zinc oxide eugenol, overlaid with glass ionomer intracoronally, followed by a preformed metal (stainless steel) crown. (Courtesy Vidya Srinivasan, Edinburgh Dental Institute, Scotland, UK.)

absorbed systemically by way of the pulpotomy route is small and may not contraindicate use of the drug.[210]

Formocresol as an Allergen

The results of studies investigating the allergenic risks of formocresol are equivocal. Studies have shown no evidence of an allergic response in nonpresensitized animals,[258] and presensitized animals showed only a weak allergic potential.[292] However, demonstration of an immune response to formocresol-fixed, autologous tissue implanted in connective tissues or injected into root canals has been reported.[24,293]

Is Formocresol Carcinogenic?

With respect to mutagenicity and carcinogenicity, it is generally accepted that FAD is genotoxic in vitro, inducing mutations and DNA damage in cells from a variety of organisms, including humans.[96,200,207,272,302] The possible link between FAD and carcinogenesis has been investigated in the field of occupational health medicine. In a review of several large longitudinal studies, the International Agency for Research on Cancer (IARC) reported that *"sufficient evidence"* exists that FAD had caused nasopharyngeal cancer in humans.[32] This was suggested to be linked to a localized combination of irritation and genotoxicity of FAD, which repeat-dose inhalation studies using rodents has corroborated.[209] In the dental context, the amount of FAD in a diluted solution of formocresol is small, but no data are available on the amounts of FAD vapor inhaled by patients or dental personnel during pulpotomy procedures and whether this may constitute a potential risk. Moreover, the often disregarded cresol ingredient itself may pose a genotoxic risk to mammalian cells.[104] Formocresol solution used in pulpotomies in children has been reported as genotoxic after postpulpotomy harvested lymphocyte cultures displaying significantly increased chromosomal aberrations were compared with nonpulpotomized controls.[160]

Despite these concerns, the formocresol pulpotomy continues to be one treatment choice available for primary teeth with vital, carious exposures of the pulp in which inflammation or degeneration is judged to be confined to the coronal pulp. The last reported worldwide survey of dental schools (in 1989)[13] showed that most pediatric dentistry departments and pediatric dentists advocated the formocresol pulpotomy technique, and it may still be widely used in clinical practice. In the United Kingdom, since 2004, a general trend away from using formocresol has been noted, driven by several factors, such as difficulty obtaining the medicament, concerns related to its safety, and promising clinical results for newer, nonaldehyde techniques.[296] However, the recent U.K. clinical guideline, Pulp Therapy for Primary Molars, still includes the formocresol pulpotomy as an option,[235] as do the AAPD guidelines.[54] Although formocresol pulpotomy is still taught in predoctoral pediatric dentistry programs in the United States,[218] consensus is lacking on its use for vital pulp therapy in primary teeth.

The current formocresol pulpotomy technique is a modification of the technique reported by Sweet in 1930.[271] The effect of formocresol on pulp tissue (i.e., the amount of tissue fixation) is controlled by the quantity that diffuses into the tissue and depends on the duration of application, the concentration used, the method of application, or a combination of these factors.[63,90,167,173]

A one-fifth dilution formocresol solution has been widely advocated based on the outcomes of both in vitro and in vivo studies comparing dilute formocresol (see Box 24-4) with the undiluted solution (Table 24-1). Histochemical investigations comparing dilute and undiluted formocresol noted little difference between initial effects on pulp tissue fixation but earlier recovery of enzyme activity and improvement in the rate of recovery from the localized cytotoxic effects of formocresol with diluted formocresol.[158,159,268] Clinical studies have shown diluted formocresol to be as successful as full-strength formocresol.[81,82,180]

There is enough evidence today to conclude that ***if formocresol is to be used at all,*** *the one-fifth concentration should be preferred for pulpotomy procedures because it is as effective as and less damaging than the traditional preparation.*

Water	31%

Formocresol and the Permanent Successor

The fear of damage to the succedaneous tooth has been offered as an argument against formocresol pulpotomy on primary teeth. Results from studies are inconsistent, ranging from the same incidence of enamel defects in treated and untreated contralateral teeth[181,236] to an increase in defects and positional alterations of the underlying permanent tooth.[177] It should be pointed out that studies of this nature are follow-up studies long after treatment, and the researchers had no knowledge of the existing status of the pulp before pulpotomy.

The effect of a formocresol pulpotomy upon the exfoliation time of primary molars is also equivocal; some studies found no consistent effect,[181,290] and others reported early exfoliation.[113,180]

Unlike the tissue response to $Ca(OH)_2$ or MTA, no dentin bridge should be anticipated after formocresol is applied to exposed pulp tissue (see Fig. 24-10, *C* and *D*). However, narrowing of the root canal through the continued deposition of dentin by the preserved radicular pulp may be observed in some cases (Fig. 24-12).

Criteria for Success

Failure of a formocresol pulpotomy is usually detected on radiographs (see Fig. 24-8). The first signs of failure are often internal resorption of the root adjacent to the area where the formocresol was applied. This may be accompanied by external resorption, especially as the failure progresses. Sometimes, however, the internal resorption is self-corrected with deposition of calcified tissue. In the primary molars, radiolucency develops in the bifurcation or trifurcation area. In the anterior teeth, a radiolucent area may develop at the apices or lateral to the roots. With more destruction, the tooth becomes excessively mobile; a sinus tract usually develops. It is rare for pain to occur with the failure of a formocresol pulpotomy. Consequently, unless patients receive follow-up checks after a formocresol pulpotomy, failure may go undetected. When the tooth

loosens and is eventually exfoliated, the parents and child may consider the circumstances normal.

The development of cystic lesions after pulp therapy in primary molars has been reported.[29,243] An amorphous, eosinophilic material shown to contain phenolic groupings similar to those present in medicaments was found in the lesions. Myers et al.[185] have observed furcal lesions in untreated, pulpally involved primary molars containing granulomatous tissue with stratified squamous epithelium, which suggests the potential for cyst formation. In a subsequent study involving failed, pulpotomized primary molars, most specimens were diagnosed as furcation cysts.[186] These findings emphasize the importance of periodic follow-up to endodontic treatment on primary teeth. Figure 24-13 shows a favorable long-term outcome after a formocresol pulpotomy in a mandibular primary molar.

ALTERNATIVES TO FORMOCRESOL PULPOTOMY

A 2006 comprehensive review by Srinivasan et al.[262] is suggested for readers requiring a more detailed look at the numerous alternative techniques available.

Glutaraldehyde Pulpotomy

Glutaraldehyde has been suggested as an alternative to formocresol as a tissue fixative for vital pulpotomy. Histologic studies showed that it produced rapid surface fixation of pulp tissue but with limited depth of penetration, so a larger amount of radicular pulp tissue remained vital.[275,300] Fixed pulp tissue may be replaced with dense collagenous tissue over time.[141] Studies have also demonstrated less systemic distribution than was thought to occur with formocresol.[51,152,187,210,301]

Glutaraldehyde has been shown to be rapidly metabolized with little toxic effect.[112,130,135,187,227] It has also been demonstrated that although glutaraldehyde has antigenic action similar to that of formocresol, it is of a lower potential.[224,226]

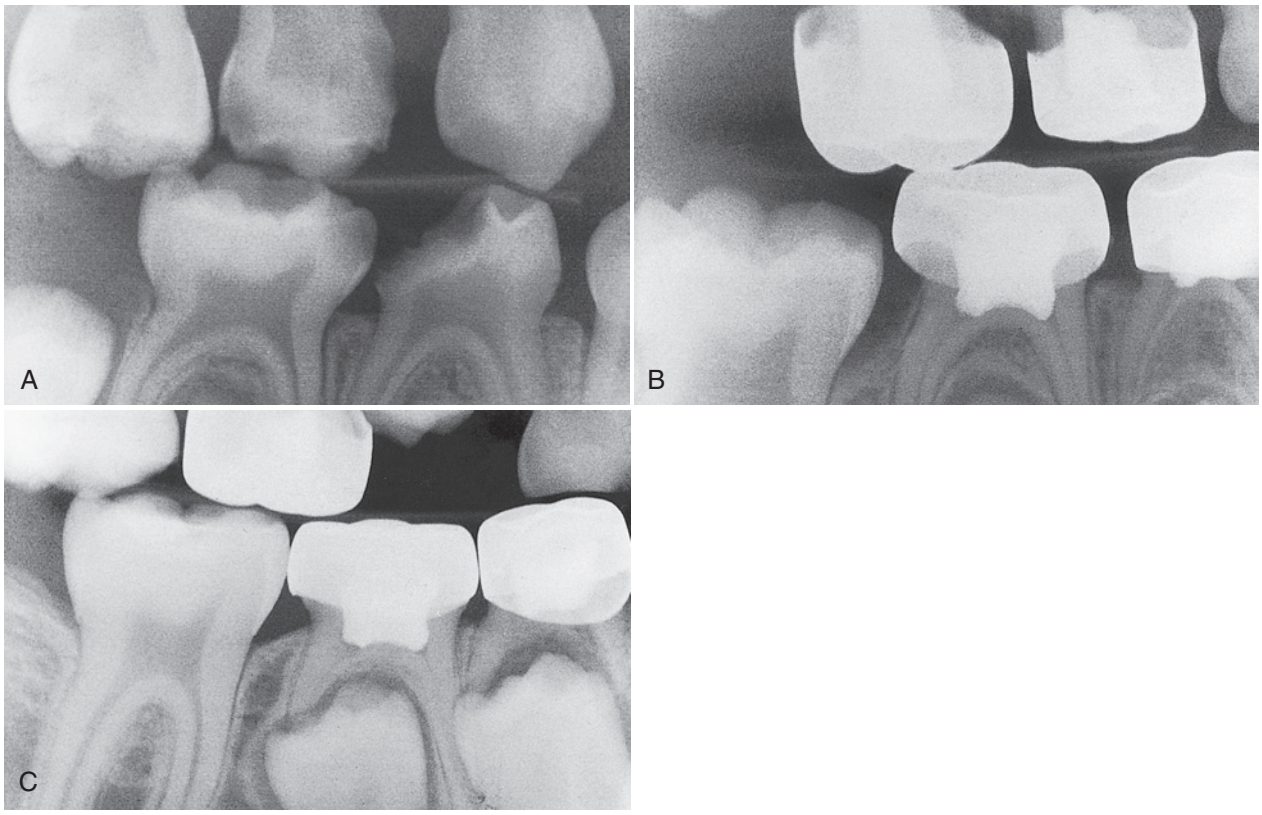

FIG. 24-13 Five-year follow-up of a primary tooth treated by formocresol pulpotomy. A, Pretreatment radiograph showing deep caries on the lower right first and second primary molars. **B,** One-year posttreatment radiograph. **C,** Five-year follow-up radiograph. Note the eruption of the lower right first permanent molar and first bicuspid.

However, there are perceived problems with the use of glutaraldehyde as a pulpotomy agent:

- Glutaraldehyde solutions are reported to be unstable.[222]
- Neither the optimum concentration nor optimal duration of application of glutaraldehyde solution have been established conclusively.[92,156,225]
- Clinical studies reported increasing failure rates with increasing time after pulpotomy,[83] with lower levels of clinical success than with formocresol.[5]

Despite its perceived enhanced safety compared with formocresol, glutaraldehyde has not gained favor over formocresol for pulpotomy in the primary dentition.[13,72]

Ferric Sulfate Pulpotomy

Technique

1. After completion of coronal pulp amputation and achievement of hemostasis with moist cotton pellets, a 15.5% solution of ferric sulfate is applied to the radicular pulp stumps for 10 to 15 seconds.
2. The ferric sulfate may be applied using a cotton pellet or by allowing small droplets of the solution to drip from a burnisher tip onto the surface of the pulp tissue. One manufacturer also supplies a special dento-infuser tip for this purpose (Astringident, Ultradent Products, Salt Lake City, Utah) (see Fig. 24-10, *E*, and Fig. 24-11, *E*).
3. Upon removal of the cotton pellet, the wounds appear brown, and no bleeding should be evident. If a small amount of residual bleeding occurs, one further application of ferric sulfate should be considered.
4. A cement base of ZOE is placed over the pulp stumps and allowed to set. The tooth may then be restored permanently as described for the formocresol pulpotomy (see Fig. 24-10, *F*).

Ferric sulfate is well esablished as a hemostatic agent for crown and bridge impressions.[75] Its hemostatic action occurs by the reaction of blood with ferric and sulfate ions within the acidic pH of the solution. The agglutinated proteins form plugs that occlude the capillary orifices and prevent blood clot formation.[153] Initially the use of ferric sulfate was recommended as a hemostatic agent during $Ca(OH)_2$ pulpotomy on the grounds that it may prevent problems arising from clot formation after coronal pulp amputation and minimize the chances for inflammation and internal resorption[246]; some consider these to be important factors contributing to the failure of pulpotomies using $Ca(OH)_2$. The first documented use of ferric sulfate in this way was in primate teeth.[145]

The use of ferric sulfate itself as a hemostatic pulpotomy agent was investigated by researchers using animal models (rat[40] and baboon[79]). Published clinical studies using ferric sulfate as a pulpotomy medicament have included both prospective comparative[71,79,123,208] and retrospective[28,261] designs.

In all the comparative studies, formocresol was included as the gold standard. The materials and methods used in all these studies are similar, which allows more meaningful comparison of their findings. Pulpotomies were performed in primary molars of healthy children who were selected on the basis of symptomless exposure of vital pulp by caries, absence of clinical or radiographic evidence of pulp degeneration, and possibility of proper restoration.

In all of the aforementioned ferric sulfate studies, the teeth were treated using the pulpotomy technique already outlined, and the teeth were restored with preformed metal (stainless steel) crowns. In a study by Papagiannoulis,[208] half of the teeth were restored with composite resin and the remaining half with preformed metal (stainless steel) crowns.

Prospective Studies

In a study by Fei et al.,[71] 27 teeth were included in the formocresol group and 29 in the ferric sulfate group. Although the sample size was small, the recall rate was excellent, and in the 3- and 6-month intervals, no statistically significant difference was found between the two groups. However, at the end of this 1-year study, a statistically significant difference was seen in the success rate in favor of ferric sulfate (97% for ferric sulfate, 78% for formocresol). The most frequent evidence of failure in this short-term study in both groups was furcation radiolucency. In a study by Fuks,[79] the sample consisted of 37 teeth in the formocresol group and 55 in the ferric sulfate group. The follow-up period ranged from 6 to 34 months, with a mean of 20.5 months. In this study, the sample size was bigger and the evaluation period much longer than in the previous one. The total success rate between the two groups over the total period of 34 months did not present any statistically significant difference; it was 92.7% for ferric sulfate and 83.8% for formocresol. Calcific metamorphosis and internal resorption were the most common radiographic findings. In this study, internal resorption that was stable and unchanged throughout the study was not recorded as failure.

In a later study by Ibricevic and Al-Jame,[123] 34 teeth were used in each group, and identical results were obtained 24 months after treatment for both ferric sulfate and formocresol: a 97% total success rate was recorded. In each group, only one tooth showed internal resorption and was therefore considered a failure.

The results of a larger comparative study[208] were published in 2002. The sample comprised 133 pulpotomy-treated molars of 90 children from 3 to 10 years old, with a mean age of 6.2 years. Sixty teeth (45%) were treated with formocresol and 73 (55%) with ferric sulfate. The number of teeth restored with either a stainless steel crown or a composite resin material was almost equal within each group. After 36 months, the clinical success rate was 97.3% for formocresol and 90.3% for ferric sulfate, but the difference in success rate between the two groups was reported to be statistically insignificant. The radiographic success rate was 78.3% for formocresol and 74% for ferric sulfate, again with no statistically significant difference between them. This success rate seems to be the lowest recorded compared with the previously mentioned comparative studies. The study's author believed that this finding could be due to three reasons: (1) the larger sample size, (2) the very good recall rate, which increased the possibility to observe and locate more failures; and (3) the very strict radiographic assessment. Internal resorption was the most common radiographic finding for both treatments, with no statistically significant difference between ferric sulfate and formocresol. However, most cases classified initially as failures because of internal resorption remained stable throughout the 36-month observation period, and in two cases the respective areas were self-filled with reparative hard tissue. Based on this observation, the data were reevaluated, and only cases of internal resorption that were either extensive in size or progressing with time were considered as failures. After the reevaluation, the overall success rate became 78.7% for ferric sulfate and 85% for formocresol, with no statistically significant difference between

them. The survival rate of the treated teeth after 6 months was 98% for both treatments and then 97% for ferric sulfate and 94% for formocresol after 1 year. These figures decreased with time for both groups, and the survival rate dropped to 81% for ferric sulfate and 78% for formocresol from 25 to 36 months.

Retrospective Studies

In a retrospective study published in 2000 by Smith et al.,[261] ferric sulfate pulpotomies performed over a period of 5 years by a private pediatric dentist were evaluated. The clinical success rate was very high: 99% up to 36 months and no further failures after 36 months. The radiographic success varied from 80% for the 4- to 12-month period, 74% for the 13- to 24-month period, 81% for the 25- to 36-month period, and 74% for the over 36-month period. The estimated tooth survival time was very high, starting with 99% up to 10 months and dropping to 80% after 43 months. The two most common radiographic findings in this study were calcific metamorphosis and internal resorption. The records in this study showed that 13 teeth that presented with internal resorption did not develop osseous lesions for the period of 43 months.

A second retrospective study, published 2 years later in 2002, reported results comparing different pulpotomy treatments; 83 formocresol pulpotomies, 45 ferric sulfate pulpotomies, and 74 pulpotomies treated with a combination of ferric sulfate and formocresol were selected from the records of children treated in a public clinic at different times and by different clinicians.[28] The initial results showed that the total success rate was similar in the three groups, but after a 36-month follow-up, the success rate was better for formocresol than for ferric sulfate, and the combination of the two agents was the worst. The last finding is not surprising because the teeth were treated initially with ferric sulfate for hemostasis and then with formocresol, and they had a poor prognosis (i.e., hyperemic and/or symptomatic). As pointed out by the authors, this study had several shortcomings, the most serious being that the pulpotomies were performed by many clinicians of different levels of experience and expertise; the criteria for selection of cases were not strictly defined; and the radiographs were not always satisfactory, compromising accurate evaluation of the periradicular and furcal areas of the treated teeth.

The studies described demonstrate a higher success rate for both ferric sulfate and formocresol in those with shorter observation times and smaller sample sizes. As the sample size increases and the observation period becomes longer, the success rate drops; this holds true for both ferric sulfate and formocresol pulpotomies. The most important finding is that no statistically significant differences in the success rates between ferric sulfate and formocresol existed, with the exception of one short-term study[71] in which a statistically significant difference was observed in favor of ferric sulfate at the 1-year period. In all the reviewed studies (prospective and retrospective), both ferric sulfate and formocresol treatments gave very good results with high tooth survival rates. Moreover, the type of restoration (stainless steel crown or composite resin) was not reported to influence the success rate for either pulpotomy agent.[208]

Clinical Outcome

In one study, the cases of internal resorption that remained unchanged throughout the 36-month observation period were not considered as failures in the final examination of the results.[208] Others proposed that internal resorption should not be considered as pulpotomy failure and based this proposal on the fact that none of the teeth with internal resorption in their sample developed an osseous lesion.[261] This proposal may be accepted only in cases of minimal or unchanged internal resorption; not for severe or progressive resorption. Internal resorption may indicate pulp inflammation that is expected at the amputation site after pulpotomy. However, if the inflammation can be restricted and confined to a very small part of the pulp while the remainder is healthy, the resorption process will cease or even self-heal by the apposition of hard tissue and therefore will not be a failure. In all the other cases, internal resorption indicates irreversible or extensive inflammation and should be considered a failure.

It can be seen from these studies and the results of a meta-analysis[157] that for human carious primary molars with reversible coronal pulpitis, ferric sulfate and formocresol pulpotomies give similarly good clinical and radiographic results, with high tooth survival rates and no statistically significant differences in success rates. These findings agreed with an earlier Cochrane Review of pulp treatment for extensive decay in primary teeth.[192]

Based on these studies, ferric sulfate can be used instead of formocresol for treatment periods up to 36 months.

Mineral Trioxide Aggregate Pulpotomy

Technique

1. After completion of coronal pulp amputation and achievement of hemostasis with moist cotton pellets, MTA powder is mixed with sterile water until the powder is adherent. Excess moisture is removed from the powder by placing a dry paper point into the mixture to act as a moisture wick.
2. The MTA may be applied to the pulp tissue using an excavator or retrograde amalgam carrier, ensuring enough material to completely cover the exposed pulp tissue to a depth of 3 to 4 mm (see Fig. 24-10, *G*).
3. The MTA mixture is gently packed over the pulp tissue using the blunt end of a large paper point and a broad-ended amalgam compactor. This layer of MTA is a permanent wound dressing.
4. A cement base of ZOE or glass ionomer cement is placed gently over the MTA and allowed to set. The MTA will take several hours to reach its optimum physical strength, so care must be taken to ensure an intact layer of MTA is in contact with the pulp tissue.
5. The tooth may then be restored permanently as described for the formocresol pulpotomy.

MTA used as a pulp capping agent in monkey teeth showed the pulp tissue responses to MTA to be superior to those produced using $Ca(OH)_2$.[215] Similar results were found when human intact third molars were used to compare the effect of pulp capping with MTA and $Ca(OH)_2$.[1] MTA was found to maintain pulp integrity after pulp capping and pulpotomy in animal studies[55,239] and to have a dentinogenic effect on the pulp expressed by the induction of dentin bridge formation (see Fig. 24-10, *H*) where it touches the pulp tissue.[239,241,288]

Clinical Studies

One of the first preliminary studies published comparing MTA with formocresol in humans[60] involved 45 pulpotomy-treated primary molars in 26 children with a mean age of 6 years, 5

months. Clinical and radiographic follow-up ranged between 6 and 30 months, involving 18 children with 32 teeth. Internal resorption was seen in one molar treated with formocresol (17 months after treatment). None of the teeth from the MTA group presented any clinical or radiographic pathosis. Pulp canal obliteration was observed in 9 of 32 (28%) molars evaluated.

Preliminary results of a 3-year prospective follow-up study comparing MTA with formocresol were reported at a scientific congress.[232] Pulpotomies were undertaken on 60 primary molars in 22 children aged 2 to 8 years, each needing at least two pulpotomies. Each child received at least one MTA and one formocresol pulpotomy, followed by application of a preformed metal (stainless steel) crown. Six months after treatment, seven teeth of the formocresol group and two of the MTA group presented abnormal radiographic findings, but these differences were not statistically significant.

More promising results were observed in a more extensive study by Holan et al.[117] that included part of the material presented by Eidelman et al.[60] and a longer follow-up time. Holan and colleagues assessed the long-term success rate of pulpotomy in primary molars with carious pulp exposure using MTA or formocresol as pulp dressing agents. Sixty-four primary molars of 35 children were treated by a conventional pulpotomy technique. After removal of the coronal pulp and hemostasis, the pulp stumps were covered with MTA in the experimental group. In the control group, formocresol was placed with a cotton pellet over the pulp stumps for 5 minutes and then removed; the pulp stumps were then covered with ZOE paste. Eight teeth from each group were restored with an amalgam restoration, and all others were covered with a preformed metal (stainless steel) crown. Thirty-three children with 62 teeth (29 treated with formocresol and 33 with MTA) were available for long-term clinical and radiographic evaluation. Follow-up ranged from 4 to 74 months, with a mean follow-up time of 38 months and with no difference between the groups. Twenty-nine teeth were followed until natural exfoliation (mean, 33 months). Failures were detected after a mean period of 16 months (range, 4 to 30 months). The success rate of pulpotomy was 97% for MTA (one failure) and 83% for formocresol (five failures). Eight teeth showed internal resorption. In four (two from each group), progress of the resorption process stopped, and the pulp tissue was replaced by a radiopaque calcified tissue. Pulp canal obliteration was observed in 55% (34 of 62) of the evaluated molars. This finding, which was not considered a failure, was detected in 58% (19 of 33) of the MTA and in 52% (15 of 29) of the formocresol group. The authors concluded that MTA showed a higher long-term clinical and radiographic success rate than formocresol as a dressing material following pulpotomy in primary molars and recommended it as a suitable replacement for formocresol.

The clinical, radiographic, and histologic effects of gray MTA, white MTA, and formocresol as pulp dressings in pulpotomy-treated primary teeth have been reported.[102] This involved 24 children with a mean age of 6 years (range, 4 to 8 years), each with at least three primary molars requiring pulpotomy, for the clinical and radiographic part of the study. An additional 15 carious primary teeth planned for serial extractions were selected for the histologic part of the study. All the teeth were evaluated periodically for 12 months except those selected for histologic evaluation; these were extracted 6 months after treatment. Sixty pulpotomy-treated teeth in 20 children were reviewed; of these, one tooth (gray MTA) exfoliated normally, and six teeth (four white MTA and two formocresol) failed because of abscesses. All the remaining 53 teeth showed success clinically and on radiographs. Pulp canal obliteration was found in 11 teeth treated with gray MTA and one treated with white MTA. The histologic evaluation demonstrated that both types of MTA induced thick dentin bridges, whereas in the formocresol group these were thin and poorly calcified. The pulpal architecture observed with the gray MTA was closer to normal than the white MTA, which presented a dense fibrotic pattern with isolated pulp calcification. These authors concluded that gray MTA was better than both white MTA and formocresol as a pulp dressing for pulpotomy-treated primary teeth. More recently, MTA pulpotomies were compared with $Ca(OH)_2$[154,273] and ferric sulfate,[56,65] with reported results showing that MTA is a suitable pulpotomy agent.

The growing evidence from clinical studies and a systematic review[257] allows MTA to be recommended as an effective pulpotomy agent in primary teeth.

MTA is commercially available in the United States as ProRoot MTA (DENTSPLY Tulsa Dental Specialties, Tulsa, OK). Angelus MTA (Angelus Indústria de Produtos Odontológicos, Londrina, Brazil) is also available in Latin America and Europe. ProRoot MTA is considered expensive, particularly because it is retailed in cartons containing a number of sealed 1-g packets. The composition of MTA is similar to that of cement used in the building industry, and such material should be kept dry during storage because contact with moist air leads to "air setting," which affects the powder's physical properties. The same could be applied to the "clinical grade" cement, and the manufacturer of ProRoot MTA recommends the 1-g sachet as single use, which would be expensive. The unused MTA remaining in a sachet may actually be stored for up to a further 4 weeks in a water-tight, air-tight container such as an Eppendorf tube (Eppendorf UK, Cambridge, Great Britain, UK), reducing its cost.[265] It has been suggested that the MTA powder can be stored indefinitely if the corner of the packet is folded firmly and the packet is stored in a sealable plastic bag. Angelus MTA is presented in a sealable glass vial, with the recommendation that 1 g may provide up to seven treatments. Care must be taken not to contaminate the MTA powder when it is dispensed.

Electrosurgical Pulpotomy

Technique

The steps in the electrosurgical pulpotomy technique are basically the same as those for the formocresol technique through the removal of the coronal pulp tissue.

1. Large sterile cotton pellets are placed in contact with the pulp, and pressure is applied to obtain hemostasis.
2. The Hyfrecator Plus 7-797 (Birtcher Medical Systems, El Paso, Texas) is set at 40% power (high at 12 W), and the 705-A dental electrode is used to deliver the electric arc. The cotton pellets are quickly removed, and the electrode is placed 1 to 2 mm above the pulpal stump.
3. The electric arc is allowed to bridge the gap to the pulpal stump for 1 second, followed by a cool-down period of 5 seconds. Heat and electrical transfer are minimized by

keeping the electrode as far from the pulpal stump and tooth structure as possible while still allowing electric arcing.
4. If necessary, this procedure may be repeated up to a maximum of three times. The procedure is then repeated for the next pulpal stump.
5. When the procedure is properly performed, the pulpal stumps appear dry and completely blackened.
6. The chamber is filled with ZOE placed directly against the pulpal stumps. Research by Fishman[76] has shown no difference between ZOE and $Ca(OH)_2$ as the dressing. The tooth should then be restored with a preformed metal (stainless steel) crown.

Although electrocoagulation on the pulps of teeth was reported in 1957,[150] it was a decade later that Mack[162] became the first U.S. clinician to routinely perform electrosurgical pulpotomies. Oringer[206] also strongly advocated this technique in his 1975 text on electrosurgery.

Electrosurgery is a nonpharmacologic, hemostatic pulpotomy technique used directly on the radicular pulp stumps after coronal pulp amputation. Depending on the currents used and thus the heat generated, incision, coagulation, or electrofulguration can occur. Electrosurgical pulpotomy carbonizes and denatures pulp tissue, producing a layer of coagulative necrosis. This acts as a barrier between the lining material and healthy pulp tissue below.[262]

Several clinical studies[237,254] have produced results comparable to those found with the use of formocresol. Conflicting results have been reported from histologic studies, ranging from results comparable to formocresol pulpotomy[253] to pathologic root resorption with periapical and furcal involvement.[255] A retrospective human study in 1993[163] showed a success rate of 99% for primary molars undergoing electrosurgical pulpotomies. Compared with a formocresol pulpotomy study of similar design, the success rate of the electrosurgery technique was shown to be significantly higher. A more recent study[197] compared the use of two different base lining materials during electrosurgical pulpotomy. Success rates at 12 months were high for both groups, 98% and 96% for ZOE and zinc polycarboxylate cements, respectively.

Laser Pulpotomy

Several reports have appeared in the literature on the use of the carbon dioxide laser for performing vital pulpotomies on primary teeth.[62,155] Elliott et al.[62] compared the use of the laser with formocresol in caries-free, primary cuspid teeth that were scheduled for extraction in children between 6 and 10 years of age. Thirty teeth were included in the study. No significant differences were found between the formocresol and laser-treated groups. Areas of isolated internal resorption were identified in one of the formocresol-treated teeth and two of the laser-treated teeth. These authors concluded that on the basis of symptomatic, clinical, and histologic findings, the carbon dioxide laser appeared to compare favorably with formocresol treatment. It was suggested that additional studies be conducted to establish the ideal applied laser energy to maximize optimum residual pulpal response and to explore the effects of laser pulpotomy upon pulps previously exposed by carious lesions.

Liu et al.[155] reported the use of the laser on primary teeth with vital carious pulpal exposures. Thirty-three teeth, 21 primary molars and 12 primary canines, were treated and observed for 12 to 27 months. All were clinically successful, and only one showed evidence of internal resorption at the 6-month follow-up visit. The authors observed complete calcification on radiographs after 9 months in approximately half of the treated teeth.

On the basis of these initial studies, the use of the carbon dioxide laser could be considered a viable alternative to formocresol. More randomized controlled human clinical trials are recommended.

In summary, the search for alternatives to the formocresol pulpotomy in cariously exposed vital primary teeth has yet to reveal an agent, instrument, or technique that has unequivocal long-term clinical success rates better than those of formocresol, although MTA is beginning to show evidence of excellent success rates in comparative studies.[56,65,270] Until such an agent, instrument, or technique is found, ferric sulfate, MTA, or formocresol (one-fifth dilution) can be used with equal confidence in primary tooth pulpotomies.[80,235,262]

NONVITAL PULP THERAPY ON PRIMARY TEETH

Pulpectomy in Primary Teeth

The anatomic and normal physiologic features of primary teeth can present challenges to the clinician wishing to undertake pulpectomy procedures. However, with knowledge of these features and how they may affect the clinical technique, pulpectomy and root canal obturation of primary teeth with irreversibly inflamed or necrotic pulp can be a clinically successful option.

In brief, these features are:

- Root anatomy: Apical positions, lateral and accessory canals
- Root physiology: The effect of exfoliation upon root anatomy and choice of root canal filling material
- The permanent tooth bud: Its proximity to the primary root apex

Effect of Resorption on Canal Anatomy and Apical Foramina

In the newly completed roots of the primary teeth, the apical foramina are located near the anatomic apices of the roots. After the deposition of additional dentin and cementum, there are multiple apical ramifications of the pulp as it exits the root, just as in the mature permanent tooth.

The physiologic resorption of the roots of the primary incisors and canines starts on the lingual surfaces in the apical third because of the position of the permanent tooth bud. In primary molars, resorption usually begins on the inner surfaces of the roots near the interradicular septum (Box 24-5).

As resorption progresses, the apical foramen may not correspond to the anatomic apex of the root but be coronal to it. Subsequently, radiographic establishment of the root canal length may be challenging (Fig. 24-14). Resorption may extend through the roots and into the root canals, creating additional communications with the periapical tissues other than through the apical foramina or lateral and accessory canals. This has been shown to occur at all levels of the root.[231] Because of these factors, use of an apex locator is not reliable to establish canal length.

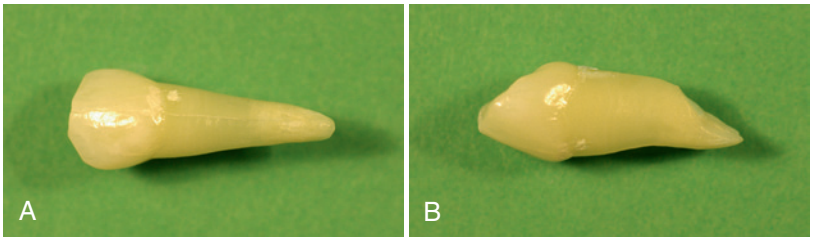

FIG. 24-14 Primary maxillary canine. A, Facial view: the apical foramen appears to be at the apex of the root. B, Physiologic root resorption has occurred at the palatal aspect of the root; the apical foramen is positioned more coronally and will not be coincident with the perceived radiographic apex of the tooth.

BOX 24-5

Physiologic Root Resorption in Primary Teeth

Physiologic root resorption begins:

- Soon after root-length completion
- In primary incisors and canines, on the lingual aspect of the apical third of the roots
- In primary molars, on the inner surfaces of the roots next to the inter-radicular septum

Permanent Tooth Bud

The effects of primary endodontic therapy on the developing permanent tooth bud should be of paramount concern to the clinician. Manipulation through the root apex of a primary tooth and overextension of root canal instruments and filling materials are to be avoided because the permanent tooth bud lies in close proximity. If radiographic signs of resorption are visible, the canal length is usually established by measurement of the diagnostic radiograph, ensuring that the working length of endodontic instruments is 2 or 3 mm short of the radiographic apex. Use of the long cone radiographic paralleling technique for maximal accuracy is recommended. Hemorrhage after pulp removal may indicate overextension into the periapical tissues.

Anesthesia is usually necessary for pulp extirpation and cleaning of the canals but may be unnecessary when primary teeth are filled at a subsequent appointment. The response of the patient can sometimes be used as a guide to the proximity of the apex and as a check of the length of the canal. However, this can only be done in cooperative patients because the discomfort caused by placing the rubber dam clamp or by the approach of the instrument to the apex might create disruptive behavior in some children.

The material used to obturate root canals in primary teeth must be resorbable, so that as the tooth resorbs, it offers no resistance or deflection to the eruption of the permanent tooth. *Permanent obturating materials, such as gutta-percha, are contraindicated in root canal therapy for primary teeth that have permanent successors.*

Pulpectomy

Pulpectomy and root canal filling procedures on primary teeth have been the subject of much controversy. Fear of damage to developing permanent tooth buds and a belief that the tortuous root canals of primary teeth could not be adequately negotiated, cleaned, shaped, and filled have led to the needless sacrifice of many pulpally involved primary teeth. Much has been written regarding potential damage to the developing permanent tooth bud from root canal fillings. The extraction of pulpally involved primary teeth and placement of space maintainers is an alternative to pulpectomy. However, there is no better space maintainer than the primary tooth. If a space maintainer is placed but adequate monitoring and preventive care are not provided, further problems often occur.

For example, with a "band and loop" design of space maintainer, loose bands and poor oral hygiene increase the risk of dental caries and gingival inflammation. Prolonged retention of the appliance may cause deflection of the erupting permanent tooth, and premature loss of the band can result in loss of space, particularly if the patient delays returning for treatment.

It has been reported that minor hypoplasia is increased in permanent successor teeth after root canal treatment of the primary precursors.[119] Coll[39] reported no such increased effect and concluded that defects result from the infection existing before the pulpectomy and not the procedure itself. It is noteworthy that these studies are retrospective, involving erupted permanent teeth; findings should be viewed with caution.

Economics has been advanced as an argument against endodontic treatment of primary teeth, but it is not a reasonable argument when compared with the cost of space maintainers, including the required follow-up treatment. In fact, endodontic treatment is probably the less expensive alternative when the entire treatment sequence is considered.

The success of endodontic treatment on primary teeth is judged by the same criteria used for permanent teeth. The treated primary tooth must remain firmly attached and function without pain or infection. Radiographic signs of furcal and periapical infection should be resolved with a normal periodontal attachment. The primary tooth should resorb normally and in no way interfere with the formation or eruption of the permanent tooth.

Success rates ranging from 75% to 100% have been reported.[10,118,147,269,305] The usual modalities of evaluating root canal treatment in primary teeth have been clinical and radiographic. More comprehensive evaluation in this area is greatly needed.

Early reports of endodontic treatment on primary teeth usually involved devitalization with arsenic in vital teeth and the use of creosote, formocresol, or paraformaldehyde pastes in nonvital teeth. The canals were filled with a variety of materials, usually consisting of zinc oxide and numerous additives.[59,93,131,263]

Rabinowitch[221] published the first well-documented scientific report on endodontic procedures on primary teeth in 1953. A 13-year study of 1363 cases of partially or totally

nonvital primary molars was reported. Only seven cases were failures; most patients were followed for 1 or 2 years clinically and with radiographs. Patients underwent multiple visits to achieve root canal fillings of ZOE and silver nitrate. Periapically involved teeth required an average of 7.7 visits to complete treatment, and teeth with no periapical involvement required an average of 5.5 visits. Rabinowitch listed internal resorption and gross pathologic external resorption as contraindications to primary root canal fillings.

Another well-documented study reported a success rate of 95% in vital and infected teeth using a filling material of thymol, cresol, iodoform, and zinc oxide.[10] (See Bennett[19] for a review of the techniques of partial and total pulpectomy.)

In a well-controlled clinical study of primary root canal treatments using Oxpara paste as the filling material,[147] five preexisting factors were reported to render the prognosis less favorable:

1. Perforation of the furcation
2. Excessive external resorption of roots
3. Internal resorption
4. Extensive bone loss
5. Periodontal involvement of the furcation

When teeth with these factors were eliminated, a clinical success rate of 96% was achieved. When all symptoms of residual infection were resolved before filling of the canals, the success rate improved.

Contraindications to Primary Root Canal Fillings

Many primary teeth with pulpal involvement that has spread beyond the coronal pulp are candidates for root canal fillings, whether they are vital or nonvital. Box 24-6 lists the categories of teeth that are not good candidates for pulpectomy.

Internal resorption usually begins just inside the root canals near the furcation area. Because of the thinness of the roots of the primary teeth, once internal resorption has become visible on radiographs, a perforation of the root by the resorption invariably has occurred (see Fig. 24-8). The short furcal surface area of the primary teeth leads to rapid communication between the inflammatory process and the oral cavity through the periodontal attachment. The end result is loss of the periodontal attachment of the tooth and, ultimately, further resorption and loss of the tooth. Mechanical or carious perforations of the floor of the pulp chamber fail for the same reasons. It has been shown that root length is the most reliable criterion of root integrity; at least 4 mm of root length is necessary for the primary tooth to be treatable.[231]

BOX 24-6

Contraindications to Pulpectomy in the Primary Dentition

- Unrestorable tooth
- Internal resorption in the roots visible on radiographs
- Teeth with mechanical or carious perforations of the floor of the pulp chamber
- Excessive pathologic root resorption involving more than a third of the root
- Excessive pathologic loss of bone support, with loss of the normal periodontal attachment
- Presence of a dentigerous or follicular cyst
- Periapical or interradicular lesion involving the crypt of the developing permanent successor

Access Openings for Pulpectomy

Anterior Primary Teeth

Access openings for endodontic treatment on primary or permanent anterior teeth have traditionally been through the lingual surface. This continues to be the surface of choice, except for discolored maxillary primary incisors, for which a facial approach is recommended, followed by an acid-etched composite restoration to improve aesthetics (Fig. 24-15).[164]

Posterior Primary Teeth

Access openings into the root canals of posterior primary teeth are essentially the same as for the permanent teeth. Important differences between the primary and permanent teeth are the length of the crowns, the bulbous shape of the crowns, and the very thin dentinal walls of the pulpal floors and roots. The depth necessary to penetrate into the pulpal chamber is much less than that in the permanent teeth. Likewise, the distance from the occlusal surface to the pulpal floor of the pulp chamber is much less than in permanent teeth. In primary molars, care must be taken not to overinstrument the relatively thin pulpal floor, owing to the high risk of perforation (Fig. 24-16).

When the roof of the pulp chamber is breached and the pulp chamber identified, the entire roof should be removed. Because the crowns of the primary teeth are more bulbous, less extension toward the exterior of the tooth is necessary to uncover the openings of the root canals than in the permanent teeth.

Technique

As in permanent endodontic therapy, the main objective of the chemical and mechanical preparation of the primary tooth is debridement of the canals. Although an apical taper is desirable, it is not necessary to have an exact shape to the canals because obturation is achieved using a resorbable paste. Figure 24-17 provides a schematic overview of the procedure.

Canal Preparation

1. A preliminary working length is determined by measurement of a radiograph taken with a paralleling technique.
2. Local anesthesia is advisable.
3. Placement of a rubber dam is mandatory.
4. The working length is determined from a radiograph with an endodontic file in the canal. The use of apex locators is often unreliable in primary teeth because root resorption may create lateral openings into the periodontal tissues at any level,[231] causing unreliable readings.
5. To prevent overextension through the apical foramen, it is advisable to shorten the working length to 2 to 3 mm short of the radiographic length, especially in teeth showing signs of apical root resorption (see Fig. 24-17, *B*).
6. After establishment of the working length, the canal is cleaned and gently shaped (as described in Chapter 6). *Because of the thin root walls, sonic and ultrasonic cleaning devices should not be used to prepare the canals. Also, the use of Gates-Glidden (GG) or Peeso drills (Pulpdent, Watertown, Massachusetts) is contraindicated because of the danger of perforation or stripping of the roots.*
7. Flexible nickel-titanium (NiTi) instruments are recommended. Hand or rotary techniques are ideal for primary

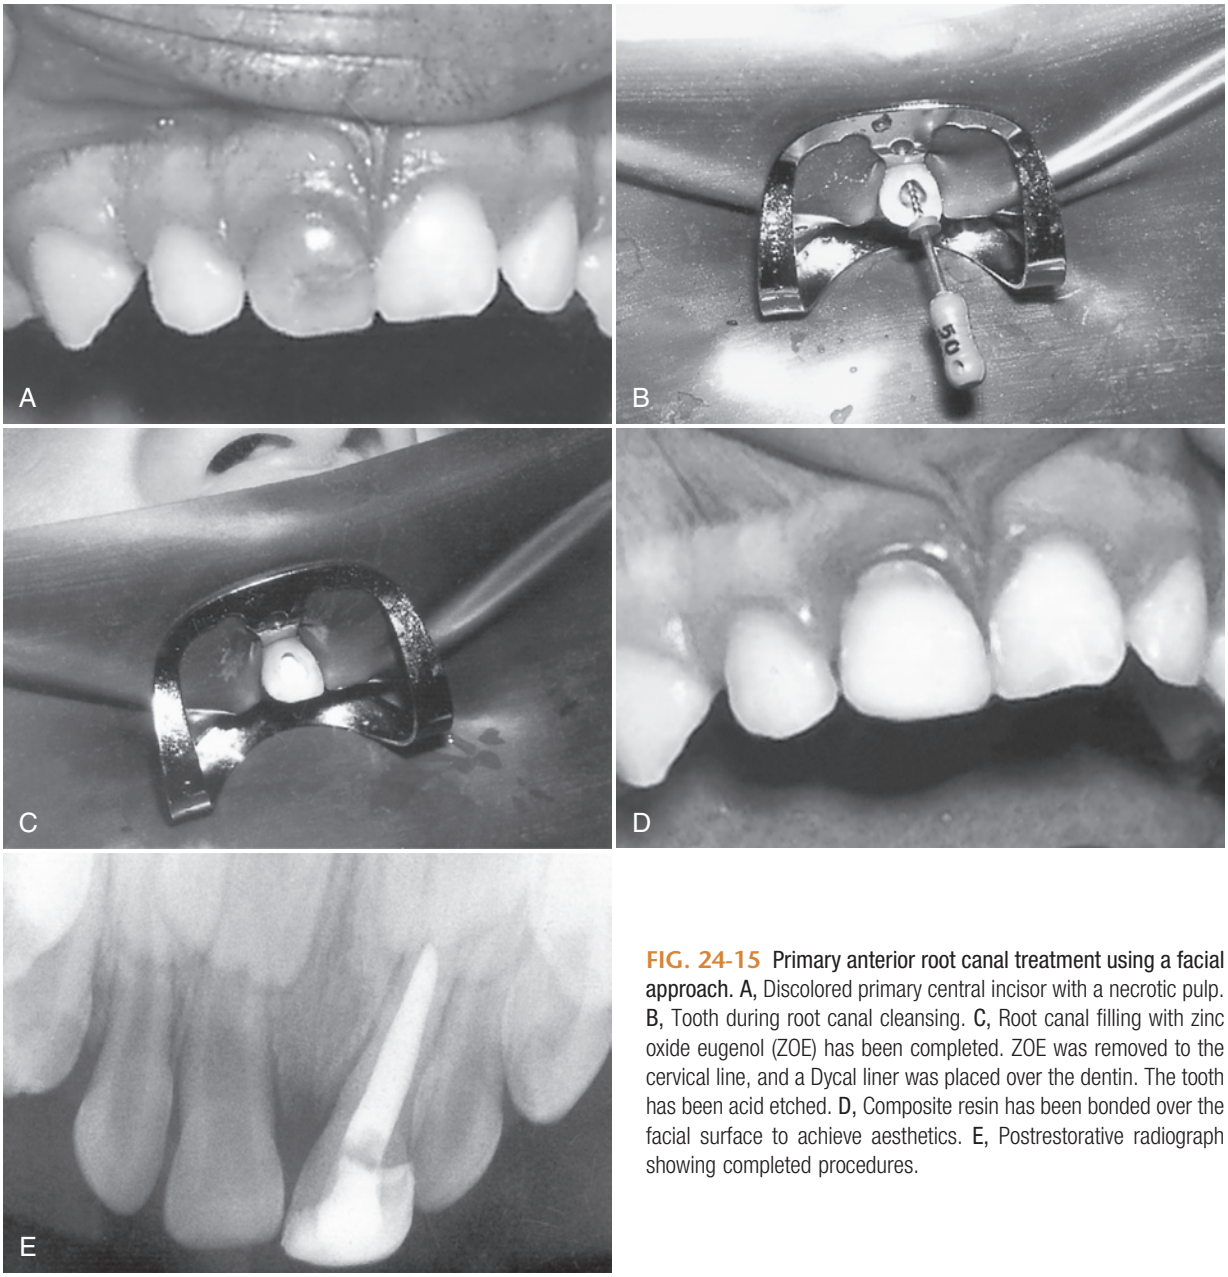

FIG. 24-15 Primary anterior root canal treatment using a facial approach. **A,** Discolored primary central incisor with a necrotic pulp. **B,** Tooth during root canal cleansing. **C,** Root canal filling with zinc oxide eugenol (ZOE) has been completed. ZOE was removed to the cervical line, and a Dycal liner was placed over the dentin. The tooth has been acid etched. **D,** Composite resin has been bonded over the facial surface to achieve aesthetics. **E,** Postrestorative radiograph showing completed procedures.

teeth. If stainless steel files are used, the instruments must be gently precurved to help negotiate the canals.

8. Care must be taken not to perforate the thin roots during cleaning and shaping procedures. The canals are enlarged several sizes past the first file that fits snugly in the canal, with a minimum size of 30 to 35.

Importance of Irrigation During Treatment

Because many of the pulpal ramifications cannot be reached mechanically, copious irrigation during cleaning and shaping must be maintained (see Chapter 6). Debridement of the primary root canal is more often accomplished by chemical means than by mechanical means.[124] This statement should not be misinterpreted as deemphasizing the importance of thorough debridement and disinfection of the canal. Initially, RC-Prep (Premier Dental Products, Norristown, Pennsylvania) may be used as the canals are negotiated. It helps to emulsify pulp tissue and is an effective lubricant. Once a working length has been established, sodium hypochlorite (NaOCl) solution is used to dissolve organic debris; this can play an important part in removal of tissue from inaccessible areas of the root canal system (see Fig. 24-17, *C*).

The Nonvital Discolored Primary Incisor

If a primary incisor is intrinsically discolored after loss of pulp vitality, aesthetics may demand an improvement of the tooth's color. Bleaching is not advised in the primary dentition. The anatomy of the maxillary primary incisors is such that access may be made successfully from the facial surface. The only variation to the opening is more extension to the incisal edge than with the normal lingual access to give as straight an approach as possible into the root canal.

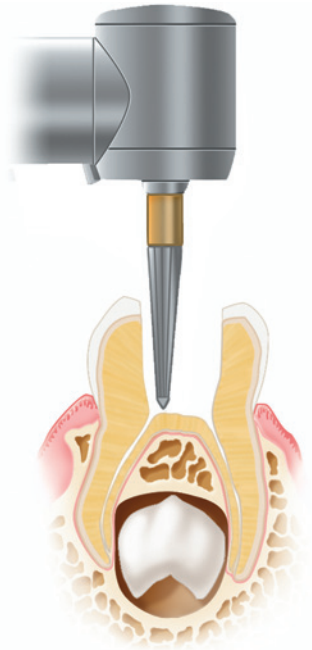

FIG. 24-16 Safe removal of the roof of a pulp chamber in a primary molar. A non–end cutting bur ensures that the relatively thin floor of the pulp chamber is not perforated inadvertently by rotary cutting instruments.

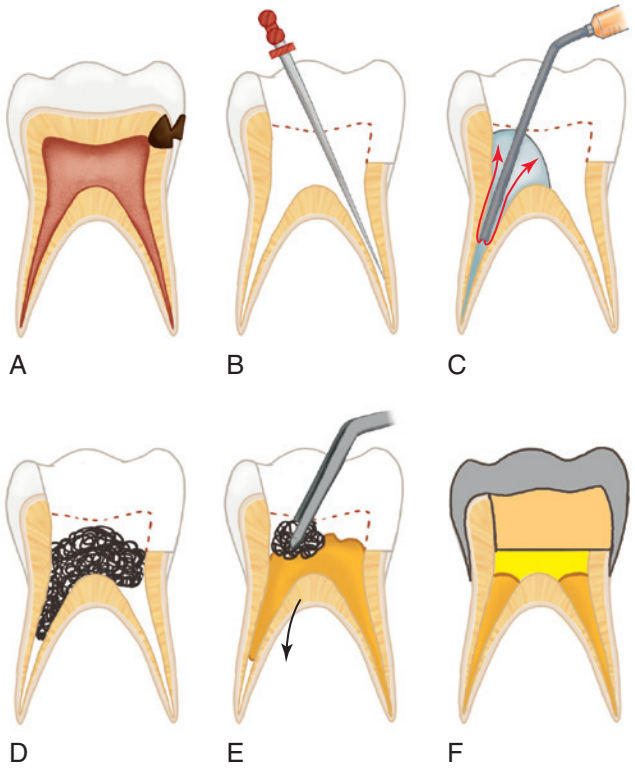

FIG. 24-17 Stages of pulpectomy and root canal filling in a mandibular second primary molar. A, Extensive approximal caries. Note the irreversible inflammation present in the coronal and radicular pulp. **B,** After caries removal and unroofing of the pulp chamber, the coronal pulp is amputated. Irreversibly inflamed tissue bleeds profusely. A premeasured hand file is placed approximately 2 mm from the radiographic apex; the canals are gently cleaned with minimal shaping. **C,** Irrigation with sodium hypochlorite or chlorhexidine digluconate solution should be performed during the cleaning phase. **D,** If the root canals are not to be obturated at the same visit, they may be dressed with nonsetting calcium hydroxide; or, the canals can be left empty and the tooth restored with a small cotton pledget and an interim intracoronal restoration. **E,** At the subsequent visit, root canals can be obturated with a resorbable root-filling material, such as zinc oxide eugenol (ZOE). This can be applied using various methods; here, the ZOE is tamped down the canal by the piston action of a cotton pledget held in tweezers. **F,** After root canal filling, the tooth is restored internally before definitive coverage with a preformed metal (stainless steel) crown.

The root canal is filled with ZOE (see the following section); then the ZOE is carefully removed to near the cervical line. A liner of calcium hydroxide cement, such as Dycal or Life, is placed over the ZOE to serve as a barrier between the composite resin and the root canal filling. The liner is extended over the darkly stained lingual dentin to serve as an opaquer. The access opening and entire facial surface are acid etched and restored with composite resin (see Fig. 24-15, *C* and *D*).

The Decision to Obturate

After canal debridement, the canals are again copiously flushed with NaOCl and then dried with sterile premeasured paper points. If the canals are dry and no exudate is present, obturation is performed in the same session. If the obturation cannot be done at the first appointment, a slurry paste of nonsetting $Ca(OH)_2$ can be injected into the canals and the tooth restored with a well-sealing temporary restoration.

At a subsequent appointment, the rubber dam is placed and the canals reentered. As long as the patient is free of all signs and symptoms of inflammation, the canals are irrigated with NaOCl to remove the intracanal dressing and dried before obturation. If signs or symptoms of inflammation are present, the canals are recleaned and remedicated, and the canal obturation delayed until a later time.

Root-Filling Materials for the Primary Root Canals

The ideal root canal filling material for primary teeth should meet the following criteria:

- Resorb at a similar rate as the primary root
- Be harmless to the periapical tissues and the permanent tooth germ
- Resorb readily if pressed beyond the apex
- Be antiseptic
- Fill the root canals easily
- Adhere to the walls of the root canal
- Not shrink
- Be easily removed if necessary
- Be radiopaque
- Not discolor the tooth[161]

No material currently available meets all these criteria. The filling materials most commonly used for primary pulp fillings are ZOE paste, iodoform paste, and $Ca(OH)_2$.

Zinc Oxide Eugenol Paste

Most reports in the U.S. literature have advocated the use of ZOE as the filler, whereas other parts of the world have used pastes containing iodoform.[118,143] The antibacterial activity of ZOE has been shown to be greater than that of an iodoform-containing paste (e.g., KRI paste, Pharmachemic AG, Zurich,

Switzerland), whereas ZOE's cytotoxicity in direct and indirect contact with cells is equal to and less than (respectively) that of KRI paste. *The filling material of choice in the United States is ZOE without a catalyst*. The lack of a catalyst is necessary to allow adequate working time for filling the canals.

Iodoform Paste

Several authors have reported the use of KRI paste, which is a mixture of iodoform, camphor, parachlorophenol, and menthol.[176,230] It resorbs rapidly and has no undesirable effects on successor teeth when used as a pulp canal medicament in abscessed primary teeth. Furthermore, if KRI paste extrudes into the periapical tissue, it is rapidly replaced with normal tissue.[118] Sometimes the material is also resorbed inside the root canal. A paste developed by Maisto has been used clinically for many years, and good results have been reported with its use.[171,274] This paste has the same components as the KRI paste, with the addition of zinc oxide, thymol, and lanolin.

Calcium Hydroxide

Several clinical and histopathologic investigations of $Ca(OH)_2$ and iodoform mixture (Vitapex, Neo Dental Chemical Products, Tokyo) have been published.[16,78,199] These authors found that this material is easy to apply, absorbs at a slightly faster rate than that of the roots, has no toxic effects on the permanent successor, and is radiopaque. For these reasons, Machida[161] considers the calcium hydroxide–iodoform mixture a nearly ideal primary tooth root canal filling material. Another preparation with similar composition, Endoflas, is available in the United States (Sanlor Laboratories, Cali, Colombia, South America). The results of root canal treatments using Endoflas were similar to those observed with KRI paste[85] and ZOE.[269]

Obturation of the primary root canal is usually performed without a local anesthetic. This is preferable, if possible, so the patient's response can be used to indicate proximity to the apical foramen. However, it sometimes is necessary to anesthetize the gingiva with a drop of anesthetic solution to place the rubber dam clamp without pain.

Obturation of the Root Canal

The chosen obturation technique depends upon the material used and the accessibility of the canal to relevant instruments.

If ZOE is used, it is mixed to a thick consistency and carried into the pulp chamber with a plastic instrument or on a Lentulo spiral. The material may be packed into the canals with pluggers or a Lentulo spiral. A cotton pellet held in cotton pliers and acting as a piston within the pulp chamber is quite effective in forcing the ZOE into the canals (see Fig. 24-17, *E*). The endodontic pressure syringe is also effective for placing the ZOE in root canals.[20,98] However, in a study of apical seal and quality of filling evaluated on radiographs, no statistically significant differences were reported between the Lentulo spiral, pressure syringe, or plugger.[50]

When the root canal is filled with a resorbable paste, such as KRI, Maisto, or Endoflas, a Lentulo spiral mounted in a low-speed handpiece can be used to introduce the material into the canal. When the canal is completely filled, the material is compressed with a cotton pellet. Excessive material is rapidly resorbed.

Vitapex is packed in a convenient sterile syringe, and the paste is injected into the canal with a disposable plastic needle. This technique is particularly easy to use for primary incisors but less practical for the narrow canals of primary molars.[203]

Regardless of the method used to fill the canals, care should be taken to prevent extrusion of the material into the periapical tissues. It is reported that a significantly greater failure rate occurs with overfilling of ZOE than with filling just to the apex or slightly underfilling.[39,118] The adequacy of the obturation is checked by radiographs (see Fig. 24-15, *E*; also Fig. 24-18, *A-C* and Fig. 24-19, A-E).

In the event a small amount of the ZOE is inadvertently forced through the apical foramen, it is left alone (because the material is absorbable). It has been reported that defects on successor teeth have no relationship to length of the ZOE filling.[39]

When the canals have been satisfactorily obturated, a fast-setting temporary cement is placed in the pulp chamber to seal over the root canal filling. The tooth may then be restored permanently. In primary molars, it is advisable to place a preformed (stainless steel) crown as the permanent restoration to ensure good coronal seal and prevent possible fracture of the tooth (see Fig. 24-17, *F*).

If a primary tooth requires pulpectomy and the permanent successor tooth is absent, the primary root canals are filled with gutta-percha and sealer in an attempt to retain the primary tooth long term (Fig. 24-20).

Follow-Up After Pulpectomy in the Primary Dentition

As previously stated, the rate of success after primary pulpectomy is high. However, these teeth should be periodically recalled to check for success of the treatment and intercept any problem associated with a failure. It has been reported that pulpectomized primary teeth may show delayed exfoliation.[39,265] One study[39] described a 20% incidence of crossbites or palatal eruption of permanent incisors after pulpectomy on primary incisors. In the posterior teeth, extraction was required in 22% of cases because of ectopic eruption of the premolars or difficulty in exfoliation of the treated primary molar.[39] After normal physiologic resorption of the roots reaches the pulp chamber, the large amount of ZOE present may impair the resorptive process and lead to prolonged retention of the crown. Treatment usually consists of simply removing the crown and allowing the permanent tooth to complete its eruption.

Retention of ZOE in the tissues is a common sequela to primary pulpectomy. One long-term study reported that after loss of the tooth, 50% of cases had retained ZOE. Teeth filled short of the apices had significantly less retained filling material, and in time, most showed complete absorption or reducing amounts. Retention of filling material was not related to success and caused no pathosis.[238] Therefore, no attempt is made to remove retained material from the tissues (see Fig. 24-18, *A*, and Fig. 24-19, *C*).

While resorbing normally without interference from the eruption of the permanent tooth, the primary tooth should remain asymptomatic, firm in the alveolus, and free of pathosis. Traditionally, root canal treatments were considered successful when no pathologic resorption associated with bone rarefaction was present.[91,118] If evidence of pathosis is detected, extraction and conventional space maintenance are recommended.

Note that no enamel defects are present on the crown, despite overfill of the root canal of the predecessor. **C,** Radiograph almost 5 years after pulpectomy and root canal filling of predecessor. Note the normal apical development and almost total absorption of ZOE remnants.

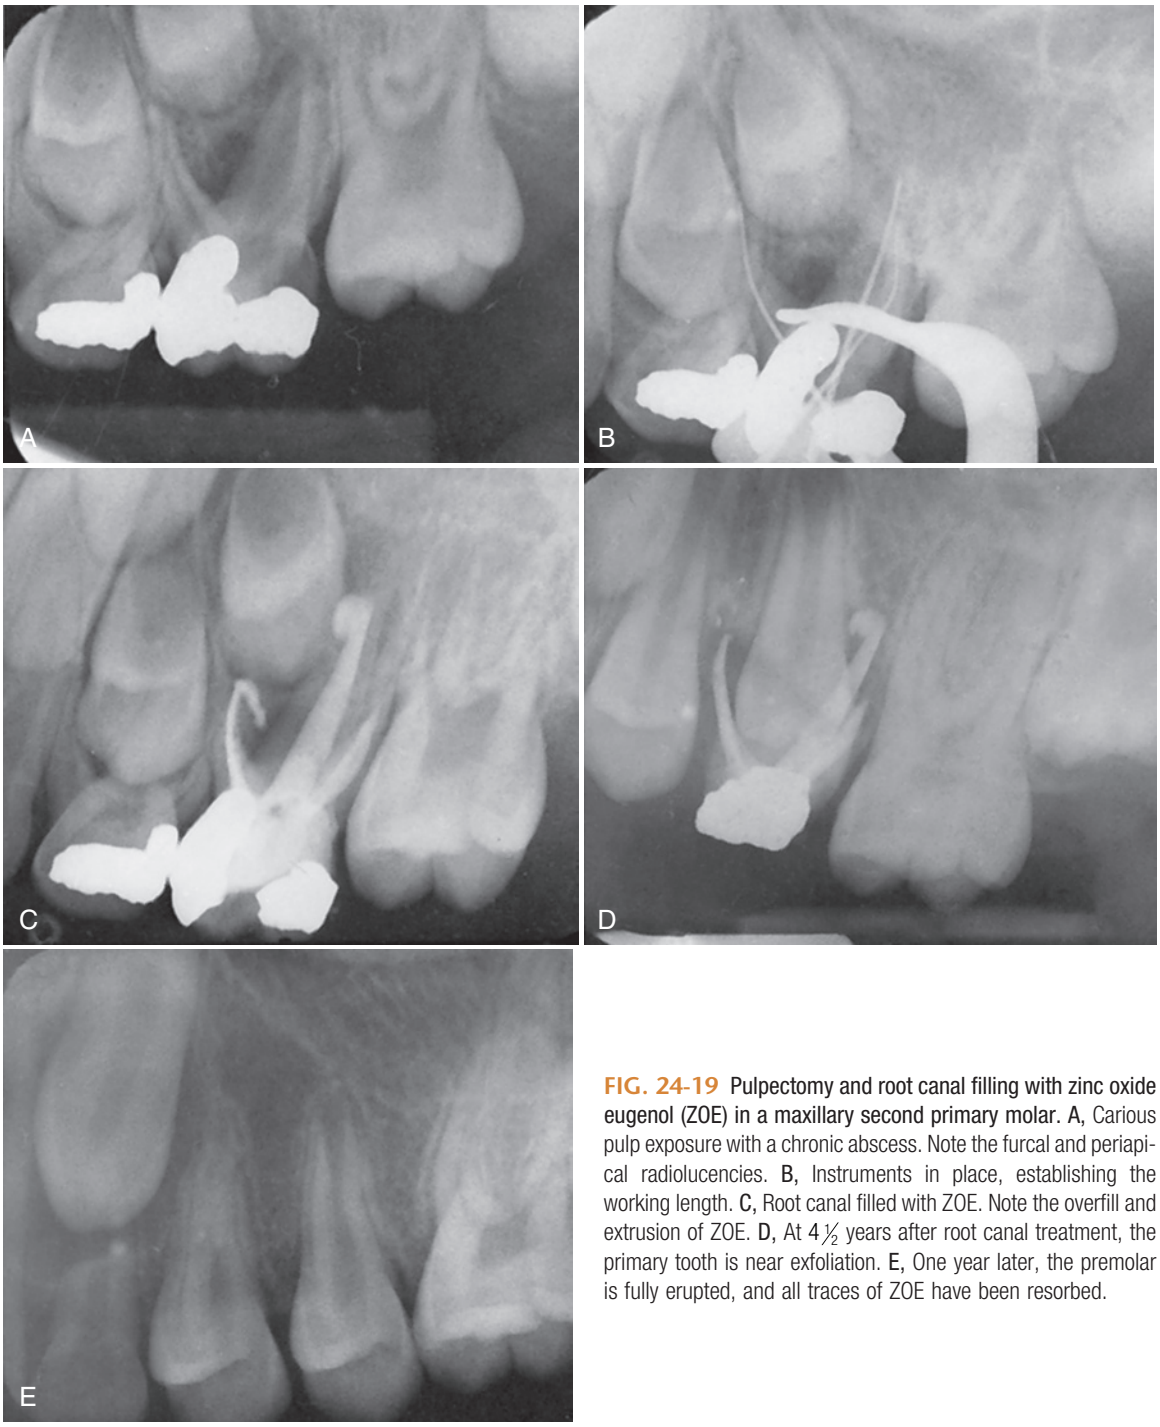

FIG. 24-19 **Pulpectomy and root canal filling with zinc oxide eugenol (ZOE) in a maxillary second primary molar. A,** Carious pulp exposure with a chronic abscess. Note the furcal and periapical radiolucencies. **B,** Instruments in place, establishing the working length. **C,** Root canal filled with ZOE. Note the overfill and extrusion of ZOE. **D,** At 4½ years after root canal treatment, the primary tooth is near exfoliation. **E,** One year later, the premolar is fully erupted, and all traces of ZOE have been resorbed.

Payne et al.[212] claim that most clinicians are prepared to accept pulp-treated primary teeth that have a limited degree of radiolucency or pathologic root resorption in the absence of clinical signs and symptoms. This is contingent on the assurance that the parent will contact the clinician if an acute problem develops, and the patient will return for review in 6 months. These criteria seem to be more suitable for pediatric dental practices and have been adopted clinically by Fuks et al.,[85] who consider such teeth to be "successfully treated."

PULPAL THERAPY FOR THE YOUNG PERMANENT DENTITION

It could be argued that mature permanent teeth can survive for a lifetime without the support of a vital pulp. For the immature permanent tooth, the future is less secure. Premature loss of a functioning pulp results in a fragile tooth with a compromised crown-to-root ratio, thin dentin walls, and a wide and often apically diverging root that presents significant endodontic and

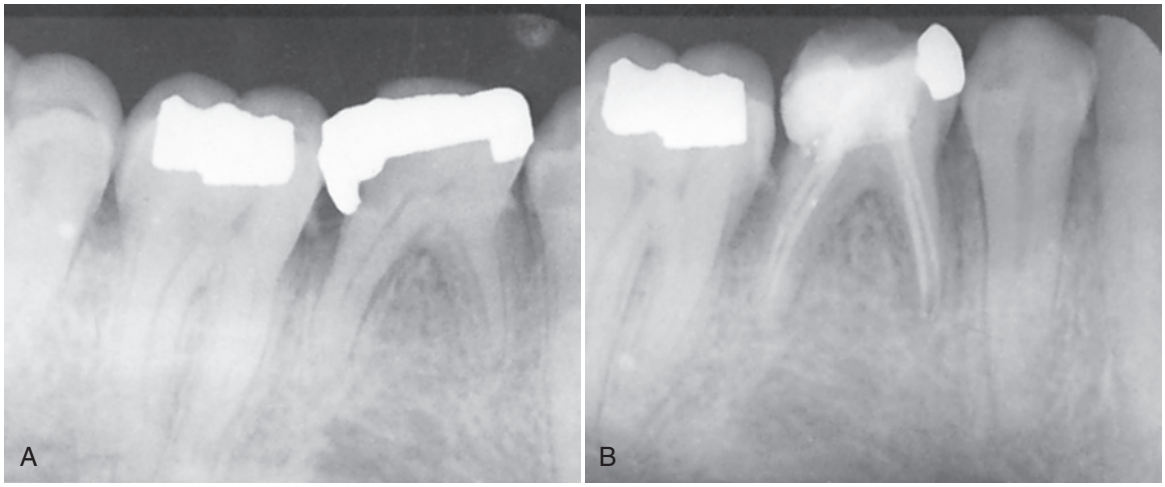

FIG. 24-20 Pulpectomy and root canal filling with gutta-percha in a retained mandibular primary second molar with no succedaneous permanent tooth. **A,** Carious exposure of the pulp. **B,** Because the permanent premolar is absent, the root canals were filled with gutta-percha and sealer rather than just zinc oxide eugenol.

FIG. 24-21 Premature loss of vital pulp functions in an immature maxillary permanent incisor. Development is arrested, leaving a fragile tooth with a compromised crown-to-root ratio, thin dentin walls, and a wide-open root end; these factors present endodontic and restorative challenges.

restorative challenges (Fig. 24-21). A central responsibility of all clinicians is therefore to safeguard pulp survival at least until dental development is complete.

The procedures described in this section have much in common with those for primary teeth and focus on preserving all or part of the pulp in a functional condition. In addition to aspects of pulp protection, indirect pulp therapy, direct pulp capping, and pulpotomy, attention is given to the root canal treatment and restoration of nonvital, immature permanent teeth. The emerging potential of pulp regeneration and bioroot engineering is also considered.

Indirect Pulp Therapy: Avoiding Pulp Exposure

The pulps of young permanent teeth are at risk of breakdown after traumatic injuries (considered fully in Chapter 20), dental caries, and restorative dentistry. Good evidence indicates that residual dentin thickness is a key determinant of pulp survival after cavity preparation,[183] and avoiding pulp exposure has been considered advantageous. The management of deep caries by partial or serial excavation has gained considerable support in recent years, reducing the risks of pulp exposure and harnessing the natural defenses of the pulp in laying down protective tertiary (reactionary) dentin.* In the case of serial excavation, the need for a secondary excavation has recently been brought into question,[166] although the need for a tightly sealing coronal restoration to ensure that any residual caries is inactivated has been acknowledged.[228] Researchers continue to investigate the role of antimicrobial treatments, including ozone fumigation,[216] photoactivated disinfection (PAD), and antimicrobial resins in sterilizing deep layers of affected dentin[286] and creating the conditions for arrest and remineralization. Considerable interest has also focused on the active up-regulation of reactionary dentinogenesis by applying bioactive agents, such as the transforming growth factor beta (TGF-β) family of molecules, to the depths of cavity preparations.[285] Therapeutic approaches present a hopeful future for pulp protection after deep caries, but significant challenges remain, not least in defining optimal agents and predictably delivering them to the pulp through the fluid-filled dentinal tubules of vital teeth.[219] More basic and clinical research is needed before such agents can be widely adopted in practice.

However, a substantial body of evidence supports the view that complete excavation is not necessary for the successful management of deep caries[200] and that indirect pulp therapy may be the most effective means of securing pulp health in asymptomatic teeth.

Note the lack of mineralization in the pulp chamber and canals.

Managing Pulp Exposure

Even when treated with the greatest clinical judgment and restorative skill, pulps are sometimes exposed during deep caries excavation. A 2007 survey showed that 62% of clinicians would remove all caries when presented with a case in which one would expect pulp exposure, whereas only 18% would partially excavate caries, and 21% would initiate root canal treatment.[204] In a comparable study among Brazilian public health dentists, 71% favored direct, complete caries excavation over more conservative approaches, although dentists graduating after the year 2000 were more likely to embrace conservative approaches.[299] Direct pulp capping has generally not enjoyed predictable success in cariously exposed teeth. One study showed a 44.5% failure at 5 years and a disappointing 79.7% failure at 10 years.[17] A more recent systematic review points to success of 73% at 3 years for permanent teeth, but longer term outcomes appear variable and uncertain.[3]

Although much of the evidence is relatively short term and involves previously uninflamed pulps, calcium silicate cements, such as MTA, are developing a profile for promoting reparative tertiary dentin bridge formation after direct pulp capping.[148,193]

In a radically different approach to the management of deep caries in immature permanent teeth where pulp diagnosis may be uncertain and the stakes for pulp preservation are high, one of the previous authors of this chapter (Dr. Joe Camp) has advocated complete caries excavation and direct capping of the exposure in the immature teeth of children (Fig. 24-22). Teeth with percussion sensitivity, swelling, or other obvious signs of pulpal necrosis are not considered good candidates, and the pulp tissue exposed during caries excavation must appear vital with no signs of degeneration or suppuration. In this procedure, the tooth is anesthetized and isolated with a rubber dam. All decay is removed with round carbide burs and copious water spray. No further pulpal tissue is removed except that occurring with the caries removal. The often profuse bleeding that occurs is controlled by rinsing the pulp with NaOCl, which is not only antimicrobial but appears to have no adverse effects on pulpal healing, odontoblastic cell formation, or dentinal bridging.[2,42] The solution may be left in contact with the exposed pulp tissue for 10 to 15 minutes; it is refreshed with new solution every 3 to 4 minutes. Care must be taken in aspirating the excess NaOCl to prevent further hemorrhage; the aspirator tip is placed lateral to, and never directly above, the crown. Once hemorrhage has been controlled, the tooth structure is cleansed with cotton pellets moistened with NaOCl, again avoiding further pulp hemorrhage.

The exposed pulp is then covered with a 0.5- to 1-mm thickness of MTA, which is gently teased against the exposed

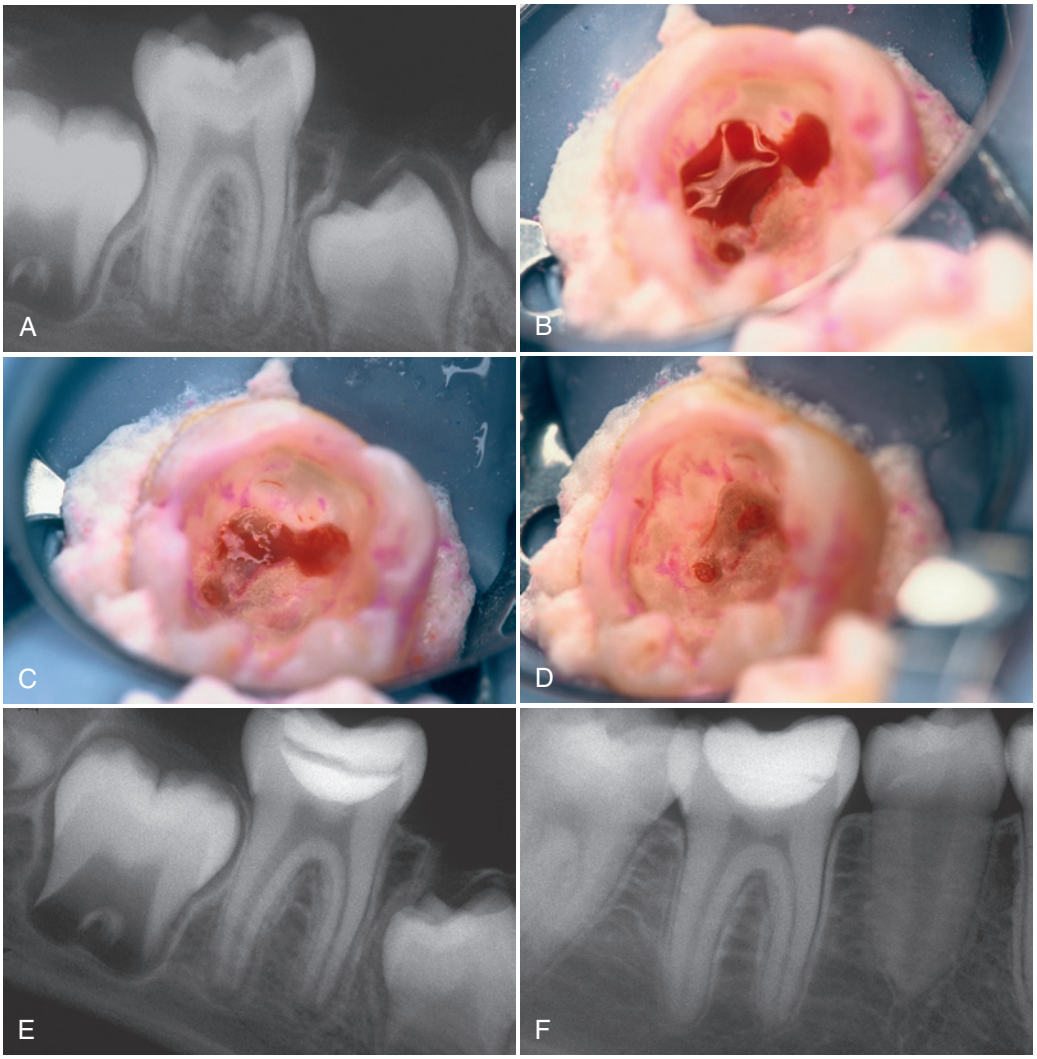

FIG. 24-23 **Radiographic and clinical sequence of mineral trioxide aggregate (MTA) direct pulp capping of a mandibular right molar in a 9-year-old female. A,** Pretreatment radiograph showing initial deep caries and immature apices. **B** to **D,** Five-minute application of 5.25% sodium hypochlorite hemostasis on two 1.5- to 2-mm exposures. **E,** Radiograph of molar with MTA, water-moistened cotton pellet, and unbonded Clearfil Photocore (Kuraray Medical, Okayama, Japan) provisional restoration after initial visit. **F,** Radiograph taken at the 5.5-year recall appointment shows permanent restoration and evidence of complete root formation. The tooth showed a normal response to cold testing. (From Bogen G, Kim JS, Bakland LK: Direct pulp capping with mineral trioxide aggregate: an observational study, *J Am Dent Assoc* 139:305, 2008.)

pulp tissue with a damp cotton pellet. Wisps of cotton are wet with sterile water and placed over the MTA so it is completely covered. The tooth is then provisionally sealed with a temporary cement, such as Cavit, to allow hardening of the MTA.

The patient is seen again within 12 to 48 hours, and the tooth is anesthetized and isolated with a rubber dam. After removal of the Cavit and cotton, the MTA is examined to ensure that it has set hard, and the tooth is restored with a bonded composite restoration. If the MTA has failed to harden, Camp advocated washing out the uncured material and repeating the procedure after removing pulp tissue to the canal orifice level. This approach has received further support from two studies. In a study by Farsi et al.,[69] 30 asymptomatic permanent molars were reviewed clinically and radiographically after caries excavation and direct pulp capping with MTA; 93% were successful at 24 months, with continued root development. In the second report, Bogen et al.[25] described a series of 53 teeth diagnosed at the outset with deep caries and reversible pulpitis but with no periapical involvement. Caries was completely eliminated with the help of a caries-detector dye and magnification (Fig. 24-23, *A* and *B*), often resulting in multiple, large pulp exposures. Hemostasis was secured by bathing the pulp with 5.25% to 6% NaOCl for 1 to 10 minutes (Fig. 24-23, *B* to *D*). One pulp that continued to bleed after this time was considered unsuitable for direct capping. After application of 1.5 to 3 mm of gray or white MTA (Fig. 24-23, *E*) and permanent bonded restorations at 5 to 10 days, the teeth were reviewed for 1 to 9 years (mean, 3.94 years). The recall rate was 92.5%, and 97.96% of the teeth were found to have favorable outcomes

on the basis of radiographic appearances, subjective symptoms, and cold testing (Fig. 24-23, *F*). Of the 15 teeth that were immature at the time of treatment, 100% went on to complete root formation.

At the time of writing, a conservative general consensus probably holds with partial or serial caries excavation, avoiding pulp exposure and attempting to create an environment that will up-regulate reactionary tertiary dentin responses.[22,228,280] However, evidence is growing that in correctly chosen cases with no indication of irreversible pulpitis or periapical change and when radical caries excavation is followed by confirmation of hemostasis, direct capping with calcium silicate cements, such as MTA, can achieve remarkable levels of success in teeth with incomplete apices.

Because the loss of vital pulp functions is so devastating in teeth with immature apices, it seems advisable to attempt conservative pulp-preserving procedures in deeply carious permanent teeth. If these procedures fail, apexification or regenerative techniques can always be considered.

PULPOTOMY

The pulpotomy procedure involves removing only part of the pulp, eliminating tissue that has inflammatory or degenerative changes and leaving intact the underlying healthy pulp tissue.[12] The healthy tissue is then covered with a wound dressing agent in an effort to promote healing at the amputation site and to promote the survival of the underlying pulp tissue. Traditionally, the term *pulpotomy* has implied removal of pulp tissue to the cervical line. However, the depth to which tissue is removed is determined by clinical judgment of how deeply the pulp is affected. Superficial amputation (partial pulpotomy) may allow better visualization of the working area but risks leaving damaged tissue that may go on to break down. In multirooted teeth, the procedure may be simplified by removing tissue to the orifices of the root canals (complete or pulp-chamber pulpotomy).

The Cvek Pulpotomy on Immature Permanent Teeth

Pulpotomy is an established technique for preserving vital pulp functions in immature teeth that have been subject to pulp-exposing trauma. A full account of the Cvek pulpotomy is provided in Chapter 20 (see Fig. 20-11). Briefly, studies have shown that inflammation is confined to the surface 2 to 3 mm of the pulp when it is traumatically exposed and left untreated for up to 168 hours.[47,108,109] In experimental animals, the results were the same whether the crowns were fractured or ground off.[47] Direct invasion of vital pulp tissue by bacteria did not occur, although the pulps were left exposed to saliva.

In a classic report, Cvek[45] described a pulpotomy technique in which only the superficial 2 to 3 mm of hyperplastic inflamed tissue was removed with a water-cooled, high-speed diamond bur[97] to place the wound in a healthy site. Hemostasis was then secured before capping with an appropriate material. If hemostasis could not be secured after several minutes of saline-moistened cotton pellet application, the preparation was checked carefully for residual superficial tags of bleeding tissue that had not been fully removed, or questions were asked about the condition of the underlying pulp. Persistent bleeding from an inflamed pulp usually indicates that the tissue should be resected at a deeper level to preserve a vital apical pulp stump (see the section on apexogenesis).

Hemostasis was obtained with saline, and a pulp cap of calcium hydroxide was overlaid with a sealing coronal restoration. Cvek reported success in an impressive 94% to 96% of cases (Fig. 24-24). More recent reports suggest that histologic tissue responses may be more favorable in response to calcium silicate cements, such as MTA, than to $Ca(OH)_2$.[133,191,193,215] Thus MTA is recommended as the pulp-capping agent of choice in cases that do not extend deeply into the roots, where subsequent retrieval may present a considerable challenge. Preference should be given to white MTA products in an effort to minimize the risk of unsightly tooth staining, although this possibility cannot be ruled out.[18]

The question, then, is whether such techniques can be applied to posterior teeth, especially those with symptomatic cariously affected pulps. The answer historically has been no, except as a short-term, pain-relieving exercise. Studies involving cavity preparations into teeth that left areas of impacted food, debris, and bacteria in contact with pulp tissue resulted in inflammation extending from 1 to 9 mm into the pulp, with abscess and pus formation.[47,108] The extent of inflammation in a cariously exposed pulp is difficult to judge. Pulpotomy may consequently be less predictable in preserving vital pulp functions after a carious pulp exposure compared to a traumatic pulp exposure.

Partial Pulpotomy on Asymptomatic Young Permanent Posterior Teeth

A technique called *partial pulpotomy for the management of vital carious pulp exposure on young permanent molars* has been reported by several researchers.[169,172,175,202] This approach has usually been reserved for teeth with little or no history of pain and in the absence of radiographic signs, percussion sensitivity, swelling, or mobility.

The procedure usually involves removal of 1 to 3 mm of pulp tissue suspected to be inflamed, beneath the exposure site, in order to reach underlying healthy tissue. After hemostasis, the exposure site traditionally has been covered with $Ca(OH)_2$ and the tooth sealed with ZOE and a permanent restoration. Mejàre and Cvek[175] followed 31 initially symptom-free teeth for a mean of 56 months (range, 24 to 140 months) and found a healing rate of 93.5%. Mass et al.[169] reported a 91.4% success rate in 35 cases followed for 12 to 48 months. Exposures exceeding 2 mm in diameter and those in which bleeding could not be controlled within 1 to 2 minutes were excluded from this study.

The use of MTA as the capping agent has met with success in the hands of the authors and others,[201,244] although long-term success has also been reported after the use of more traditional materials in properly selected cases.[170]

Pulpotomy on Symptomatic Young Permanent Teeth

Although some success has been reported,[175] vital pulp therapy in permanent teeth with a history of pain has generally been contraindicated. However, reports do support this pulp-preserving approach, even for symptomatic teeth (see Chapter 26 for more details).[244] In the study by Mejàre and Cvek,[175] of the six teeth with temporary pain, widened periodontal

FIG. 24-24 **Follow-up of a Cvek pulpotomy. A,** Pretreatment radiograph of a right maxillary central incisor after traumatic pulp exposure. **B,** Four months after Cvek pulpotomy and application of a calcium hydroxide dressing, formation of a dentin bridge can be seen. **C,** Three-year recall shows continued root formation. In this case, the dentin bridge has not thickened. There is no evidence of uncontrolled mineralization in the pulp space.

ligament space, and/or condensing osteitis that were managed by $Ca(OH)_2$ pulpotomy, 66.7% healed. A study by Calişkan[30] undertook a similar $Ca(OH)_2$ pulpotomy procedure on 26 permanent vital molars with carious pulp exposures and apical periodontitis. Observation between 16 and 72 months revealed that 24 (92.3%) were free of clinical symptoms, responded to sensibility testing, and showed evidence of hard tissue barrier formation, resolution of periapical involvement, and the absence of intraradicular pathosis radiographically.

Partial pulpotomy was also found to be successful in a randomized, controlled trial[220] that compared $Ca(OH)_2$ and MTA pulpotomies in the permanent molars (n = 64) of children. Mean follow-up was 34.8 months (range, 25.5 to 45.6 months), and success was comparably favorable in both the $Ca(OH)_2$ (91%) and MTA (93%) groups.

A full coronal pulpotomy may be more predictable in the symptomatic case in which the depth of pulp inflammation is difficult to predict. Follow-up of MTA pulpotomies in 15 children with immature molars revealed no clinical or radiographic failures at 12 months, although four pulps had undergone calcific metamorphosis.[61] In a 2006 clinical report, Witherspoon et al.[304] described a series of 23 irreversibly pulpitic anterior and posterior teeth in children and adolescents, treated by full coronal pulpotomy, hemostasis for 1 minute with 6% NaOCl, and wound dressing with MTA. Follow-up of 6 to 53 months (mean, 19.7 months) revealed that 79% had healed, 16% were healing, and only 5% had evidence of persistent disease. More research is needed, but the MTA pulpotomy seems to be gaining an evidence base as a reliable technique for preserving vital pulp functions in both asymptomatic and symptomatic teeth in children.

This body of evidence suggests that young teeth, with their rich vascular supply, are good candidates for conservative pulp-preserving treatments. Again, the stakes are high, and efforts to secure vital pulp functions are to be commended. Outcomes are probably more predictable in asymptomatic cases than symptomatic, and care should be taken preoperatively to distinguish between cases with symptoms of reversible and irreversible pulpitis. However, the correlation of clinical symptoms with histologic state is poor.[57]

Follow-Up After Pulp Capping and Pulpotomy

Patients undergoing pulp capping and pulpotomy procedures should be seen periodically for 2 to 4 years to determine

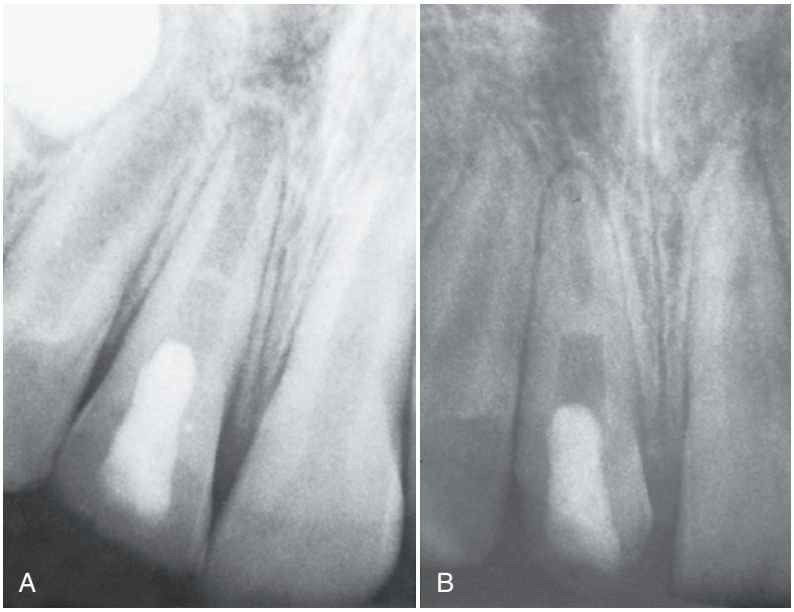

FIG. 24-25 Deep pulpotomy for apexogenesis. A, Immature maxillary central incisor 10 weeks after traumatic pulp exposure and a deep pulpotomy dressed with calcium hydroxide. Note the early formation of a dentin bridge. **B,** At three-year recall—the dentin bridge has thickened, and root formation is complete; the tooth remained asymptomatic and required no further treatment at that time. Note the absence of uncontrolled mineralization in the apical pulp space.

success. Although normal sensibility tests (e.g., electrical and thermal sensitivity tests) are reliable after pulp capping, they are not usually helpful in the pulpotomy-treated tooth. Because histologic success cannot be determined, clinical success is judged by the absence of any clinical or radiographic signs of pathosis and the presence of continued root development in teeth with incompletely formed roots.

Controversy exists as to whether the pulp should be reentered after the completion of root development in the pulpotomy-treated tooth. Langeland et al.[146] believe that pulp capping and pulpotomy procedures invariably lead to progressive calcification of the root canals. They advocated that, after successful root development, pulpectomy and root canal treatment should be performed before canals became obliterated, and difficult to manage endodontically if they did become infected. However, it has been the experience of the authors and others[48,84,109] that with good case selection, a gentle technique in removing infected tissue and dentin chips, and care in avoiding the compaction of pulp dressing into underlying pulp tissue, calcification of the pulp is an infrequent sequela of pulpotomy (see Fig. 24-24, *C*, and Fig. 24-25). The routine use of microscopy has also transformed the management of many cases that might in the past have been considered untreatable. The prophylactic root canal treatment of teeth after successful pulpotomy is therefore difficult to justify.

In a follow-up study of clinically successful pulpotomies,[45] researchers removed the pulps 1 to 5 years later for restorative reasons and found the tissue to be histologically normal.[48] They concluded that the changes observed do not present sufficient histologic evidence to support routine pulpectomy after pulpotomy in accidentally fractured teeth with pulp exposures. Thus, routine reentry to remove the pulp and place a root canal filling after completion of root development is contraindicated unless dictated by restorative considerations, such as the need for a retentive post. Nevertheless, calcific obliteration, internal resorption, and pulp necrosis are potential sequelae of pulp-capping and pulpotomy procedures, and the clinician should screen for these problems during recall appointments. Although unlikely, they are possible, and the patient should be clearly informed.

Formocresol Pulpotomy on Young Permanent Teeth

Because of the historical track record of formocresol pulpotomy in primary teeth, interest developed in this technique for the management of young permanent teeth. Reports have demonstrated the potential for continued apical development after formocresol pulpotomy in young permanent teeth,[73,184,240,294] although the high incidence of internal resorption[82,213] adds to broader concerns about the use of formocresol in pediatric endodontics.

In most circumstances, the formocresol pulpotomy has been performed as an emergency treatment, with reports showing that teeth may remain symptom free after 3 years.[282] However, alternatives to the formocresol pulpotomy are preferred, and renewed interest has been shown in the potential of pulpotomy with materials such as MTA as a short- and long-term treatment strategy for damaged pulps.[259]

APEXOGENESIS

Apexogenesis is a treatment designed to preserve vital pulp tissue in the apical part of a root canal so that formation of the root apex may be completed (Fig. 24-26).[107]

The clinical procedure is essentially a deep pulpotomy undertaken to preserve the formative capacity of the radicular pulp in immature teeth that have deep pulpal inflammation.

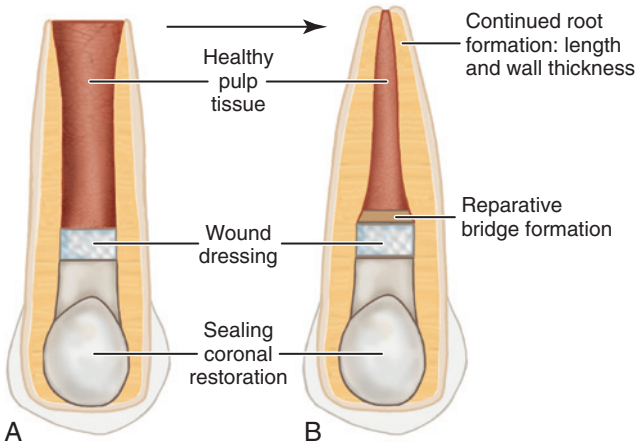

FIG. 24-26 Schematic representation of apexogenesis. *Apexogenesis* is a treatment designed to preserve at least the apical portion of pulp tissue in a healthy condition so that root formation can be completed. **A,** After a deep pulpotomy and hemostasis, the radicular pulp is dressed and a sealing coronal restoration is applied. **B,** Success is evidenced by continued root development (length and wall thickness) and formation of a calcific barrier in response to the wound dressing.

Examples include carious exposures and some trauma cases in which treatment of the exposed pulp is delayed and it becomes necessary to extend farther into the canal to reach healthy tissue.

Deep resection of pulp tissue is usually undertaken in single-rooted anterior teeth with a small endodontic spoon excavator or round, abrasive diamond bur (see Fig. 24-25). In posterior teeth, the use of endodontic files or reamers may be necessary if tissue is to be amputated within the canals. Extension of the amputation site into the root canals is undertaken only when there is little confidence that more superficial pulp capping or pulpotomy will be successful and when there is a desperate desire to preserve pulp functions in teeth with wide-open, blunderbuss apices (Fig. 24-27).

Bleeding is usually controlled with saline-soaked cotton pellets or NaOCl. If hemostasis cannot be secured by conventional means, this may indicate that even the deep pulp is inflamed and treatment will be compromised. Despite the risks, it is legitimate to attempt pulp-preserving treatment after controlling the hemorrhage with hemostatic chemicals such as aluminum chloride or ferric sulfate.

The pulp wound is then covered with a dressing material before the crown is securely restored. It is challenging to determine the status of pulp tissue deep in the root canal, and its capacity for survival is difficult to predict. Radiographic and clinical follow-up is mandatory, and if there is no evidence of

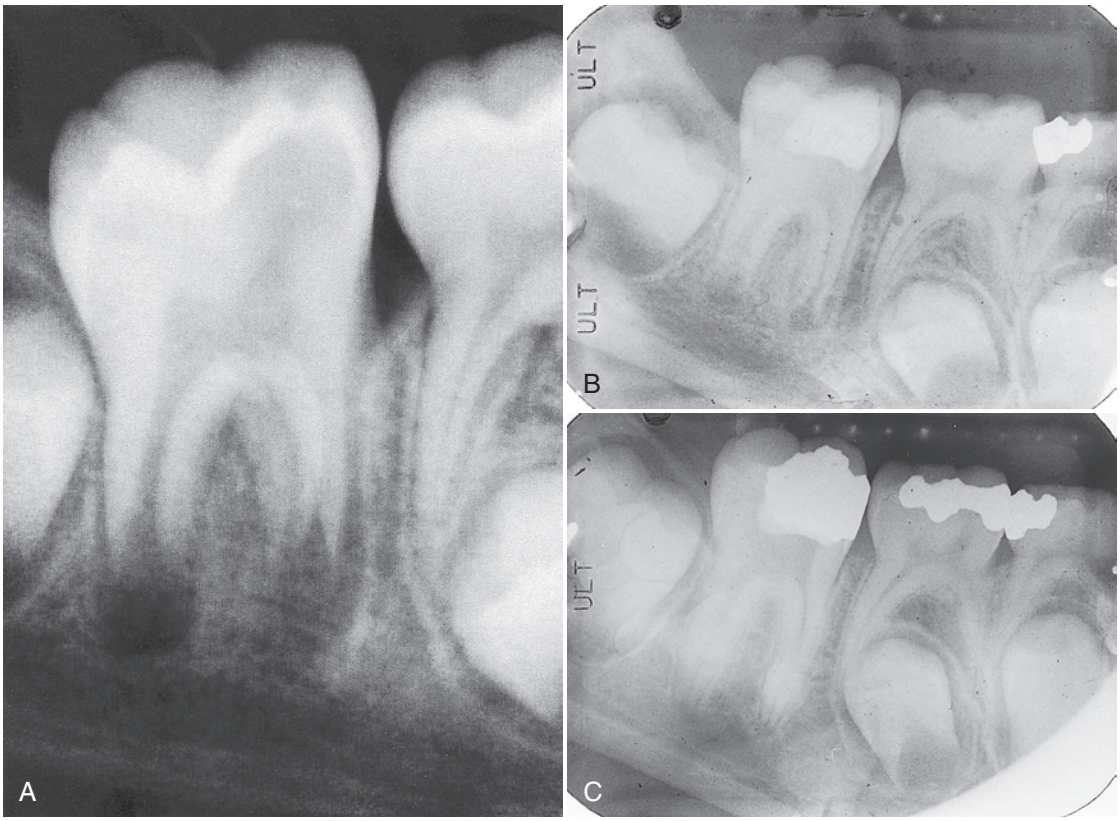

FIG. 24-27 Apexogenesis after deep calcium hydroxide pulpotomy on a mandibular permanent molar. **A,** Pretreatment radiograph showing extensive caries, incomplete root development, and possible periapical pathosis. The tooth was asymptomatic. **B,** One year after deep pulpotomy (which extended several millimeters into the canals), hemostasis, and restoration. Root formation is progressing, and the periapical tissues appear healthy. **C,** Two years later, root formation is complete.

continued root formation and calcific barrier formation in response to the dressing, apexification or a regenerative technique may be considered.

Because of the depth at which this procedure is performed, preference has usually been given to the use of $Ca(OH)_2$ rather than MTA because, in the event of failure, this may facilitate reentry to the root canal to perform apexification or pulp regeneration. Also, if apexogenesis is successful and root-end formation is complete, the tooth could be reentered if desired for conventional root canal treatment. It is unclear whether these concerns hold true in an era of microscopy and contemporary microinstrumentation.

Calcium hydroxide powder has usually been preferred over hard-setting products, carried into the canal with an amalgam carrier or gun system used for MTA application. Small increments of $Ca(OH)_2$ powder are carefully teased against the entire surface of the pulp stump with a rounded-end, plastic instrument, ideally with microscope control. Care must be taken not to pack the $Ca(OH)_2$ into the pulp tissue because this causes greater inflammation and increases the chances of failure. Even if pulpotomy is successful, there is an increased risk that the remaining pulp tissue will mineralize around impacted particles of $Ca(OH)_2$.[287]

Commercial nonsetting calcium hydroxide pastes may also be spun or injected to flow lightly over the pulp stump. Care must be taken to avoid trapping air bubbles when such products are applied, and it is recommended that they be overlaid with a hard-setting calcium hydroxide or glass ionomer cement[44] before meticulous cleaning of the cavity walls and restoration with a bonded composite resin restoration. Although little has been published on this topic, MTA probably represents a viable alternative to calcium hydroxide, provided the challenges in its retrieval are recognized.

APEXIFICATION

Apexification, or root-end closure, is the process in which a nonvital, immature, permanent tooth that has lost the capacity for further root development is induced to form a calcified barrier at the root terminus (Fig. 24-28). This barrier forms a matrix against which root canal filling or restorative material can be compacted with length control.

Unlike the pulp capping, pulpotomy, and apexogenesis procedures described previously, apexification at best results in closure of the root end and cannot be expected to cause further root development in terms of length or wall thickness. Apexification thus is regarded as a treatment of last resort in immature teeth that have lost pulp vitality. The growing body of recent evidence on pulp regeneration, even in infected, nonvital immature teeth, may also relegate this approach to the history archives in the years to come.[120]

For now, root-end closure techniques, both those involving the generation of a biologic calcific barrier and those involving artificial root-end closure with a material such as MTA, still have a place in practice and should be considered.

Before the introduction of conservative apical closure techniques, the usual approach to this problem was surgical. Although this could be successful, psychological and patient-management issues in patients who were usually young children offered many contraindications. Local dental considerations presented a further disincentive, including a reduction in the crown-to-root ratio if root-end reduction was required,

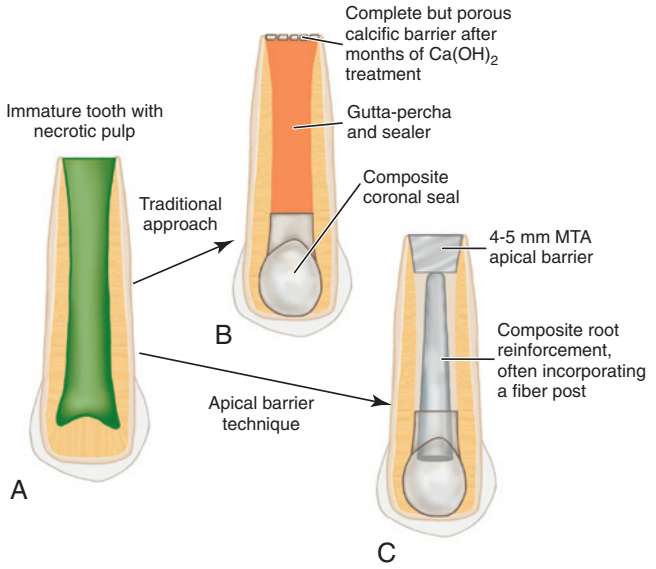

FIG. 24-28 Schematic representation of apexification. *Apexification* is a treatment performed to develop a hard barrier at an open root end. **A,** Immature permanent tooth with a nonvital pulp. **B,** Traditional approach: a "calcified barrier" forms at the root end after repeated dressing over many months with calcium hydroxide. The canal is subsequently filled with gutta-percha and sealer before coronal restoration. **C,** Artificial apical barrier technique: a 4- to 5-mm plug of mineral trioxide aggregate is placed at the root end. The canal space is subsequently restored with dual-curing composite resin, often accompanied by a fiber post to provide mechanical support.

and the intrinsic difficulties of sealing a fragile, incompletely formed apex with traditional materials. A more predictable and less traumatic approach was desirable.

Until recently, the most widely accepted technique has involved cleaning and filling the canal with a temporary paste, most commonly $Ca(OH)_2$, which was replaced at intervals over several months to stimulate the formation of an apical calcified barrier (see Fig. 24-28, *A* and *B,* and Fig. 24-29).[266]

Diagnosis of pulpal necrosis in a tooth with an incompletely formed apex is often difficult; the electronic pulp tester rarely provides meaningful data, and thermal tests often give equivocal or false results in young children and traumatized teeth. The presence of acute or chronic pain, percussion sensitivity, mobility, coronal discoloration, or a discharging sinus may be helpful guides, whereas radiographic diagnosis can be complicated by the normal radiolucencies appearing at the apices of developing teeth. Comparison of root formation with contralateral teeth should always be considered.

If any doubt persists, it is usually wise to adopt a watch and wait approach before entering the immature tooth endodontically. Only when convincing evidence indicates pulp breakdown should the tooth be entered, and in the interim, exposed dentin should be covered to reduce the risks of microbial entry to a potentially compromised pulp.

The extent of apical closure may be difficult to ascertain with plain radiographs. Three-dimensional imaging offers new opportunities to understand the complexity of root ends, which may have different conformations in mesiodistal and faciolingual dimensions (see Fig. 24-9). In practical terms, the precise limit of apical opening that can be filled by conventional means is unclear.

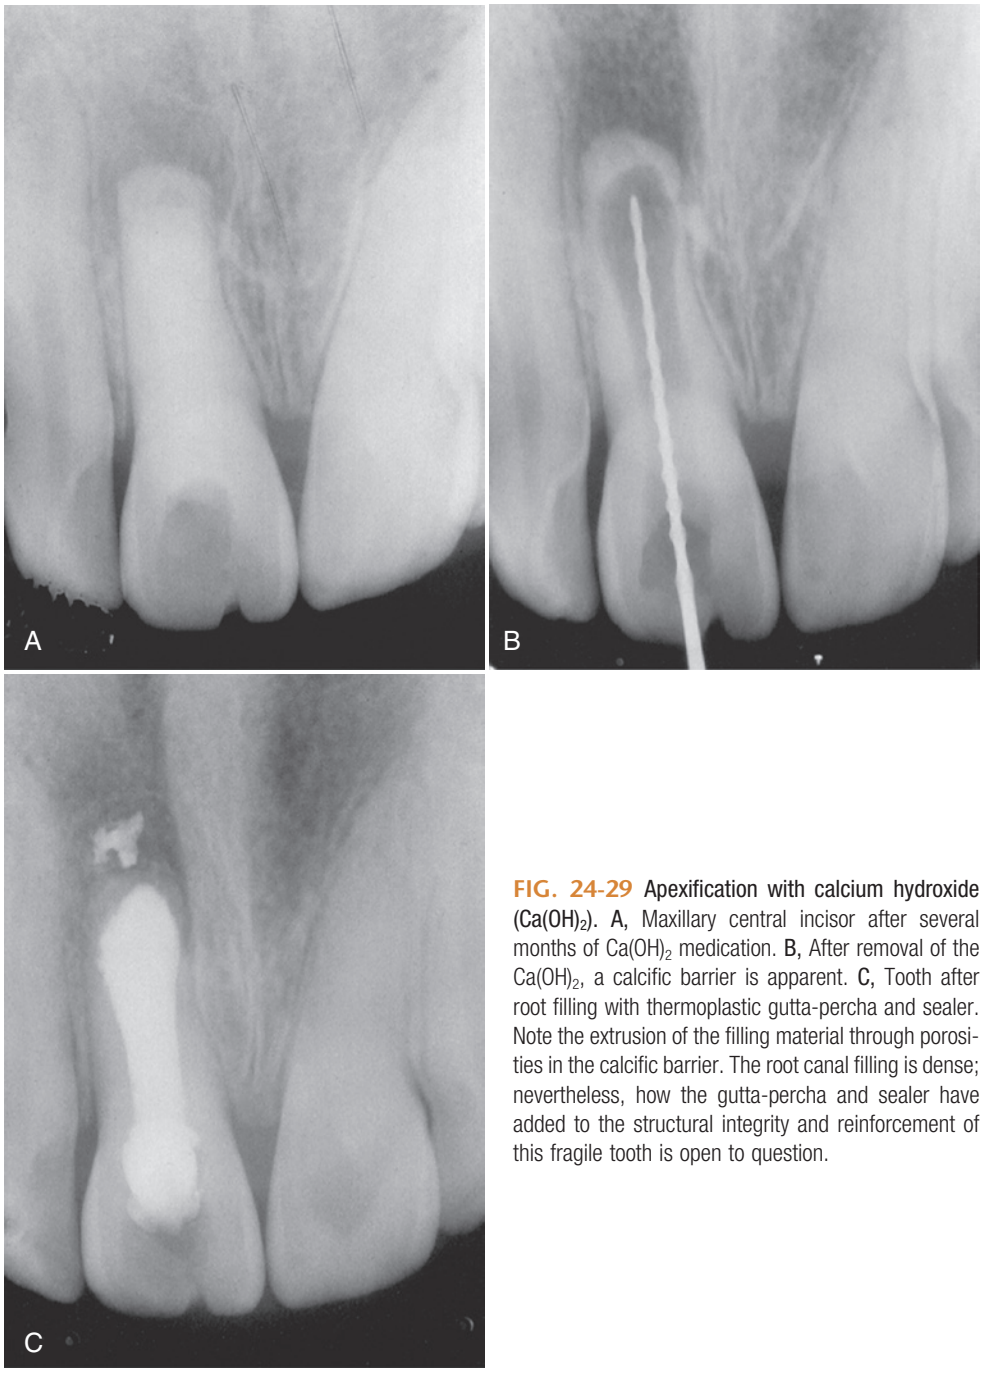

FIG. 24-29 **Apexification with calcium hydroxide ($Ca(OH)_2$).** **A,** Maxillary central incisor after several months of $Ca(OH)_2$ medication. **B,** After removal of the $Ca(OH)_2$, a calcific barrier is apparent. **C,** Tooth after root filling with thermoplastic gutta-percha and sealer. Note the extrusion of the filling material through porosities in the calcific barrier. The root canal filling is dense; nevertheless, how the gutta-percha and sealer have added to the structural integrity and reinforcement of this fragile tooth is open to question.

Many materials have been reported to stimulate apexification successfully. The use of nonsetting $Ca(OH)_2$ was first reported by Kaiser in 1964.[134] The technique was popularized by the work of Frank.[77] Since that time, $Ca(OH)_2$ alone or in combination with other drugs was the most widely accepted material for promoting apexification, until the development of MTA and the potential for rapid, artificial barrier formation.

For historical perspective, $Ca(OH)_2$ powder has been mixed with camphorated mono-chlorophenol (CMCP), metacresyl acetate, Cresanol (i.e., a mixture of CMCP and metacresyl acetate), physiologic saline, Ringer's solution, distilled water, and local anesthetic solution. All have been reported to stimulate apexification. Most reports in the U.S. literature[31,103,267] have advocated mixing $Ca(OH)_2$ with CMCP or Cresanol, whereas reports from other parts of the world[44,174] showed the same success using distilled water or physiologic saline as the vehicle. The addition of 1:8 barium sulfate to $Ca(OH)_2$ enhanced radiopacity with no apparent adverse effects on apexification.[298] Comparable outcomes have been noted in humans and animals with tricalcium phosphate,[41,140,233] collagen calcium phosphate,[198] osteogenic protein-1,[252] bone growth factors,[281] and a number of other materials.[298]

The most important factors in achieving apexification seem to be thorough debridement of the root canal to remove all necrotic pulp tissue and microbial infection, and sealing of the tooth to prevent the ingress of bacteria and substrate.[64]

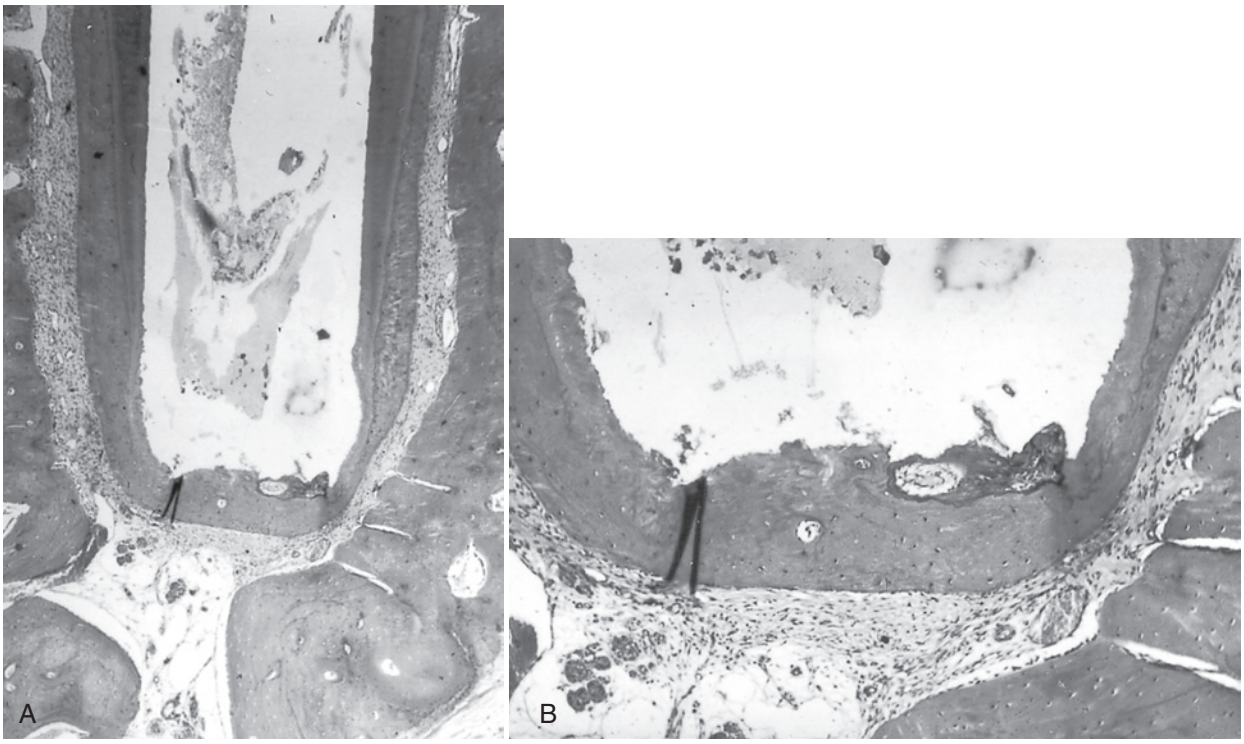

FIG. 24-30 Histologic section of a dog's tooth after calcium hydroxide apexification. A, Cementum-like mineralized tissue is closing the wide-open root end. Debris is apparent in the canal because of inadequate debridement before filling. B, Higher magnification shows cellular detail; the periodontal ligament is free of inflammation. Root canal filling material was lost in the histologic preparation. Note the presence of tissue communication through the apical barrier (stain, H&E).

Apexification does not occur when the apex of the tooth penetrates the cortical plate. To be successful, the apex must be completely within the confines of the medullary space.

Apexification Technique

In the apexification technique, the canal is cleaned and disinfected in line with the principles defined in Chapter 6. The use of a rubber dam is mandatory, and resourcefulness may be needed to isolate partially erupted or damaged teeth in children.

The access opening may require some extension to fully unroof pulp horns, but care should be taken not to heavily instrument the already thin and relatively fragile walls of the root.

The length of the canal is established by radiographs because the absence of an apical constriction may make electronic methods unreliable.[122,138] A constant drying point, determined with paper points, may provide helpful additional information on length.[14] Irrigation is central to the debridement of immature teeth, and with proper precautions, operators should not hesitate to benefit from the antimicrobial and tissue-solvent properties of NaOCl. Sonic, ultrasonic, and other vibratory devices capable of activating the irrigant within the canal may be advantageous,[291] and benefit may also come from the use of small brushes of the sort that are designed for interproximal tooth brushing or the application of etchants to post channels. After thorough debridement, the canal is dried and medicated with a fluid $Ca(OH)_2$ paste, carried into the canal with a Lentulo spiral or injected from a proprietary paste syringe. There is little evidence to commend any commercial $Ca(OH)_2$ paste over another in this application. The tooth is then sealed coronally, and the patient is recalled at 3-month intervals so that the clinician can wash out the $Ca(OH)_2$ paste and inspect clinically (with the aid of gutta-percha or paper points or by direct visual inspection through the microscope) and radiographically for the development of a calcified barrier (see Fig. 24-29, *B*). Treatment typically extends over 9 to 24 months, with obvious demands on patient and parent compliance. The reduced mechanical properties of root dentin and consequential risks of cervical root fracture after exposure to $Ca(OH)_2$ for 5 weeks or longer are also recognized.[46,307]

Histologic studies consistently report the absence of Hertwig's epithelial root sheath, and normal root formation should never be anticipated. Instead, differentiation of adjacent connective tissue cells into specialized cells appears to occur, and calcified tissue is deposited adjacent to the filling material. The calcified material that forms over the apical foramen was histologically identified as an osteoid (i.e., bonelike) or cementoid (i.e., cementum-like) material (Fig. 24-30).[31,103,266] In a primate study, bridging of the root end with osteodentin was reported after vital pulpectomy and canal medication with $Ca(OH)_2$/parachlorophenol paste. The material appeared to be distinct from but continuous with the cementum, dentin, and predentin at the root apex.[58] The closure of the apex may be partial or complete, but minute communications with the periapical tissues are consistently seen (see Fig. 24-28, *B*; Fig. 24-29, *C*; and Fig. 24-30). For this reason, apexification stimulated by

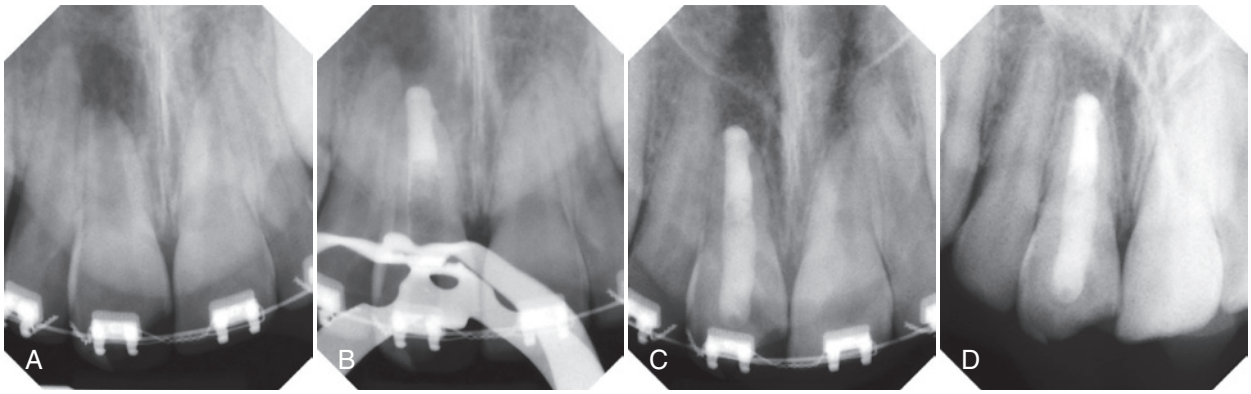

FIG. 24-31 **Mineral trioxide aggregate (MTA) apical barrier apexification procedure and restoration with bonded composite. A,** Maxillary right central incisor with a large periapical lesion. The patient is undergoing orthodontic treatment. **B,** After placement of MTA in the apical 4 mm of the canal. **C,** Six months later; the entire canal coronal to the MTA apical barrier is filled with bonded composite resin. Note that calcification has occurred periapically as orthodontic treatment has continued. **D,** Thirty months after treatment; the periapical lesion has healed.

pastes must always be followed by obturation of the canal with a permanent root canal filling, traditionally of thermoplastic gutta-percha and sealer, although MTA would be a good contemporary alternative.

Although the apexification technique with $Ca(OH)_2$ has enjoyed considerable tooth-preserving success, the many disadvantages of this protracted treatment have justified a search for alternatives, such as artificial barrier techniques, with their potential for more rapid treatment, and regeneration techniques, with their potential for continued tooth development.

Artificial Apical Barrier Techniques

(see Fig. 24-28, *C*)

Coviello and Brilliant[41] reported the use of tricalcium phosphate as an apical barrier in 1979. The material was packed into the apical 2 mm of the canal, against which gutta-percha was compacted. The treatment was completed in one appointment, and radiographic assessment confirmed successful apexification comparable to that achieved with $Ca(OH)_2$. Calcium hydroxide powder has also been used successfully as an apical barrier against which to pack gutta-percha.[248]

The use of MTA as an apical barrier was first reported in 1996,[281] and subsequent clinical investigations in animals[252] and humans[217,242,260] have established this as the standard, with biologic outcomes in terms of periapical healing and root-end closure at least comparable to those treated with $Ca(OH)_2$.[217] Simon et al.[260] treated 57 teeth in patients with a mean age of 18 years (standard deviation, 12 years). Of the 43 teeth with at least 12-month follow-up, healing had occurred in 81%. More recently, a series of 17 nonvital immature incisors in children with a mean age of 11.7 years was followed up for a mean of 12.5 months. This study reported 94.1% clinical success, with radiographic healing in 76.5% and a further 17.6% uncertain.[242] One study of 38 cases also suggested that the presence of a preoperative periapical lesion had no influence on the outcome.[195] This approach to the problem of root-end closure allows treatment to be completed on a short time scale, with advantages including improved patient compliance, reduced cost of clinical time, and the ability to securely restore the tooth at an earlier stage.[49] The risk of tooth fracture due to long-term $Ca(OH)_2$ medication is also eliminated.[307]

MTA Barrier Technique (see Fig. 24-28; also Figs. 24-31 and 24-32)

In the apexification technique, the canal is cleaned and disinfected as described for $Ca(OH)_2$ apexification. Lee et al.[151] have suggested that the tissue pH may affect the hydration reaction and final physical properties of MTA, and it has become standard practice to medicate canals for at least 1 week with $Ca(OH)_2$ to raise the acidic pH of the inflamed periapical tissues before permanent sealing.

When the tooth is free of signs and symptoms of infection, it is reisolated with a rubber dam and the $Ca(OH)_2$ is washed free, often with the help of ultrasonics and small brushes. After it is dried with large, sometimes inverted, premeasured paper points, the canal is filled incrementally with MTA, which is delivered to the canal with a dedicated MTA carrier or deposited in small pellets from an amalgam gun. The material can then be worked up the canal with premeasured pluggers, or inverted paper-points, set some 1 to 3 mm short of the root end, often with the help of sonic or ultrasonic energy to settle the material.[308] Apical matrices have not generally been considered necessary to limit the flow of MTA, although impressive-looking results may be obtained by packing the apical region with calcium sulfate before MTA application.[283] An apical plug 4- to 5-mm thick is usually considered optimal (see Fig. 24-31, *B*).[289] The adequacy of the apical plug is verified radiographically.

All excess MTA is removed from the canal walls by scrubbing with large, moistened paper points or brushes. Meticulous cleanup is important to allow optimal bonding of the subsequent composite resin restoration, which will extend deeply into the canal and offer internal reinforcement of the fragile root.

A very wet cotton pellet is placed in the canal to provide moisture for the setting reaction. The pellet should not be in contact with the MTA because fibers of the cotton can become impregnated into the material. Excess water in the access

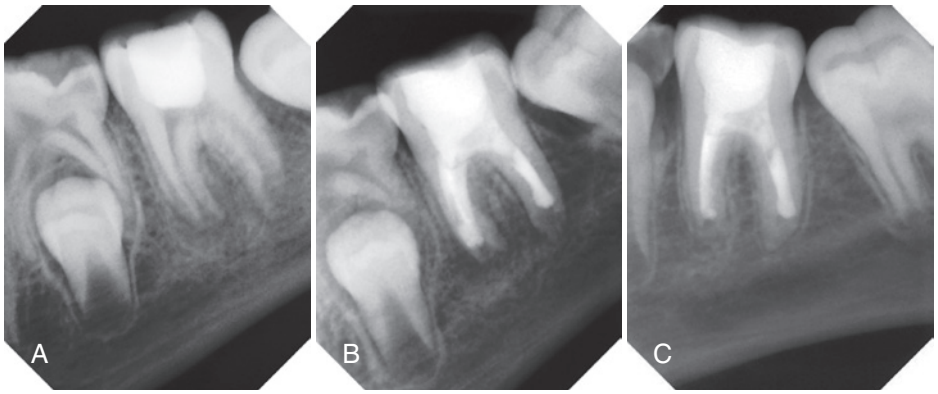

FIG. 24-32 Apexification with mineral trioxide aggregate (MTA) barriers in a mandibular permanent molar. **A,** Periapical lesion reveals open apices in this pulpless molar. **B,** Apical plugs of MTA and the remainder of the pulp space are restored with bonded composite resin. **C,** Two years later; closure of the root ends with cementum.

preparation is dried with cotton pellets, and the opening is sealed with a provisional restorative material, such as Cavit. At a subsequent appointment, the tooth is reisolated and the hard set of the MTA verified with an endodontic file or probe. If for some reason the MTA has not hardened, the canal can be recleansed and the procedure repeated before final bonded restoration.

Restoration After Apexification

Immature teeth, particularly those that are pulpless and have undergone apexification, are at high risk of fracture. It has been reported that, within 3 years of long-term $Ca(OH)_2$ medication and root filling with gutta-percha, 28% to 77% of immature teeth suffered a cervical root fracture.[46] The degree of dental development appeared to be a key variable. Clinically, it is the impression of the authors that rapid MTA plug techniques, in combination with the internal placement of bonded composite resin, appear to have virtually eliminated cervical root fractures. Many of the studies are laboratory based, using simulated rather than real immature teeth, but the use of contemporary dentinal bonding techniques has been shown to strengthen endodontically treated teeth to levels close to those of intact teeth.[100,110,136] A 2004 study[149] demonstrated significantly greater resistance to root fracture after placement of a 4-mm thick apical plug of MTA followed by an intracanal composite resin, compared with MTA followed by gutta-percha and sealer. Root reinforcement has also been reported to be improved by the cementation of a metal post within the channel created by removal of a light-transmitting composite curing post.[34] The potential of fiber-reinforced posts would also appear great,[26,251] though little clinical evidence has yet been published on the clinical treatment of immature teeth.

Alternative materials that have been suggested to bond and reinforce fragile roots include resin-modified glass ionomer cements[95] and, most recently, Resilon.[277] However, the evidence on Resilon remains contentious,[303] and the ideal of predictable bonding and tooth reinforcement throughout the length of the root canal system has not yet been achieved.[276]

Bonding of dual- or light-curing composite resin directly over the MTA plug, with no interposing layer of gutta-percha, has become an established clinical method (see Fig. 24-28, *C*, and Fig. 24-31, *C*). The clinician should take care to etch and bond the canal according to the manufacturer's instructions, with proper washout of etchant and avoiding gross pooling of unfilled resin. Complete resin infiltration of dentin cannot be guaranteed in the depths of a root canal, and the potential exists that host-derived metalloproteinases liberated by acid etching may degrade resin-dentin bonds with time. Flushing the preparation after etching with a synthetic protease inhibitor, such as 2% chlorhexidine, may help counter some of these adverse events.[33]

Clear light-transmitting posts (e.g., Luminex System, Dentatus USA, New York) have been developed to ensure complete bonding of deep increments of light-activated composite. This may be less of an issue with dual-curing materials.

In the Luminex technique, the clinician places a light-curing composite resin in the canal, building up 2-mm increments with care to avoid trapping air bubbles. The Luminex post is placed to the depth of the preparation, and the composite is cured by transmitting light through the post. After curing, the plastic post is trimmed to the cervical line, and the incisal opening is restored.

If a core is needed for crown placement, a Luminex post without serrations is used for curing the composite. Because the composite does not bond to the smooth post, it can be gently removed and a corresponding metal Dentatus post cemented into the space with a resin cement. A composite buildup for crown retention may then be completed.

A variety of commercial quartz and glass fiber post systems are also available for use in such applications, ensuring the delivery of light deep into the canal system and offering the potential for internal reinforcement (see Fig. 24-28, *C*).[245] The heads of fiber posts should always be covered with composite resin to prevent them from absorbing oral fluids and delaminating.

NEW HORIZONS FOR PULP REGENERATION

Until recently, few treatment options were available for the nonvital, permanent immature tooth. On confirming pulp necrosis, efforts could be made to preserve the tooth by apexification, or it could be extracted within a broader orthodontic treatment plan. This view has recently been challenged by a

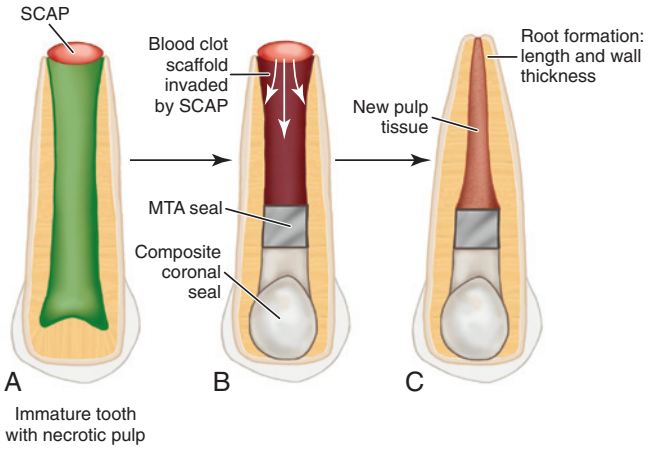

FIG. 24-33 Schematic representation of pulp regeneration. **A,** Immature, nonvital permanent tooth, showing the location of the apical papilla with its rich collection of stem cells. **B,** After the canal has been medicated, classically with a triantibiotic paste, it is overinstrumented to encourage bleeding up to the cervical level. A subsequent blood clot is overlaid with MTA and a sealing restoration, forming a scaffold for invasion by stem cells from the apical papilla (i.e., SCAP cells). **C,** Pulp regeneration is expected to allow continued root formation in a previously pulpless tooth.

number of ground-breaking reports in which nonvital immature teeth with clear evidence of pulp breakdown and periapical suppuration were encouraged to resume root formation (length and wall thickness), possibly by the regeneration of pulp tissue (see also Chapter 10).[15,37,128,132,279] Success is believed to depend on the activity of a newly identified population of stem cells, the so-called stem cells from apical papilla (SCAP) cells (Fig. 24-33, *A*), a hidden treasure with enormous potential for tissue regeneration and bioroot engineering.[121]

The potential of bioengineering is huge, and work continues to optimize scaffolds that may encourage revascularization of the pulp space and to explore the options of seeding cell populations into the properly sterilized pulp spaces of immature teeth.[182] Our call for action has never been louder as we seek effective, biologically based treatments for our pediatric patients.

ACKNOWLEDGMENT

The authors of this chapter acknowledge with gratitude the legacy of former principal authors Joe H. Camp and Anna B. Fuks, whose meticulous and steadfast work has authoritatively informed clinicians and scientists over many decades, and whose wisdom lays the foundations for this edition.

CHAPTER 25

Endodontic and Periodontal Interrelationships

DAVID G. KERNS | GERALD N. GLICKMAN

CHAPTER OUTLINE

Intercommunication between Pulpal and Periodontal Tissue
Influence of Pulpal Pathologic Condition on the Periodontium
Influence of Periodontal Inflammation on the Pulp
Theoretic Pathways of Osseous Lesion Formation
Primary Endodontic Lesions
Primary Endodontic Lesions with Secondary Periodontal Involvement
Primary Periodontal Lesions
Primary Periodontal Lesions with Secondary Endodontic Involvement
True Combined Lesions
Concomitant Pulpal and Periodontal Lesions
Differential Diagnosis
Lateral Periodontal Cysts
Treatment Alternatives
Forced Eruption or Extrusion
Summary

The interrelationships between pulpal and periodontal disease primarily occur by way of the intimate anatomic and vascular connections between the pulp and the periodontium; these interrelationships have been traditionally demonstrated using radiographic, histologic, and clinical criteria. Pulpal and periodontal problems are responsible for more than 50% of tooth loss.[16] Diagnosis is often challenging because these diseases have been primarily studied as separate entities, and each primary disease may mimic clinical characteristics of the other disease. Some studies suggest that these two diseases may have etiologic influences on the progression of the other disorder. Pulp tissue succumbs to degeneration by way of a multitude of insults, such as caries, restorative procedures, chemical and thermal insults, trauma, and periodontal disease. When products from pulp degeneration reach the supporting periodontium, rapid inflammatory responses can ensue that are characterized by bone loss, tooth mobility, and sometimes sinus tract formation. If this occurs in the apical region, a periradicular lesion forms. If this occurs with crestal extension of the inflammation, a retrograde periodontitis or reverse pocket is formed. However, the lesion formed has little anatomic similarity to a periodontally induced defect.

Periodontal disease, in contrast, is a slowly progressing disease that may have a gradually atrophic effect on the dental pulp. A periodontal lesion is used to denote an inflammatory process in the periodontal tissues resulting from dental plaque accumulation on the external tooth surfaces. Research has shown that periodontitis is characterized by the presence of localized inflammation or tissue infarction, a decrease in cells, resorption, fibrosis, and coagulation necrosis.* Dystrophic calcification may cause some degeneration in the pulp and further influence periodontal disease. In addition, periodontal treatments, such as deep root planing or curettage, use of localized medicaments, and gingival injury or wounding, may accelerate further pulpal inflammation and provoke the interrelated disease process.[72,78,79]

In recent years, periodontal disease has been shown to be related to (and possibly even the cause of) pulpal disease, and pulpal disease may cause periodontal lesions that behave differently from chronic destructive periodontitis. The effects of periodontal disease on the pulp and the potential for healing of certain periodontal lesions after endodontic therapy have been documented extensively.† This chapter discusses the intercommunication between pulpal and periodontal tissues; the effects of pulpal disease on the periodontium; periodontal disease and its effects on the pulp; and the classification, differential diagnosis, and management and prognosis of endodontic and periodontal problems.

INTERCOMMUNICATION BETWEEN PULPAL AND PERIODONTAL TISSUE

Several possible channels between the pulp and periodontium that lead to the interaction of the disease process in both

TABLE 25-1
Incidence of Furcation Canals

Investigators	Techniques	Incidence
Rubach and Mitchell (1965)[67]	Sectioned teeth	45%
Lowman et al. (1973)[54]	Dissecting microscope	Maxillary molars: 59% Mandibular molars: 55%
Burch and Hulen (1974)[13]	Radiopaque dye	Accessory furcal canals: 76%
Vertucci and Williams (1974)[83]	Hematoxylin dye	46%
Kirkham (1975)[43]	Radiopaque dye	23%
Gutmann (1978)[33]	Safranin dye	Maxillary molars: 28.4% Mandibular molars: 27.4%

tissues have been suggested. These include neural (i.e., reflex) pathways, lateral canals, dentinal tubules, palatogingival grooves, periodontal ligament, alveolar bone, apical foramina, and common vasculolymphatic drainage pathways. The most interconnected and evidenced relationship between the two tissues is by way of the vascular system, as illustrated anatomically by the presence of the apical foramen, lateral (i.e., accessory) canals, and dentinal tubules.* These communications, when they exist, may serve as paths for inflammatory reciprocity.†

The apical foramen is the most direct route of communication to the periodontium, but by no means is it the only location where pulpal and periodontal tissues communicate with each other. Lateral and accessory canals, mainly in the apical area and in the furcation of molars, also connect the dental pulp with the periodontal ligament. Table 25-1 lists the incidence of furcation canals. These have been suggested as a direct pathway between pulp and periodontium and typically contain connective tissue and vessels that connect the circulatory system of the pulp with that of the periodontium. Research has demonstrated that inflammation in the interradicular periodontal tissues may develop after induction of pulpal inflammation.[71,72] Serial sectioning of 74 teeth has revealed that 45% of accessory canals are present primarily in the apical region.[67] More significantly, lateral accessory canals in eight teeth were located more coronally on the roots. Among them, connection of the accessory canals with periodontal pockets was microscopically demonstrable in five of the specimens. Gutmann[33] introduced safranin dye into 102 molar teeth that were placed in a vacuum chamber and found that 28% of the teeth had furcation canals, although only 10% of the total group showed canals on the lateral root surface.

In addition to the apical foramen and lateral accessory canals, dentinal tubules have been suggested as another common pathway between the periodontium and pulpal tissue. Dentinal tubules contain cytoplasmic extensions or odontoblastic processes that extend from the odontoblasts at the pulpodentin interface to the dentinoenamel junction (DEJ) or the cementodentinal junction (CDJ). It has been reported that the pulp chamber can communicate with the external root surface by way of dentinal tubules, especially when the cementum is denuded.[33,86]

Palatogingival grooves are developmental anomalies of the maxillary incisor teeth; lateral incisors are more often affected than central incisors (4.4% versus 0.28%, respectively).[87] These grooves usually begin in the central fossa, cross the cingulum, and extend apically for varying distances. Generally, the incidence of palatogingival grooves ranges from 1.9% to 8.5%.[26,87] In their study, Everett and Kramer[26] reported that 0.5% of the teeth examined had a palatogingival groove extension to the root apex, thus contributing to an endodontic pathologic condition. Bilateral buccal radicular grooves have also been reported on maxillary incisors.[41]

Perforation of the root creates a communication between the root canal system and the periodontal ligament. This may occur as a result of overinstrumentation during endodontic procedures, internal or external root resorption, or caries invading through the floor of the pulp chamber. The prognosis for teeth with root perforation is usually determined by the location of the perforation, the time left unsealed, the ability to seal the perforation, the chance of building new attachments, and the accessibility of the remaining root canals. Teeth that have perforations in the middle or apical third of the root have the greatest chance of healing. The closer the perforation is to the gingival sulcus, particularly into the coronal third of the root or the furcation region, the greater the likelihood of apical migration of the gingival epithelium in initiation of a periodontal lesion.[4]

A vertical root fracture can produce a "halo" effect around the tooth radiographically (see also Chapter 2).[65] Deep periodontal pocketing and localized destruction of alveolar bone are often related to longstanding root fractures. The fractured root can mimic a radiographic profile of occlusal trauma, with localized loss of lamina dura, altered trabecular pattern, and a widened periodontal ligament. The fracture site provides a portal of entry for irritants from the root canal system to the surrounding periodontal ligament. Vertical root fractures have contributed to the progression of periodontal destruction in the presence of apparently successful endodontic tooth therapy and overall periodontal site stability.[66]

INFLUENCE OF PULPAL PATHOLOGIC CONDITION ON THE PERIODONTIUM

Pulpal pathosis as a cause of periodontal disease has received much attention during the past decade. Pulpal degeneration results in necrotic debris, bacterial by-products, and other toxic irritants that can move toward the apical foramen, causing periodontal tissue destruction apically and potentially migrating toward the gingival margin. Investigators termed this *retrograde periodontitis* to differentiate the process from *marginal periodontitis,* in which the disease proceeds physically from the gingival margin toward the root apex. When pulpal disease progresses beyond the confines of the tooth, inflammation extends and affects the adjacent periodontal attachment apparatus.[75] This inflammatory process often results in dysfunction of the periodontal ligament and resorption of alveolar bone, cementum, and even dentin.

*References 7, 18, 45, 54, 69, and 79.
†References 13, 33, 45, 47, 54, and 67.

The endodontic infection has been regarded as a local modifying risk factor for periodontitis progression if left untreated.[23] It is believed that an unresolved periapical infection could sustain endodontic pathogen growth, and infectious products would egress into the periodontium by way of the apex and lateral or accessory canals, as well as encourage osteoclastic activity. These may aggravate periodontal pocket formation and bone loss and impair wound healing to accelerate further periodontal disease development and progression. In addition, the high concentrations of the medicaments used for root canal therapy (e.g., calcium hydroxide, corticosteroids, and antibiotics) can irritate the periodontal attachment apparatus.[10,11] The nature and extent of periodontal destruction depend on several factors, including the virulence of the irritating stimuli present in the root canal system (e.g., microbiota, medications, foreign body reactions); the duration of the disease; and host defense mechanisms.[16] The rare development of endodontic-periodontal lesions argues that periradicular pathoses in general have little effect on localized inflammatory bone resorption, given that few combined lesions are seen in cases of apical periodontitis.

The ability of the periodontium to regenerate lost attachment apparatus on pulpless teeth has been questioned, especially if these teeth contain a root canal filling and have been denuded of cementum. One investigator suggested that endodontically treated teeth may not respond as well as untreated teeth to periodontal procedures. He found 60% osseous regeneration of periodontal defects in teeth not treated endodontically, compared with 33% defect fill in endodontically treated teeth.[68] However, in a monkey study, others reported that all tissue of the periodontium had the potential for regeneration after periodontal surgery, regardless of the status of the pulp (vital, filled, medicated, or open).[20] Another study reported that pulpal status has little influence on initial cementogenesis and that substances leaching from certain root canal filling materials do not alter deposition of new cementum.[63]

Although endodontic infections have been highly correlated with deeper periodontal pockets and furcation involvement in mandibular molars, the causal relationship between the two pathoses has not yet been established.[39] It has been suggested that endodontic treatment should occur before treatment of furcation lesions (i.e., bone regeneration) to ensure successful results. Extensive evidence is lacking to prove this hypothesis, but there is general agreement that with the proper endodontic treatment, periodontal disease of pulpal origin should heal. The question of whether endodontic infections play a significant role in affecting the health of the periodontium remains to be further elucidated.[59]

INFLUENCE OF PERIODONTAL INFLAMMATION ON THE PULP

Clinically, it is not uncommon to observe an advanced periodontitis spreading to the apical foramen, with associated pulp necrosis. It is also recognized that infection from a periodontal pocket may spread to the pulp through accessory canals, which occur most often in the furcation and closer to the apex of teeth.[58] Investigators proved that pulpitis and pulp necrosis can occur as a result of periodontal inflammation involving accessory and apical canals.[67] Bacterial products and toxins may also gain access to the pulp by way of exposed dentinal tubules. The pulpal reaction is influenced not only by the stages of periodontal disease, but also by the type of periodontal treatment, such as scaling, root planing, and administration of medication.[32] Inflammatory lesions of varying severity and necrotic pulp tissue are usually found in teeth with large canals or in cases in which periodontal breakdown has extended to the apex.[32] Whyman[86] stated that during periodontal therapy, the blood vessels supplying the pulp by way of accessory canals may be damaged. Another animal study found that 70% of root specimens examined showed no pathologic changes despite the fact that 30% to 40% of the periodontal attachment was lost.[8] The remaining 30% of roots displayed only small inflammatory cell infiltrates or formation of reparative dentin, or both, in areas where pulp was adjacent to root exposed through periodontal destruction. These tissue changes were frequently associated with root surface resorption, which suggests that dentinal tubules must be uncovered before irritation can be transmitted.

These observations suggest that the presence of an intact cementum layer is important for the protection of the pulp from toxic elements produced by the plaque microbiota, so periodontal disease and periodontal treatments should be regarded as potential causes of pulpitis and pulpal necrosis. It has also been reported that the pulps of teeth with longstanding periodontal disease develop fibrosis and various forms of mineralization. Canals associated with periodontally involved teeth were reported to be narrower than canals of teeth that were not periodontally involved. This result is thought to be a reparative process rather than an inflammatory response.[7,49]

Although consensus supports the theory that a degenerating or an inflamed pulp can affect the periodontium, not all researchers agree about the effect of periodontal disease on the pulp. Specifically, inflammatory alterations and localized pulp necrosis have been observed adjacent to lateral canals in roots exposed by periodontal disease.[67,71,72] Additional studies have failed to confirm a direct correlation between periodontal disease and pulp tissue changes.[19,57,81] When pathologic changes occur in the pulp as a result of periodontal disease, the pulp usually does not degenerate so long as the main canal is not involved.[48] It seems plausible to assume that periodontal disease rarely jeopardizes the vital function of the pulp. Generally, if the blood supply through the apical foramen remains intact, the pulp is usually capable of withstanding physiologic insults induced by periodontal disease.

THEORETIC PATHWAYS OF OSSEOUS LESION FORMATION

For the clinician, the close relationship between pulpal and periodontal disease is reasonably established on clinical and radiographic levels. Because interpretations vary as to which came first (the proverbial "chicken or egg" controversy), clinical data gathering in endodontic and periodontal problems is often complex, requiring a medical history review, pulp vitality testing, pocket and furcation probing, tooth mobility determinations, and critical examination of radiographs. When formulating a differential diagnosis, the clinician should first consider both the periodontal and pulpal status of the affected tooth. If an interrelationship in disease entities exists, appropriate treatment must be rendered to remove true causative factors and enhance the prognosis for tooth retention.[74] Figure 25-1 shows interrelationships between pulpal and periodontal disease.

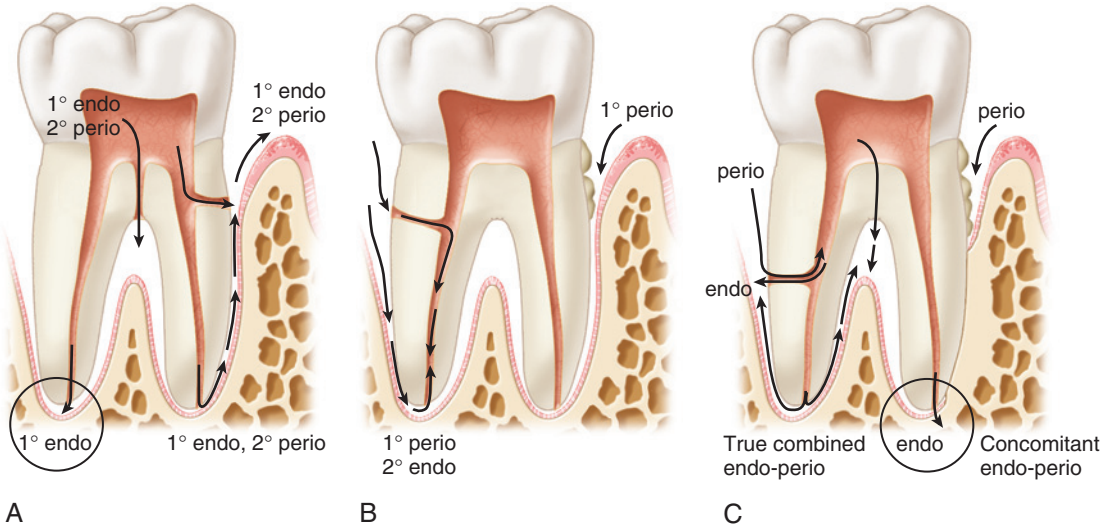

FIG. 25-1 Endodontic and periodontal pathways. **A,** Endodontic lesions. The pathway of inflammation is through the apical foramen, furcation canals, and lateral accessory canals to the periodontium. This results in a primary endodontic lesion, sometimes progressing to secondary periodontal involvement. **B,** Periodontal lesions. This is the progression of periodontitis by way of the lateral canal and apex to induce a secondary endodontic lesion. **C,** True combined endodontic and periodontal lesion and concomitant endodontic and periodontal lesions.

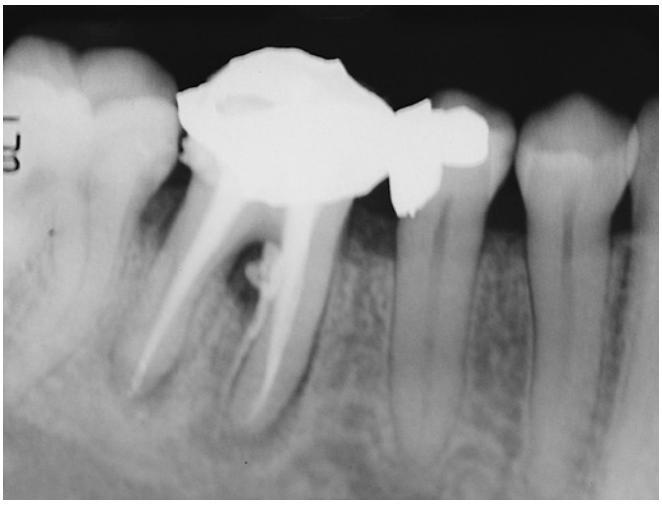

FIG. 25-2 Primary endodontic lesion. Mandibular molar showing endodontic filling material extending into the furcation and along the lateral root surface because of inadequate canal preparation. Furcation could be probed.

Primary Endodontic Lesions

Disease processes of the dental pulp frequently involve inflammatory changes. Caries, restorative procedures, and traumatic injuries are the most common causes. Typically, endodontic lesions resorb bone apically and laterally and destroy the attachment apparatus adjacent to a nonvital tooth. Inflammatory processes in the periodontium that occur as a result of root canal infection not only may be localized at the apex, but also may appear along the lateral aspects of the root (Fig. 25-2) and in furcation areas of two- and three-rooted teeth (Fig. 25-3).

The emergence of these processes may be associated with clinical signs of inflammation: pain, tenderness to pressure and percussion, increased tooth mobility, and swelling of the marginal gingiva, simulating a periodontal abscess. The suppurative process may cause a sinus tract along the periodontal ligament space or through patent channels (including the apical foramen and lateral accessory canals). This usually results in a narrow opening of the sinus tract into the gingival sulcus and pocket that can be easily traced with a gutta-percha cone or a periodontal probe. Such a tract can readily be probed down to the tooth apex, where no increased probing depth would otherwise exist around the tooth. In multirooted teeth, a periodontal ligament sinus tract can drain off into the furcation area and resemble a Grade III through-and-through furcation defect resulting from periodontal disease.

Clinically, endodontic testing procedures should reveal a necrotic pulp or, in multirooted teeth, at least an abnormal response, indicating that the pulp is degenerating. Because the primary lesion is an endodontic problem that has merely manifested itself through the periodontal ligament, complete resolution is usually anticipated after nonsurgical endodontic therapy, without any periodontal treatment.

Primary Endodontic Lesions with Secondary Periodontal Involvement

When a lesion of endodontic origin is not treated, pathosis usually continues, leading to destruction of the periapical alveolar bone and progression into the interradicular area, causing breakdown of surrounding hard and soft tissues (Fig. 25-4). As drainage persists through the gingival sulcus, accumulation of plaque and calculus in the purulent pocket results in periodontal disease and further apical migration of the attachment. When this occurs, not only does the diagnosis become more difficult, but the prognosis and treatment may be altered. Diagnostically, these lesions have a necrotic root canal and plaque or calculus accumulation, demonstrable by a probe and radiograph. Radiographs may show generalized periodontal disease with angular defects at the initial site of the endodontic involvement.

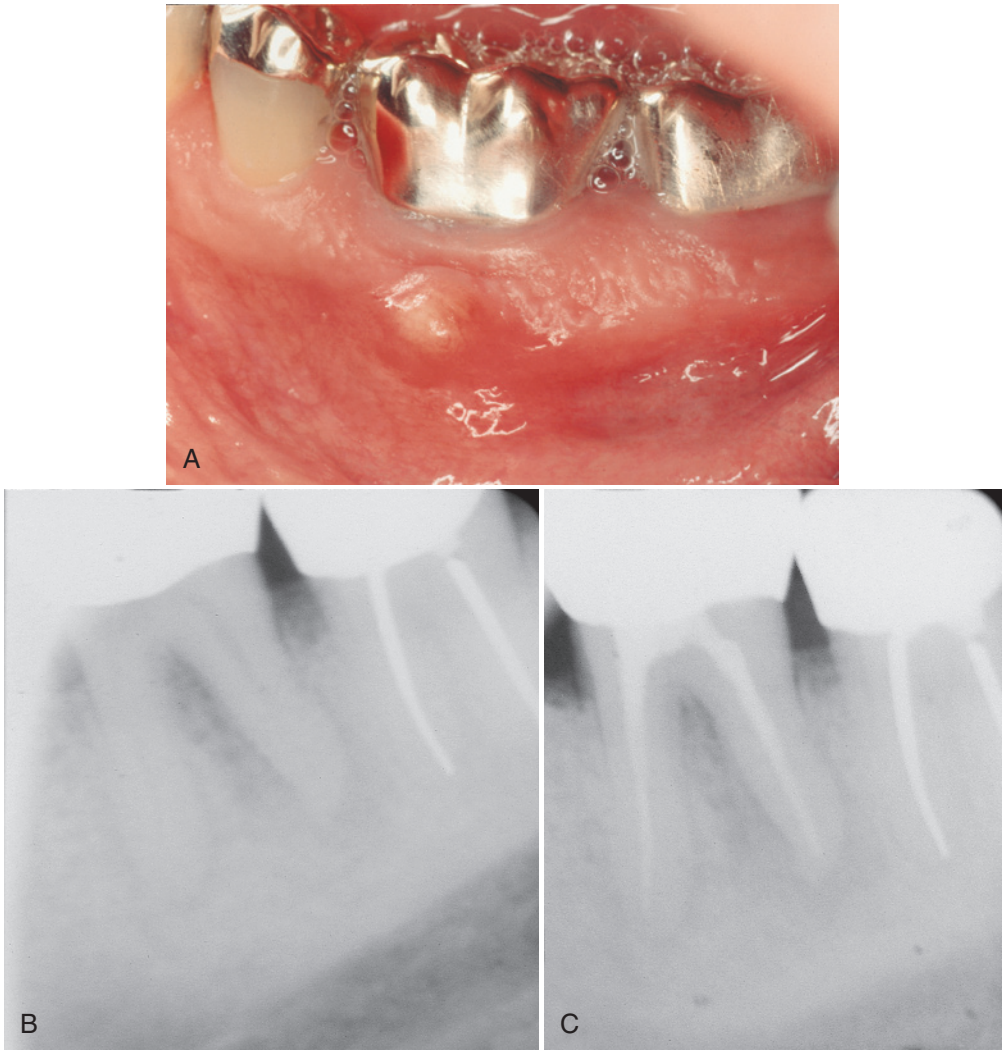

FIG. 25-3 **Primary endodontic lesion on mandibular first molar. A,** An abscess was noted on the buccal surface of the tooth. **B,** Apical radiolucency was evident on the distal root. **C,** Six months after root canal treatment, there is evidence of osseous healing at both the apex and furcation area.

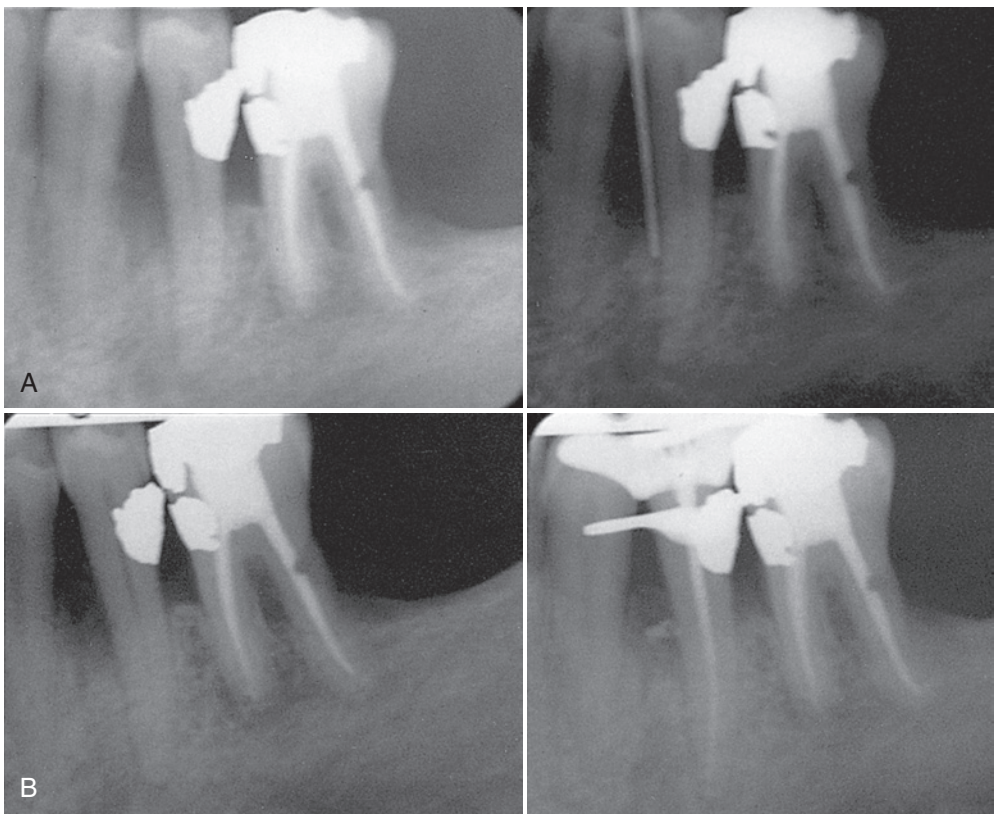

FIG. 25-4 **Primary endodontic lesion with secondary periodontal involvement. A,** The mesial aspect of the mandibular second premolar had deep periodontal pocketing (a periodontal probe in place demonstrated 6 mm of probing depth), even after periodontal therapy. **B,** Pulp tests were performed on the premolar; the tooth was nonresponsive. After endodontic treatment, the periodontal pocket resolved (filling of a lateral accessory canal after obturation is demonstrated).

Resolution of the primary endodontic and secondary periodontal lesion relies on treatment of both conditions. When only endodontic therapy is provided, only part of the lesion can be expected to heal. If endodontic therapy is adequate, the prognosis depends on the severity of periodontal involvement and efficacy of periodontal therapy.

Primary Periodontal Lesions

Periodontal disease has a progressive nature. It begins in the sulcus and migrates to the apex as deposits of plaque and calculus produce inflammation, causing loss of surrounding alveolar bone and supporting periodontal soft tissues. This leads to a loss of clinical attachment and formation of a periodontal abscess during the acute phase of destruction.[73] The progression of periodontal disease to the formation of osseous defects and subsequent radiographic appearance along lateral aspects of roots and in furcation areas is well known. These defects may or may not be in association with trauma from occlusion, which can often be the cause of an isolated periodontal problem. Osseous lesions of periodontal origin are usually associated with tooth mobility, and the affected teeth respond positively to pulp testing. In addition, careful periodontal examination usually reveals broad-based pocket formation and an accumulation of plaque and calculus. The bony lesion is usually more widespread and generalized than are lesions of endodontic origin (Fig. 25-5).

The prognosis for teeth affected by periodontitis worsens as the disease process and periodontal destruction progress. Treatment depends on the extent of the periodontitis and on the patient's ability to comply with potential long-term treatment and maintenance therapy. Because this is purely a periodontal problem, the prognosis depends exclusively on the outcome of periodontal therapy.

Primary Periodontal Lesions with Secondary Endodontic Involvement

As stated earlier, periodontal disease can have an effect on the pulp through dentinal tubules, lateral canals, or both. Primary periodontal lesions with secondary endodontic involvement differ from the primary endodontic lesion with secondary periodontal involvement only by the temporal sequence of the disease processes. The tooth with primary periodontal and secondary endodontic disease exhibits deep pocketing, with a history of extensive periodontal disease and, possibly, past treatment. When the pulp becomes involved, the patient often reports accentuated pain and clinical signs of pulpal disease. This situation exists when the apical progression of periodontal disease is sufficient to open and expose the pulp to the oral environment by way of lateral canals or dentinal tubules. On radiographs, these lesions may be indistinguishable from primary endodontic lesions with secondary periodontal involvement. The prognosis depends on continuing periodontal treatment subsequent to endodontic therapy.

True Combined Lesions

Pulpal and periodontal disease may occur independently or concomitantly in and around the same tooth. Once the endodontic and periodontal lesions coalesce, they may be clinically indistinguishable (Fig. 25-6). The prognosis of multirooted teeth with combined pulpal and periodontal lesions depends largely on the extent of the destruction caused by the periodontal disease component. A necrotic pulp or a failing endodontic treatment, plaque, calculus, and periodontitis will be present in varying degrees.

Concomitant Pulpal and Periodontal Lesions

An additional classification has been proposed for lesions that may commonly be seen clinically and reflect the presence of two separate and distinct entities.[6] This is referred to as the *concomitant pulpal and periodontal lesion* (Fig. 25-7). In essence, both disease states exist, but with different causative factors and with no clinical evidence that either disease state has influenced the other. This situation often goes undiagnosed, and treatment is rendered to only one of the diseased tissues in the hope that the other responds favorably. In actuality, the two disease processes must be treated concomitantly, and the prognosis depends on the removal of the individual etiologic

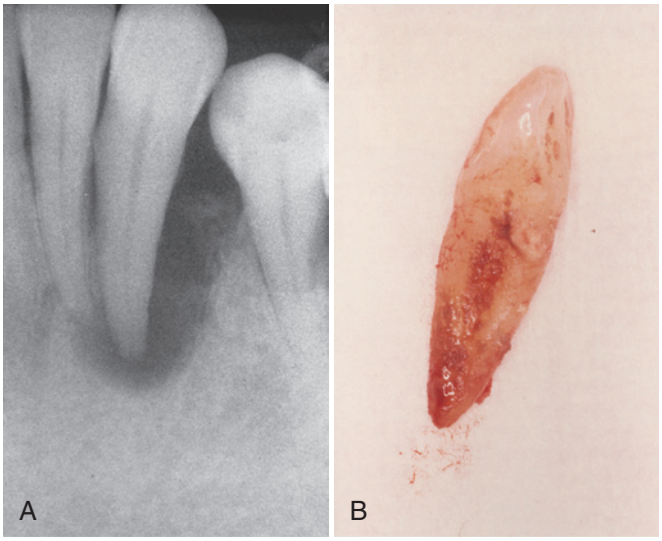

FIG. 25-5 **Primary periodontal lesion. A,** Mandibular cuspid exhibits extensive periodontal destruction; the tooth responded normally to pulp tests. **B,** Extracted tooth depicts extensive calculus accumulation and root concavity.

FIG. 25-6 True combined pulpal and periodontal lesions on the mandibular second premolar and first molar. Periodontal probing depths were to the apices in both teeth.

FIG. 25-7 Concomitant pulpal and periodontal lesion on the maxillary second premolar. An endodontic lesion was noted at the apex, with a noncommunicating periodontal pocket on the distal side.

factors and the prevention of any further factors that may affect the respective disease processes.

With the application of research findings and clinical experience, pathways of osseous lesion formation may be theorized. These concepts are intended as a guide for the evaluation and understanding of the clinician's successes and failures in treating teeth with osseous lesions. By understanding the nature of their formation, the clinician can better anticipate the healing potential after treatment.

DIFFERENTIAL DIAGNOSIS

During the course of treatment, clinicians are frequently presented with the dilemma of accurately assessing the contribution of endodontic and periodontal lesions. These lesions may be very separate from each other and present no extraordinary therapeutic consideration. In a few other situations, there is no obvious demarcation between the two lesions, which appear as one, both on radiographs and clinically. In the diagnosis of radiographic osseous lesions, the clinician must resist the temptation to label everything a "combined lesion." Table 25-2 summarizes the differential diagnosis between pulpal and periodontal lesions and highlights a number of common characteristics of these lesions.

Root fractures, especially vertical root fractures, present particular problems in diagnosis (Fig. 25-8). Symptoms and signs associated with vertical root fractures show a varying character and are frequently difficult to distinguish from those associated with periodontal and endodontic lesions. Breakdown can manifest itself on radiographs in a number of different ways. This may be anything from nothing detectable on radiographs to an area of rapid vertical bone loss, given that there is no way to predict when a patient may present for treatment. It is imperative for the clinician to take more than one radiograph at different angles, especially when no clear diagnosis emerges. In these cases, a minor alteration in the angulation may reveal a tooth fracture or periodontal furcation involvement. The diagnosis of vertical root fractures is often difficult because the fracture is usually not detectable by clinical inspection and radiographic examination unless there is a clear separation of the root fragments. Cemental tears or detachment of cementum from a root surface by means of trauma or aging has been reported.[14,51] The lesion often results in periodontal destruction and endodontic involvement (Fig. 25-9).[52,53]

Sometimes the definitive diagnosis of vertical root fractures has to be confirmed by exploratory surgical exposure of the root for direct visual examination.[84] Vertical root fractures have been associated with root-filled teeth where excessive lateral forces were applied during compaction or possibly with stress induced by post placement in root-filled teeth.[60] Clinical survey of fractured teeth also reveals that fractures are more common in teeth with extensive restorations, in older patients, and in mandibular posterior teeth.[30] The prognosis for teeth with vertical root fractures that involve the gingival sulcus and periodontal pocket usually is hopeless because of continuous bacterial invasion of the fracture space from the oral environment. Single-rooted teeth are generally extracted. In multirooted teeth, a treatment alternative is hemisection or resection of the fractured root. (See Chapter 21 for further discussion of vertical root fractures.)

Developmental grooves, primarily found in maxillary central and lateral incisors, are also capable of initiating localized periodontal destruction along the root surface.[26,41,50] It is

TABLE 25-2
Differential Diagnosis Between Pulpal and Periodontal Disease

	Pulpal	Periodontal
Clinical		
Etiology	Pulp infection	Periodontal infection
Vitality	Nonvital	Vital
Restorative	Deep or extensive	Not related
Plaque/calculus	Not related	Primary cause
Inflammation	Acute	Chronic
Pockets	Single, narrow	Multiple, wide coronally
pH value	Often acid	Usually alkaline
Trauma	Primary or secondary	Contributing factor
Microbial	Few	Complex
Radiographic		
Pattern	Localized	Generalized
Bone loss	Wider apically	Wider coronally
Periapical	Radiolucent	Not often related
Vertical bone loss	No	Yes
Histopathologic		
Junctional epithelium	No apical migration	Apical migration
Granulation tissues	Apical (minimal)	Coronal (larger)
Gingival	Normal	Some recession
Therapy		
Treatment	Root canal therapy	Periodontal treatment

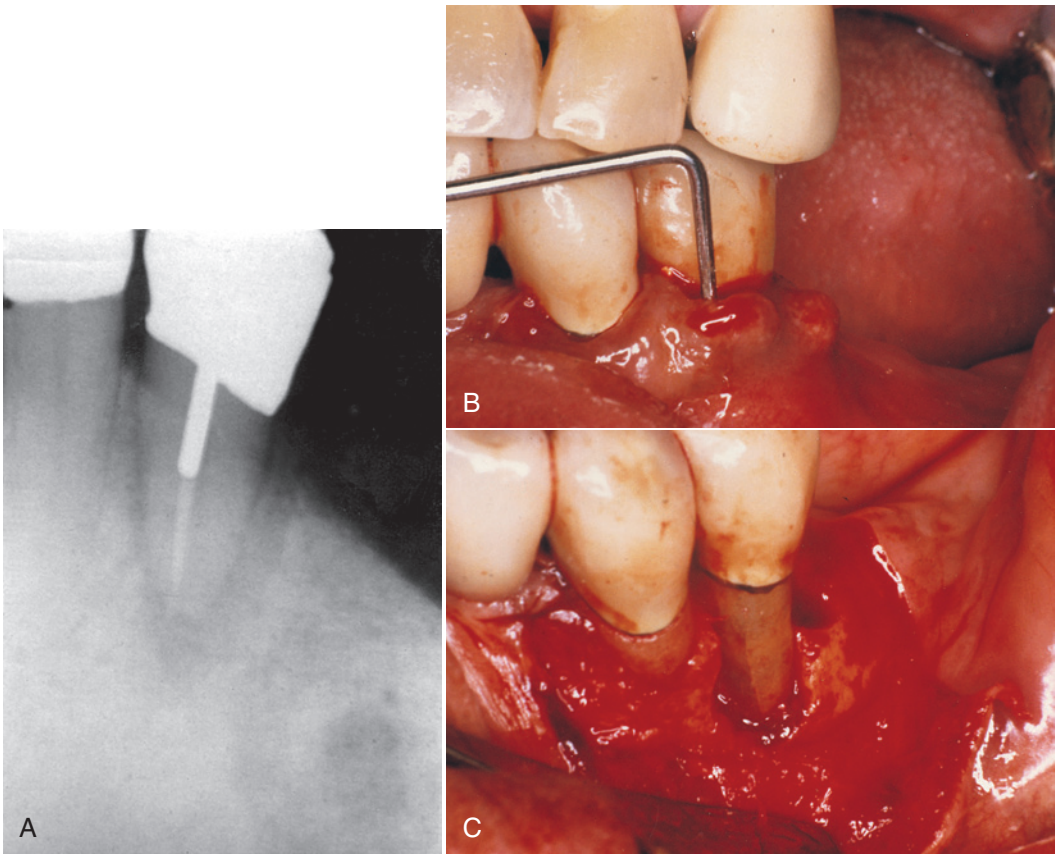

FIG. 25-8 **Vertical root fracture.** **A,** A radiograph revealed a widened periodontal ligament with a J-shaped radiolucency around the apex. **B,** A periodontal probe indicated more than 12 mm of probing depth. **C,** Exploratory surgery confirmed a vertical root fracture.

thought that they may be a genetic attempt to form an accessory root, but once plaque and calculus invade the epithelial attachment, the groove becomes a pathway for microbes and their noxious allies (toxins), with ample substrate from food debris to create a self-supporting periodontal lesion. Bone demineralization follows the path of the groove. Palatogingival grooves are often associated with poor periodontal health because of patients' inability to keep these areas clean, and a poor prognosis is usually assigned regardless of proper conventional therapy.[30,87] It is easy to identify these grooves if the clinician is aware of their existence. Clinically, these grooves may be asymptomatic, or symptomatic periodontal problems (either acute or chronic) may occur. It is thought that the pulp of these teeth may become secondarily involved and demonstrate symptoms of pulpal disease (Fig. 25-10). These lesions are often confused with the enamel projections in the furcation area of mandibular molars.[57] The prevalence of cervical enamel projections (Fig. 25-11) ranges from 18% to 45%.[36,57] Depending on the apical extent of these cervical grooves, some authors[36,57] also find a high association with pathologic furcation involvement (up to 82.5%[36]).

Lateral Periodontal Cysts

The clinical presentation of a lateral periodontal cyst is often without symptoms (Fig. 25-12). It may present as a gingival swelling on the facial aspect that may show pain and tenderness on palpation. Radiographic features are a well-circumscribed round or ovoid radiolucent area that usually has a sclerotic margin. Most lateral periodontal cysts are less than 1 cm in diameter and lie somewhere between the apex and cervical margin of a tooth. Three possible etiologies are reported in the literature: (1) reduced enamel epithelium, (2) remnants of dental lamina, or (3) cell rests of Malassez. Histologic evaluation reveals that these cysts are lined by epithelium that closely resembles reduced enamel epithelium lining. The lesion occurs predominantly in the fifth to seventh decades of life, with a predilection for males.[3] The lesion is usually slow growing. Treatment consists of careful excision to help prevent recurrence. The most common location is the mandibular cuspid-bicuspid area, although numerous cases have been reported in the anterior maxilla.

Altini and Shear[3] reported finding unicystic and multicystic (including botryoid) varieties. They found that lateral periodontal cysts were lined predominantly or exclusively by thin, reduced enamel, epithelium-like tissue that contained many clear cells, and epithelial thickenings referred to as *plaques*. Glycogen was present in the epithelium of two thirds of the cases, although not exclusively in the clear cells, many of which were not positive for glycogen. Some of their botryoid variety differed histologically, being lined predominantly by nonkeratinizing stratified squamous epithelium with crowded and pyknotic nuclei and no clear cells. One case contained melanin, and another showed epithelial crypt formation and superficial palisaded low columnar cells, as seen in the glandular odontogenic cyst. This raised the question of whether the latter may form part of the clinicopathologic spectrum of

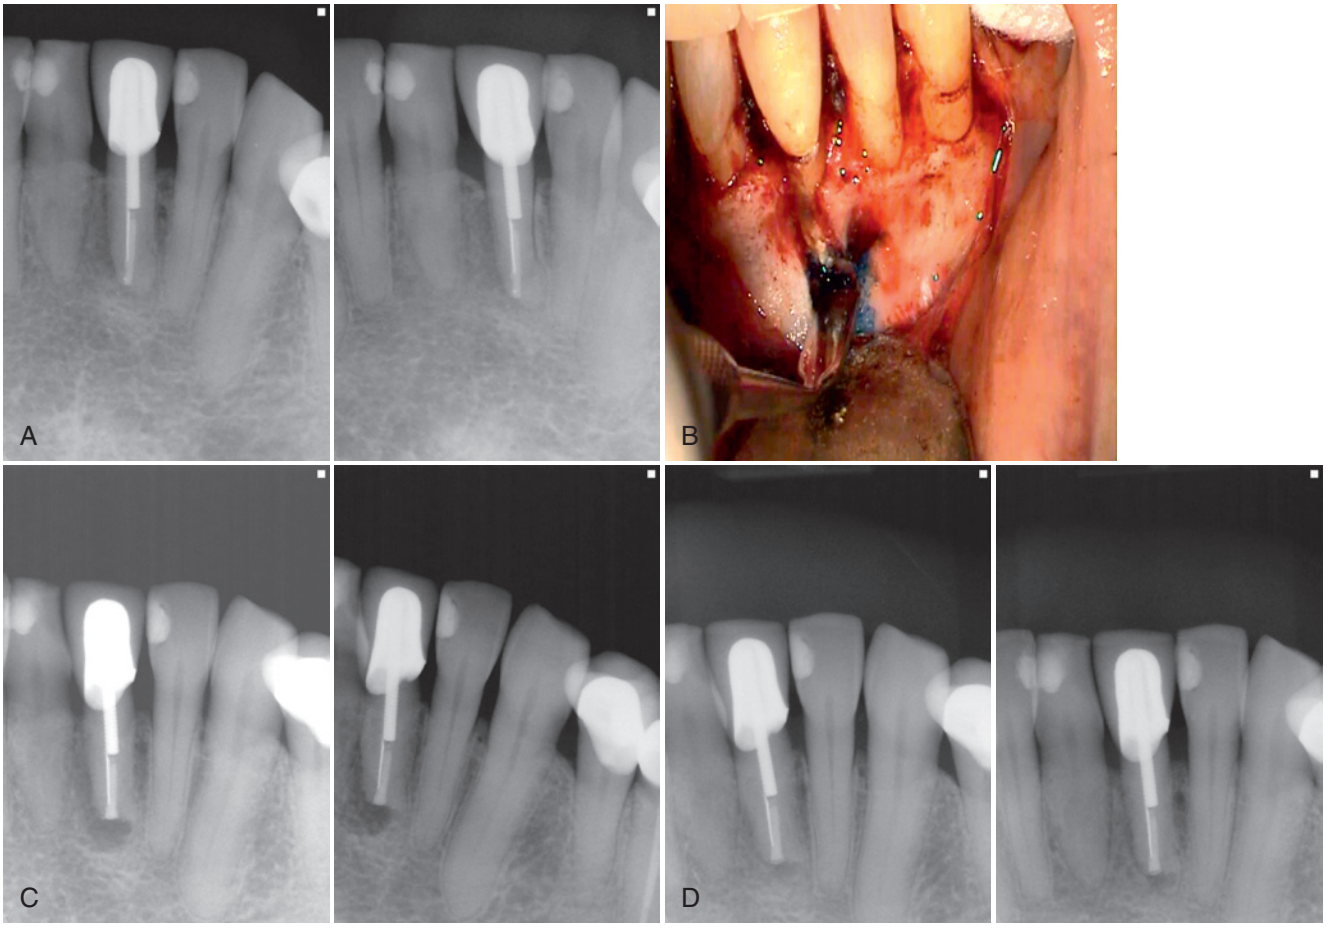

FIG. 25-9 **Cemental tear. A,** Radiographs revealed an endodontically treated tooth with post, separated instrument, and apical osseous breakdown; the tooth was very tender to both percussion and palpation. **B,** An "eggshell" piece of cementum on the buccal surface of the root before root-end resection; the cementum was removed with curettage. **C,** Postoperative radiographs after root-end resection, root-end preparation, and root-end filling. **D,** Six-month follow-up radiographs demonstrate periapical healing; the tooth was asymptomatic.

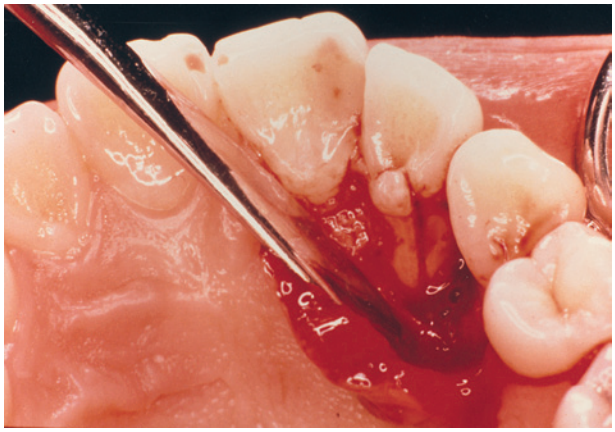

FIG. 25-10 Palatogingival groove on a maxillary lateral incisor with a periodontal defect.

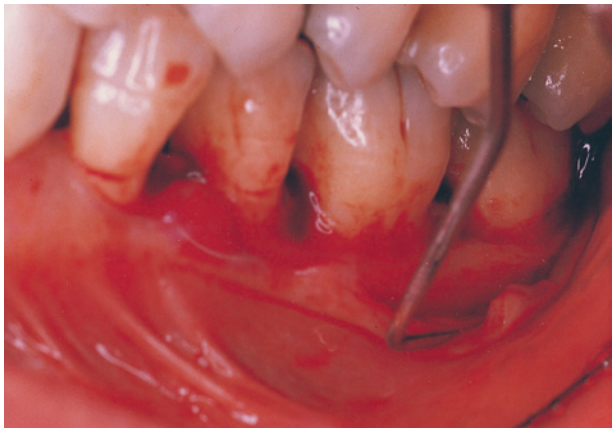

FIG. 25-11 Cervical enamel projection on a mandibular molar.

a lateral periodontal cyst. The histogenesis of lateral periodontal cysts is uncertain, but these cysts favor origin from reduced enamel epithelium. Some cases either do not fit a characteristic endodontic or periodontal lesion or do not respond to treatment as expected. A biopsy and histologic analysis are often recommended. Systemic diseases such as scleroderma, metastatic carcinoma, and osteosarcoma can mimic endodontic and periodontal disease visible on a radiograph. *The conscientious clinician must always be alert for lesions of nonendodontic or nonperiodontal origin and look for other causes.*

FIG. 25-12 Lateral periodontal cyst. **A,** Clinical photograph showing mild gingivitis around tooth #24; there is a 5-mm probing defect on the mesial aspect of tooth #24. **B,** A radiograph depicts the beginning lesion 2 years earlier. **C,** A radiograph shows the extent of the lesion at the time of referral to the periodontist. **D,** Initial flap reflection; the lesion is present interproximally between teeth #24 and #25.

TREATMENT ALTERNATIVES

When traditional endodontic and periodontal treatments prove insufficient to stabilize an affected tooth, the clinician must consider treatment alternatives. Generally, a localized periodontal defect associated with an endodontically untreatable tooth or an iatrogenic tooth problem is reason to explore other treatment options. Alternate treatments often consist of resection or regenerative approaches. Resection techniques focus on eliminating the diseased roots or teeth; regenerative efforts are aimed at restoring lost biologic structures. Resection methods involve removal of affected roots or extraction of involved teeth. When a tooth requires extraction, one of the first options for restoring occlusal function should include placement of dental implants with hybrid prostheses. Bone replacement grafts using guided tissue and bone regeneration techniques are ways to reestablish biologic structures that were lost during this disease process. Fixed partial dentures are still a viable option for some patients and certainly should be considered if abutment teeth already have restorations or endodontic treatment.

Root resection is the removal of a root, with accompanying odontoplasty before or preferably after endodontic treatment.[27] Formerly it was used when root canal therapy was considered too difficult, but now its indications are restricted to multirooted teeth in which one or more roots cannot be saved. The indications for root resection often include (but are not limited to) root fracture, perforation, root caries, dehiscence, fenestration, external root resorption involving one root, incomplete endodontic treatment of a particular root, severe periodontitis affecting only one root, and severe grade II or grade III furcation involvement. Root resection is a technique-sensitive procedure (Fig. 25-13) requiring a careful diagnostic process for selection of teeth that would likely be successful candidates, followed by meticulous interdisciplinary treatment. Factors such as occlusal forces, tooth restorability, and the value of the

FIG. 25-12, cont'd E, The lesion was enucleated and submitted for histologic evaluation; the diagnosis was a lateral periodontal cyst. F, Three-month posttreatment clinical photograph; tooth #24 was nonvital and symptomatic and was referred for root canal treatment. G, One-year posttreatment radiograph showing completed root canal treatment and osseous defect still present; continuous recall recommended. H, One-year posttreatment clinical photograph; probing depths were within normal limits; continuous recall was recommended.

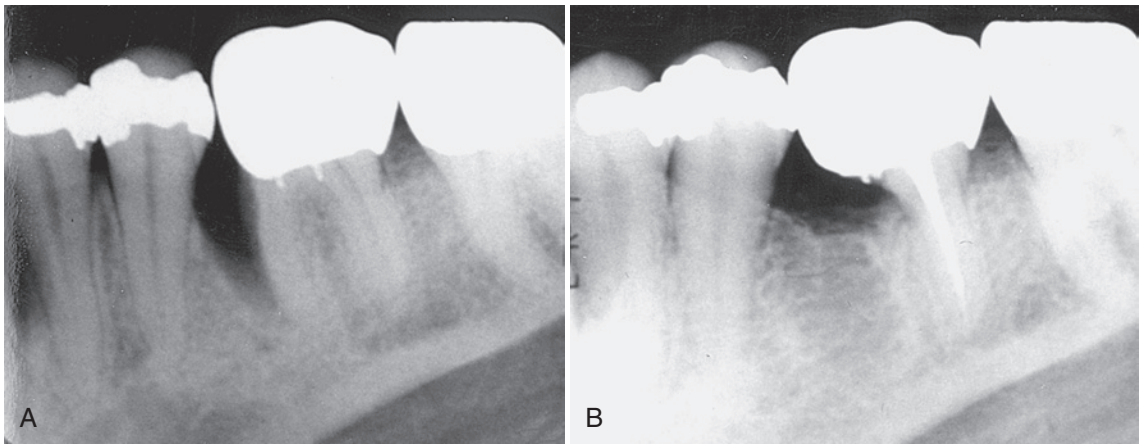

FIG. 25-13 Root resection to correct endodontic and periodontal defect. A, Pretreatment radiograph depicts severe periodontal involvement on the mesial. Endodontic treatment was performed before surgical removal of the mesial root. B, Five-year follow-up shows the remaining tooth well maintained.

remaining roots must be examined before treatment. A carefully constructed treatment plan is crucial to the success of this resection procedure.[31] Proper reshaping of the occlusal table and restoration of the clinical crown are essential, and the root surface must be recontoured to remove the root stump, thus preventing formation of a potential food trap.[42]

The effectiveness of this approach remains controversial, owing to the disparity of results reported in several long-term studies.* Retrospective longitudinal studies have observed the fate of sectioned teeth for time frames ranging from 3 to 12 years and have reported success rates ranging from 62% to 100%, with a low incidence (i.e., 10%) of periodontal breakdown. However, as most long-term studies will point out, the major cause of failure of resection procedures resides in failure of the endodontic and restorative components. Unique anatomic features, such as root length, curvature, shape, size, position of adjacent teeth, and bone density, may influence the end result. For example, root fusion makes resection all but impossible. The removal of roots purely to eliminate a resorptive or traumatic perforation defect, fractured root, or endodontically inoperable root usually results in definitive treatment. If, however, localized or generalized periodontal disease is present, conditions favorable for healing must be created, and concomitant periodontal therapeutic procedures can be implemented to restore the health of the periodontium.[31] The final restoration of root-resected teeth depends significantly on the nature of the resection, the amount of remaining tooth structure, the periodontal status, and the patient's occlusion. The prosthetic aspects of tooth restoration must be carefully assessed and integrated into the anticipated surgical procedure to ensure proper positioning of tooth margins relative to the osseous crest and also to manage the anticipated changes in occlusal relationships and masticatory forces.[85] Hemisection is the surgical separation of a multirooted tooth, usually a mandibular molar with severe furcation involvement, through the furcation in such a way that a root and associated portion of the crown may be removed or retained. A fixed partial denture often is placed in the area to restore the lost portion of the occlusal table (Fig. 25-14).

Controversy has also existed regarding the benefits of and need for endodontic therapy before root resection. Instances develop in which exploratory surgery is necessary; should the periodontal problem be more extensive than determined presurgically, removal of a root should be carried out at that time. In these instances, removal of the involved root without endodontic treatment would be acceptable, but root canal therapy should be performed as soon as possible after root removal.[29,77,80] After resection of a vital root, the pulpal opening in the crown may be sealed and restored with a permanent amalgam restoration or sedative base material (e.g., Dycal) as a temporary solution. Investigators evaluated vital-root resection in maxillary molar teeth for 9 years.[27] Amputated pulps were covered with Dycal base and amalgam. At 1 year, 38% of molar teeth remained vital, but at 5 years only 13% maintained vitality. These findings imply that the long-term prognosis for vital-root resection is poor, so *endodontic therapy should be done before or immediately after resection*. However, Haskell[35] reported that vitality of resected teeth can be maintained even after 16 years. Nonetheless, it is generally agreed that whenever possible, endodontics should be performed in advance (before root resection). If this is not possible, the endodontic treatment should be performed as soon as possible after vital-root amputation. Otherwise, pulpal complications may occur, such as internal resorption, pulpal inflammation, and necrosis.[2,79]

The concepts of guided tissue regeneration (GTR) and guided bone regeneration (GBR) have been used to promote bone healing after endodontic surgery.[28,62] Figure 25-15 illustrates an endodontic defect successfully treated with the GTR approach. Theoretically, the GTR barrier prevents contact of connective tissue with the osseous walls of the defect, protecting the underlying blood clot and stabilizing the wound.[34] An investigator treated large periradicular lesions with GTR barrier membranes and demonstrated that periradicular healing occurred more rapidly at membrane sites than at control sites.[61,62] The quality and quantity of the regenerated bone were superior with adjunctive use of the membrane than without such use. Similar findings were published in a case report with histologic examination of biopsy material obtained at barrier removal.[64] In addition, during examination of clinical cases, the closer the lesion is to the gingival margin, the greater the fluid and bacterial contamination from the sulcus (and the greater the risk of mechanical trauma). When GTR is considered, the combined endodontic and periodontal lesion probably has the least favorable prognosis compared with cases having only a periodontal lesion.[61]

Many varieties of GTR membranes are available for clinical use, but it is logical to use bioresorbable collagen and polymer membranes in endodontic surgeries because there is often no need for a second surgery to retrieve the membrane. Studies reveal similar results achieved with nonresorbable and resorbable membranes.[17] Long-term studies need to be completed to evaluate the success of this approach.

For more than 40 years, bone grafts have been used to treat osseous defects associated with periodontal disease.[70] Because the "apicoectomy" (i.e., root-end resection) defect has a surrounding bony wall, the need for adjunctive bone grafting during this procedure is questionable (unless the lesion is exceptionally large in diameter). With the introduction of the GTR concept, a combination of bone replacement graft and GTR membrane (Fig. 25-16) has shown promising results.[1,21,40,64,82] Further studies are required to explore the true benefit of this combination treatment approach in root-end resection procedures.

Forced Eruption or Extrusion

Teeth that have fractured, undergone extensive decay, or experienced internal or external root resorption or lateral perforation may be candidates for a forced eruption procedure, especially straight, tapering, single-rooted teeth (Fig. 25-17). To obtain good access for endodontic or restorative procedures, along with reduced probing depths, it may be necessary to perform extensive resection surgery to gain crown lengthening. Forced eruption may offer a better solution than surgical crown lengthening, which may produce poor aesthetics in some cases. A review of the literature reveals that most successfully treated cases are extrusions of less than 4 mm.[5,9,46] The infrequently used treatment method of forced eruption serves as an alternative to the sacrifice of the natural root system. Forced eruption can preserve the natural root system and related periodontal architecture, resulting in years of additional service for the patient. It also can maintain adjacent tooth structure while

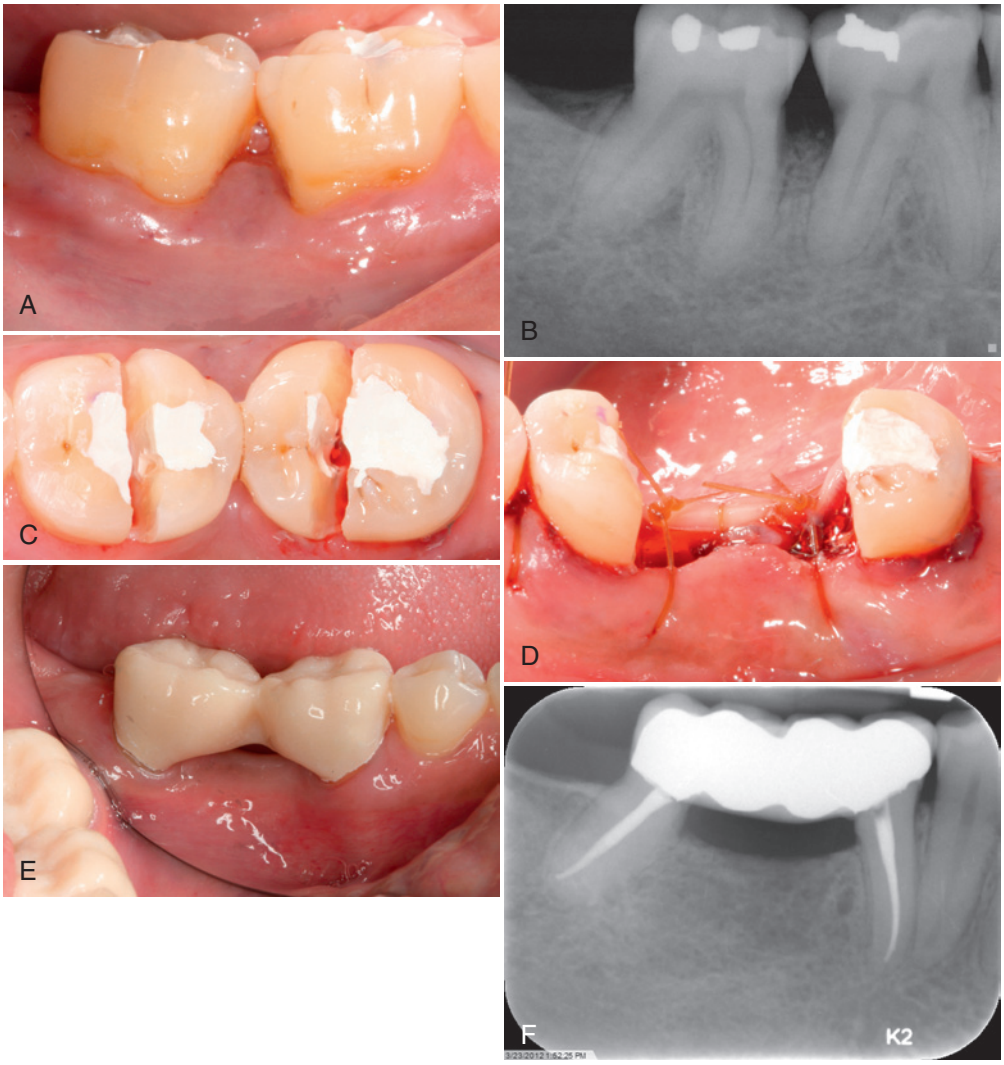

FIG. 25-14 Hemisection. **A,** Initial presentation of mandibular molars with severe attachment loss on the mesial aspect of tooth #31 and the distal aspect of tooth #30. **B,** Radiograph exhibiting interproximal periodontal defects. **C,** Occlusal view of hemisection after endodontic treatment. **D,** Suturing after removal of mesial half of tooth #31 and distal half of tooth #30. **E,** Eighteen-month follow-up with fixed restoration in place. **F,** Postoperative radiograph at 18 months showing normal bony and periodontal architecture.

retaining the option for future implant reconstruction if needed. Given the reported success of forced eruption, the technique should be used more often by dentists.[22,25] The increased use of implants in clinical treatments has stimulated clinicians' interest in augmenting bone in patients who have deficient alveolar ridges that might preclude ideal implant placement.

A nonsurgical technique for using the available bone for implant site development and fixture placement is orthodontic extrusion or forced eruption. The concept of extruding a tooth coronally by orthodontic forces and the clinical alterations in the soft tissue architecture of the periodontium demonstrated during orthodontic extrusive movement of periodontally compromised teeth have demonstrated probing depth reduction in some cases.[56] An investigator reported that tooth movement in the presence of inflammation might cause deepening of osseous defects. Often extrusions are accompanied by an immature-appearing tissue that is red compared with adjacent tissue. This results from the eversion of junctional epithelium, which is nonkeratinized in the sulcus; the vasculature is more readily visible until the newly exposed tissue has a chance to keratinize, in about 28 days.[37,38] Most extruded teeth should be retained in place twice as long as it took to force-erupt them to minimize relapse before attempting definitive restorative procedures.

SUMMARY

Endodontic and periodontal lesions result from the close interrelationship of pulp tissue and the periodontium. The major pathways of communication between the two types of tissue are the apical foramina, lateral and accessory canals, and dentinal tubules. The differential diagnosis of endodontic and periodontal lesions is not always straightforward and requires

clinical data accumulation from a number of diagnostic tests to obtain a correct diagnosis. When examining and treating the combined or individual lesion in endodontics and periodontics, the clinician must bear in mind that successful treatment depends on a correct diagnosis. Lesions with combined causes require both endodontic and periodontal therapy, and endodontic therapy should usually be completed first. Root resection and regenerative techniques offer alternative approaches, enhancing the clinician's ability to deal with these complex clinical problems.

CHAPTER 26

Effects of Age and Systemic Health on Endodontics

CARL W. NEWTON | JEFFREY M. COIL

CHAPTER OUTLINE

An Aging Society
Medical History
Chief Complaint
Dental History
Subjective Symptoms
Objective Signs
Diagnosis and Treatment Plan
Consultation and Consent
Treatment
Isolation
Access
Preparation
Obturation
Success and Failure
Endodontic Surgery
Restoration

Dental service requirements are determined by four demographic and epidemiologic factors:

1. The population at risk
2. The incidence and prevalence of dental diseases
3. The accepted standards of care
4. The perceived need and expectations toward dental health by the public[26]

These factors are changing as a result of the aging of the population.

AN AGING SOCIETY

According to the U.S. Census Bureau, America's population aged 65 years or older grew by 82% between 1965 and 1995.[104] Between 1980 and 1995 this same population grew by 28%, and according to the most current demographic information, the number was 40.4 million in 2010, an increase of 15.3% since 2000. That represents 13.1% of the total U.S., population.[107] The *oldest old* are defined as those who are at least 85 years of age. This group is the fastest growing segment of America's senior citizen population. The number of people 85 years or older has more than doubled since 1965 and has grown by 40% since 1980.

The 75 million people born in the United States between 1946 and 1964 constitute the baby boom generation. In 1994, baby boomers represented nearly one third of the U.S. population. These people began to enter the 65 years or older category in 2011. As the baby boomers continue to age, the United States will see an unparalleled increase in the absolute number of older people.[16] One in eight Americans was age 65 or older in 1994; in a little more than 30 years, about one in five is expected to be in this group (Fig. 26-1).[107]

Information from the U.S. Census Bureau and the National Institute on Aging indicates that America's older population is unevenly distributed among geographic locations. The most populous states have the largest number of older adults; Florida and the Midwestern states currently have the highest proportions of older adults. In 1993, Florida was the only state where older adults accounted for greater than 16% of the population; however, it is predicted that 32 states will fall into this category by 2020.[73]

The increased longevity of the dentition, made possible by expanding fields of advanced restorative procedures and periodontology, implies that dentistry will see a substantial growth in the number of older patients.[24] Until 1983, individuals aged 65 years or older made an average of 1.5 dental visits annually, a lower utilization rate than for any other age group.[106] Between 1983 and 1986, a 29% increase in visits by those age 65 or older was noted by the National Health Survey.[105] According to this survey, older adults currently make more visits per year, on average, than those in the "all ages combined" category. The percentage of office visits, services provided, and patient expenditures attributed to patients age 65 or older exceeded the percentage of the population in that age group.[64] In the future, clinicians will routinely serve a growing number of older people, who will account for one third to two thirds of their workload.[62,63,65]

The growth of the population age 65 or older has affected every aspect of U.S. society, presenting both challenges and opportunities to policymakers, families, businesses, and health

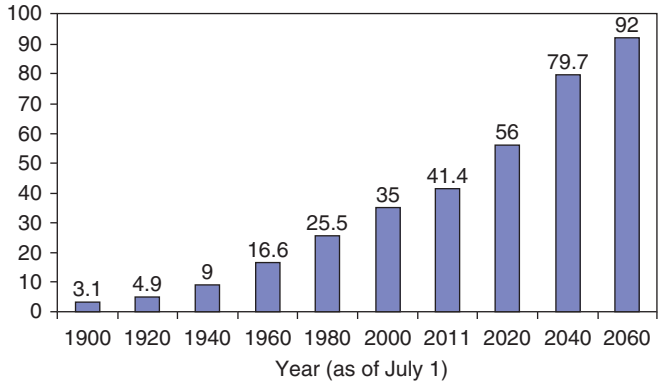

FIG. 26-1 Projected growth of U.S. adults age 65+ years to the year 2060. (From U.S. Department of Health and Human Services, Administration on Aging: A profile of older Americans: 2012. Available at: http://www.aoa.gov/. Accessed June 2014.)

care providers.[73] Age, ability to cooperate with dental treatment, and type of residence are important considerations in identifying preventive and treatment strategies.[69] Future dental services for older patients (including root canal procedures) are expected to be of two general types:

1. Services for relatively healthy older adults who are functionally independent
2. Services for older patients with complex conditions and problems who are functionally dependent[70]

The second group will require care from clinicians who have advanced training in geriatric dentistry. This age group is being targeted in dental education programs and advanced training through improved curriculums, research, and publications on aging. The National Institute on Aging has stated that all dental professionals should receive education in the treatment of older adults as part of their basic professional education.[21,70]

This chapter discusses the effect of aging on the diagnosis of pulpal and periapical disease and on successful root canal treatment. The quality of life for older patients can be significantly improved by saving teeth through endodontic treatment and can have significant value for overall dental, physical, and mental health.

With age, the simple pleasure of being able to eat what one wishes often becomes an issue, as does the increased need for proper diet and nourishment. Every tooth may be strategic, and old age is no time to be forced to replace sound teeth with removable appliances or dentures. Age is a factor in reduced stability and retention of removable partial dentures.[47] Consultation with older patients should help them overcome what may be a very limited knowledge of root canal treatment and lack of appreciation for regular dental care. Well-meaning friends and spouses who contend that their dentures are as good or better than their natural teeth may have had a lifetime of poor dental experiences or may have forgotten what it is like to enjoy natural dentition.

Negative social attitudes toward older adults tend to carry over into their care. Older patients are in danger of being dismissed as hopeless or not worth the effort. At times, clinicians shy away from providing care for seniors because of the perceived difficulty or cost of certain treatment procedures or because of complicated medical conditions. Clinicians sometimes consider older patients less able to pay for treatment because of their age and appearance. However, most older adults engage in normal activities and can recognize and afford the value of good dentistry.[9]

Most older patients have led active, productive lives; they are very interested in maintaining their dignity and do not consider themselves a bad investment. Tooth loss is often associated with the prospect of aging and loss of vitality.[31] As with any age group, older patients must be considered as individuals. This may prove difficult in the face of the tendency of many health care professionals to assign any person older than 65 years to the classification *geriatric* and to stereotype patients (e.g., confusion, dementia, poor treatment response). Each older adult patient comes with a unique psychological and social life history and a set of values, needs, and resources unlike those of any other patient the provider will see. Most seniors are more concerned with maintaining control of their lives than they are about being old.[82] Clinicians' perception of the effects of aging on the diagnosis and treatment of pulp and periradicular disease is also improving, along with the rate at which older patients need and seek specialty care.[40]

Because the primary function of teeth is mastication, it is presumed that loss of teeth leads to detrimental food changes and reduction in health.[49] However, this may not be the driving force when seniors are seeking treatment. Many times, social issues are the motivation for a senior to visit a clinician. After suggesting a mandibular anterior tooth extraction to an 89-year-old man, one clinician was told by the patient, "I can't, Doctor. I'm taking a cruise next week with my older brother and our girlfriends, I can't look like that." Most people older than age 60 who still have their own natural anterior teeth would not wish for a change in appearance if they needed prosthodontic reconstruction.[43]

Clinicians should not presume that they know what is best for senior patients or what they can afford without talking with the patient. The needs, expectations, desires, and demands of older people may exceed those of any age group, and the gratitude shown by older patients is among the most satisfying of professional experiences.

The desire for root canal treatment among aging patients has increased considerably in recent years. Older patients are aware that treatment can be performed comfortably and that age is *not* a factor in predicting success.*

In addition, obtaining informed consent requires that root canal treatment be offered as a favorable alternative to the trauma of extraction and the cost of prosthetic replacement. The distribution of specialists, the many technologic advances, and the improved endodontic training of all clinicians have broadened the availability of most endodontic procedures to everyone, regardless of age. Expanded dental insurance benefits for retirees and a heightened awareness of the benefits of saving teeth have encouraged many older patients to seek endodontia rather than extraction.[110] People with private dental insurance are more likely to visit a clinician. There is a trend toward less insurance in most demographic groups except the elderly, who also enjoyed benefits during their working years.[112] Most dental coverage in the United States is obtained through plans offered by employers; however, basic Medicare does not include such benefits, so seniors' spending on dental care is more sensitive to income than spending by

*References 7, 35, 52, 74, 88, 98, and 100.

younger age groups. Unfortunately, oral health provisions in recent U.S health care reform does not benefit older patients.[27]

This chapter compares the typical geriatric patient's endodontic needs with those of the general population. (Pulp changes attributable to age are discussed in Chapters 12 and 13; their effects on clinical treatment are also discussed in this chapter.)

MEDICAL HISTORY

It is important to focus on the factors that truly indicate the risks undertaken in treating the older patient. Clinicians must recognize that the biologic or functional age of an individual is far more important than his or her chronologic age. A medical history should be taken before the patient is brought into the treatment room, and a standardized form (see Chapter 1, Fig. 1-2) should be used to identify any disease or therapy that would alter treatment or its outcome. In general, the dramatic changes to the cardiovascular, respiratory, and central nervous systems caused by aging result in most of the older patient's drug therapy needs. However, the clinician also should consider the decline in renal[14] and liver function in older patients when predicting the behavior and interaction of drugs that may be used in dental treatment (e.g., anesthetics, analgesics, antibiotics).

The review of the patient's medical history is the clinician's first opportunity to talk with the patient. The time and consideration taken at the outset set the tone for the entire treatment process. This first impression should reflect a warm, caring clinician who is highly trained and able to help patients with complex treatments. Some older patients may need assistance filling out forms, and they may not be fully aware of their conditions or history. Some patients may withhold their date of birth to conceal their age for reasons of vanity or even fear of ageism. Some may not list current medications because they think it would be unnecessary information for the clinician to know. Vision deficits caused by outdated glasses or cataracts can adversely affect a patient's ability to read the small print on many history forms. Consultation with the patient's family, guardian, or physician may be necessary to complete the history; however, oral health care professionals function as primary caregivers in today's health care environment, and they are ultimately responsible for involving the patient in decision making and treatment choices.[38]

Today's dental office can be a confusing environment of required paperwork. An updated history, including information on compliance with any prescribed treatment and sensitivity to medications, must be obtained at each visit and reviewed. The elderly usually take more drugs, prescription and nonprescription, than the general adult population, and drug interactions and adverse drug reactions are more likely to result from polypharmacy.[44] As polypharmacy continues to increase, the likelihood of adverse drug interactions in older dental patients also will increase.[45] It is very important that the clinician take a careful history and update it at every visit.[66] *The Physicians' Desk Reference* (PDR) should be consulted, and any precaution or side effect of a medication noted. The PDR is available online (*www.pdr.net/*). Several other websites (e.g., Epocrates *[www.epocrates.com]*) have been developed specifically to be consulted about drug interactions and dental treatment.

Although geriatric patients are usually knowledgeable about their medical history, some may not understand the implications of their medical conditions in relation to dentistry or may be reluctant to let the clinician into their confidence. Their perceptions of their illnesses may not be accurate, so any clue to a patient's condition should be investigated.

Symptoms of undiagnosed illnesses may present the clinician with a screening opportunity that can disclose a condition that might otherwise go untreated or may lead to an emergency. Management of medical emergencies in the dental office is best directed toward prevention rather than treatment. Squamous cell carcinoma and salivary gland tumors increase with age, especially past age 80, and the prognosis is less favorable.[19]

Osteonecrosis of the jaw (ONJ) is a painful condition secondary to bisphosphonate therapy. Although it occurs at a much higher rate in patients receiving intravenous treatment for bone diseases than it does in older patients receiving the oral treatment common for osteoporosis, forced eruption and tooth or root retention are recommended alternatives to the risk of extraction (Fig. 26-2).[90] In addition, when discussing treatment options of endodontic retreatment versus endodontic surgery, the clinician should steer patients at risk for developing ONJ away from the surgical option (Fig. 26-3). The American Association of Endodontists' position paper on the endodontic implications of ONJ is available online (*www.aae.org/guidelines*).

Few families are without at least one member whose life has been extended as a result of medical progress. A great number have had diseases or disabilities controlled with therapies that may alter the clinician's case selection. Root canal treatment is certainly far less traumatic in the extremes of age or health than is extraction and implant placement.

Chief Complaint

Most patients experiencing dental pain have a pulpal or periapical problem that requires root canal treatment or extraction. Dental needs are often manifested initially in the form of a complaint, which usually contains the information necessary to make a diagnosis. The diagnostic process is directed toward determining the vitality of the pulp, whether pulpal or periapical disease is present, and which tooth is the source (see Chapter 1).

Without leading, the clinician should allow the patient to explain the problem in his or her own way. This gives the examiner an opportunity to observe the patient's level of dental knowledge and ability to communicate. Visual and auditory impairments may become evident at this time. An effort should be made to maintain privacy if the clinician is required to speak louder because of a patient's hearing impairment.

Patiently encouraging the patient to talk about problems may lead into areas of only peripheral interest to the clinician, but it establishes a needed rapport and demonstrates sincere interest. A patient may show some feelings of distrust if there is a history of failed treatments or if well-meaning, denture-wearing friends or relatives have claimed normal function and extolled their freedom from the need for dental treatment. The effect of the "focal infection" theory is still evident when other aches and pains cannot be adequately explained and loss of teeth is accepted as inevitable. The best patients are those who have already had successful endodontic treatment. Older patients are more likely to have already had root canal treatment and have a more realistic perception about treatment comfort.

Most geriatric patients do not complain readily about signs or symptoms of pulpal and periapical disease and may consider them to be minor compared with other health concerns and

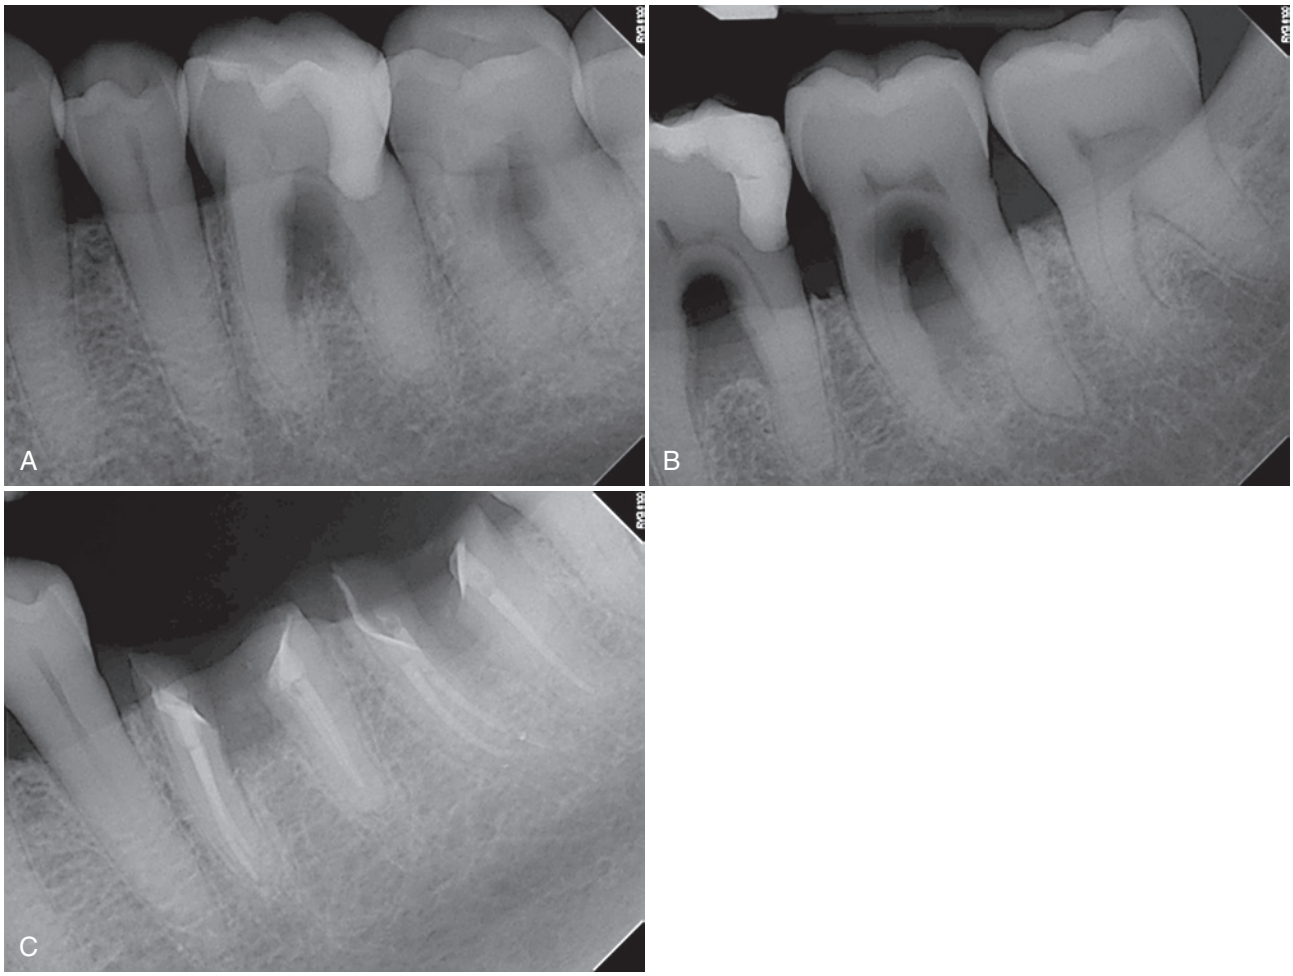

FIG. 26-2 **A** and **B**, This patient had undergone IV bisphosphonate chemotherapy and presented for consultation about these asymptomatic vital teeth. The root decay is a consequence of increased decay susceptibility due to gingival recession and xerostomia. **C**, After consultation with the patient's oncologist, it was agreed that nonsurgical root canal therapy (NSRCT) was the best option to avoid the complication of pain and infection from certain exposure during decay removal and restoration on teeth that would otherwise be extracted as unrestorable. (Courtesy Dr. Joe Spires.)

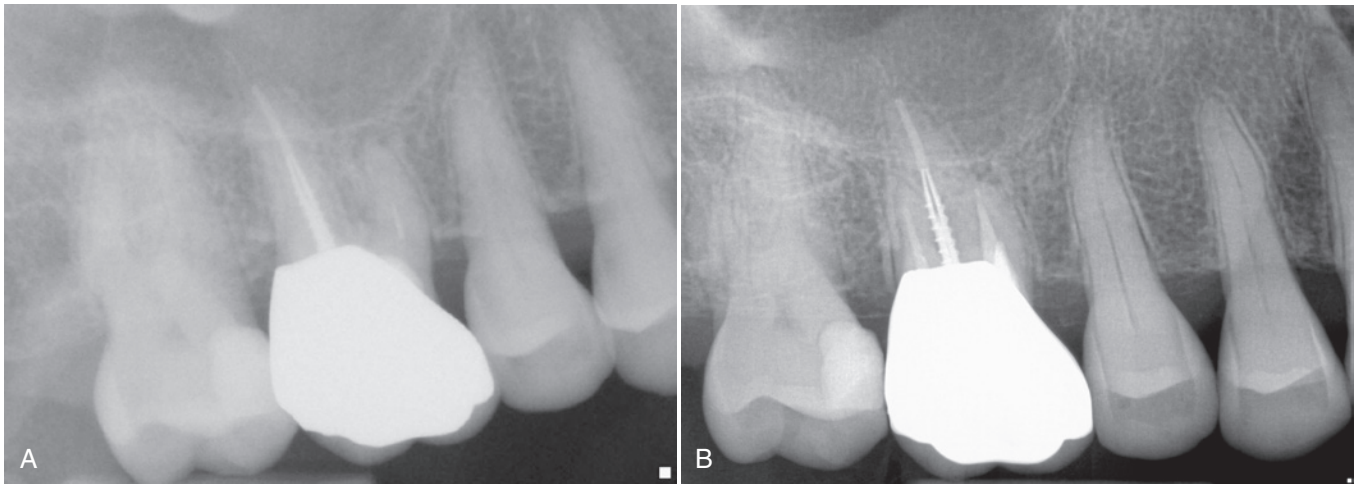

FIG. 26-3 **A**, A female patient at risk for osteonecrosis of the jaw had a symptomatic molar tooth with a broken instrument in the MB root. **B**, Nonsurgical root canal retreatment was performed on the MB root to avoid surgery.

discomfort. A disease process usually arises as an acute problem in children but assumes a more chronic or less dramatic form in the older adult. The *mere presence* of teeth indicates proper maintenance or resistance to disease. A lifetime of experiencing pain puts a different perspective on interpreting dental pain.

Pain associated with vital pulps (i.e., referred pain; pain caused by heat, cold, or sweets) seems to be reduced with age, and its severity seems to diminish over time. Heat sensitivity that occurs as the only symptom suggests a reduced pulp volume, such as that occurring in older pulps.[51] Pulpal healing capacity is also reduced, and necrosis may occur quickly after microbial invasion, again with reduced symptoms.

Although complaints are fewer, they are usually more conclusive evidence of disease. The complaint should isolate the problem sufficiently to allow the clinician to take a periapical radiograph before proceeding. Studying radiographs before an examination can prejudice rather than focus attention; accordingly, they should be reviewed *after* the clinical examination has been completed.

DENTAL HISTORY

The clinician should search patients' records and explore their memories to determine the history of involved teeth or surrounding areas. The history may be as obvious as a recent pulp exposure (Fig. 26-4) and restoration, or it may be as subtle as a routine crown preparation 15 or 20 years earlier (Fig. 26-5). Any history of pain before or after treatments may establish the beginning of a degenerative process. Subclinical injuries caused by repeated episodes of decay and its treatment may accumulate and approach a clinically significant threshold that can be later exceeded after additional routine procedures. Multiple restorations on the same tooth are common (Fig. 26-6).

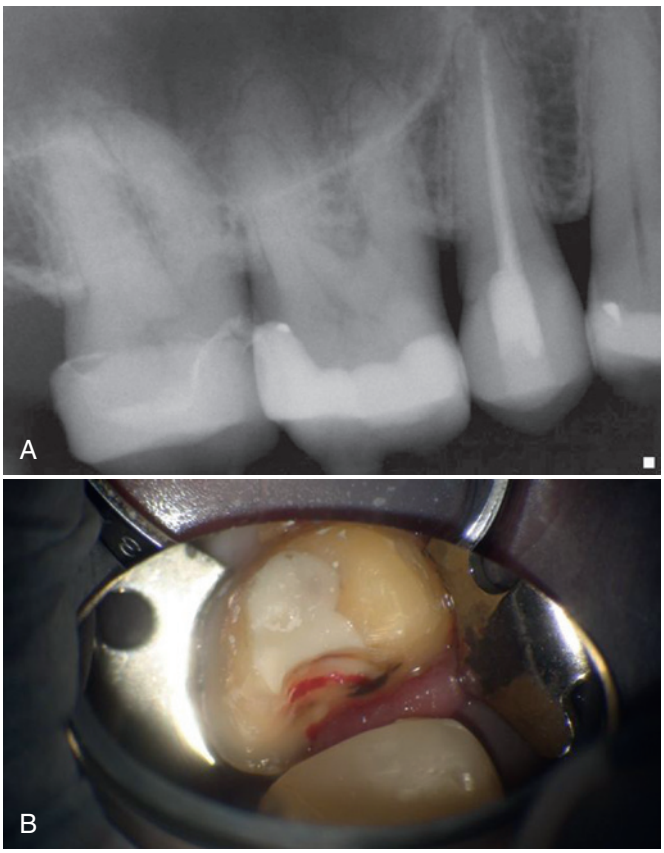

FIG. 26-4 **A,** Recent crown preparation of tooth #2 resulted in tooth ache pain. **B,** Removal of the temporary crown restoration revealed a pulp exposure along the mesial wall.

Recording information at the time of treatment may seem to be unnecessary "busy work," but it could prove to be helpful in identifying the source of a complaint or disease many years later. A patient's recall of dental treatments is usually limited to a few years, but the presence of certain materials or appliances, such as silver points, can sometimes date a procedure. Aging patients' dental histories are rarely complete and may indicate treatment by several clinicians at different locations. These patients are likely to have outlived at least one clinician and been forced to establish a relationship with a new, younger clinician. This new clinician may find dental needs that require an updated treatment plan.

Subjective Symptoms

The examiner can pursue responses to questions about the patient's complaint, the stimulus or irritant that causes pain, the nature of the pain, and its relationship to the stimulus or irritant. This information is most useful in determining whether the source of the pain is pulpal in origin, if the problem is reversible, and whether inflammation or infection has extended to the apical tissues. Thus the clinician can determine what types of tests are necessary to confirm findings or suspicions (see Chapter 1 for further information).

Diagnostic Procedures

It is important to remember that pulpal symptoms are usually chronic in older patients, and other sources of orofacial pain should be ruled out when pain is not soon localized. One example is herpes zoster, which commonly has a prodromal period of 2 to 4 days, when shooting pain, paresthesia, burning, and tenderness appear along the course of the affected nerve (Fig. 26-7). Although it rarely occurs in the maxillary or mandibular divisions of the trigeminal nerve, the viral eruptions may include peripheral nerve endings in the pulp and periodontal ligament (PDL), possibly leading to pulpitis, necrosis, or internal resorption and apical periodontitis.[41,42,80,84,92]

Much information obtained from the complaint, history, and description of subjective symptoms can be gathered in a screening interview by the clinician's assistant or over the phone by the receptionist. The potential need for treatment can be established, and the information obtained can provide a focus for the examination and for the determination of how much chair time will be required.

Objective Signs

The intraoral and extraoral clinical examination provides valuable firsthand information about disease and previous treatment. The overall oral condition should not be overlooked while the patient's chief complaint is evaluated, and all abnormal conditions should be recorded and investigated. Exposures to factors that contribute to oral cancers accumulate with age. Oral premalignant and malignant mucosal lesions require state-of-the-art diagnostic tools to ensure early diagnosis of these lesions.[87] Furthermore, many systemic diseases may initially manifest with prodromal oral signs or symptoms.[21]

Missing teeth contribute to reduced functional ability. The resultant loss of chewing efficiency leads to a higher

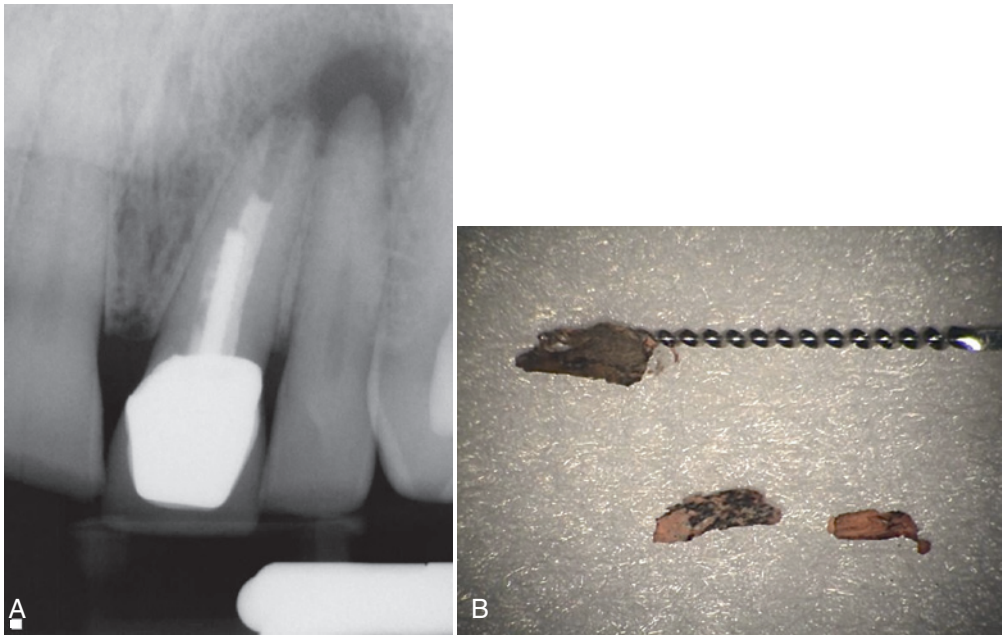

FIG. 26-5 A, This 70-year-old patient recalled having a crown and root canal procedure on this maxillary central incisor 20 years earlier. Teeth #9 and #10 were symptomatic, and radiographs revealed a periapical lesion associated with the root apices; previous root canal treatment of #9 showed an uncleaned and unfilled portion of the apical third of the root canal. B, Endodontic retreatment of #9 revealed that a cotton pellet had been left in the apical portion of the root canal. This contaminated pellet ultimately contributed to the symptomatic apical periodontitis.

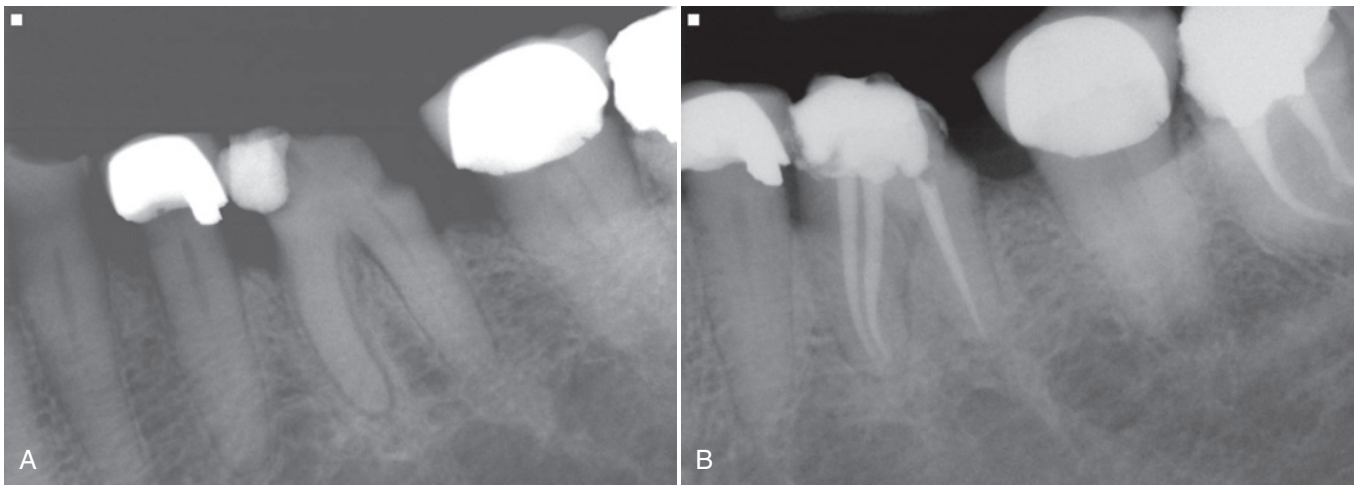

FIG. 26-6 A, Multiple restorations and a missing crown in this 71-year-old patient suggested repeated episodes of caries and restorative procedures, with pulpal effects that accumulated in the form of subclinical inflammation and calcification. B, Limited opening increased the difficulty of performing root canal treatment on calcified tooth #19.

carbohydrate diet of softer, more cariogenic foods. Increased sugar intake to compensate for loss of taste[34,68] and xerostomia[8] are also factors in the renewed susceptibility to decay. Saliva plays a significant role in the maintenance of oral and general health and may be of diagnostic value in evaluating overall health.[39] Aging per se has no significant clinical impact on salivary secretion. The most common cause of salivary hypofunction in the elderly is medication use, and it is most commonly associated with dental caries and oral fungal infections.[71,94]

Gingival recession, which creates sensitivity and is difficult to control, exposes cementum and dentin, which are less resistant to decay than enamel (Fig. 26-8). A clinical study of 600 patients over age 60 showed that 70% had root caries and 100% had some degree of gingival recession.[111] Caries and the use of removable prostheses can synergistically compromise tooth survival in older patients. Patients who wore prostheses and had multiple active carious teeth had the highest risk of losing teeth soon after the decay was treated.[17] The removal of root caries is irritating to the pulp and often results in pulp exposures, reparative dentin formation, or a deep restoration that could affect negotiation of the canal if root canal treatment is later needed (Fig. 26-9).[30] Asymptomatic pulp exposures on

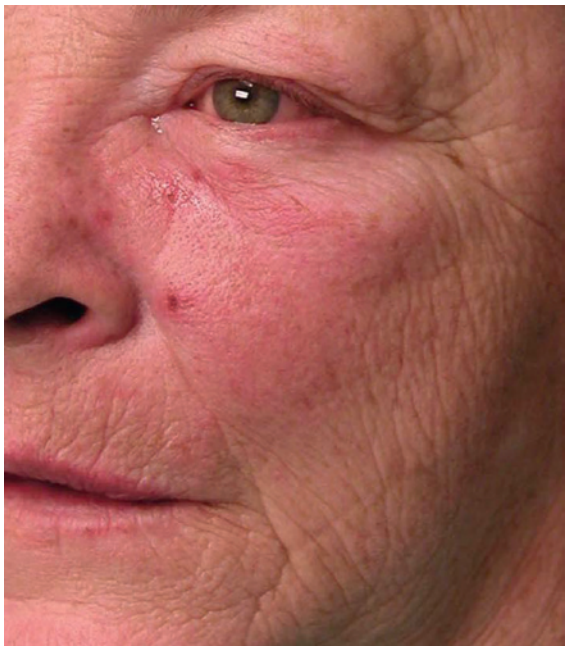

FIG. 26-7 Herpes zoster can cause dental pain and even pulpal involvement. Lesions eventually appeared as a diagnostic finding to confirm shingles.

FIG. 26-8 Missing teeth and the subsequent tilt, rotation, and supraeruption of adjacent and opposing teeth contributed to reduced functional ability and increased susceptibility to caries and periodontal disease.

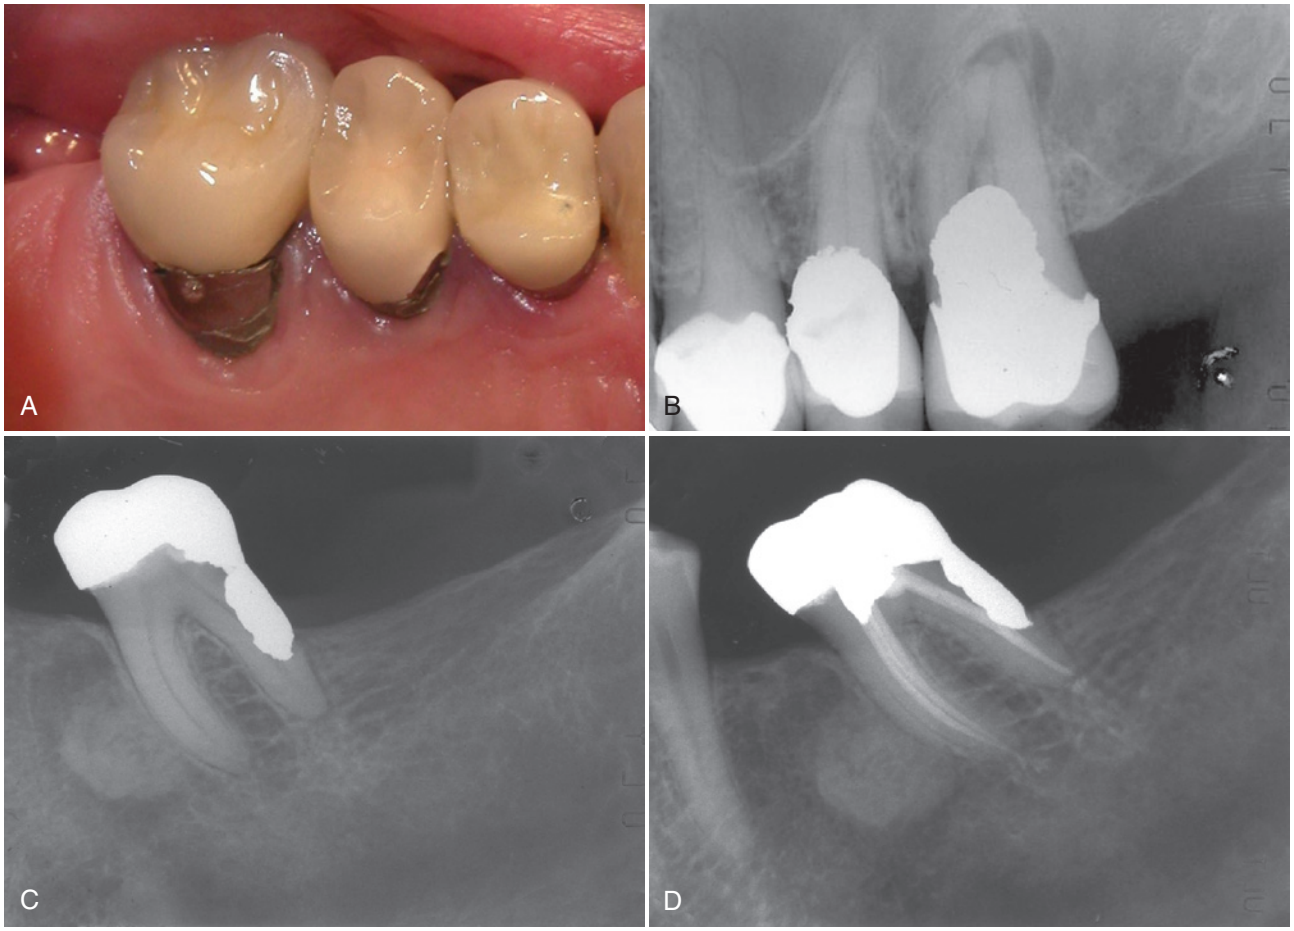

FIG. 26-9 Gingival recession exposed cementum and dentin, which are less resistant to caries. A and B, Restoration on the palatal root surface blocked access to the palatal canal. C and D, Root caries often results in pulp exposures that require endodontic treatment.

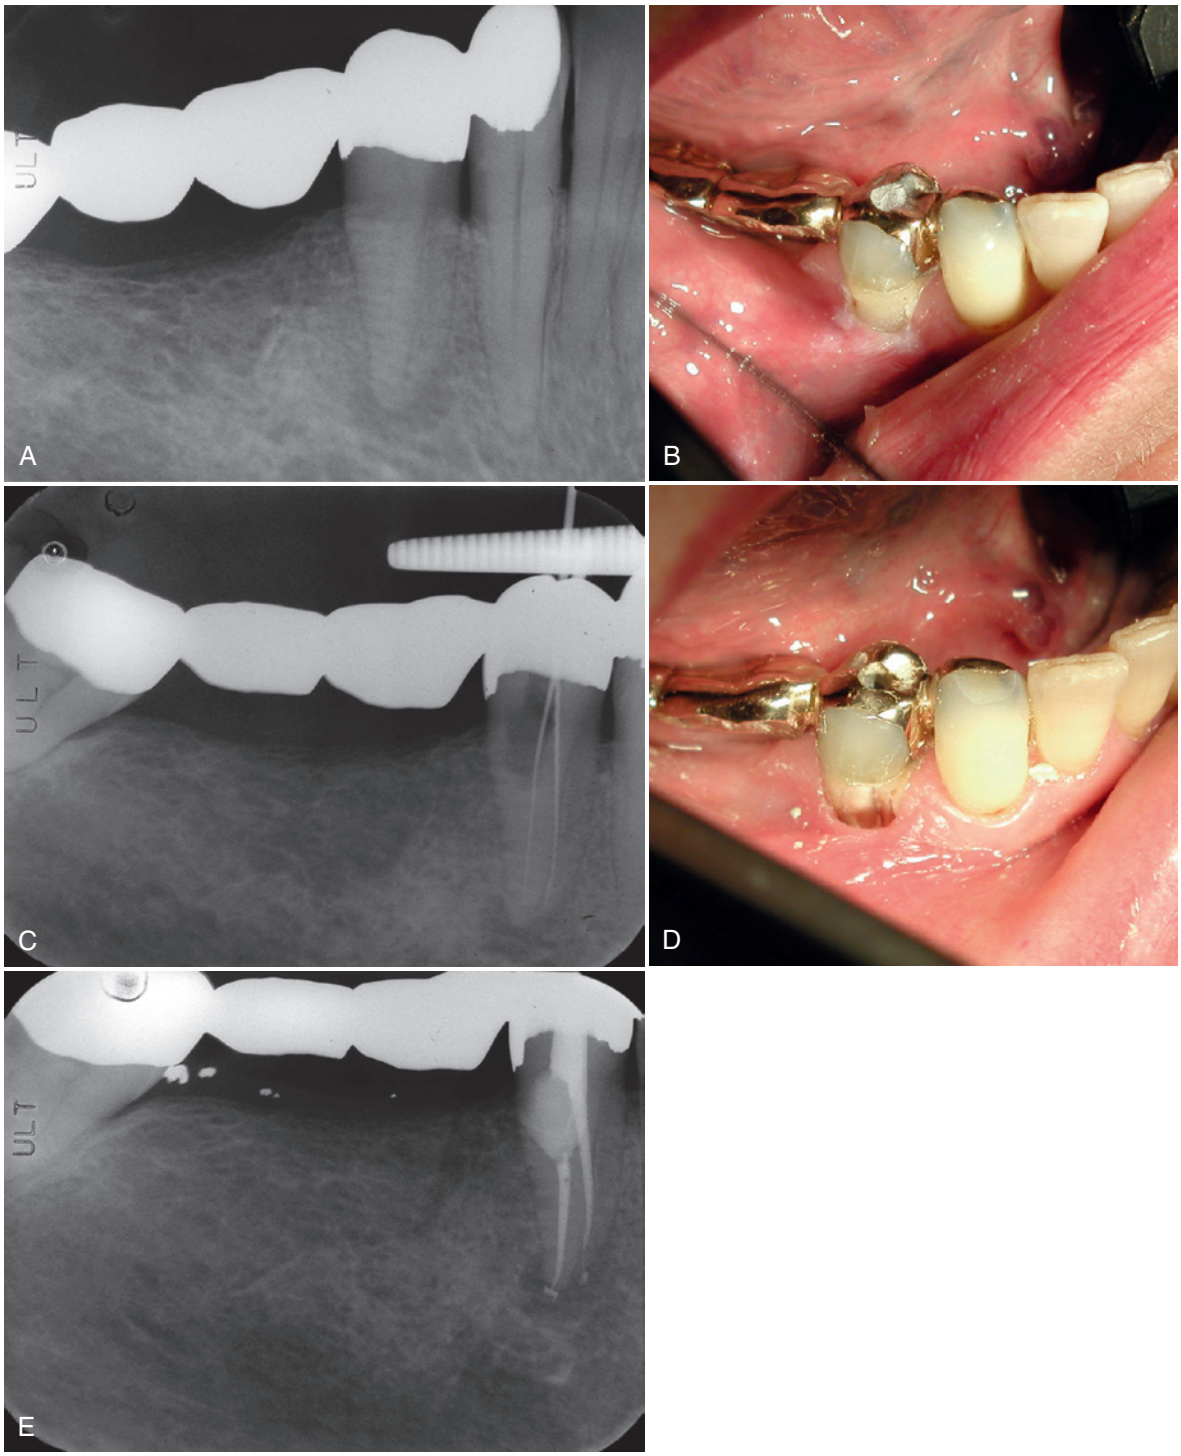

FIG. 26-10 A, Deep root caries that appeared to involve the pulp. B, Mesial abutment for a long fixed bridge. C, Canals were negotiated through the buccal access cavity. D, Buccal canal access. E, Treatment was completed, and the access cavity was permanently restored.

one root surface of a multirooted tooth can result in the uncommon clinical situation of the presence of both vital and nonvital pulp tissue in the same tooth (Fig. 26-10).

Interproximal root caries is difficult to restore, and restoration failure as a result of continued decay is common (Fig. 26-11). Although the microbiology of diseases is not substantially different in different age groups, the altered host response during aging may modify the progression of these diseases.[102]

Attrition (see Fig. 26-11), abrasion, and erosion (Fig. 26-12) also expose dentin through a slower process that allows the pulp to respond with dentinal sclerosis and reparative dentin.[95] Secondary dentin formation occurs throughout life and may eventually result in almost complete pulp obliteration. In maxillary anterior teeth, the secondary dentin is formed on the lingual wall of the pulp chamber[78]; in molar teeth, the greatest deposition occurs on the floor of the chamber.[13] Although this

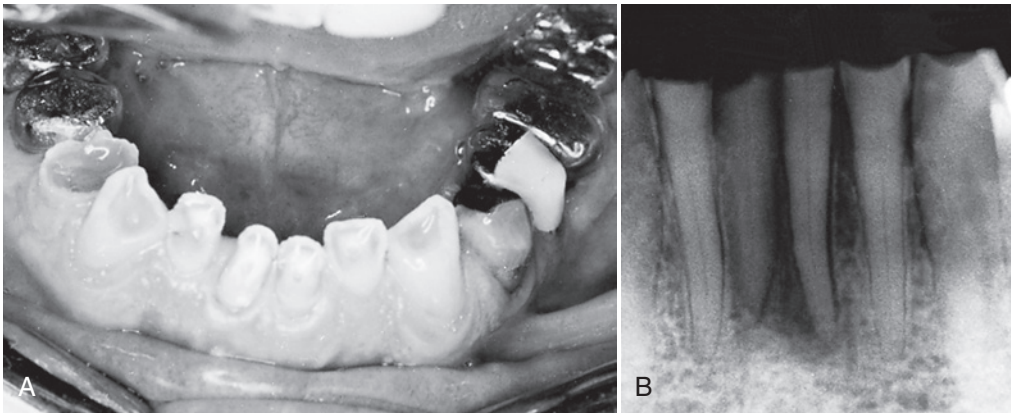

FIG. 26-11 A, Attrition exposes dentin through a slow process that allows the pulp to respond with reparative dentin, but pulp exposure eventually becomes clinically evident (B).

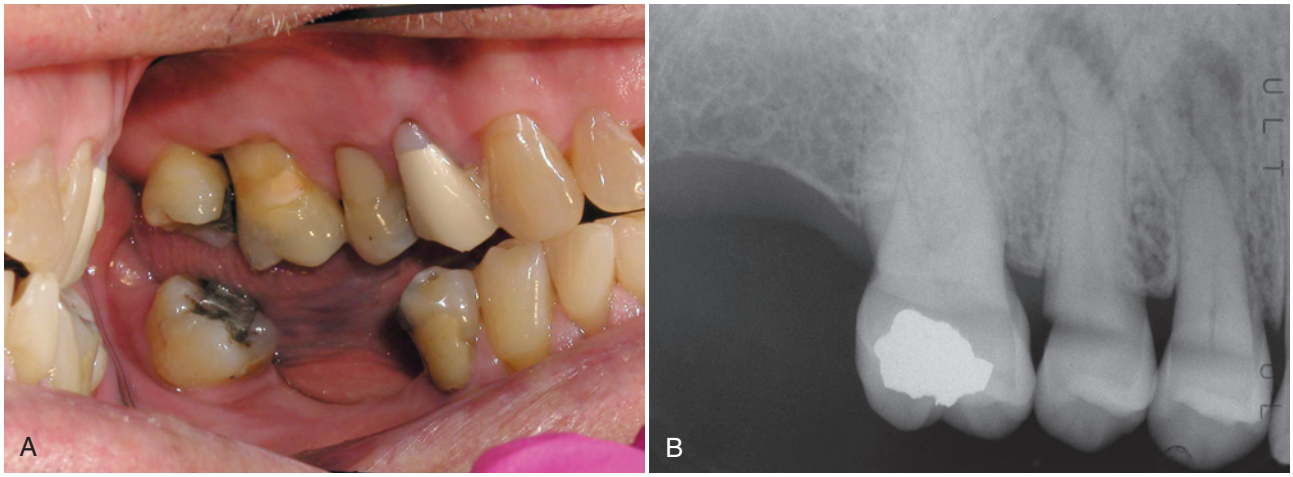

FIG. 26-12 Gingival recession also exposes cementum and dentin, which are less resistant to abrasion and erosion. This can result in exposure of the pulp or require restorative procedures that could cause pulp irritation.

pulp may appear to recede, small pulpal remnants may remain or leave a less calcific, more permeable, tract that may lead to pulp exposure.

In general, canal and chamber volume is inversely proportional to age: as age increases, canal size decreases (Fig. 26-13). Reparative dentin resulting from restorative procedures, trauma, attrition, and recurrent caries also contributes to diminution of canal and chamber size. In addition, the cementodentinal junction (CDJ) moves farther from the radiographic apex with continued cementum deposition (Fig. 26-14).[57] The thickness of young apical cementum[85] is 100 to 200 µm, and it increases with age to two or three times that thickness.[116]

The calcification process associated with aging appears clinically to be of a more linear type than that which occurs in a younger tooth in response to caries, pulpotomy, or trauma (Fig. 26-15). Dentinal tubules become more occluded with advancing age, reducing tubular permeability.[67] Lateral and accessory canals can calcify, thus decreasing their clinical significance.

The compensating bite produced by missing and tilted teeth (or attrition) can cause temporomandibular joint (TMJ) dysfunction (less common in older adults) or loss of vertical dimension. Diminished eruptive forces occur with age, reducing the amount of mesial drift and supraeruption.[86] Any limitation in opening reduces available working time and the space needed for instrumentation.

The presence of multiple restorations indicates a history of repeated insults and an accumulation of irritants. Marginal leakage and microbial contamination of cavity walls are a major cause of pulpal injury.[15] Violating principles of cavity design combined with the loss of resiliency that results from a reduced organic component to the dentin can increase susceptibility to cracks and cuspal fractures. In any further restorative procedures on such teeth, the clinician should consider the effect on the pulp and the effect on gaining access to and negotiating canals through such restorations if root canal therapy is indicated later.

Many cracks or craze lines (see Fig. 26-12) may be evident as a result of staining, but they do not indicate dentin penetration or pulp exposure.[18,50] Pulp exposures caused by cracks are less likely to present acute problems in older patients and often penetrate the sulcus to create a periodontal defect in addition to a periapical one. If incomplete cracks are not detected early, the prognosis for cracked teeth with necrosis is questionable (Fig. 26-16).[10]

Periodontal disease may be the principal problem for dentate seniors.[25] The relationship between pulpal and

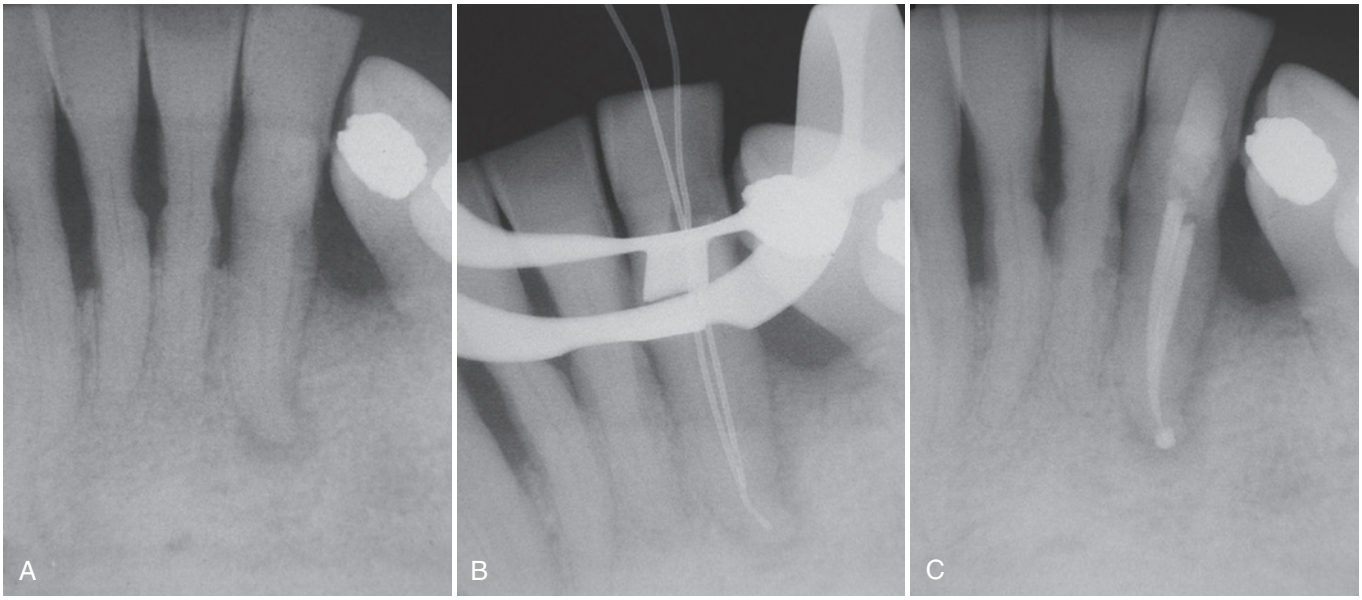

FIG. 26-13 A, In general, canal chamber volume is inversely proportional to age. As age increases, canal and chamber volume decreases, as seen in these lower incisor teeth in a 90-year-old patient. B, After both canals in tooth #23 were instrumented, final disinfection was performed. Two 30-gauge side-vented irrigation needles are seen here inserted to working length. C, Treatment was completed for these calcified canals, and obturation was performed using GuttaCore.

FIG. 26-14 Radiographic image of tooth #15 in an older individual shows increased cementum deposition with age.

FIG. 26-15 This radiograph illustrates pulp volume changes in mandibular premolars. Left to right, A normal pulp; reparative dentin adjacent to a shallow restoration; more extensive reparative dentin adjacent to a more extensive restoration; and the overall reduced volume that occurs during aging.

periodontal disease can be expected to be more significant with age. Retention of teeth alone demonstrates some resistance to periodontal disease. The increase in disease prevalence is largely attributable to an increase in the proportional size of the population who have retained their teeth.[61] The periodontal tissues must be considered a pathway for sinus tracts (Fig. 26-17). Narrow, bony-walled pockets associated with nonvital pulps are usually sinus tracts, but they can be resistant to root canal therapy alone when, with time, they become chronic periodontal pockets. Patients with diabetes have increased periodontal disease in endodontically treated teeth and have a reduced likelihood of success of endodontic treatment in cases with preoperative periradicular lesions.[33]

Periodontal treatment can produce root sensitivity, disease, and pulp death.[60] In developing a successful treatment plan, it is important that the clinician determine the effects of periodontal disease and its treatment on the pulp (Fig. 26-18). Age was not a factor in response to periodontal therapy for advanced periodontal tissue breakdown.[59] The mere increase in incidence and severity of periodontal disease with age increases the need for combined therapy. The chronic nature of pulp disease demonstrated with sinus tracts can often be manifested in a periodontal pocket. Root canal treatment is commonly indicated before root amputations are performed. With age, the size and number of apical and accessory foramina are actually reduced, which reduces these foramina's function as pathways

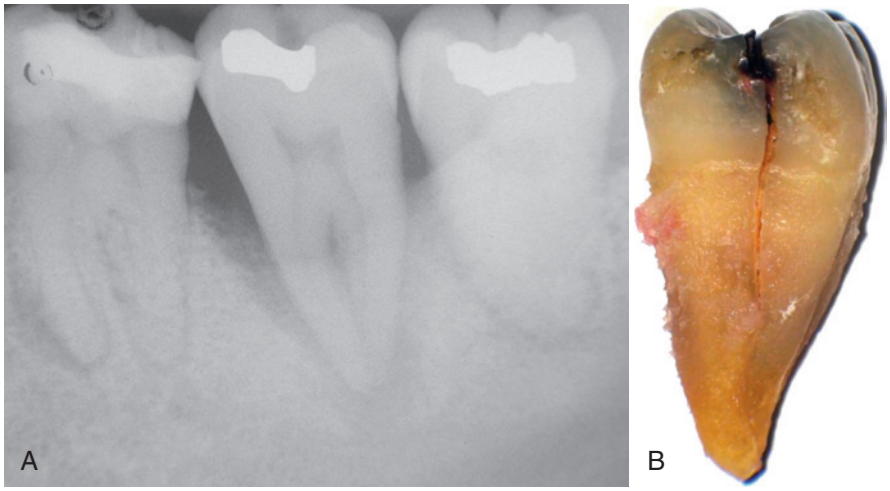

FIG. 26-16 A split tooth should always be considered when a nonvital pulp and chronic apical periodontitis are evident on a minimally restored or nonrestored tooth. The crack usually extends into the periodontium, and the prognosis generally is hopeless.

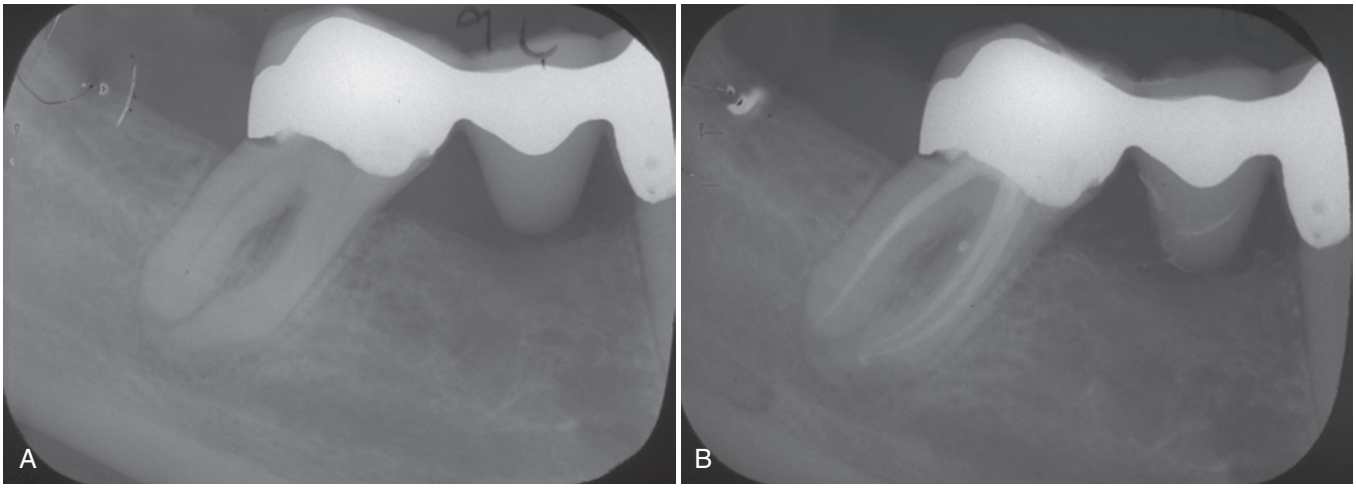

FIG. 26-17 A, A deep periodontal pocket is probed in the buccal furcation on this mandibular molar abutment. B, This could indicate pulpal or periodontal disease, or both. Root canal treatment resulted in reduction of the pocket depth, confirming the pulpal cause of this periradicular lesion.

of communication.[83] The permeability of dentinal tubules also is reduced.

Examination of sinus tracts should include tracing with gutta-percha cones to establish the tracts' origins (Fig. 26-19). Sinus tracts may have long clinical histories and usually indicate the presence of chronic periapical inflammation. Their disappearance after treatment is an excellent indicator of healing. The presence of a sinus tract reduces the risk of interappointment or postoperative pain, although drainage may follow canal debridement or filling.

Pulp Testing

Information collected from the patient's complaint, history, and examination may be adequate to establish pulp vitality and direct the clinician toward the techniques that are most useful in determining which tooth or teeth are the object of the complaint. During pulp testing, it is often very difficult to quantify the response to a stimulus applied to a tooth; age can also be a factor in sensitivity testing.[72] Slow and gentle testing should be done to determine pulp and periapical status and whether palliative or definitive therapy is indicated. Vitality responses must correlate with clinical and radiographic findings and must be interpreted as a supplement in developing clinical judgment. (Techniques for clinical pulp testing procedures are discussed in Chapter 1.)

Transilluminating[79] and staining have been advocated as means to detect cracks, but the presence of cracks is of little significance in the absence of complaints because most older teeth, especially molars, demonstrate some cracks. Vertically cracked teeth should always be considered a pathway for bacteria when pulpal or periapical disease is observed, especially where there is little or no cause for pulpal irritation observed clinically or radiographically. The high magnification available with microscopes during access opening and canal exploration permits visualization of the extent of cracks in determining the prognosis. Abbot[1] showed that 60% of all teeth requiring endodontic treatment demonstrated cracks after the complete removal of all restorations.

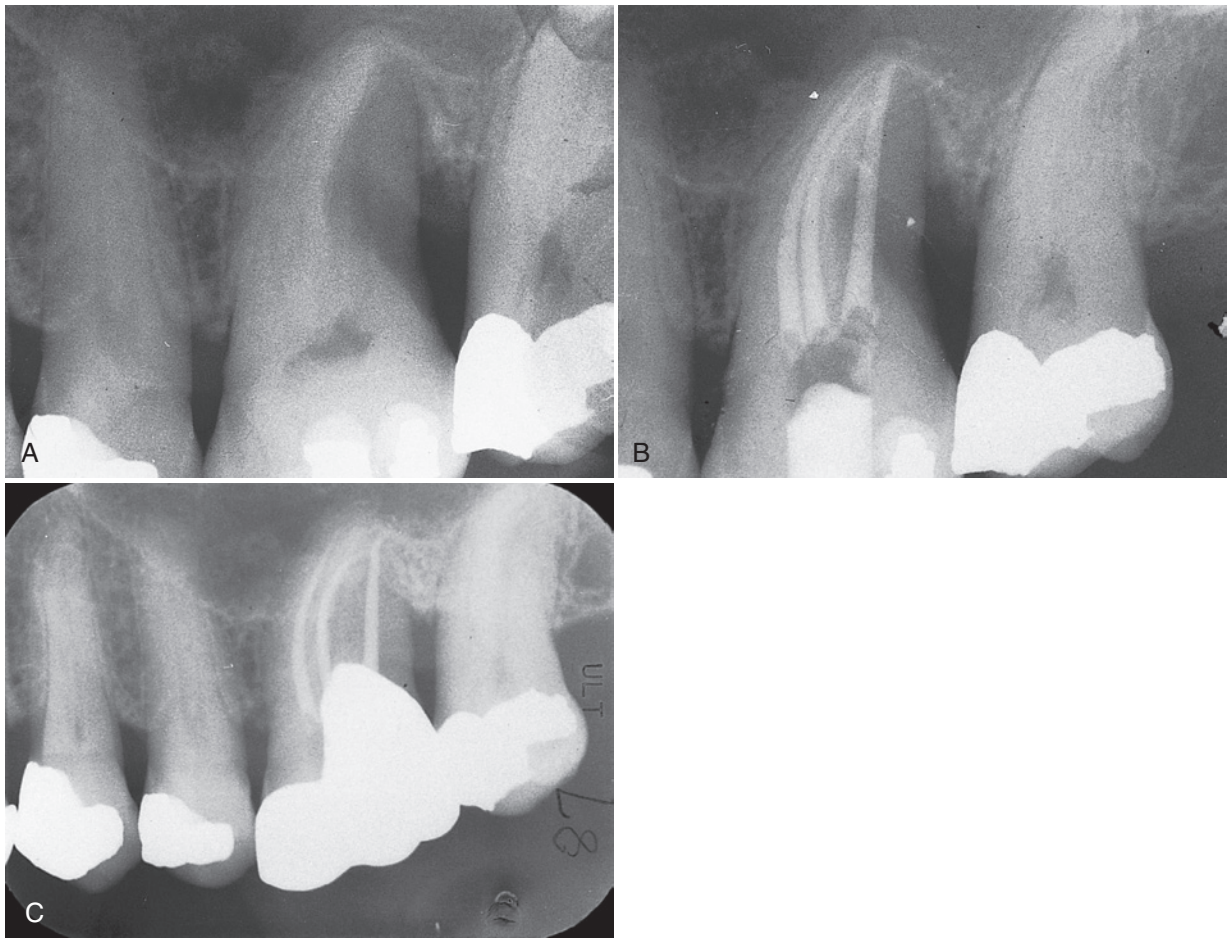

FIG. 26-18 A, Unexpected root amputation on vital pulps may occur during periodontal surgery. This requires root canal treatment on the remaining roots (B) and a crown with good marginal adaptation (C).

Cracks that are detected while the pulp is still vital can offer a reasonable prognosis if immediately restored with full cuspal coverage.[56] The chronic nature of any periapical pathologic condition caused by vertically cracked teeth indicates that it is longstanding, and the prognosis is questionable[10] (even when pocket depths appear normal). Periodontal pockets associated with cracks indicate a poor prognosis.[46]

The reduced neural and vascular components of aged pulps,[12] the overall reduced pulp volume, and the change in character of the ground substance[96] create an environment that responds differently to both stimuli and irritants than does that of younger pulps (Fig. 26-20). Arteriosclerosis, a common condition in older people, has not been shown to occur in the pulp.[55]

Fewer nerve branches are present in older pulps. This may be due to retrogressive changes resulting from mineralization of the nerve and nerve sheath (Fig. 26-21).[11] Consequently, the response to stimuli may be weaker than in the more highly innervated younger pulp.

No correlation exists between the degree of response to electric pulp testing and the degree of inflammation. The presence or absence of response is of limited value and must be correlated with other tests, examination findings, and radiographs.[72] Extensive restorations, pulp recession, and excessive calcifications are limitations in both performing and interpreting results of electric and thermal pulp testing. An alternative to the electric pulp test is assessment of pulp vitality by applying a thermal stimulus to the tooth surface. The electric pulp tester, CO_2 snow, and difluorodichloromethane were found to be more reliable than ethyl chloride or ice in producing a positive response.[37] Attachments that reduce the amount of surface contact necessary to conduct the electric stimulus are available (SybronEndo, Orange, California), and bridging the tip to a small area of tooth structure with an explorer has been suggested.[76] Use of even this small electric stimulus in patients with pacemakers[113] is not recommended; any such risk would outweigh the benefit. The same caution holds true for electrosurgical units.

A test cavity is generally less useful as the test of last resort because of reduced dentin innervation. Vital pulps can sometimes be exposed and even negotiated with a file with minimal pain (Fig. 26-22); then the root canal treatment becomes part of the diagnostic procedure. Test cavities should be used only when other findings are suggestive but not conclusive.

Diffuse pain of vague origin is also uncommon in older pulps and limits the need for selective anesthesia. Pulpal disease is progressive and produces diagnostic signs or symptoms in a relatively short time. Nonodontogenic sources should be considered when factors associated with pulpal disease are not readily identified or when acute pain does not localize within a short time.

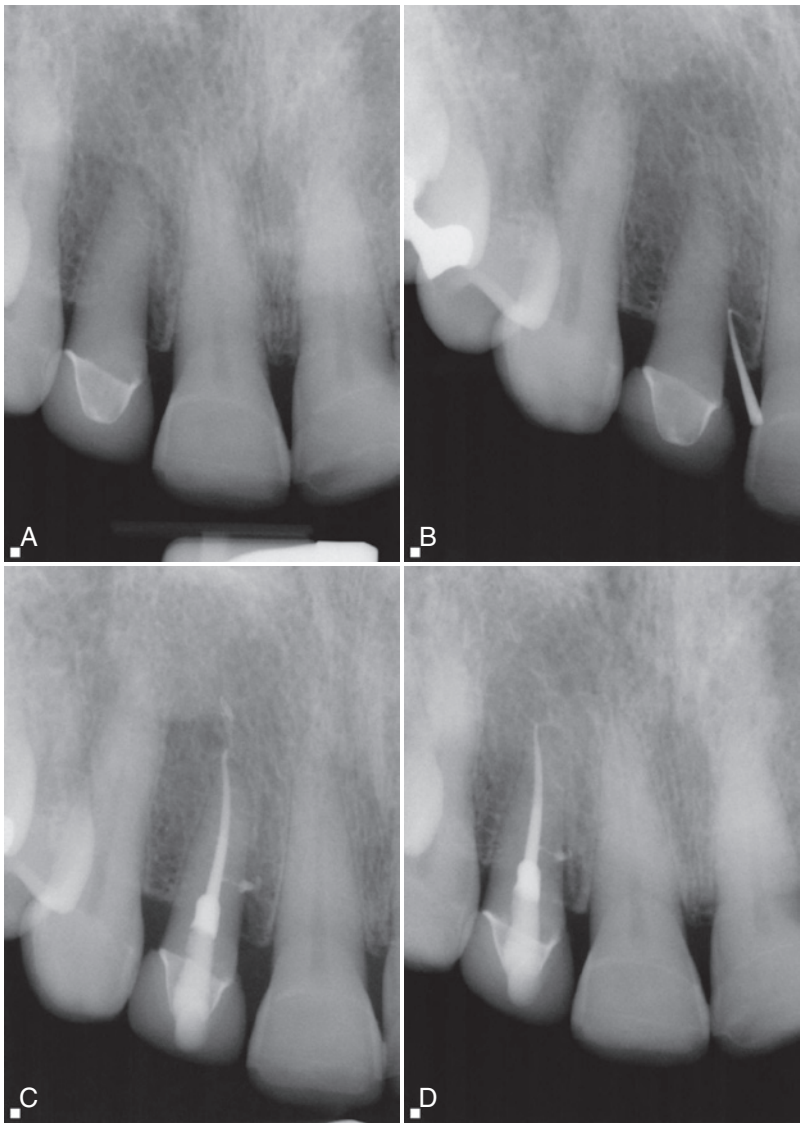

FIG. 26-19 A, This radiograph shows that tooth #7 has a well-fitting crown, but it also has periradicular inflammation along the mesial root surface. B, The origin of a sinus tract is traced with a gutta-percha point. C, Very challenging root canal treatment saved this valuable tooth. D, At the 6-month recall examination, the sinus tract was healing, and the patient was asymptomatic.

FIG. 26-20 The cellularity of older pulp tissue gradually decreases. Odontoblasts decrease in size and number and may disappear altogether in certain areas, particularly on the pulpal floor in multirooted teeth.

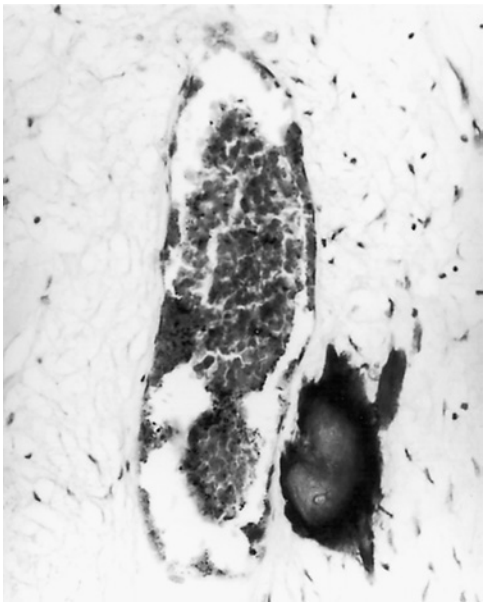

FIG. 26-21 Fibrosis appears to occur along the pathways of degenerated vessels and may serve as foci for pulpal calcification.

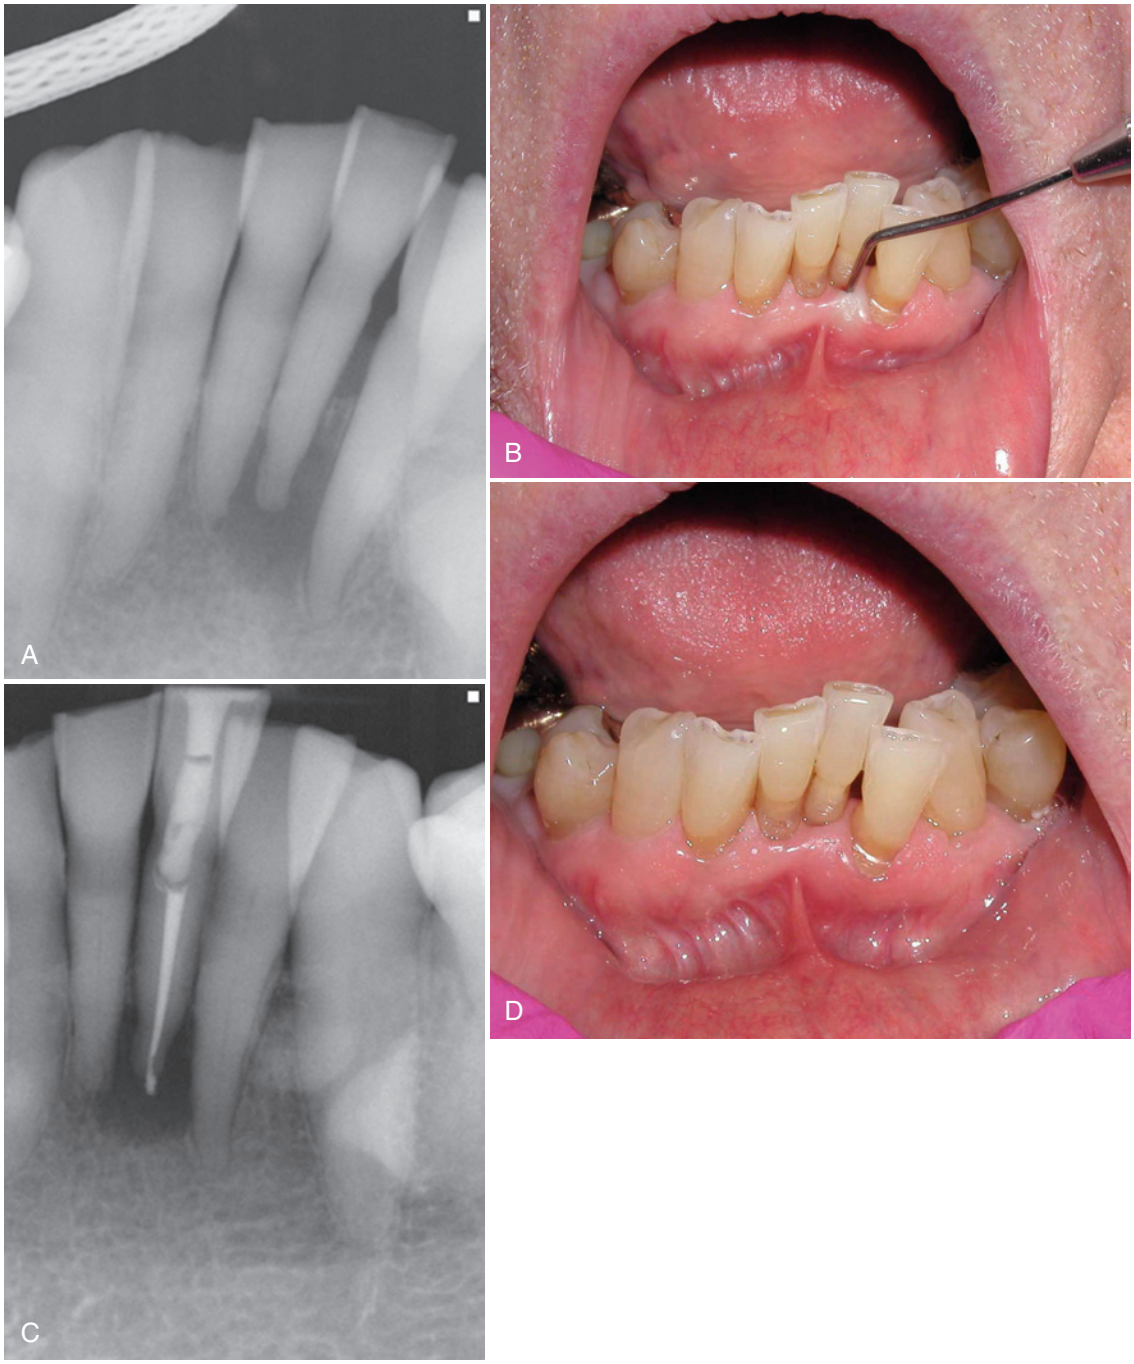

FIG. 26-22 A and B, Vital pulp testing was inconclusive for this 91-year-old patient. C and D, Treatment was performed without local anesthesia to confirm pulp status.

Discoloration of single teeth may indicate pulp death, but this is a less likely cause of discoloration with advanced age. Dentin thickness is greater, and the tubules are less permeable to blood or breakdown products from the pulp. Dentin deposition produces a yellow, opaque color that would indicate progressive calcification in a younger pulp, but this is common in older teeth.

Radiographs

Indications and techniques for taking radiographs do not differ much among adult age groups. However, several physiologic and anatomic changes can significantly affect their interpretation. Film placement may be adversely affected by tori but can be assisted by the apical position of muscle attachments that increase the depth of the vestibule. Older patients may be less capable of assisting in film placement, and holders that secure the position should be considered. The presence of tori, exostoses, and denser bone (Fig. 26-23) may require increased exposure times for proper diagnostic contrast. The subjective nature of interpretation can be reduced with correct processing, proper illumination, and magnification.

The periapical area must be included in the diagnostic radiograph, which should be studied from the crown toward the apex. Angled radiographs should be ordered only if the

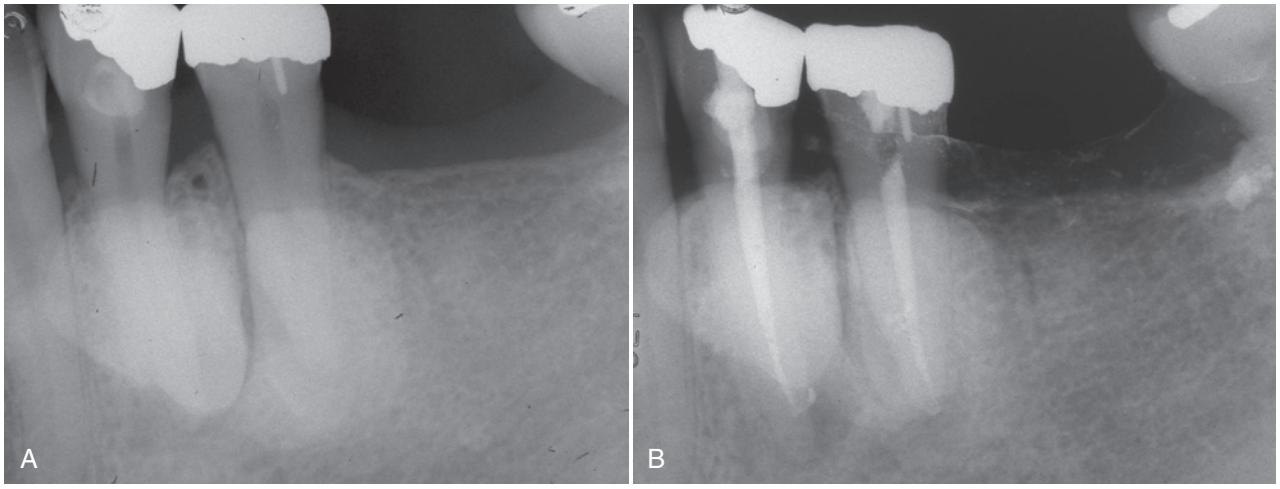

FIG. 26-23 Mandibular tori can make periapical radiography challenging. Such dense bone may indicate the need for increased exposure times to improve the contrast needed to see the canal and root anatomy.

original diagnostic radiograph suggests that more information is needed for diagnosis or to determine the degree of treatment difficulty. Digital radiography may be more useful than conventional radiography in detecting early bone changes.[115] Cone beam computed tomography (CBCT) is a very promising adjunct for a more accurate assessment of changes in the root supporting structures.[20,28,108]

In older patients, pulp recession is accelerated by reparative dentin and complicated by pulp stones and dystrophic calcification. Deep proximal or root decay and restorations may cause calcification between the observable chamber and root canal.

The depth of the chamber should be measured from the occlusal surface and its mesiodistal position noted. Receding pulp horns that are apparent on a radiograph may remain microscopically much higher. Deep restorations or extensive occlusal crown reduction may produce pulp exposures that were not expected. The axial inclinations of crowns may not correlate with the clinical observation when tilted teeth have been crowned or become abutments for fixed or removable appliances. Access to the root canals is the most limiting condition in root canal treatment of older patients.

Canals should be examined for their number, size, shape, and curvature. Pulp has been demonstrated histologically even when not visible on radiographs, but in general, the two measurements did not differ even when pulp calcifications were present.[58] Comparisons with adjacent teeth should be made. Small canals are the rule in older patients. Midroot disappearance of a detectable canal may indicate bifurcation rather than calcification. Canals calcify evenly throughout their length unless an irritant (e.g., caries, restoration, cervical abrasion) has separated the chamber from the root canal. Root-end fillings during root-end resection (more common during retreatment of older patients) indicate missed canals and roots as a common cause of failure.[2]

The lamina dura should be examined in its entirety and anatomic landmarks distinguished from periapical radiolucencies and radiopacities. The incidence of some odontogenic and nonodontogenic cysts and tumors characteristically increases with age, and this should be considered when vitality tests do not correlate with radiographic findings. However, the incidence of osteosclerosis and condensing osteitis decreases with age.

Resorption associated with chronic apical periodontitis may significantly alter the shape of the apex and the anatomy of the foramen through inflammatory osteoclastic activity (Fig. 26-24).[23] The narrowest point in the canal may be difficult to determine; it is positioned farther from the radiographic apex because of continued cementum deposition.

A continued normal rate of cementum formation may be demonstrated by a canal or foramen that appears to end or exit short of the radiographic apex, and hypercementosis (Fig. 26-25) may completely obscure the apical anatomy.

DIAGNOSIS AND TREATMENT PLAN

A clinical classification that accurately reflects the histologic status of the pulp and periapical tissues is not possible and not necessary beyond determining whether root canal treatment is indicated. A clinical judgment can be made based on the patient's complaint, history, signs, symptoms, testing, and radiographs as to the vitality of the pulp and the presence or absence of periapical pathologic conditions. This classification has not been shown to be a factor in predicting success, interappointment or postoperative pain, or the number of visits necessary to complete treatment when the objectives of cleaning, shaping, and filling are clearly understood and consistently met.[35] Of great clinical significance in treatment procedures is the assessment of pulp status to determine the depth of anesthesia necessary to perform the treatment comfortably.

One-appointment procedures offer obvious advantages to older patients. No detectable difference was found in the effectiveness of root canal treatment in terms of radiologic success between single and multiple visits.[32] The length of a dental appointment does not usually cause inconvenience, as may more numerous appointments, especially if a patient must rely on another person for transportation or needs physical assistance to get into the office or operatory.

Root canal treatment as a restorative expediency on teeth with normal pulps must be considered when cusps have fractured or when supraerupted or malaligned teeth, intracoronal

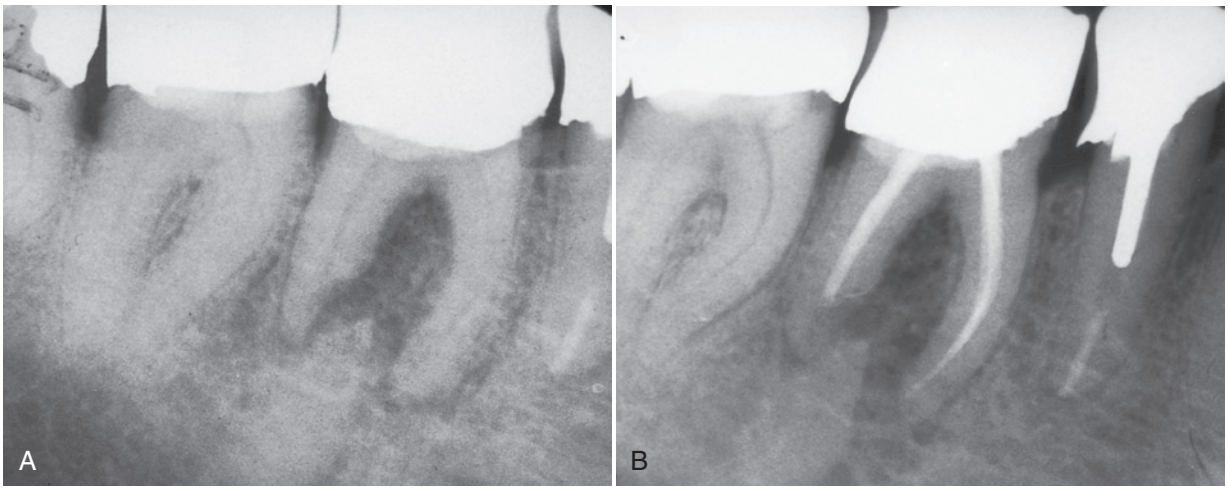

FIG. 26-24 A, Resorption associated with chronic apical periodontitis may alter the shape and position of the foramen through osteoclastic activity. B, The narrowest point in the canal is now positioned farther from the radiographic apex.

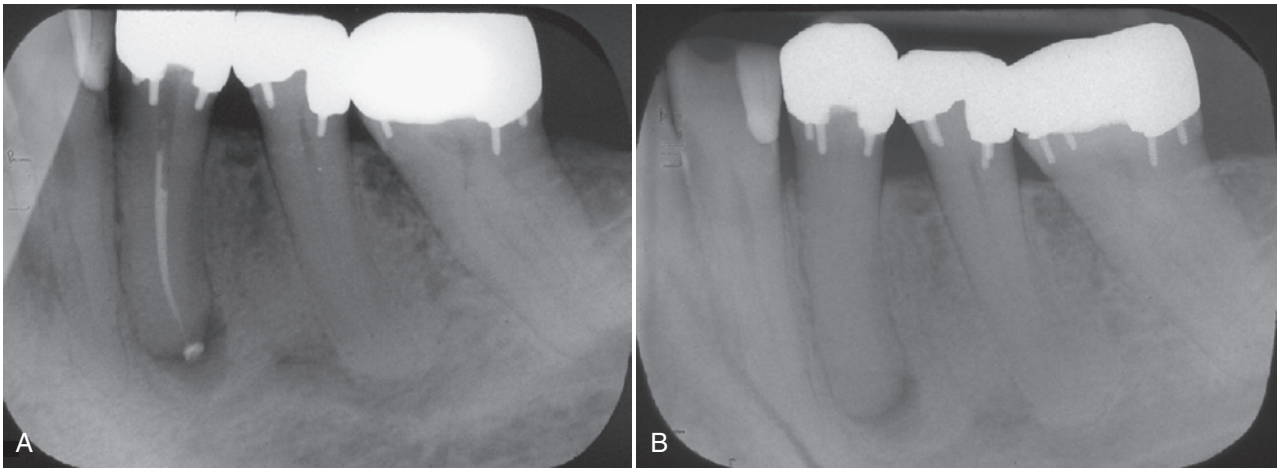

FIG. 26-25 A, Hypercementosis may completely obscure the apical anatomy and result in a constriction farther from the radiographic apex (B).

attachments, guide planes for partial abutments, rest seats, or overdentures require significant tooth reduction (Fig. 26-26). Predicting the need for future root canal treatment and a clinician's ability to perform treatment later are even more important because the risk of losing the restoration during later access preparation increases with the thickness of the restoration and the reduction in canal size (Fig. 26-27). Because of a reduced blood supply, pulp capping is not as successful in older teeth as in younger ones, so it is not recommended. Any risk to the patient's future health and the effect health may have on his or her ability to withstand future procedures should also be considered. Endodontic surgery at a later time is not as viable an alternative as for a younger patient.

Consultation and Consent

Good communication should be established and maintained with all patients, regardless of whether they are physically impaired or unable to make treatment decisions for themselves. Relatives or trusted friends should be included in consultations if their judgment is valued by the patient or needed for consent, but the clinician should direct the discussion toward the patient (Fig. 26-28).

Clinicians should explain procedures in a way that is completely comprehensible and provides an opportunity for questions from the patient. Patient-friendly pamphlets are available from the American Association of Endodontists (AAE) that thoroughly explain and illustrate most endodontic procedures. A signed consent to outlined treatment is required and may be especially useful if the patient is forgetful or feels challenged by his or her understanding of the technology of current communication techniques.

Determining the patient's desires is as important as determining his or her needs, and it is required in obtaining informed consent (Fig. 26-29). Priorities in treating pain and infection to properly and aesthetically restore teeth to health and function should be unaffected by age (Fig. 26-30). A patient's limited life expectancy should not appreciably alter treatment plans and is no excuse for extractions or poor root canal treatment. It is important that all older patients be well informed of risks and alternatives (Fig. 26-31, *A*). Patients deserve a

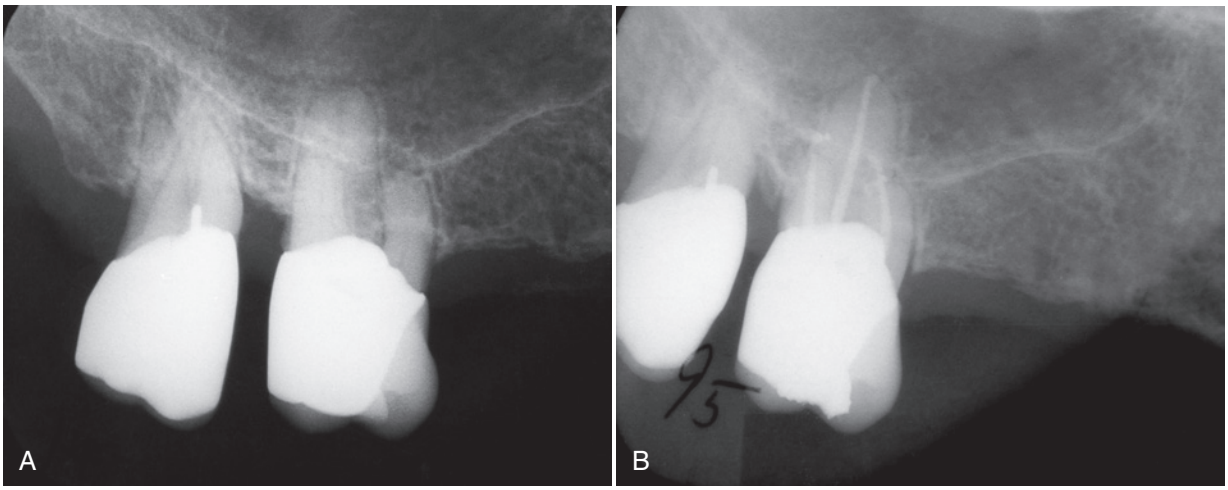

FIG. 26-26 A, Valuable maxillary first- and second-molar abutments in an 85-year-old patient. B, Later need for endodontic therapy was made very challenging because of access abutments.

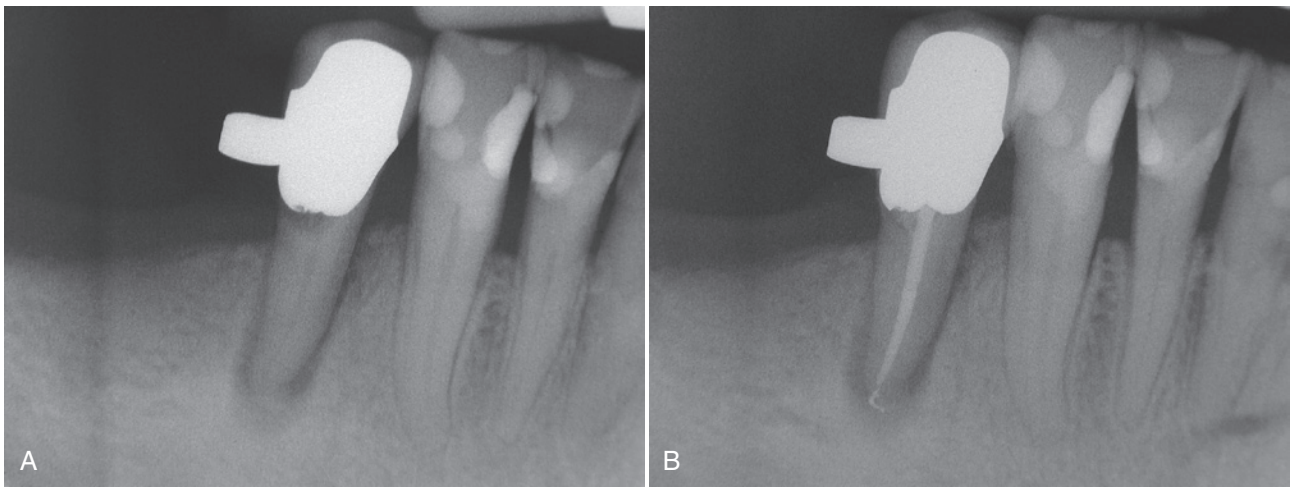

FIG. 26-27 A, Intracoronal attachments, guide planes, and rest seats for partial abutments require significant tooth reduction and a bulk of metal that makes endodontic treatment more likely and difficult. This patient was referred because the root canal could not be located. B, Successful treatment and preservation of the restoration when the canal is small are challenges to the most skilled clinician. An intracoronal post and perforation repair was done for this compromised tooth.

better explanation for their disease than that it is caused by age. When a physician told one patient that the problem with his knee was due to age, the patient replied, "The other knee is the same age, and nothing is wrong with it."

Acceptance of the eventual loss of teeth has been replaced by an understanding of the psychological and functional importance of maintaining dentition. Older patients whose lives have been changed for the worse by a previous surgical procedure may readily recognize the implications of the loss of teeth. Although older patients prefer to save their natural teeth, the retention rate of restored implants compares favorably to restored root canal–filled teeth.[3,48] The implant-retained mandibular overdenture is often the most desired choice for an edentulous mandible (Fig. 26-31, *B*).[22]

The capability of the clinician and the availability of endodontic specialists should also be considered. The obligation to offer root canal treatment as an alternative to extraction may exceed a clinician's ability to perform the procedure efficiently or successfully, and referral may be indicated. Older patients are more likely to be aware that specialists are available who can perform root canal surgery, but patients usually trust and do what their clinician recommends. In advance of the scheduled visit, the referring clinician should provide the endodontist with as much information about the patient as possible (and thoroughly explain the reason for referral to the patient). To support treatment adherence and understanding, the clinician should consider making the referral appointment for the patient while the person is in the dental office and follow up to determine compliance.

Obtaining informed consent before dental procedures usually is not a problem. However, if a patient is medically compromised or cognitively impaired, it may be difficult to acquire valid informed consent. Neuropsychiatric impairment may result in gross manifestations and indicate a reduced level of competency. Physicians or mental health experts should be consulted as needed, and no elective procedures should be

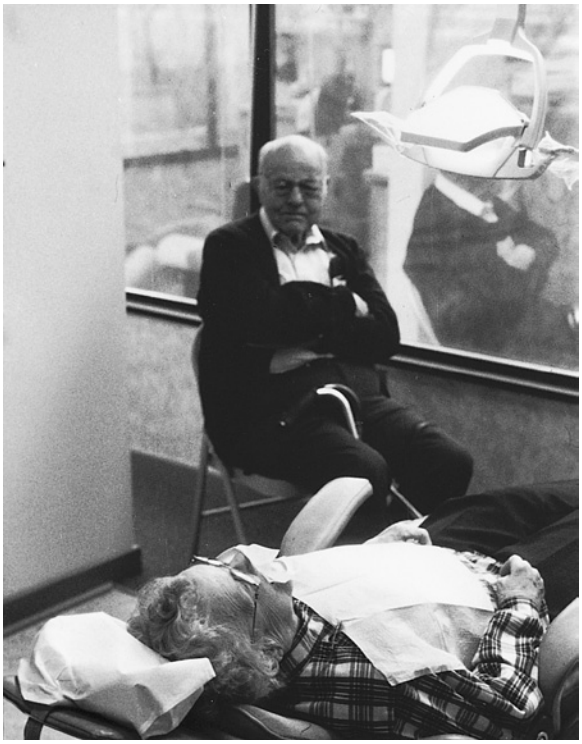

FIG. 26-28 Some patients may request or require that a family member be present during consultation or treatment.

FIG. 26-29 Many geriatric patients benefit from the use of a pillow for neck support.

performed until valid consent is established. Fortunately, acute pulpal and periapical episodes in which immediate treatment is indicated for pain or infection are less common than the low-grade signs and symptoms of chronic disease.

TREATMENT

Most geriatric patients who need and demand endodontic therapy are ambulatory and not institutionalized. Institutionalized and nonambulatory patients require clinicians trained in those environments and facilities designed for access to dental health care. Such access is a benefit required in most

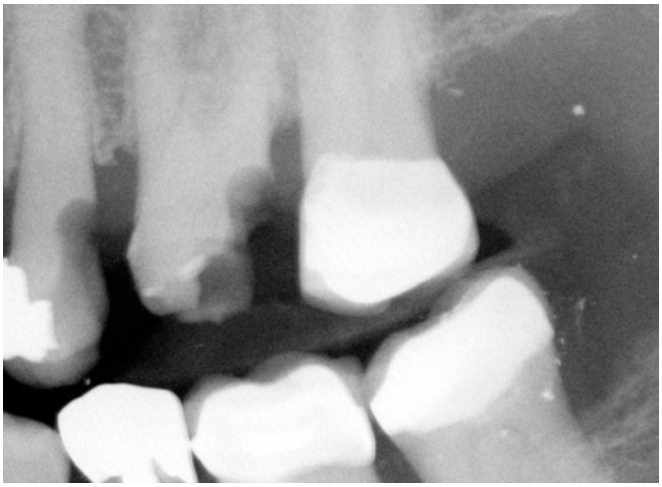

FIG. 26-30 This 86-year-old patient was pleased to find that all these broken-down teeth could be saved with endodontic therapy and crowns. She was eager to make the investment in time and money, despite her limited life expectancy. Her concern focused on why these procedures had not been recommended by her previous dentist, whom she visited regularly.

institutions, but alternatives to root canal therapy may be the only services available. Extended health care facilities are now required to have clinicians on staff before Medicare certification can be obtained. The dental office building, including both the interior design and the exterior approach, must be able to accommodate people with special needs (Fig. 26-32).[75] Access for those who use ambulation aids (e.g., canes, walkers, wheelchairs) should include comfort and safety in the parking lot, reception room, operatory, and restroom. Dental units can be designed to accommodate patients who remain in their own wheelchairs so that they do not require transfer.[101]

A physical and mental evaluation of the patient should determine the ideal time of day and length of time necessary to schedule treatment. A patient's daily personal, eating, and resting habits should be considered, in addition to any medication schedule. Morning appointments are preferable for some older patients, and their comfort, which varies with the procedure indicated, dictates the length of the appointment. Some patients prefer late morning or early afternoon visits to allow "morning stiffness" to dissipate.[29]

Older patients are more likely to tolerate long appointments, although chair positioning and comfort may be more important for older adults than for younger patients. Patients should be offered assistance into the operatory and into or out of the chair, and chair adjustments should be made slowly (and the ideal position established and used if possible). Pillows should be offered, as should assistance in positioning them comfortably. Every effort should be made to accommodate the ideal position, even at some expense to the clinician's comfort or access.

The patient's eyes should be shielded from the intensity of the clinician's light. If the temperature selected for the comfort of the office staff is too cool for the patient, a blanket should be available. As much work as possible should be performed at each visit, and a restroom break should be offered at intervals as the patient's needs indicate. Jaw fatigue is readily recognizable and may be the most limiting factor in a long procedure, requiring periods of rest; however, once such

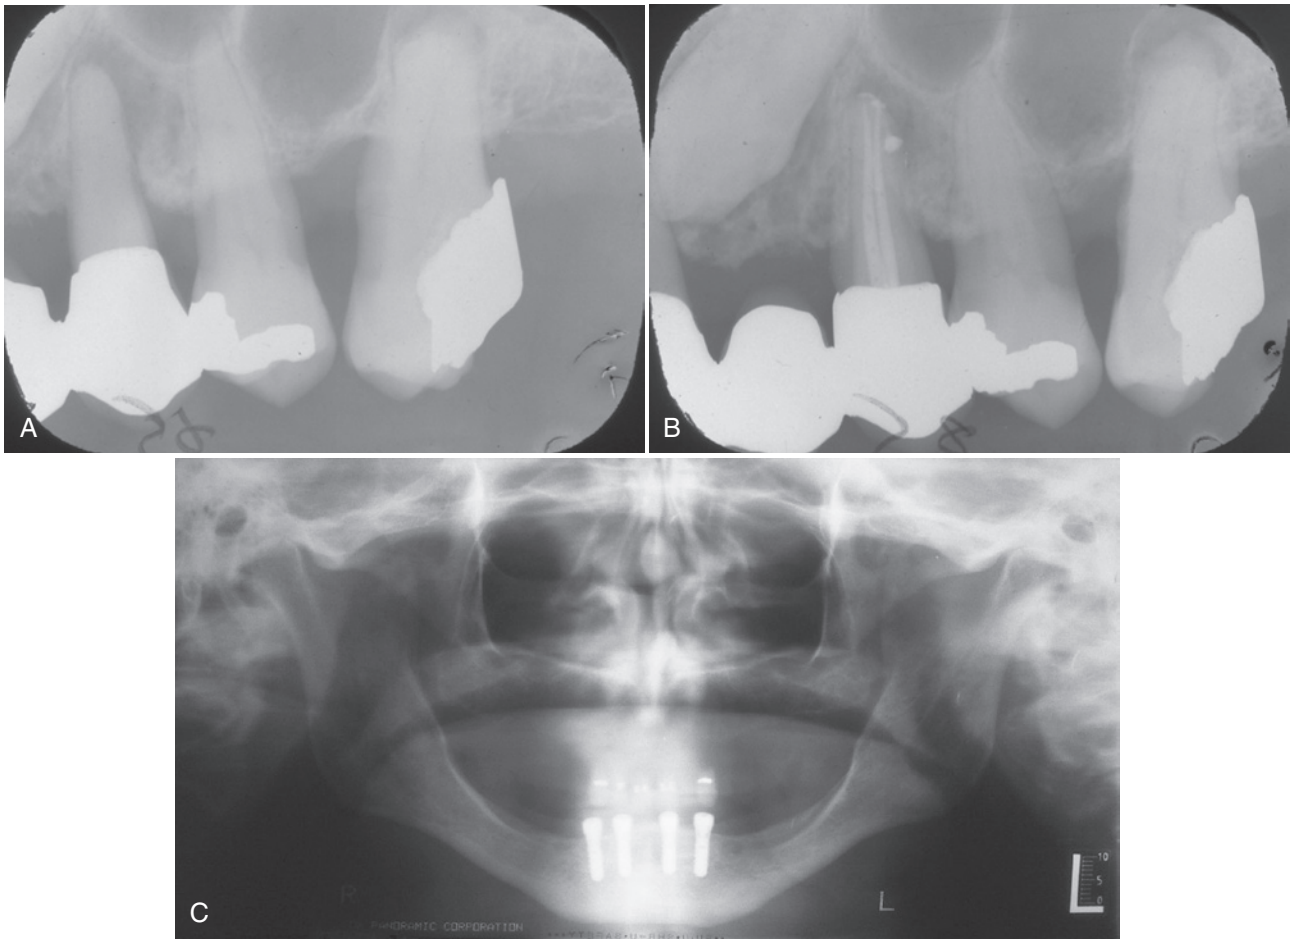

FIG. 26-31 A, Preoperative radiograph showing the calcified canals of this premolar abutment tooth. B, Postoperative radiograph after root canal treatment of the two-canaled premolar tooth, showing conservation of tooth structure. C, A 97-year-old man who had implant placement for mandibular denture retention. He tolerated the procedure well.

FIG. 26-32 A, The office design should consider access for wheelchairs and walkers. B, Staff members should be experienced in assisting patients into and out of the dental chair and operatory.

fatigue is evident, the procedure should be terminated as soon as possible. Bite blocks are useful for comfortably maintaining freeway space and reducing jaw fatigue.

Retired individuals may rely on rides from friends or relatives or public transportation to get to the dental office. Although they often arrive early for appointments, most older patients are in no hurry once they arrive. Enough time should be scheduled to allow some social exchange, and a sincere personal interest should be demonstrated before proceeding. Endodontic specialists need to consider separate consultations for making this initial social contact and evaluating the degree of difficulty that will determine the chair time needed to perform treatment. Staff should allow patients to initiate handshakes, which may be very uncomfortable for people with arthritic joints. From a behavioral and management standpoint, geriatric patients are among the most cooperative, available, and appreciative.

Older, medically compromised patients are at no more risk of complications than those in any other age group, and the chronicity of their diseases can alert the clinician to necessary precautions. Once again, clinicians should recognize that root canal therapy is far less traumatic than extraction for older patients.

The pulp vitality status and the cervical positioning of the rubber dam clamp determine the need for anesthesia. Older patients more readily accept treatment without anesthesia, and sometimes they must be persuaded that anesthesia is necessary for root canal treatment if their routine operative procedures have been performed without it. Generally, older patients demonstrate less anxiety about dental treatment and may have previous experience with root canal treatment. Therefore, anxiolytic medication is rarely necessary.

The cutting of dentin does not produce the same level of response in an older patient for the same reason that a test cavity is not as revealing during examination. The number of low-threshold, high-conduction-velocity nerve endings in dentin is reduced or absent, and the nerve endings do not extend as far into the dentin. In addition, the dentinal tubules are more calcified.[12,96] A painful response may not be encountered until actual pulp exposure has occurred.

Anatomic landmarks used as guides to needle placement during block and infiltration injections are usually more distinguishable in older patients. The effects of epinephrine should be considered when selecting anesthetics for routine endodontic procedures. Anesthetics should be deposited very slowly (and skeletal muscle avoided) if epinephrine is the vasoconstrictor.

The reduced width of the periodontal ligament[54] makes needle placement for supplementary intraligamentary injections more difficult. Placing an anesthetic under pressure produces an intraosseous anesthesia that extends to the apex and to adjacent teeth, but it also distributes small amounts of solution systemically.[91] Intraosseous injections can significantly increase the success of pulpal anesthesia but can be associated with a transient increase in heart rate when anesthetics contain epinephrine. Cortical perforation requires less pressure and rarely causes irritation. Smaller amounts of anesthetic should be deposited during intraosseous injections, and the depth of anesthesia should be checked before the procedure is repeated. Like intrapulpal anesthesia, intraosseous anesthesia is not prolonged; the pulp tissue must be removed within 20 minutes. Most patients receiving an intraosseous injection of 2% lidocaine with 1:100,000 epinephrine (correct ratio) experience a transient increase in heart rate. This would not be clinically significant in most healthy patients, but in the older patient whose medical condition, drug therapies, or epinephrine sensitivity suggest caution, 3% mepivacaine is a good alternative for intraosseous injections (see Chapter 4 for further information).[81]

The reduced volume of the pulp chamber makes intrapulpal anesthesia difficult in single-rooted teeth and almost impossible in multirooted teeth. Initial pulp exposures are also hard to identify. Wedging a small needle into each canal to produce the necessary pressure for anesthesia is the method of last resort. Every effort should be made to produce profound anesthesia. Patients should be encouraged to report any unpleasant sensation, and a prompt response should be made to any complaint. Patients should never be expected to tolerate pulpal pain.

Isolation

Single-tooth isolation is preferred, but multitooth rubber dam isolation may be required. Badly broken-down teeth may not provide an adequate purchase point for the rubber dam clamp, so alternate rubber dam isolation methods should be considered (see Chapter 5). Multiple-tooth isolation may be used if adjacent teeth can be clamped and saliva output is low or a well-placed saliva ejector can be tolerated (Fig. 26-33). A three-holed rubber dam, with the tooth in question in the middle, allows for better maneuverability, especially when the dental operating microscope is used. A petroleum-based lubricant for the lips and gingiva reduces chafing from saliva or perspiration beneath the rubber dam. A reduction in salivary flow or an exaggerated gag reflex reduces the need for a saliva ejector. Tissue can be aspirated into the perforated tip of the saliva ejector and torn upon removal. Artificial saliva is available and should be used just before isolation because it is difficult to apply after the dam is in place.

Canals should be identified and their access maintained if restorative procedures are indicated for isolation. The clinician should not attempt isolation and access in a tooth with questionable marginal integrity of its restorations. Fluid-tight

FIG. 26-33 Multiple-tooth isolation techniques protect the patient from instruments but do not provide the fluid-tight environment preferred for the safe use of sodium hypochlorite.

isolation cannot be compromised when sodium hypochlorite is used as an irrigant. In initial preparation, defects that are difficult to isolate because of root decay present a good indication for the use of sonic handpieces that use flow-through water as an irrigant.

The many merits of single-visit root canal procedures are generally recommended when isolation is compromised (see Chapters 3 and 5). The few minor benefits of multiple-visit treatment are further reduced if an interappointment seal is difficult to obtain or the interval between visits is extended for any reason.

Access

Adequate access and identification of canal orifices are likely the most challenging aspects of providing root canal treatment for older patients. Although the effects of aging and multiple restorations may reduce the volume and coronal extent of the chamber or canal orifice, its buccolingual and mesiodistal positions remain the same and can be predicted from radiographs and clinical examination. In general, there is a good correlation between the size of a canal in relationship to its radiographic image, but there can be large discrepancies, especially when canals appear very small on radiograph.[58] Canal position, root curvature, and axial inclinations of roots and crowns should be considered during the examination (Fig. 26-34). The effects of access on existing restorations and the possible need for actual removal of the restoration should be discussed with the patient before treatment is begun (Fig. 26-35). Coronal tooth structure or restorations should be sacrificed when they compromise access for preparation or filling (Fig. 26-36). Perhaps all restorations should be removed before endodontic treatment so as to remove the common factors (caries, marginal breakdown, cracks) that may have caused the pulp and periradicular disease and to allow assessment of the tooth's prognosis and future treatment needs. One study found that these factors were present in almost all teeth (93%); however, only 56% were detectable clinically or on radiographs.[1] (See Chapter 5 for more details on proper access openings.)

Magnification in the range of ×2.5 to ×4.5 (e.g., Designs for Vision, Ronkonkoma, New York) has become a common tool and can be designed to fit the clinician's most comfortable working distance. The growing acceptance and availability of endodontic microscopes[4,53] offer clear magnification ranging up to ×25 or greater, and these microscopes have obvious advantages in the treatment of smaller and narrower geriatric canals.

Location and penetration of the canal orifice are often difficult and time-consuming in calcified canals. The most important instrument for initial penetration is the DG-16 explorer. The explorer does not stick in solid dentin, but it resists dislodgment in the canal. Once the canal has been distinguished, negotiation is attempted with a stainless steel (SS) #8, #10, or #15 K-file. The #6 file lacks stiffness in its shaft and easily bends and curls under gentle apical pressure. Nickel-titanium (NiTi) files lack strength in the long axis and are not useful for initial negotiation. The canal can be negotiated using a watch-winding action with slight apical pressure. Chelating agents are seldom of value in locating the orifice but can be very useful during canal negotiation. Dyes may distinguish an orifice from the surrounding dentin.

Pain, bleeding, disorientation of the probing instruments, or an unfamiliar feel to the canal may indicate a perforation (Fig. 26-37). The size of the perforation and the extent of contamination determine the success of repair (which should be done immediately) and do not necessarily indicate failure (Fig. 26-38). Supraerupted teeth can be easily perforated (Fig. 26-39) if the reduced distance to the furcation is not noted.

A lengthy, unproductive search for canals is fatiguing and frustrating to both the clinician and the patient. Scheduling a second attempt at this procedure is often productive. Personal clinical experiences and judgment determine when the search for the canals must be terminated and referral or alternatives to nonsurgical root canal treatment considered (Fig. 26-40).

Modifications to enhance access vary from widening the axial walls, to increasing visibility or light, to complete removal of the crown. Alterations may be indicated after canal penetration to the apex if tooth structure interferes with instrumentation or filling procedures.

Teeth with apical periodontitis usually have patent canals, even if they are undetectable on radiographs (Fig. 26-41). Surgical access (Fig. 26-42) may be preferred if the risk of deviation from the long axis exists when canals are calcified and the tooth is heavily restored (Fig. 26-43).

Very few canals of older teeth, even maxillary anterior teeth, have adequate diameter to allow safe and effective use of broaches. The clinical appearance of older pulps may reflect

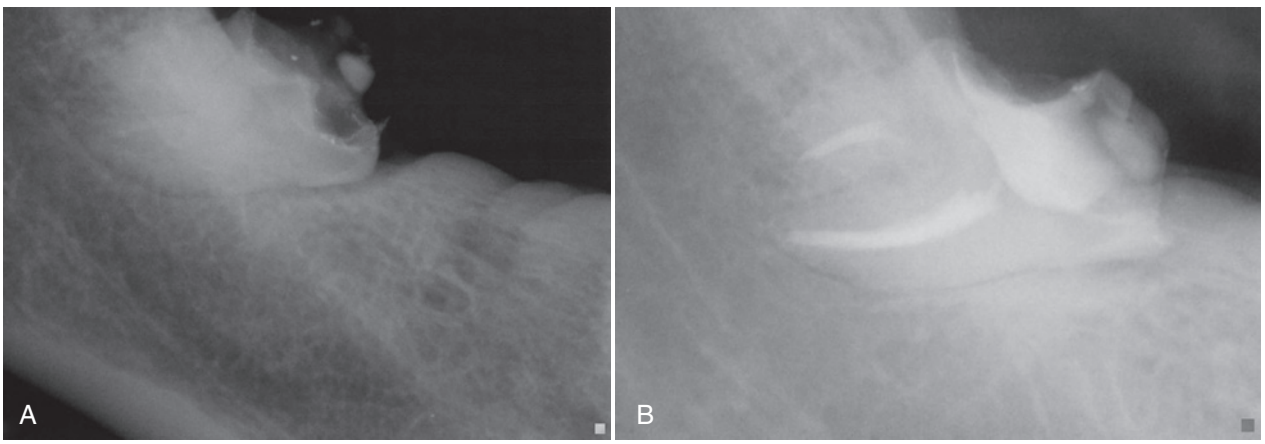

FIG. 26-34 A and B, This severely tilted mandibular third molar, which had a questionable prognosis, was saved in a patient at risk for bone osteonecrosis (BON).

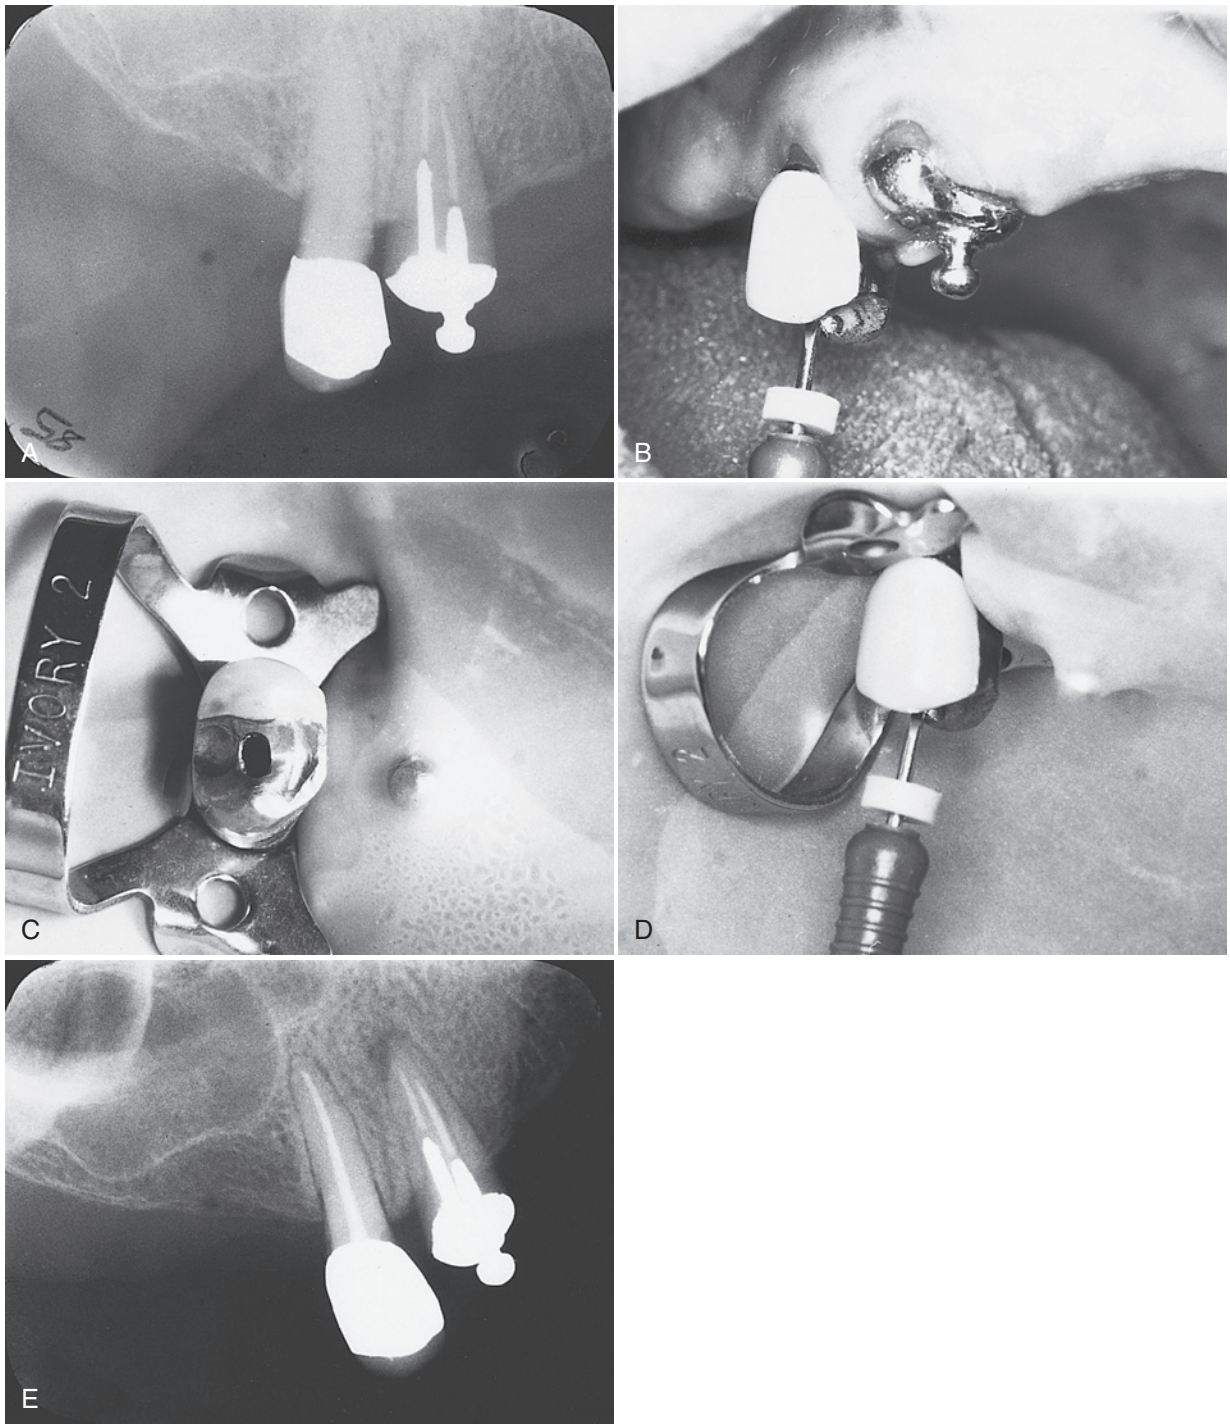

FIG. 26-35 A, Radiograph of a strategic abutment and a calcified canal. B, To increase visibility and alignment, access was initiated before isolation. C, An access opening that conserved tooth structure and provided straight-line access was isolated with the rubber dam (D), and treatment was provided (E).

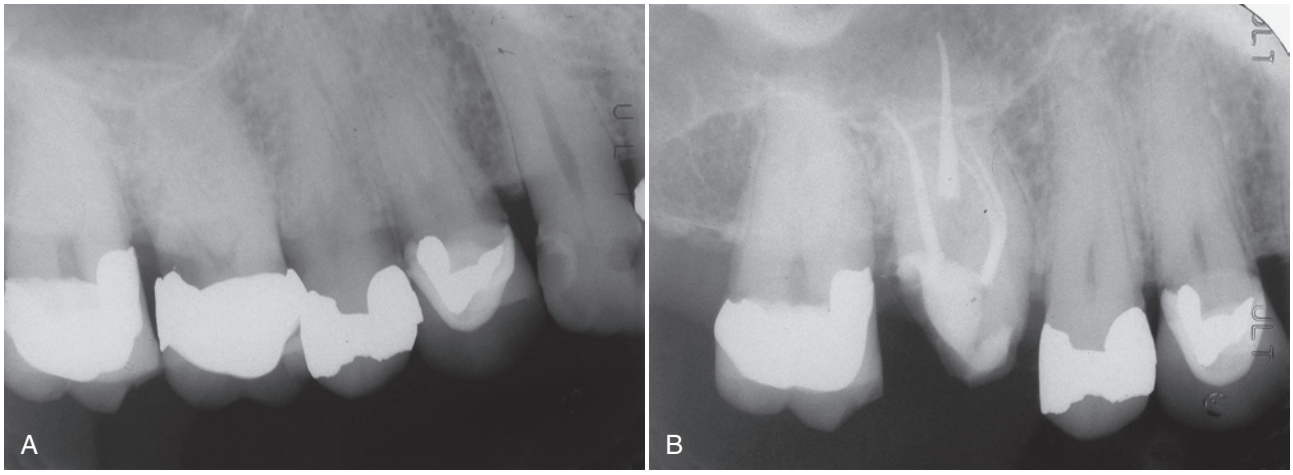

FIG. 26-36 A, Caries control and isolation of this tooth necessitated crown removal. B, Endodontic treatment was completed in one visit.

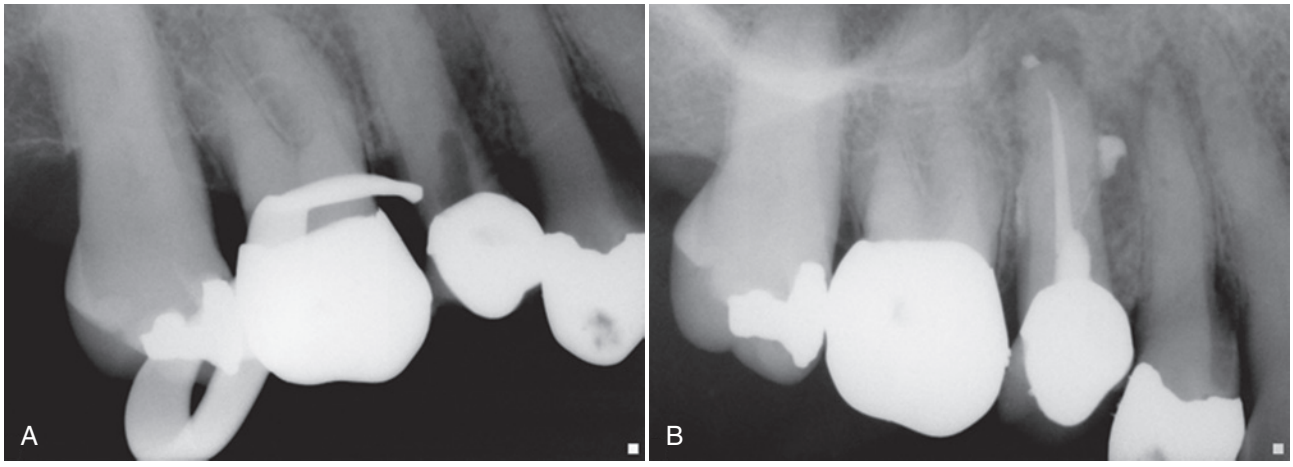

FIG. 26-37 A, Pain, bleeding, or disorientation of the probing instrument may indicate a perforation, which should be immediately investigated with a radiograph. B, Repair has the best chance of success when the perforation opening is pinpoint size and the periodontal tissues are normal.

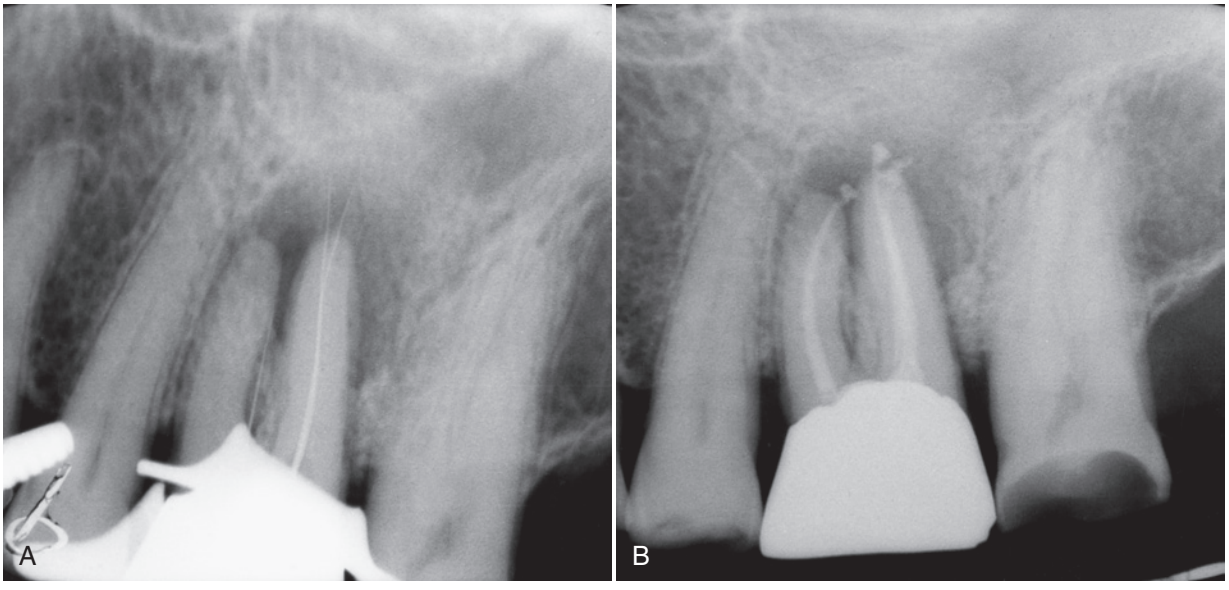

FIG. 26-38 A, Perforation occurred during access of these calcified canals. B, Endodontic treatment was immediately completed after the perforation repair.

their calcified, atrophic state; they may have the stiffened, fibrous consistency of a wet toothpick. Any broached canals should be thoroughly cleaned and shaped at the same appointment.

Preparation

The calcified appearance of the canals resulting from the aging process presents a much different clinical situation than that of a younger pulp in which trauma, pulpotomy, decay or caries, or restorative procedures have induced premature canal obliteration. Unless further complicated by reparative dentin formation, this calcification appears to be much more concentric and linear. This allows easier penetration of canals once they are found. An older tooth is more likely to have a history of earlier treatments, with a combination of calcifications present. (Chapter 6 includes a description of cleaning and shaping root canals.)

The length of the canal from the actual anatomic foramen to the CDJ increases with the deposition of cementum throughout life.[57] The advantage of this situation in the treatment of teeth with vital pulps is countered by the presence of necrotic, infected debris in this longer canal when periapical pathosis is already present. The actual CDJ width or most apical extent of the dentin remains constant with age.[97]

Flaring of the canal should be performed as early in the procedure as possible to provide for a reservoir of irrigation solution and reduce the stress on metal instruments that occurs when they bind with the canal walls. Thorough and frequent irrigation should be performed to remove the debris that could block access. Files with a triangular or square cross section may penetrate into the walls, resulting in greater strain than small files (when used with a reaming action) and create more instrument torque and fracture. Instrumentation techniques used for the preparation of calcified canals require an advanced understanding of the variations in taper, tip geometrics, rake angle, pitch, and metallurgy. Instruments with little or no rake angle and a crown-down technique are recommended.

Because this CDJ is the narrowest constriction of the canal, it is the ideal place to terminate the canal preparation. This point may vary from 0.5 to 2.5 mm from the radiographic apex and may be difficult to determine clinically. Calcified canals reduce the clinician's tactile sense in identifying the constriction clinically, and reduced periapical sensitivity in older patients reduces the patient's response that would indicate penetration of the foramen. An increased incidence of hypercementosis, in which the constriction is even farther from the apex, makes penetration into the cemental canal almost impossible. Achieving and maintaining apical patency are more difficult. Apical root resorption associated with periapical pathosis further changes the shape, size, and position of the constriction. The use of electronic apex-finding devices is

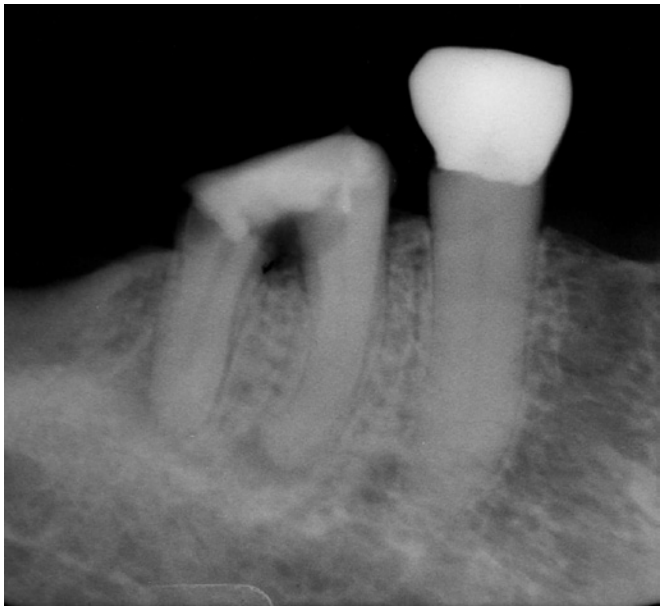

FIG. 26-39 Supraerupted mandibular first molar that was perforated during access.

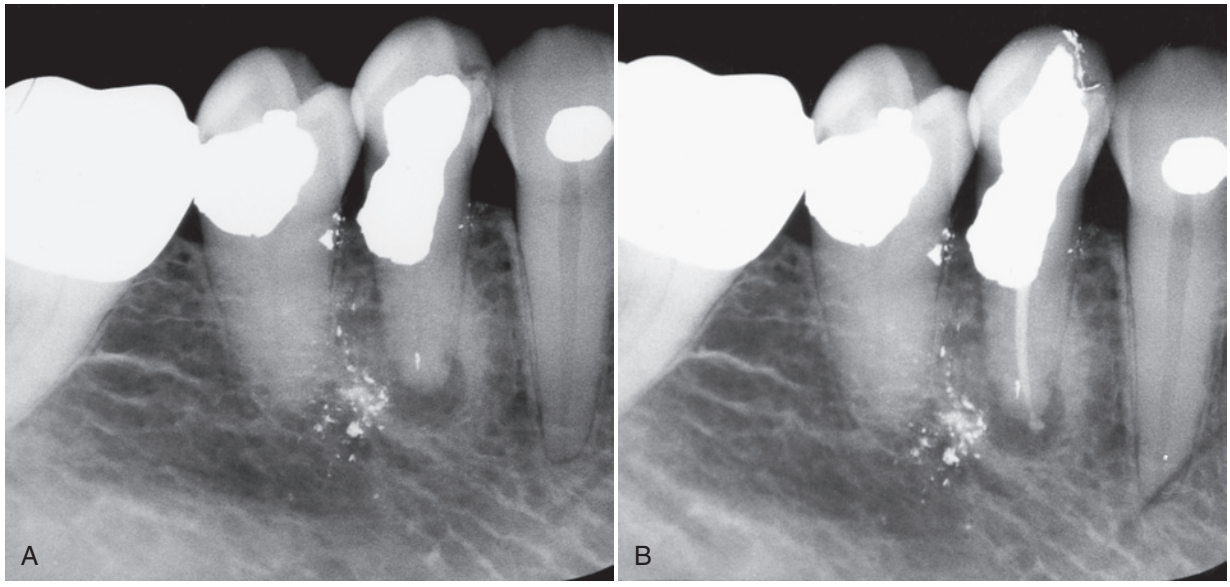

FIG. 26-40 A, Midtreatment referral of a mandibular first premolar after perforation and repair with amalgam. B, The canal was still detectable with enhanced vision techniques, and treatment was completed.

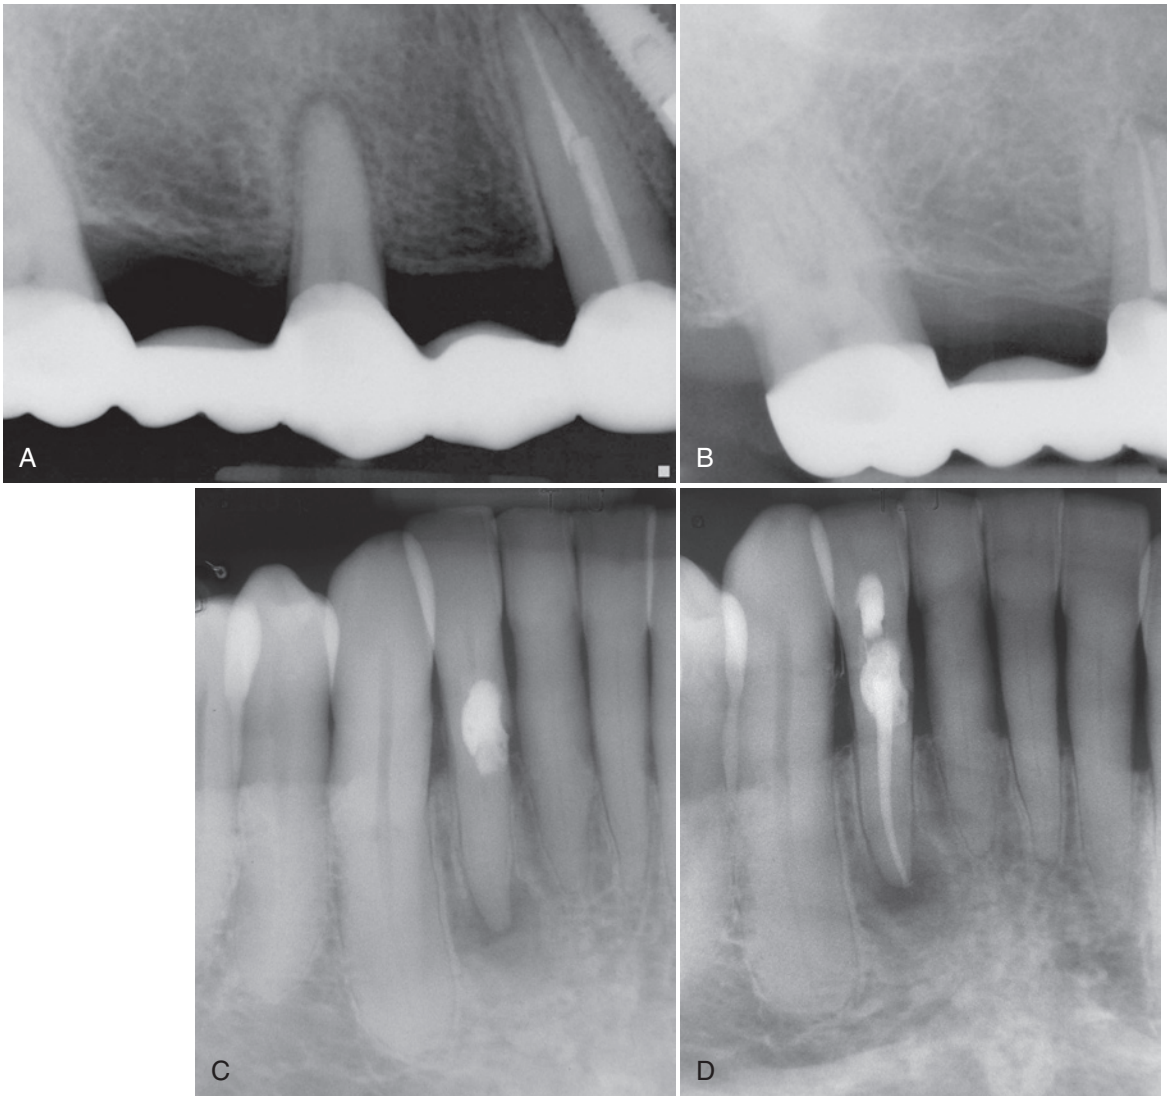

FIG. 26-41 A, Strategic middle abutment for a long fixed bridge presents a challenge to the most skilled clinician for minimally invasive root canal treatment. B, Root canal treatment should have been considered before this longstanding premolar was established as an abutment. C, Calcified canals can usually be detected and treated when a nonvital pulp and chronic apical periodontitis are present, even when the canals are not apparent on the radiograph. Asymptomatic, calcified canals in teeth with vital pulps are much more difficult to find and negotiate. D, External resorption repair before endodontic treatment made negotiation and instrumentation of this incisor tooth more difficult.

sometimes limited in heavily restored teeth when contact with metal can bleed off the current.

The incidence and intensity of flare-ups[103] after cleaning and shaping have not been shown to be related to the amount of preparation, the type of interappointment medication or temporary filling, the pulp or periapical status, the tooth number or age, or whether the root canal filling is completed at the same appointment.[100] The more constricted CDJ permits a much smaller pulp wound and resists penetration, even with the initial small files. Patency is difficult to establish and maintain. Dentin debris creates a matrix early in the preparation[114] and further reduces the risk of overinstrumentation or the forcing of debris into the periapical tissues,[77] which could cause an acute apical periodontitis or abscess. Further access to periapical tissues through the canal is likewise limited with a dentinal plug. Crown-down rotary instrumentation creates less apical dentin than the push-pull motion typical of hand instrumentation.

Obturation

For the older patient, the prudent clinician selects gutta-percha filling techniques that do not require unusually large midroot tapers and do not generate pressure in this area, which could result in root fracture (Fig. 26-44). (See Chapter 7 for the most appropriate technique to use to seal the canal.)

The coronal seal plays an important role in maintaining an apically healthy environment, and it has a significant impact on long-term success.[99] Even a root-filled tooth should not have its canals exposed to the oral environment.[107] Permanent restorative procedures should be scheduled as soon as possible, and intermediate restorative materials should be selected and properly placed to maintain a seal until that time. When

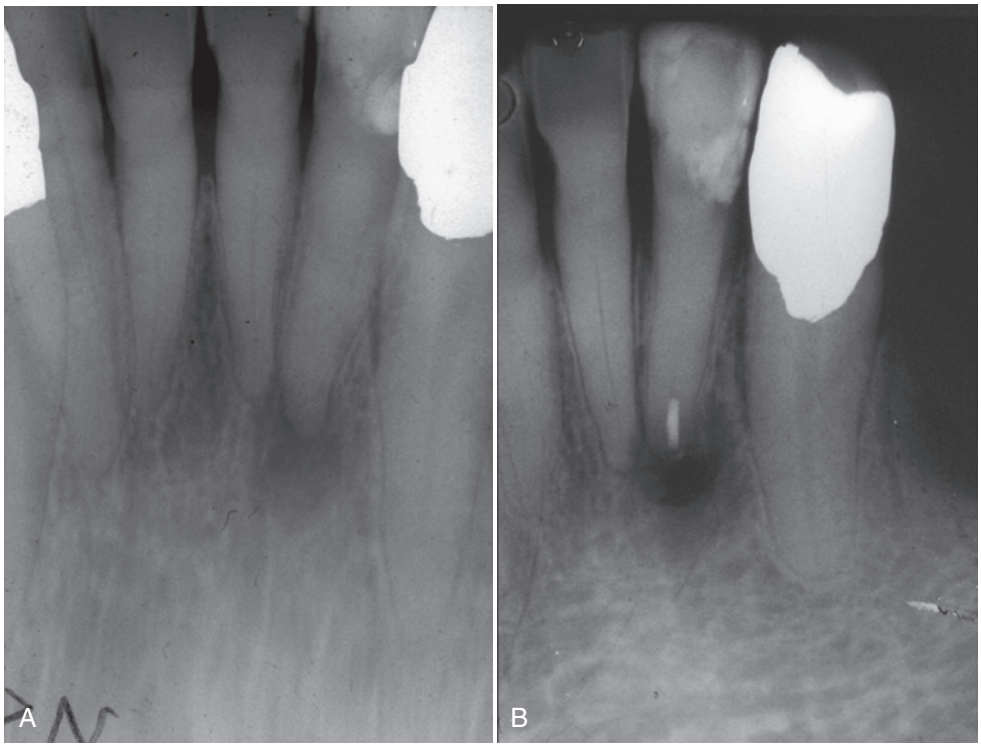

FIG. 26-42 A, Extremely calcified canals and thin roots make the risk of perforation high. B, The operator chose to perform surgical access and root-end filling, rather than weakening the tooth trying to locate the root canal system via an orthograde approach.

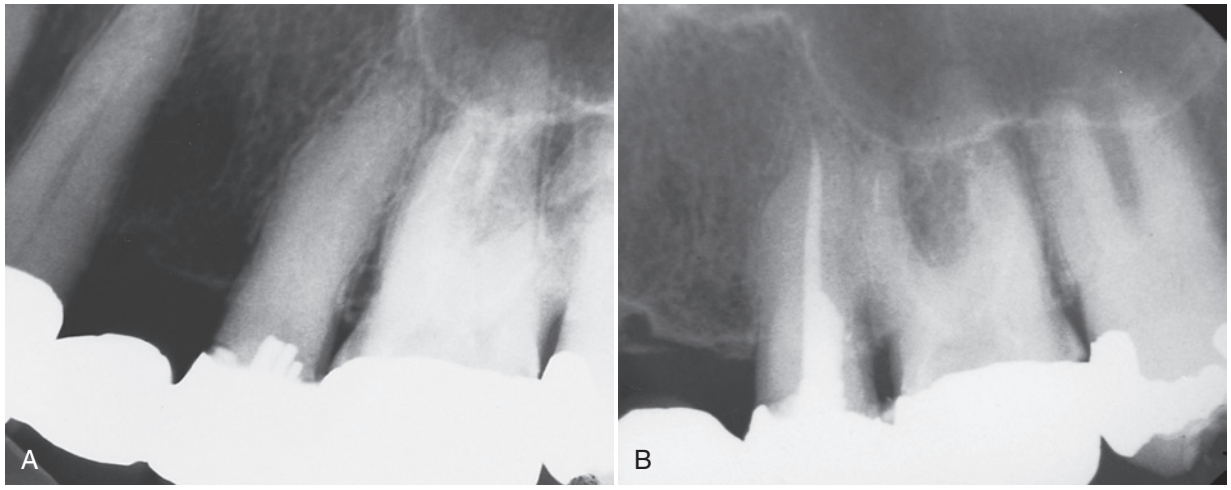

FIG. 26-43 A, Multiple pins were used to restore this middle abutment on a fixed bridge. B, Extreme care and exceptional skill are required to maintain proper alignment to find and treat the canal with a deep access opening.

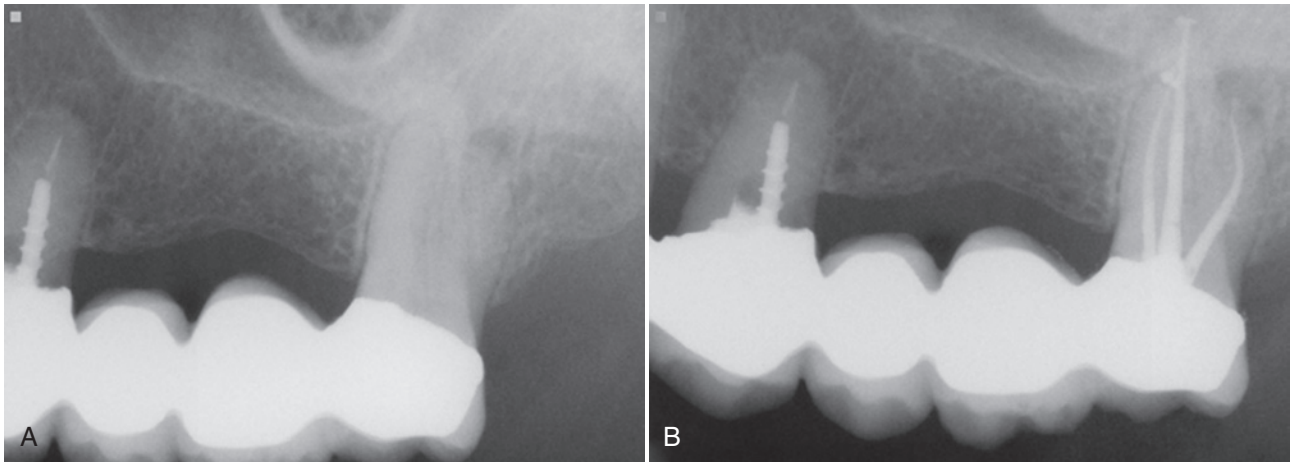

FIG. 26-44 A, Third molar abutment for a seven-unit bridge in an 84-year-old patient with limited opening. B, Instrumentation of this molar was performed without excessive removal of coronal or midroot dentin.

mechanical retention is not ensured with the preparation, glass ionomer cements are recommended.

Success and Failure

Repair of periapical tissues after endodontic treatment in older patients is determined by most of the same local and systemic factors that govern the process in all patients. With vital pulps, periapical tissues are normal and can be maintained with an aseptic technique, confining preparation and filling procedures to the canal space. In infected nonvital pulps with periapical pathosis, this process must be altered in favor of the host tissue, and repair is determined by the ability of this tissue to respond. Factors that influence repair have their greatest effect on the prognosis of endodontic therapy when periapical abnormalities are present. Patients with diabetes have increased periodontal disease in teeth involved endodontically and have a reduced likelihood of success of endodontic treatment in cases with preoperative periradicular lesions.[33] With aging, arteriosclerotic changes in blood vessels increase and the viscosity of connective tissue is altered, making repair more difficult. The rate of bone formation and normal resorption decreases with age, and the aging of bone results in greater porosity and decreased mineralization of the formed bone. Although periradicular tissues heal as readily in the elderly as in young patients,[100] a 6-month recall period to evaluate repair by means of radiographs may not be adequate (Fig. 26-45).[36]

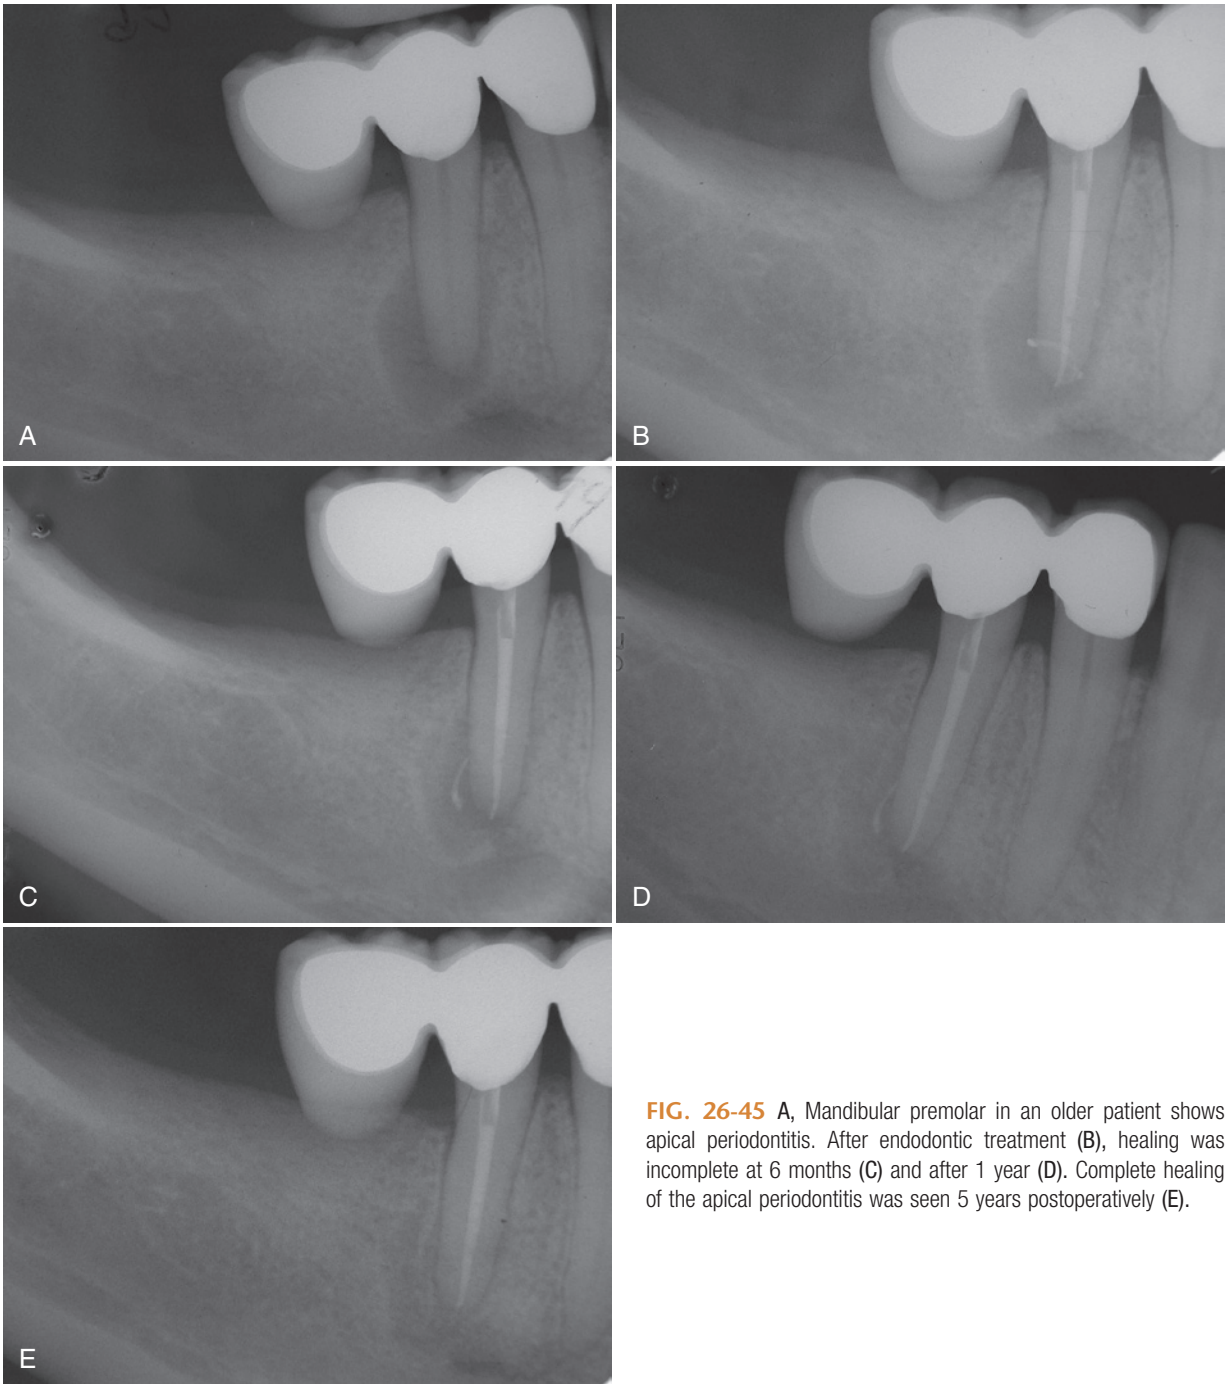

FIG. 26-45 A, Mandibular premolar in an older patient shows apical periodontitis. After endodontic treatment (B), healing was incomplete at 6 months (C) and after 1 year (D). Complete healing of the apical periodontitis was seen 5 years postoperatively (E).

Studies that suggest differences in success among age groups must note the smaller numbers (usually in this older treatment group) and the local factors that make treatment difficult. Overlooked canals are a more common cause of failure in older patients (Fig. 26-46), which explains the increased clinical indications for retrograde fillings when surgical treatment is attempted.[2] As an isolated symptom, heat sensitivity may indicate a missed canal. (See Chapters 8 and 11 for further information on assessing failures and possible retreatment.)

FIG. 26-46 The incidence of root-end filling during periradicular surgery increases with age because calcified canals become more difficult to detect and negotiate, causing failure of nonsurgical treatment.

ENDODONTIC SURGERY

Generally, considerations and indications for endodontic surgery are not affected by age. The need to establish drainage and relieve pain is not a common indication for surgery. Anatomic complications of the root canal system, such as small (Fig. 26-47) or completely calcified canals, nonnegotiable root curvatures, extensive apical root resorption, or pulp stones, occur with greater frequency in older patients. Perforation during access, losing length during instrumentation, ledging, and instrument separation are iatrogenic treatment complications associated with treatment of calcified canals.

Medical considerations may require consultation but do not contraindicate surgical treatment when extraction is the alternative (Fig. 26-48). In most instances, surgical treatment may be performed less traumatically than an extraction, which may also result in the need for surgical access to complete root removal. Many older patients receive low-dose aspirin therapy to prevent blood clot formation and may be subject to embolic formation if the treatment is interrupted. Aspirin therapy should be continued throughout dental procedures, even during extraction or surgery. Local measures are sufficient to control bleeding.[5] Interrupting therapeutic levels of continuous anticoagulation therapy for dental surgery is not based on scientific fact but seems to be based on its own mythology.[109] An international normalized ratio (INR) value recorded the day of the procedure provides the most useful measurement of bleeding risk. Many patients on anticoagulation therapy are aware of their INR value, but a current measurement should be made. In patients receiving combined anticoagulation-aspirin therapy, simple tooth extraction can be performed safely without discontinuing either oral anticoagulant or antiplatelet therapy if the INR is within therapeutic range and appropriate local hemostasis measures are provided.[6] Clinicians should also reassess historical recommendations that

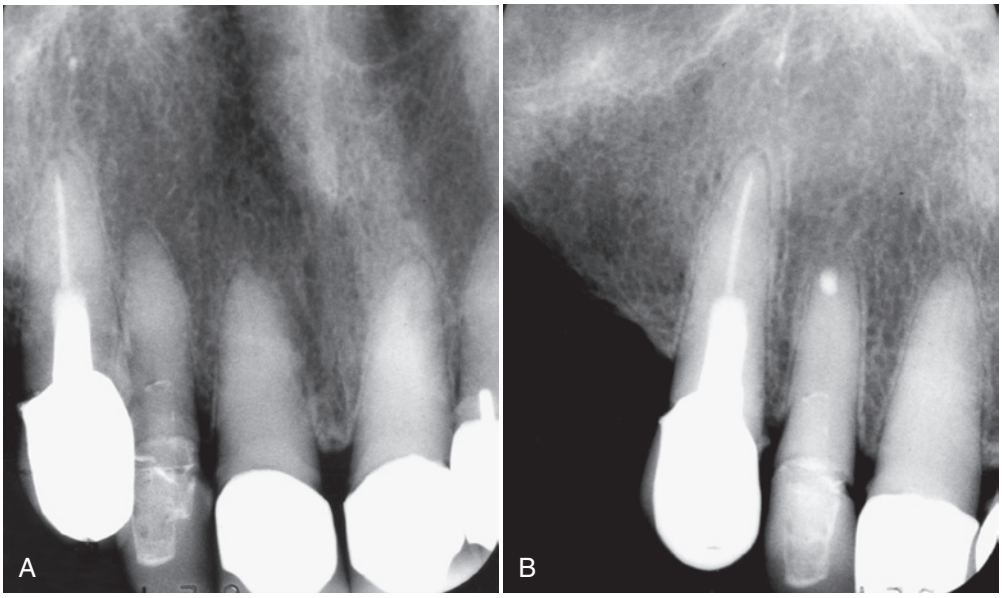

FIG. 26-47 **A**, A small canal is detectable on the radiograph, even though it appeared that an earlier, unsuccessful attempt had been made to find it. **B**, It was decided that the risk of damage to a satisfactory restoration justified surgical treatment for this patient.

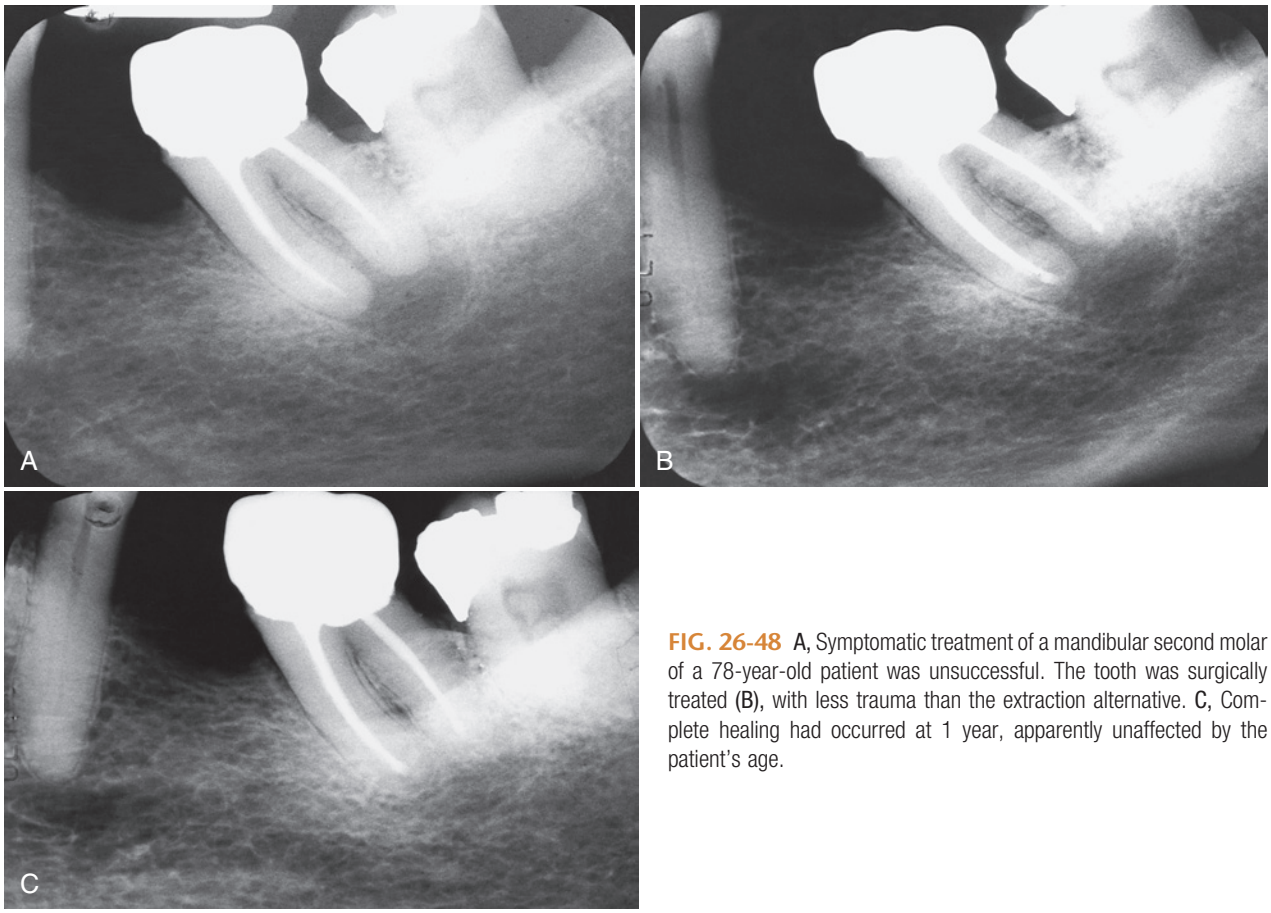

FIG. 26-48 A, Symptomatic treatment of a mandibular second molar of a 78-year-old patient was unsuccessful. The tooth was surgically treated (B), with less trauma than the extraction alternative. C, Complete healing had occurred at 1 year, apparently unaffected by the patient's age.

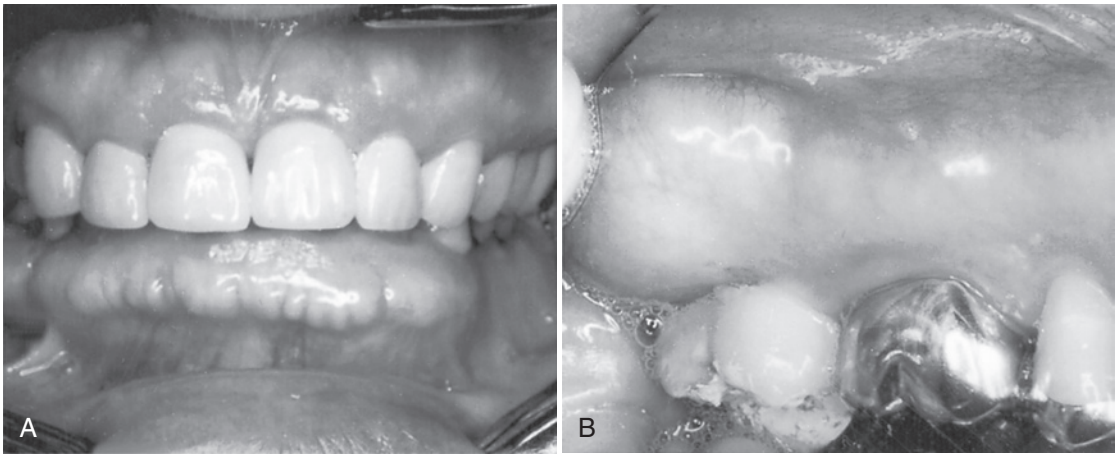

FIG. 26-49 Exostoses are shown in this mandibular anterior tooth (A) and maxillary molar (B), covered with thin tissue that can easily be torn during flap reflection. Another consideration is the more obvious heavy bone and its effect on surgical access.

dental care in older patients be postponed for as long as 6 months after ischemic vascular events.[89] A thorough medical history and evaluation should reveal the need for any special considerations, such as prophylactic antibiotic premedication, sedation, hospitalization, or more detailed evaluation.

Local considerations in the treatment of older patients include an increase in the incidence of fenestrated or dehisced roots and exostoses (Fig. 26-49). The thickness of overlying soft and bony tissue is usually reduced, and apically positioned muscle attachments extend the depth of the vestibule. Smaller amounts of anesthetic and vasoconstrictor are needed for profound anesthesia. Tissue is less resilient, and resistance to reflection appears to be diminished. The oral cavity is usually more accessible with the teeth closed together because the lips can more easily be stretched. The apex can actually be more surgically accessible in older patients. The ability to gain such

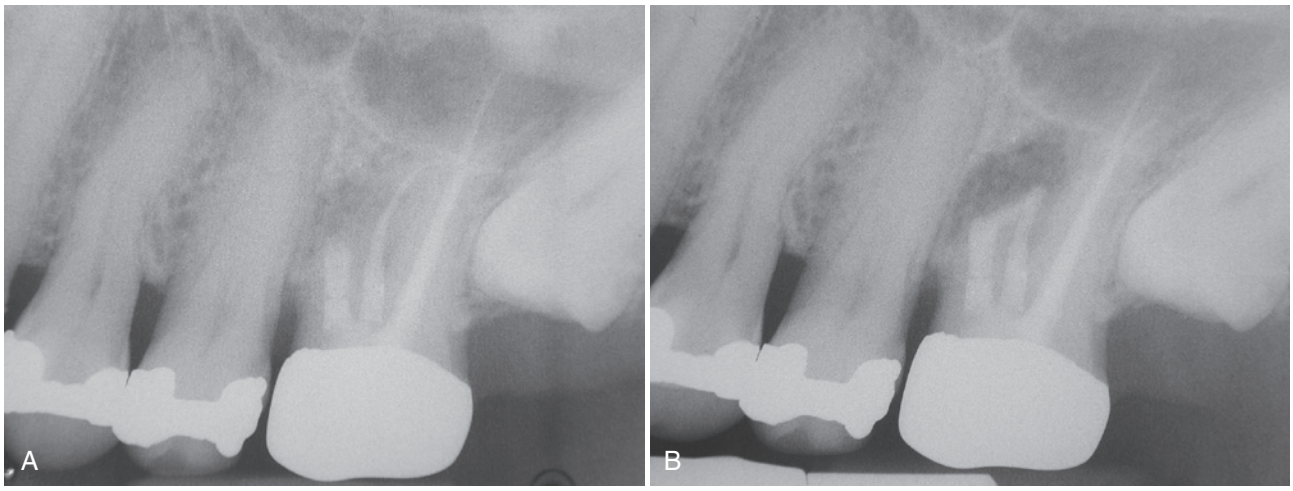

FIG. 26-50 A, Tooth #15 showing failed surgery; it appears that only part of the MB root was resected. B, Apicoectomy of the entire MB root, retrocavity preparation of the MB1 and MB2 canals and joining isthmus, and retrofilling with mineral trioxide aggregate (MTA).

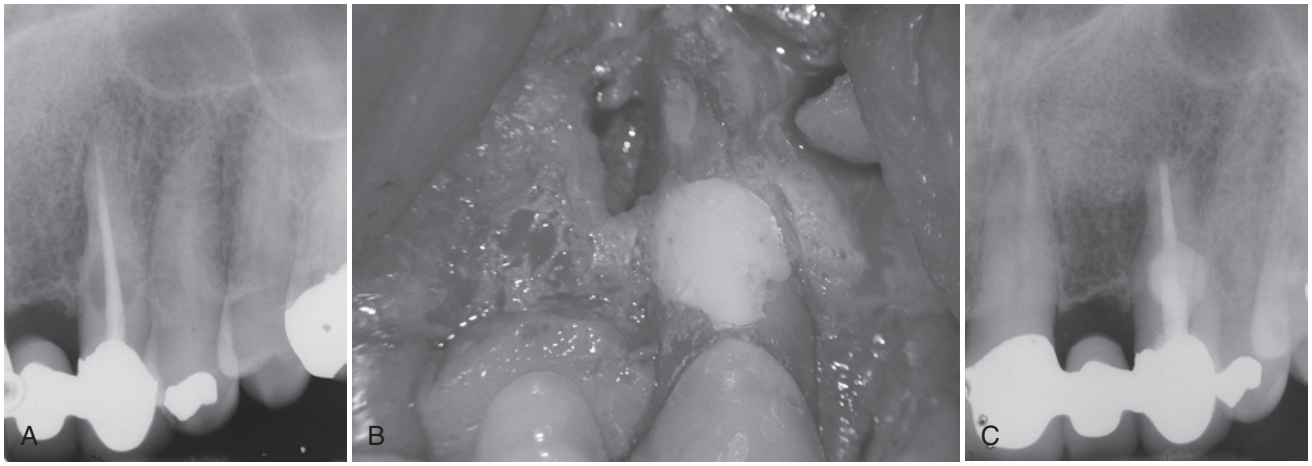

FIG. 26-51 A, External root resorption accompanied by periradicular periodontitis in an important canine abutment tooth. Endodontic retreatment, surgical repair of the resorptive defect (B), and apicoectomy (C) were performed.

access varies with the skill of the surgeon; however, some areas are unreachable by even the most experienced clinicians.

The position of anatomic features (i.e., the sinus, floor of the nose, and neurovascular bundles) remains the same, but their relationship to surrounding structures may change when teeth have been lost. The need may arise to combine endodontic and periodontal flap procedures, and every effort should be made to complete these procedures in one sitting.

When root-end surgery is to be performed, the surgeon must consider whether the root that will be left is long enough and thick enough for the tooth to continue to remain functional and stable (Fig. 26-50). This factor is especially important when the tooth will be used as an abutment (Fig. 26-51). (Detailed surgical procedures are presented in Chapter 9.)

Ecchymosis is a more common postoperative finding in older patients and may appear to be extreme. The patient should be reassured that this condition is normal and that normal color may take as long as 2 weeks to return. The blue discoloration changes to brown and yellow before it disappears. Immediate application of an ice pack after surgery reduces bleeding and initiates coagulation to reduce the extent of ecchymosis. Later, application of heat helps dissipate the discoloration.

RESTORATION

Root canal treatment saves roots, and restorative procedures save crowns. Combined, these procedures are returning more teeth to form and function than were thought possible just a few decades ago. Successful restorative outcomes have been shown to be related to full coverage restorations on molars and older patient age.[93] Special consideration must be given to post design, especially when small posts are used in abutment teeth; root fracture is common in older adults when much taper is used. Post failure or fracture occurs when small-diameter parallel posts are used (Fig. 26-52). Posts are not usually needed

FIG. 26-52 This fracture of a cast post presents a very difficult challenge for removal.

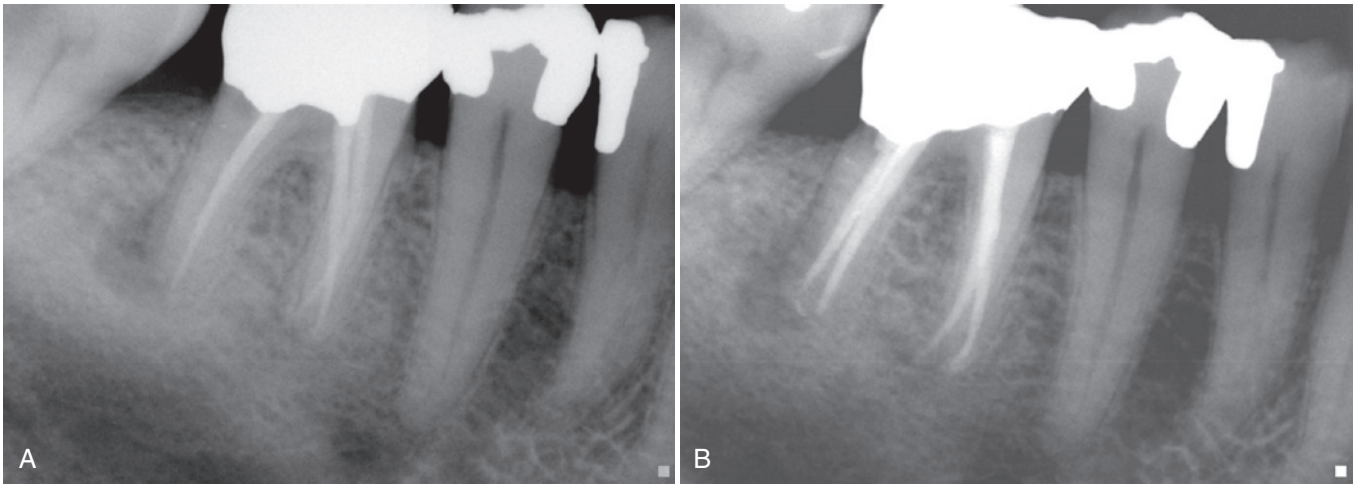

FIG. 26-53 A, Intact margins permitted the continued use of this crown. B, Root canal failure was due to an uncleaned and unfilled second distal canal. The access cavity was restored with an amalgam-bond core.

when root canal treatment is performed through an existing crown that will continue to be used (Fig. 26-53). (General considerations and procedures for postendodontic restoration are detailed in Chapter 22.)

The value of the tooth, its restorability, its periodontal health, and the patient's wishes should be part of the evaluation preceding endodontic therapy. The restorability of older teeth can be affected when root decay has limited access to sound margins or reduced the integrity of remaining tooth structure (Figs. 26-54 and 26-55). There can also be insufficient vertical and horizontal space when opposing or adjacent teeth are missing. The patient's desire to save appliances can sometimes be fulfilled with creative devices that may outlive them (Fig. 26-56).

Geriatric endodontics will gain a more significant role in complete dental care as an aging population recognizes that a complete dentition, and not complete dentures, is part of its destiny. Saving teeth for the aging population is a valuable and important aspect of helping older individuals maintain their quality of life.

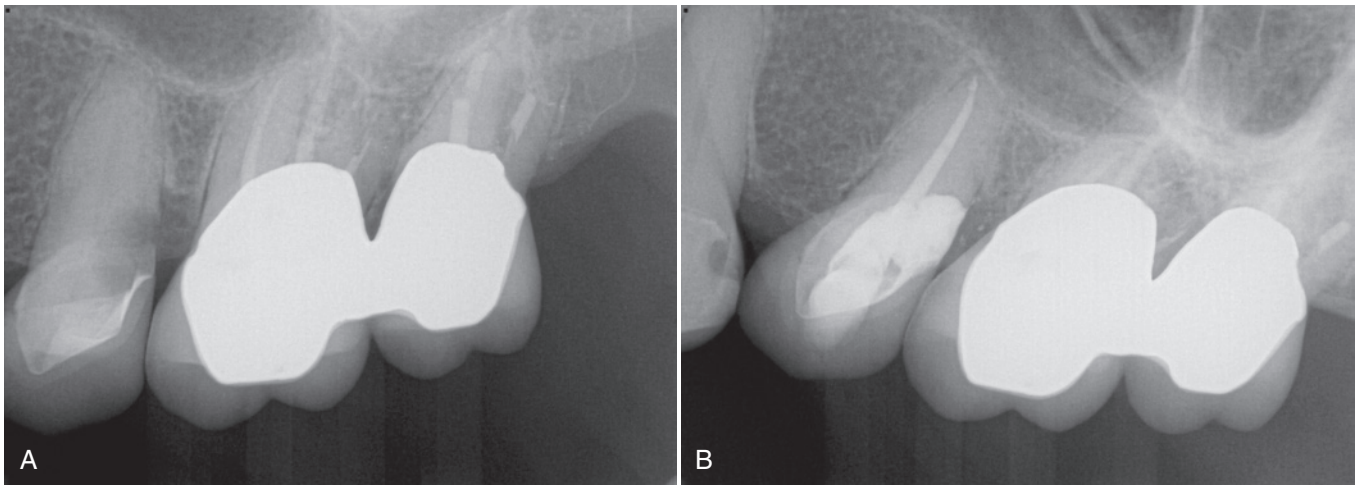

FIG. 26-54 A, This 82-year-old woman insisted on saving her tooth despite extensive root caries on the distal aspect of tooth #13. B, Root canal treatment was performed, followed by a surgical approach to remove the root caries. Restoration was done with Geristore.

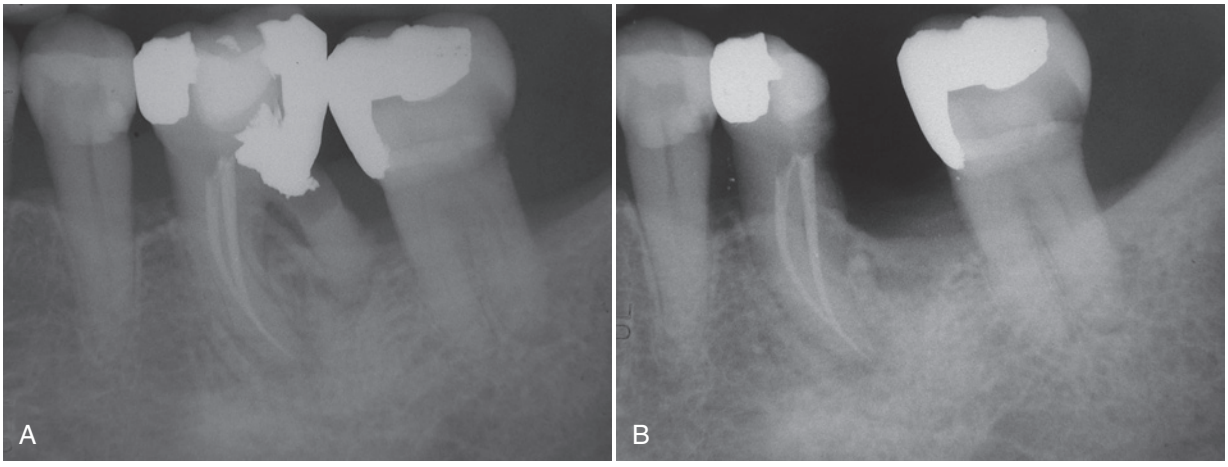

FIG. 26-55 A, Root caries and periodontal involvement of this mandibular molar tooth necessitated hemisection to retain the mesial root for restoration (B).

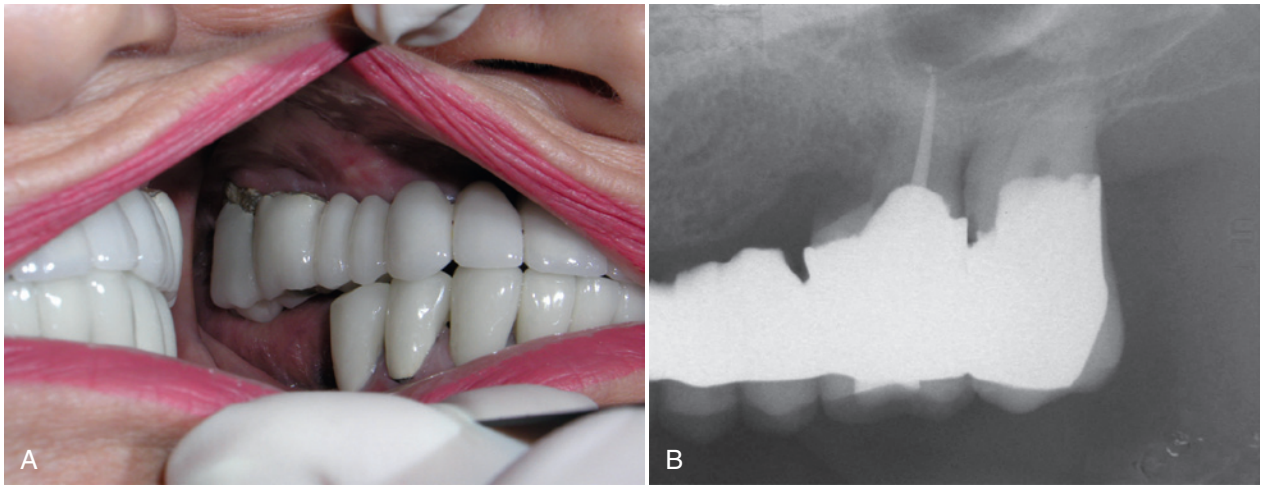

FIG. 26-56 A, Unrestorable caries contraindicated endodontic treatment on this molar abutment. B, Amputation of the buccal roots was performed to extend the life span of this bridge.

Risks and Complications Associated with Tooth Bleaching
Risks Associated with Internal Tooth Bleaching
Risks Associated with External Tooth Bleaching
Prognosis of Bleaching

Society, in general, is more concerned about beauty and perfect looks than ever before. In particular, the "perfect smile" has gained more and more importance, including straight and light-colored teeth. Tooth whitening has become a veritable business, of both the dental profession that offers vital in-office bleaching procedures, as well as of commercial companies that sell over-the-counter tooth "whitening" products. Whereas vital tooth bleaching aims to lighten the entire arch, nonvital bleaching procedures are used to treat individual discolored teeth so that they will blend in with adjacent teeth.

ETIOLOGY OF TOOTH DISCOLORATIONS

Discoloration of teeth can be attributed to various etiologies. Discoloration was described as "any change in the hue, color, or translucency of a tooth due to any cause."[174] Great differences exist in severity, localization, and appearance. Intrinsic discolorations are incorporated into the tooth structure. Extrinsic discolorations are attached to the tooth surface. Intrinsic and extrinsic discolorations may exist in combination and can affect enamel, dentin, or the pulp. Tooth discolorations may be hereditary, related to patient behavior, age, and disease, or caused iatrogenically by dental and medical treatment (Table 27-1).

Systemic Intrinsic Causes

Genetic Causes

Amelogenesis imperfecta (AI) describes a group of hereditary conditions associated with mutations in five genes—AMEL (amelogenin), ENAM (enamelin), MMP20 (matrix metalloproteinaise-20), KLK4 (kallikrein-4), and FAM83H—affecting the structure and appearance of enamel in the primary and secondary dentition.[66] Enamelin defects may cause variable hypoplasia ranging from local pitting to generalized thinning of the enamel. Amelogenin defects can lead to abnormal maturation and mineralization defects; disorganized, hypoplastic enamel; or other phenotypic variations ranging from hypoplasia to hypomaturation or hypomineralization.[66] Clinical appearance and morphologic structure of the enamel can be affected by discoloration as well as increase sensitivity and fragility. Due to the impaired mineralization resulting from the developmental changes in the enamel matrix formation, discoloring agents in the oral cavity may gain easy access to the mineral structure. The tooth color may be brown or yellow. Bleaching attempts may be, although successful, of a temporary nature and seen as an adjunct to comprehensive restorative treatment.

Dentinogenesis imperfecta (DGI) and dentinal dysplasia (DD) are a group of hereditary autosomal dominant genetic dentine disorders, characterized by an abnormal dentine structure.[18] Either primary or both, primary and secondary dentitions may be affected.[18] Dentinogenesis imperfecta is most commonly categorized into three subtypes: DGI type I, DGI type II, and DGI type III; dentinal dysplasia is categorized into two subtypes: DD type I and DD type II. DGI type I is associated with osteogenesis imperfecta and involves mutations in the collagen type 1 encoding genes COL1A1 and COL1A2. With the exception of DD type I, all other forms of dentinogenesis imperfecta and dentinal dysplasia are related to mutations in the gene encoding dentine sialophosphoprotein (DSPP).[18] All patients affected by osteogenesis imperfecta also suffer from brittle bones. Patients with dentinogenesis imperfecta have weaker teeth that are more prone to fracture. Patients suffering from DGI type I, DGI type II, and DGI type III have teeth with yellow-brown, deep amber, or blue-gray discolorations and higher translucency. Bleaching treatment will have

TABLE 27-1

Overview of Intrinsic and Extrinsic Discolorations

Color of Stain	Extrinsic	Intrinsic (Single Tooth)	Intrinsic (Multiple Teeth)
Black	Betel nut Chromogenic bacteria Coffee Dental plaque Metals Tea Tobacco Wine	Amalgam restorations Glass ionomer restorations Pulpal trauma with hemorrhage Minocycline (revascularization procedures) Metals (silver, gold, alloys)	Minocycline (oral) Tetracycline (oral)
Gray		Metals (silver, gold, alloys) Silicate compounds (e.g., MTA)	Dentinogenesis imperfecta Thalassemia
Brown/reddish	Coffee Dental plaque Doxycycline Drugs (e.g., khat, marijuana) Iodine Metals/halides Oral rinses (e.g., chlorhexidine) Other foods Tea Tobacco Wine	Caries (active, arrested) Cervical root resorption Composite resin, glass ionomer restorations Dental trauma Endodontic irrigation solutions Iodine Minocycline (revascularization procedures) Pulpal trauma with hemorrhage Resorcinol-formaldehyde resin	Amelogenesis imperfecta Congenital erythropoietic porphyria Dental trauma Dentinogenesis imperfecta Fluorosis Infection during enamel formation Tetracycline (oral) Thalassemia
Green	Chromogenic bacteria Metals Tea	—	Hyperbilirubinemia Thalassemia
Orange	Chromogenic bacteria Metals Doxycycline	—	—
Yellow	—	Caries (active) Composite resin, glass ionomer restorations Dental trauma	Aging Amelogenesis imperfecta Dentinogenesis imperfecta Dental trauma Dentinal dysplasia Fluorosis Hemolytic diseases Hemoglobin, heme Hyperbilirubinemia Nutrition deficiency (e.g., rickets, scurvy)
White	—	Caries (incipient) Dental trauma	Calcification due to trauma Fluorosis Infection during enamel formation Nutrition deficiency (e.g., rickets, scurvy)

minimal to no effect; comprehensive restorative treatment is indicated, but it is difficult to execute due to the compromised tooth structure.

Other diseases causing tooth discoloration include porphyria, erythroblastosis fetalis or thalassemia, and sickle cell anemia. Congenital erythropoietic porphyria is a disease resulting from abnormalities in the synthesis of porphyrins, organic compounds essential for the function of hemoglobin. It may result in reddish or brownish discoloration. Erythroblastosis fetalis is a hemolytic disease wherein fetal erythrocytes in Rh-positive fetuses or newborns of Rh-negative mothers are destroyed by antigens that cross the placenta, leading to hyperbilirubinemia. Bilirubin, a yellow breakdown product of hemoglobin, is incorporated into developing teeth, creating yellow-green and blue-green discolorations. Thalassemia, a blood disease causing characteristic malformations of the skull and long bones, and sickle cell anemia, a hereditary blood disorder displaying an abnormality of the oxygen-carrying hemoglobin molecule causing red blood cell malformations, may result in intrinsic blue, green, and brown discolorations.

Disease-Related Causes

High fevers experienced during the ages of tooth development may cause chronologic enamel hypoplasia leading to banding

type discolorations on the tooth surface. Vitamin and mineral deficiencies may induce hypoplasia. Rickets, a vitamin D deficiency, may lead to white hypoplasias resulting from osteomalacia, developmental anomalies in the bones. Scurvy, vitamin C deficiency in conjunction with vitamin A deficiency, and disturbances of phosphorus uptake can cause enamel hypoplasias.

Metabolic Causes

Enamel hypoplasia may also occur after excessive exposure to fluoride during tooth formation. This exposure can lead to alterations in the mineralized tooth structure, especially in the enamel matrix, and give the appearance of a mottled tooth. The extent of hypoplasia directly correlates with the fluoride uptake during tooth formation and will impact the degree of discoloration.[39] Shades of discoloration may vary greatly and can range from white spots with opaque or chalky appearances to yellow or brown stains on the facial side of the affected tooth, in severe cases with surface pitting of the enamel. No damage to the shape of the crown can be found. It can be related to amelogenesis imperfecta or hereditary hypophosphatemia. Tumors, infections, or trauma may be contributing factors. In situations of moderate severity, external bleaching may be sufficient, whereas in severe cases, a restorative approach may be indicated.

Drug-Related Causes

Tetracycline is an antibiotic used to treat diseases such as urinary tract infections, chlamydia, and acne. It was frequently used from the 1950s through the early 1980s. In particular in young children, it causes gray or brown, deep, dark stains that may affect the entire tooth or occur as a pattern of horizontal stripes. Many adults also currently suffer from tetracycline stains on their teeth. Tetracycline induces discolorations in permanent teeth manifest during tooth development, when tetracycline becomes calcified in the tooth, generating the characteristic stains. The discolorations are embedded in enamel and dentin. Children are susceptible to tetracycline discolorations from the time they are in utero until the age of 8. Because tooth development starts prior to birth, women are advised to avoid taking tetracycline during pregnancy. Tetracycline stains are obvious and were viewed as always permanent in the past. However, several studies reported successful cases after application of a walking bleach technique[2,4,7,11,58,82,126,230] and even prolonged bleaching with carbamide peroxide.[111,121,134,156,204,227] The walking bleach technique will, however, require intentional devitalization and endodontic treatment of the tooth to allow for the application of the bleaching agent into the pulp chamber.[2,4] A patient must be thoroughly informed about the risks, advantages; and disadvantages of this treatment.[2,4] Today, "power bleaching" and veneers are among the suggested treatments for tetracycline stains. Nevertheless, great care must be taken to avoid issues with bonding systems after the application of bleaching agents. Severe cases of tetracycline discoloration may require full coverage restorations.

Local Intrinsic Causes

Pulpal Hemorrhage

Dental trauma may lead to the rupture of intrapulpal blood vessels with subsequent intrapulpal hemorrhage and the release of blood components into the dentinal tubules.[12] The hemolysis of erythrocytes will result in the degradation of hemoglobin into globin and the heme protein, containing an iron atom.[145] The iron, in the form of iron sulfides, may reach dentinal tubules, causing stains and discolorations in the surrounding dentin. Depending on whether the pulp recovers or becomes necrotic, the discoloration may revert or persist. If the pulp survives, the tooth may eventually revert to its initial shade; however, in situations where pulp necrosis takes place, the discoloration may remain and become worse. Intracoronal bleaching has proved effective in these situations.[60,184,232]

Pulp Necrosis

Irritation of the dental pulp can happen chemically, mechanically, or by microbial insult, especially by bacteria and their toxic by-products. After initial inflammation, the pulp develops local microabscesses followed by tissue necrosis and eventually complete necrosis. Disintegration products from pulp necrosis may become incorporated into dentinal tubules and cause discoloration of the surrounding dentin. The intensity of the discoloration appears proportional to the time the discoloring agents remain in the pulp chamber. These types of discolorations tend to respond favorably to intracoronal bleaching.[174]

Pulp Tissue Remnants

Remnant pulp tissue that was left behind after endodontic therapy will eventually disintegrate and may discolor tooth structure. As a clinical consequence, pulp horns and all other pulp tissues in the access chambers should be carefully removed during treatment.

Restorative Materials

Metallic filling materials, such as amalgam or gold, may cause discolorations. Gold fillings—for example, gold foil compaction fillings, inlays, or onlays, but also pins or posts—mostly cause color changes, reducing tooth translucency and adding dark hues through thin remaining tooth portions. Amalgam fillings, over time, will undergo corrosive changes and degradation, with by-products causing color alterations in tooth structure.[157] For any metallic filling that remains visible through existing tooth structure, removal of the filling and exchange with an aesthetic filling material is the preferred choice. Effective dentinal discolorations by amalgam can be bleached but may be prone to recurrence. Composite resin restorations may leak at the margins and allow for discoloring agents to penetrate into the tooth and dentinal tubules.

Intracanal Medicaments and Root Filling Materials

A variety of endodontic medications and filling materials may be responsible for discolorations. Silver points, historically used for root fillings, can cause gray, dark discolorations in teeth and the surrounding tissues due to corrosive processes.[3,29] Gutta-percha was reported to cause a light pink discoloration.[164,225] Resorcinol-formaldehyde resin paste ("Russian Red") was reported to cause discolorations ranging from pink to dark burgundy.[146,189] Phenols or iodine containing intracanal medications (e.g., camphorated monochlorophenol [CMCP] or iodine-potassium-iodine [IKI]) may reside in the root canal space and start gradual discolorations by penetration of dentinal tubules through oxidation.

Endodontic sealers, particularly those containing metallic compounds (e.g., silver), can cause dark discoloration, either if the material is incompletely removed from pulp chambers and access cavities or because some components interact with moist dentine over time.[8,163,229] For example, AH26 (Dentsply De Trey, Konstanz, Germany), an epoxy resin cement, contains bismuth trioxide as a filler and radiopacifier. Within dentin, various bismuth compounds that range in color from green to black may occur and cause discoloration.[229] The corrosion of silver in the sealer may cause a gray to black discoloration.[8,49] In addition, incomplete removal of AH26 can cause discoloration in reaction with intracanal medicaments.[208] Epiphany (SybronEndo, Orange, CA), an adhesive root canal cement, showed signs of tooth discoloration.[191]

Mineral trioxide aggregate (MTA), a dental material known for excellent biocompatibility, is used for apexifications, perforation repair, root-end filling, and revascularization procedures. MTA may discolor teeth and adjacent soft tissues.[21,26,27,101,106,155,198,233] The discoloring effects were shown for both gray and white formulations.

Antibiotic pastes in various combinations are used to initiate revascularization of immature necrotic teeth. In particular, use of the triple antibiotic combination of metronidazole, minocycline, and ciprofloxacin has produced cases of dark discolorations of hard tissue structure.[112] Minocycline, a tetracycline derivate, binds calcium ions of the root dentin and forms an insoluble complex. Other medications shown to induce discolorations include corticosteroid preparations[113] or formocresol and iodoform-based medications.[78,123] Repeated applications of formocresol will penetrate dentin and cementum, particularly in the teeth of younger patients.

Discolorations may also occur due to irrigation solutions. Sodium hypochlorite can discolor dentin based on its destructive effect on erythrocytes and the ability to crystallize on the dentin surface.[78] In contact with chlorhexidine, sodium hypochlorite forms a dark brown precipitate containing parachloroaniline, which can only be removed by mechanical action.[19,20,96,117,226] MTAD (a mixture of a tetracycline isomer, citric acid and a detergent; Dentsply Tulsa Dental, Tulsa, OK) can cause brown discolorations,[214] probably caused by dentinal absorption and release of the doxycycline.

Dental Caries

Progressing caries can cause tooth discoloration. Early stages of caries are characterized by white, opaque enamel lesions. If caries arrests, the lesion may darken by taking up pigments from exogenous sources, frequently rendering it a deep dark brown or black color.[207] Explanations for discoloration include the formation of melanin or lipofuscin; the sugar-protein reaction also known as the Maillard reaction or nonenzymatic browning[16]; melanin[116] or food dye[110] uptake into the lesion, or compounds diffusing ahead of the bacterial penetration of demineralized dentine. Dietary chromogens entering the dentine is seen at least as a co-staining factor facilitated by the increased porosity of the hard tissues by the carious process.

Calcific Metamorphosis/Dystrophic Calcification

Calcific metamorphosis can be caused by trauma, resulting in obliteration of the pulp with mineralized tissue. Odontoblasts can become destroyed by the traumatic impact and replaced by cells from adult stem cell populations in the pulp. These cells may initiate rapid deposition of reparative dentin, resulting in yellowish or yellow-brownish discolorations. Anterior teeth are mostly affected. The reparative dentin may occupy the entire pulp chamber, and in certain cases also major parts of the root canal system, resulting in a loss of translucency of the crown. Depending on whether or not the remaining uncalcified portions of the pulp remain vital, endodontic therapy may be indicated, yet difficult to execute, depending on the extent of the calcification.[232] Dystrophic calcification involves the formation of foci of calcification frequently found in the aging pulp, usually in perivascular or perineural locations.

Root Resorption

Cervical root resorptions can lead to pink discolorations of teeth. The granulation tissue of the resorptive defect may be visible through a thin dental enamel layer, giving the characteristic "pink spot" appearance. Treatment involves the removal if the granulation tissue, etching with trichloroacetic acid to remove tissue remnants, and an adhesive restoration of the defect. The treatment may involve a surgical exposure of the resorption or, in severe cases, extraction of the tooth.

Aging

Aging-related tooth discolorations are the result of a physiologic process attributed to the uptake of discoloring agents into the hard tissue structure over time.[227] Age-related changes such as incisal wear, craze lines, or cracks allow for easier penetration. Furthermore, over time, enamel becomes thinner, and the change in ratio between dentin and enamel structure results in additional optical darkening of the teeth. Extracoronal bleaching can partially whiten age-related stains.

Extrinsic Causes

Extrinsic stains are food-, beverage-, or smoking-related superficial stains and discolorations. Pigments from beverages such as coffee or tea or tar from smoking may cause dark, brownish discolorations. Extensive consumption of oranges, carrots, licorice, or chocolate may lead to food-related stains. In areas with diverse populations, betel chewing and areca nut use may be prevalent. In particular, people with origins in Southeast and East Asia, India, Nepal, Bangladesh, Sri Lanka, Pakistan, and parts of China, Melanesia, Taiwan, and the Pacific Islands may be affected. Consistent chewing of betel nut and related substances may cause large-scale black discolorations. Discoloring agents are also included in marijuana. The effects of staining may be accelerated or enhanced if demineralization from acidic food or poor oral hygiene creates rougher tooth surfaces. In general, extrinsic stains respond well to scaling, polishing, or bleaching.

TREATMENT PLANNING FOR INTERNAL BLEACHING

The etiology of tooth discolorations may vary greatly. The outcome of bleaching procedures is also very dependent on the nature of the discolorations. Prior to any bleaching procedures, the situation must be carefully assessed and potential bleaching outcomes discussed with the patient, together with the patient's expectations.[74] If bleaching procedures are indicated, they should be integrated into the overall treatment plan.[194] The referring dentists may have to be made part of the conversation, if applicable. To establish a correct diagnosis, the patient's dental and medical histories need to be assessed, including

family history, genetic or systemic disorders, past and current medications, as well as any history of dental or facial trauma or orthodontic, restorative, and endodontic treatment. Radiographic analysis, including periapical and bitewing radiographs (as well as, if applicable, CBCT) is indicated. The assessment of the pulpal and periapical status is a prerequisite. Particular to treatment planning bleaching procedures, the dentition must be evaluated for caries prevalence and type, plaque control, and tooth surface stains, as well as the type, quality, and extent of existing restorations. Transillumination may aid in finding dental decay or pulp chamber calcifications.

CONTRAINDICATIONS OF BLEACHING

Tooth bleaching is not indicated for every situation and every patient. A thorough investigation and diagnosis of the patient's history and clinical situation may surface issues with the underlying stain that imply that a good aesthetic outcome is either impossible or difficult to achieve.[38,167] The patient's aesthetic expectations should be critically evaluated and the prognosis for the treatment discussed thoroughly. This includes potentially unrealistic expectations by the patient, either due to the clinical facts or the patient's over-expectations. The clinician should be aware of any psychological or emotional problems that a patient may have with the current clinical situation and should advise patients if a bleaching procedure is not in their best interest. All findings and discussions with the patient should be well documented for legal purposes and future reference.

The patient must be made aware of additional dental procedures, such as restorative, periodontal, endodontic, or orthodontic treatments that may be necessary to achieve a desired aesthetic goal.[167,194] Bleaching of teeth with white[23,76] or brown spot[109] discolorations could increase the existing contrast.[201] Teeth with existing decay or discolored or leaking older restorations may require technique variations[53] or new restorative procedures to remove diseased hard tissue structures to match the adjacent tooth aesthetically.

Patients with confirmed severe attrition, abrasion, abfractions or erosion, caries, or insufficient restorations may experience dentin hypersensitivity prior to a bleaching procedure. This sensitivity could be strongly enhanced by an in-office or at-home external bleaching procedure, particularly if patients can control the amount of bleaching agent used. Clinicians are advised to resolve the underlying issues prior to engaging in tooth whitening procedures. Patients with suspected or confirmed bulimia should not receive bleaching procedures. The underlying psychological condition must be resolved prior to treatment. Most patients suffering from bulimia require veneers or full coverage restorations.

If orthodontic treatment with fixed orthodontic appliances is scheduled, no bleaching procedures should take place 2 to 3 weeks prior to any adhesive placement of brackets.[201] The oxygen released from the peroxide compounds will interfere with the bonding strength of the composite resins to hard tissue structure.[53,153]

ALTERNATIVES TO BLEACHING

Microabrasion is an alternative to bleaching with peroxide compounds for superficial irregularities and shallow intrinsic stains in the enamel surface. Briefly, the technique involves mixing 18% hydrochloric acid solution with fine pumice powder to form a thick paste and applying it to the stained tooth surface. A rotating rubber cup in a slow speed handpiece with light pressure is used to distribute the paste. Liquid or sheet rubber dam placement is mandatory. Prior to using the rubber cup, the paste should be placed on the tooth for about 5 seconds, followed by the rubber cup activation for 15 seconds. While the enamel is carefully monitored for any damages, this procedure is repeated for up to 12 to 15 times, depending on the effectiveness of the stain removal. If the stain is not fully removed after this many applications, the procedure should be terminated to avoid permanent enamel damage. Copious irrigation with water is used to remove excessive paste material. The application of topical fluoride for several minutes concludes the procedure.[170] Several case reports with successful long-term follow-up have been reported.[199]

CHEMISTRY OF BLEACHING

The most common classification for tooth discoloration was described by Nathoo[157] and defines three classes:

Nathoo type 1 (N1): The discoloring agent (chromogen) binds to the tooth surface, with a color similar to that of dental stains caused by chromogenic bacteria, coffee, tea, wine, and metals.

Nathoo type 2 (N2): The discoloring agent is a Nathoo type 1 food stain that changes color to darker after binding to the tooth surface for a certain amount of time.

Nathoo type 3 (N3): A prechromogen or in its base state colorless material binds to the tooth and causes a stain after a chemical reaction. These types of stains are often due to carbohydrate-rich foods (e.g., apples, potatoes), stannous fluoride, or chlorhexidine.

Tooth bleaching involves the alteration of light-absorbing or light-reflecting properties of enamel and dentin stains, resulting in apparent whitening. In-office bleaching, internally and externally, has been practiced since the early 20th century, employing peroxide compounds. At-home bleaching procedures were only introduced in the 1980s. Historically, a variety of bleaching materials has been tried, including substances such as oxalic acid or chlorine.[23,72,157] Requirements for active tooth bleaching ingredients include a quick reaction with the stain components, fewer reactions with oral hard and soft tissues, ease of use, and an acceptable shelf life. Alkaline bleaching solutions may cause less demineralization damage than acidic solutions and are less likely to penetrate the pulp.[64,65] Bleaching materials should cause as minimal oxidative damage to tissues as possible[59,178] (Fig. 27-1).

Contemporary bleaching techniques rely on oxidative processes that actively break down pigmenting molecules. Oxidation is initiated by active peroxide compounds.[73,83] Peroxides and oxygen radicals are reactive free agents that are formed in all body cells that use oxygen. Reactive oxygen is, however, usually only found in low concentrations. Natural antioxidants, such as vitamin E, prevent the accumulation.[34,137] Cell damage may occur if reactive oxygen reacts with iron or copper ions.[59]

The active peroxides in concurrent bleaching techniques primarily derive from hydrogen peroxide and carbamide peroxide for external, vital bleaching and sodium peroxide for internal, nonvital bleaching. Hydrogen peroxide (H_2O_2) is the simplest peroxide, and in its pure form is a colorless liquid of

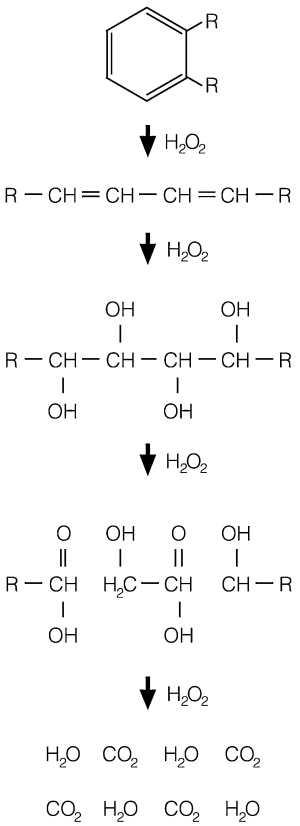

FIG. 27-1 Chemistry of tooth whitening with hydrogen peroxide. Breakdown of pigmented organic materials consisting of carbon ring structures with unsaturated, double carbon bonds to hydrophilic, nonpigmented carbon structures with saturated carbon bonds, resulting in effective whitening. Further degradation over this step may complete disintegration of the organic matrix with the release of carbon dioxide and water. (Modified from Cohen S, Burns C: *Cohen's pathways of the pulp*, ed 8, Part III, Chapter 21, Fig. 21-1. St. Louis, 2002, Mosby.)

a slightly higher viscosity than water. It can be utilized for in-office as well as at-home bleaching procedures. An increase in temperature accelerates the speed of the bleaching reaction. Hydrogen peroxide is more effective as a bleaching agent at pH values that are close to the dissociation constant.[56] Enzymes such as peroxidases can break down hydrogen peroxide into oxygen and water. High concentrations of hydrogen peroxide must be handled with great care. If accidentally brought into contact with soft tissues, it is caustic and may cause chemical burns by free oxygen radicals. For external bleaching procedures, the use of a rubber dam with additional blockout isolation around the gingival margins is mandatory to avoid iatrogenic complications. Typically, at-home concentrations range from 3% to 7.5%; however, some exceptionally strong concentrations can reach 14%. In-office concentrations may range from 25% to 38%. Hydrogen peroxide was shown not to induce significant changes in the organic and inorganic relative contents of enamel, but to whiten teeth by oxidizing the organic matrix.[54]

Carbamide peroxide ($CH_6N_2O_3$), or urea hydrogen peroxide, will break down into carbamide and hydrogen peroxide in aqueous solution.[157] It is an efficient bleaching agent.[223] The carbamide portion urea is well tolerated by the human body.[180] Carbamide peroxide is available as crystallized powder or white crystals that contain H_2O_2 in a concentration of about 35%. Most common home bleaching products contain carbamide peroxide at about 10% strength, but it can reach up to 30% (equivalent to 3.5% to 8.6% hydrogen peroxide). Carbamide peroxide can be used for internal bleaching.[223] At 35%, it shows very low extraradicular diffusion rates compared to hydrogen peroxide and sodium perborate.[128,129,141] Common bleaching preparations may contain glycerin or propylene glycol, sodium stannate, phosphoric or citric acid, and flavor additives. Carbopol, a water-soluble polyacrylic acid polymer, may be added as a thickening agent. It prolongs the release of active peroxide. At room and oral temperatures, the reaction of carbamyl peroxide takes place at a slower rate compared to hydrogen peroxide.[85] The release of oxygen from hydrogen peroxide occurs within seconds of contacting tooth surfaces, whereas carbamide peroxide remains active for 40 to 90 minutes.[157]

Sodium perborate ($NaBO_3$) comes in different preparations, mostly as a stable, dry powder or as a gel. It is available as a monohydrate, trihydrate, and tetrahydrate, with varying contents of oxygen. Depending on the oxygen content of the preparation, the compounds have a different bleaching efficiacy.[234] The perborate ion comprises 95% of the molecule and provides close to 10% of the available oxygen. Acids, water, and warm air initiate its decomposition to sodium metaborate, hydrogen peroxide, and nascent oxygen. The pH of sodium perborate solutions used for dental bleaching is alkaline. Because sodium perborate can be more easily controlled, it is considered safer to work with than hydrogen peroxide and more popular for intracoronal bleaching.

In an aqueous solution, due to heat or in an acidic environment, both carbamide peroxide and sodium perborate decompose and release hydrogen peroxide. Hydrogen peroxide then diffuses through enamel and dentin. Subsequently, the oxidative process provides for lightening of stains in comparison to the surrounding tooth structure. Double bonds of complex molecular chains with high molecular weight pigments are broken down by the chemical reactions with the free radicals. As a consequence, the change in pigment configuration and size leads to a change in the wavelength of the reflected light and the change of the stain to a lighter color.[64,65,157] In a best-case scenario, this leads to an effective reduction or elimination of the discoloration. However, after the bleaching process a shade rebound effect may be observed, resulting from a reformation of double bonds of the molecules.

Walking Bleach Technique

The walking bleach technique was described early on as leaving a mix of sodium perborate and distilled water in the pulp chamber for a period of several days, with the access cavity sealed with a temporary restoration.[186,196] Later on, the use of 30% hydrogen peroxide instead of water was suggested to provide better bleaching effectiveness.[161] The mix of sodium perborate with water or, alternatively, anesthetic solution remains the most commonly used technique for internal bleaching of nonvital teeth. The enhancement of the mixture with 30% hydrogen peroxide is being used less due to concerns of cervical root resorption but remains an option for stains resistant to whitening that require stronger chemical compounds to achieve good bleaching results.[15,24,152,162,190]

Walking Bleach Clinical Protocol

1. Prior to initiating the bleaching procedure, a diagnosis must be made following thorough evaluation of the etiology and the origin of the stain. The patient must be informed about the history, the procedures involved in the treatment, the expected outcome of the procedure, and the potential for rediscoloration.
2. The endodontic status of the tooth must be assessed clinically and radiographically. In the case of symptoms, the presence of periapical pathology, or an insufficient root filling, retreatment of the existing endodontic filling is advised, unless the apical periodontitis is on a tooth with a history of recent, well-executed root canal treatment or is verifiably in the process of healing.
3. Existing coronal restorations need to be checked for quality and shade and replaced if defective. In certain situations, the reason for discoloration may be a leaking restoration or discolored filling materials. Replacement of a defective restoration and cleaning of the access chamber may resolve the discoloration.
4. Clinical photographs should be taken at the beginning, throughout, and at the end of the treatment with the tooth next to a shade guide to act as a reference for the practitioner and the patient.
5. Rubber dam isolation is mandatory. It is important to provide a seal at the gingival margin to prevent leakage of bleaching agents into the surrounding soft tissues. Depending on whether a single tooth or multiple teeth are being isolated, this may involve the placement of clamps, wedges, ligatures, floss, or light curing blockout material. Local or topical anesthesia may be applied if the patient is sensitive to the discomfort exerted during the isolation procedures.
6. The access cavity needs to be prepared so that all restorative filling materials, root-filling material and sealer remnants, and necrotic pulp tissues remnants are completely removed. This procedure requires good visualization through cavity refinement and the elimination of all undercuts, especially in the area of pulp horns. The practitioner should exercise care to avoid labial perforations.
7. Materials should be removed to a level just below the labial gingival margin. Solvents such as xylene, eucalyptus oil, or orange solvent may be used to help clean the pulp chamber. Also, rinsing the cavity with sodium hypochlorite was suggested for cleanliness and disinfection or, alternatively, with alcohol to reduce surface tension.[15] Although some studies have recommended cavity treatment with 37% phosphoric acid or EDTA (ethylenediaminetetraacetic acid) to allow for deeper penetration of the bleaching agents, others have suggested that phosphoric acid was unnecessary and offered no better prognosis and no improvement in the bleaching effectiveness of either sodium perborate or a high concentration of hydrogen peroxide.[15,35] Acidic pretreatment may increase the risk of adverse effects on the periodontium.[97]
8. A protective layer of at least a 2-mm thickness should be placed over the root-filling material. To avoid further pigmentation the protective layer should be white or tooth colored. Without this protective layer, bleaching materials may penetrate the root filling toward the apical foramen.[45,80,195] Materials that had been suggested include glass-ionomer cements, intermediate restorative material (IRM), Cavit and Coltosol, resin composites, photoactivated temporary resin materials such as Fermit, zinc oxide–eugenol cements, polycarboxylate cements, and zinc phosphate cements.[197] Cavit and IRM provide better sealing than zinc phosphate cement,[148] and Cavit offers a better leakage barrier than IRM.[80] Cavit and Coltosol also provided the most favorable seal when tightly compacted and proved to be superior to Fermit.[98] A protective barrier at the cementoenamel junction (CEJ) will furthermore reduce the risk of cervical root resorption and damage to the periodontal ligament.[197] Ideally, the vertical outline of the protective barrier should be 1 mm coronally to the CEJ to cover lingual, labial, and proximal CEJ areas.[185] Clinically, however, this may be difficult to achieve in confined spaces. A barrier level with the labial CEJ will leave a substantial area of proximal dentinal tubules unprotected. Clinically, Cavit is also easily removable using ultrasonic instruments and chlorhexidine, thus minimizing the amount of tooth structure loss. Glass-ionomer cements may remain in place after the bleaching procedure is completed and do not need to be removed (Figs. 27-2 and 27-3).
9. Sodium perborate (tetrahydrate) is mixed with an inert liquid (distilled water, saline, or anesthetic solution) to achieve the consistency of wet sand. Mixing the paste instead with hydrogen peroxide is an option to accelerate the speed of the bleaching process, yet this technique is risky due to the increased possibility of cervical root resorption. If it is required, due to the severity of the stain, it should be used at 3% strength,[161] and it should be refrained from a 30% solution. The long-term results of a sodium perborate and water mix do not significantly differ from mixes with hydrogen peroxide.[95,180,184] A plastic instrument or amalgam carrier can be used to place the material in the pulp chamber. It is then carefully

condensed with a plugger, without missing areas such as pulp horns (Fig. 27-4).

10. Excessive bleaching material should be removed, the paste carefully dapped with a cotton pellet without removing too much moisture, and a temporary filling material that is ideally 3 mm thick with well-sealing margins placed (Cavit, 3M ESPE, St. Paul, MN). Though some have advocated the use an acid-etched adhesive as a temporary filling to avoid recontamination, restaining, and to offer the best possible prevention from leaking walking bleach,[228] this may not be practical in small cavities where it becomes difficult to selectively etch the enamel without the risk of opening dentinal tubules for hydrogen peroxide and the subsequent risk of cervical resorption. Moreover, because this procedure would have to be repeated at every visit, it would add to the amount of tooth structure loss. Any walking bleach remnants on the external tooth surfaces or the rubber dam isolation need to be removed to avoid irritation of the soft tissues.
11. The rubber dam is removed and all tissues inspected.
12. The patient should be informed about the procedure. Depending on the reaction of the stain to the bleaching agent, the time to expect results may vary. Usually, a patient should be instructed to return between 3 to 10 days to evaluate the results and to change the walking bleach if necessary. To avoid overbleaching,[15] the patient needs to be instructed to self-monitor the color status of the tooth and to report back earlier than the scheduled appointment date if the color change has reached the desired result or if the temporary filling material is starting to wash out.

Although a rarely documented event, it was advocated to instruct the patient about an increased susceptibility to tooth fracture in the time that the tooth is filled with a bleaching agent and not a supportive buildup.[17]

13. If desired results cannot be obtained, a mix with 3% H_2O_2 can be considered. However, the patient needs to be informed about the risks and that most good bleaching results can be accomplished by a sodium perborate and water/anesthetic mix.[184] If the aesthetic outcome with the results is acceptable, a potential for resorption may be minimized.
14. If a clinical case does not show improvement after three to four attempts, the diagnosis and treatment plan should be reevaluated for a different etiology.
15. At the conclusion of the bleaching procedure, a postoperative radiograph should be taken to check for any adverse effects of the bleaching agents. A permanent adhesive restoration should be placed about 1 to 3 weeks after the last appointment[36,192,193,221] (see next section, Permanent Restoration of Teeth Following Internal Bleaching).
16. The patient should be scheduled for yearly follow-ups to include a clinical examination and periapical radiographs.[42]

Thermocatalytic Bleaching

Heat-activated Superoxol had been advocated for its increased bleaching effect for internal bleaching of endodontically treated teeth.[99] Hydrogen peroxide with a concentration of 30% to 35% is placed in the pulp chamber and activated via heat application with electric heating devices or special lamps.[24,25,32,100,118,145,206] All preparatory steps follow the clinical protocol described previously for the walking bleach technique. However, in lieu of placing a sodium perborate/water mix, the pulp chamber is filled with 30% to 35% hydrogen peroxide and a heating device applied (e.g., Touch'n Heat, System B; SybronEndo, Orange, CA; SuperEndo Alpha, B&L Biotech, Fairfax, VA). The heat application will create foaming of the hydrogen peroxide, with a subsequent release of free radical oxygen. This procedure is repeated in three to four office visits. In addition, some protocols advocate the placement of 30% to 35% hydrogen peroxide in the pulp chamber between the chair-side appointments.[40,143,235] Temporary filling placement follows the same steps as outlined earlier for the walking bleach technique. If this technique is used, great care needs to be taken to avoid overheating of teeth, periodontal ligament, and gingival tissues. Regular cooling breaks are recommended. Products such as Vaseline, Orabase, or cocoa butter have been suggested for additional thermal insulation. However, due to the increased risk of cervical root resorption when using this clinical technique, the walking bleach technique is seen as more favorable today. If a decision is made to apply the thermocatalytic technique, the patient must be thoroughly informed about the risks and potential long-term consequences.

PERMANENT RESTORATION OF TEETH FOLLOWING INTERNAL BLEACHING

A good permanent restoration is one of the foundations of long-term success, as it prevents coronal microleakage from the access cavity and avoids the risk of renewed discoloration through open dentinal tubules.[17,238] It is generally accepted that an acid-etched and bonded composite resin restoration provides the most favorable results. For preexisting resin composite restorations, a rebonding of the filling has been suggested to reduce the risk of microleakage at the dentinal margins after bleaching with 15% carbamide peroxide.[151] The restoration must be placed at a depth that provides both an adequate seal for the access cavity as well as incisal support. The placement of a white base material below the resin restoration was viewed favorably in situations where the composite resin restoration may compromise the translucency of the tooth. Lighter shade composites were suggested for teeth, with a not entirely satisfactory bleaching result.[4,70] Consensus exists that the adhesive bond strength between glass-ionomer cements and composite resins to dentin and enamel is temporarily compromised following bleaching procedures[52,67,104,210-212] by remnants of peroxide or free oxygen, which inhibit resin polymerization.[52,215] Several remediation techniques have been suggested to overcome the negative influence of hydrogen oxide–containing bleaching agents, including dehydrating agents such as 80% alcohol and the use of acetone-containing adhesives,[105] the application of sodium hypochlorite to dissolve remnants of peroxide,[180] catalases,[173] the antioxidant sodium ascorbate,[107,125] or the use of alpha-tocopherol.[236] At least 1 week of contact with an aqueous solution was recommended to achieve adequate bonding.[5,210,216] Optimal bonding to bleached dentin and enamel was shown to be reestablished after 3 weeks.[36,193] Calcium hydroxide medication in the pulp cavity was advocated to achieve a buffering effect for an acidic pH that may be present after internal bleaching[17,108]; however, it may be unnecessary after a walking bleach technique, due to the weaker nature of sodium perborate compared to Superoxol. Light curing of the composite resin restoration should occur from labial so that shrinkage toward the axial walls can reduce a potential risk of microleakage.[130]

EXTERNAL BLEACHING

External bleaching may involve single teeth or entire arches. Whereas internal bleaching requires endodontic treatment of the tooth, external bleaching can also be applied to vital teeth. Steady advancements have been made in external bleaching techniques since its inception.[87,102] Various techniques exist, including in-office and at-home methods.

In-Office External Bleaching

The in-office or chair-side techniques are completely in the hand of the dental professional. Almost all techniques involve the application of hydrogen peroxide gels of concentrations between 25% and 38%. Liquid solutions at higher concentrations are associated with higher complication rates of soft tissue damage, as they are more difficult to control in terms of handling. Furthermore, high concentrations of hydrogen peroxide solutions are thermodynamically unstable and may explode if not stored in dark bottles in a refrigerator.

Although early techniques also employed heat activation, electric currents, or combinations with other chemicals to make hydrogen peroxide more effective,[136] contemporary techniques commonly use bleaching gels applied on their own or in combination with light activation by special lamps. Patients should undergo a hygiene treatment with cleaning and polishing of the tooth surfaces prior to external bleaching, as well as a careful evaluation of the nature of the stain or the possibility that the discoloration is related to an existing restoration.

If external bleaching is indicated, the treatment involves the placement of a rubber dam, as described in the protocol for the walking bleach technique. Great care must be taken to avoid soft tissue damage. If liquid hydrogen peroxide solutions and no gels are used, the additional placement of gauze to act as a reservoir for hydrogen peroxide is recommended to keep the solution in the proximity of the teeth. More gauze can be placed underneath the rubber dam as an additional safety to catch excess solution before it can damage gingiva, mucosa, or lips. However, these complications can be greatly reduced by a gel application with or without light activation.

Light sources used for bleaching include conventional ultraviolet (UV) bleaching lights, tungsten-halogen and Xe-halogen lights, plasma arc lamps, light-emitting diodes (LED), or laser lights. The wavelengths of the various light sources may range from the high ultraviolet to low visible blue light spectra, and invisible infrared light, such as employed by a CO_2 laser.[32,172] Although all of these lights have been used to activate the bleaching agent or expedite the whitening effect, there are great differences among them. Limited research on bleaching lights exists, with sometimes controversial results. Although some studies emphasized certain effects after light-activated bleaching, others reported no differences between teeth bleached with and without light activation.[32,122,172,203] In the 1980s, the Fuji HiLite dual-cure material containing 35% hydrogen peroxide was used. When the paste was mixed, it had a green color that would turn white upon activation with a standard UV light upon the release of oxygen. In comparison to other light activation techniques, this was a more time-consuming process and less comfortable for the patient. In addition to light activation alone, various photocatalysts were suggested, including methylene blue and ultraviolet or visible light-activated titanium dioxide.[200]

Tungsten-halogen curing lights are the standard dental curing lights that provide heat and stimulate the initiation of the chemical reaction by activating light-sensitive chemicals in the bleaching agent. Depending on manufacturer recommendations, the individual bleaching time with activation of the gel is 30 to 60 seconds per application per tooth, which is rather time consuming for the patient and the dental professional because up to three passes are recommended. Some products available were based on a premixed 35% hydrogen peroxide gel with carotene that converts light energy to heat upon activation and increased the breakdown of the bleaching agent into active free radicals. Xenon-halogen curing lights are newer generation dental curing lights used to the same effect. Some specialized bleaching lights offer full-arch adaptors. A randomized clinical trial of in-office tooth whitening identified blue light–activated bleaching as the one technique with results most favored by patients.[9]

Xenon plasma arc lamp systems are primarily based on thermal activation and the activation of chemical catalysts in the bleaching gel. The light employed is of high intensity, produces great heat energy, and limits the application to 3-second intervals for up to three passes. Due to the high heat intensity, there is a potential for dental trauma to the pulp and the surrounding tissues, which is why these lights have to be used with great care. Some manufacturers produced lights that allowed an on-off mode setting over 5-second bursts to have a safer and lower-intensity output.

LED lamps emit cold blue light with a wavelength of around 465 nanometers, which allows activation of hydrogen peroxide gels and accelerates the bleaching process. LED lights are placed close to the patient's teeth for 15- to 20-minute treatments, which may have to be repeated up to three times. Cosmetic specialists with no dental background have adopted this method of bleaching because it offers low risk, as no heat activation is involved.

Lasers are used for tooth bleaching at 830 nm and 980 nm wavelengths for tooth bleaching in combination with 30% to 35% hydrogen peroxide gel. Gels prepared for laser activation may contain fumed silica and a blue dye, the latter absorbing the laser wavelength leading to an increase in temperature and a controlled breakdown of the hydrogen peroxide. Gels are commonly applied in a 2- to 3-mm thickness over the teeth. An application of 1 to 2 W of laser energy for 30 seconds per tooth is recommended. Dental professionals and patients are required to wear protective eyewear while operating lasers. Some studies reported no significant advantage to using laser light for bleaching,[32] whereas others showed a decrease in color regression after a combination of at-home bleaching with an in-office laser-assisted bleaching session in comparison to an at-home bleaching regimen on its own.[6]

"Power Bleaching"

The technique normally termed power bleaching refers to accelerated vital in-office tooth whitening procedures that employ either xenon plasma arc-curing lights or lasers. Either dental hygienists or dental assistants may carry out this procedure, depending on individual licensing issues state by state. In particular, the use of laser lights might be more strictly regulated and may not be allowed to dental professionals other than the dentist. For a delegated procedure, liquid rubber dam is often applied in lieu of a sheet of rubber dam, which would require active retention techniques, such as wedges, floss, or ligatures. Liquid rubber dam can be applied easier without assistance, but it does not give additional protection to gingival tissues or the mucosa.

Power Bleaching Clinical Protocol

1. Prior to initiating the bleaching procedure, a diagnosis must confirm that the discolorations can be resolved by external bleaching. The patient must be informed about the history, the procedures involved in the treatment, the expected outcome of the procedure, and the potential for rediscoloration.
2. A thorough clinical examination should be performed to detect caries, developmental defects, endodontic or periodontal diseases, and other pathologic conditions in the oral cavity. Existing restorations need to be checked for quality and shade and replaced if defective. For certain teeth, the reason for discoloration may be leaking restorations or discolored filling materials. Replacement of a defective restoration may resolve most of the discoloration.
3. Patients should have a hygiene appointment prior to the bleaching session to check for sound gingival tissues and ensure that areas to be bleached are free of calculus or plaque.
4. Clinical photographs should be taken in the beginning, throughout, and at the end of the treatment with the tooth next to a shade guide to act as a reference for the practitioner and the patient.

5. The patient and dental professionals should wear proper protective eyewear (sunglasses). The patient should be prepared to signal if a tingling sensation to the gingiva, mucosa, lips, or teeth is felt or the temperature is perceived as too hot. As a precaution, vitamin E capsules, a powerful antioxidant, should be ready at hand. In case of an emergency, these can be cut open and the oil inside the capsules applied to the injured tissues with a cotton pellet.
6. The teeth should be cleaned again with rubber cups and pumice. The cheeks should be retracted with photo retractors or cotton rolls. The cotton rolls serve as an additional safety feature if any hydrogen peroxide is leaking. Rubber dam isolation is mandatory. This can be either liquid rubber dam (light-cured resin dam) around the gingival margins or ligated sheet rubber dam. Liquid rubber dam bears a higher risk of tissue injury. It is important to create a tight seal at the gingival margin to prevent leakage of bleaching agents. If a sheet rubber dam is used, the inversion of the rubber dam in the sulcus with an air syringe followed by dental floss ligature is recommended.
7. The power bleach gel is mixed according to the manufacturer's recommendation and applied on the labial surfaces of the teeth in a 2- to 3-mm thickness with a disposable brush.
8. Depending on the light source, each individual tooth is exposed for up to three passes for 3 to 10 s, according to manufacturer's recommendations. The gel may stay on the teeth for another 3 to 5 minutes without light activation.
9. The gel should be removed with a wet gauze and copious amounts of water, then cleaned with pumice for a second time, and rinsed again to ensure all remnants of the bleaching gel were removed.
10. The rubber dam and any remaining cotton rolls and retractors are removed. Water rinses are used again, and all tissues inspected.
11. The teeth should be polished and a neutral pH sodium fluoride gel applied.
12. The patient should be informed about the procedure. Depending on the individual situation, results may vary. The patient should be instructed that increased sensitivity of the teeth may be present for 2 to 3 days.
13. The patient ought to be instructed to refrain from tobacco, coffee, tea, cola, and wine for a period of 2 weeks.[44]

At-Home External Bleaching

For patients who do not want to undergo an in-office procedure, the possibility of at-home external bleaching with custom-made bleaching trays exist. These may be readily available from a pharmacy, requiring only crude adaptation after softening in hot water, or can be fabricated in a dental laboratory. Over-the-counter products most commonly come with bleaching gels, although some come with pastes. Some products are offered as simple, low-strength hydrogen peroxide strips or pastes that can be brushed onto the teeth. Occasionally, pre-rinses are offered. However, these may come at a rather acidic pH, as these solutions may become unstable more easily.

Professional home bleaching involves the fabrication of a well-adapted custom tray after impressions are taken and models are poured. The patient will wear gel loaded in a tray that slowly releases the bleaching agents for several hours or overnight every day for 2 to 6 weeks until a satisfactory result has been achieved.[38,83-87]

Trays are usually made using alginate impressions. Upon delivery, trays must be checked for fit, smoothness at the margins, and occlusion. The patient should place several drops of bleaching gel into the tray before every application. The most common bleaching agent for at-home bleaching is 10% to 22% carbamide peroxide with an effective yield of 4% to 7.5% hydrogen peroxide. Patients who wear the trays during the daytime may choose to replace the gel every 2 hours. If any disturbance (e.g., thermal sensitivity, abnormal taste, or tissue irritation) occurs, the patient should stop the procedure and seek advice from the dentist. Patients who use the trays in the daytime should be seen once per week for 3 weeks; nighttime users should be seen every other week for 6 weeks.

The success of at-home bleaching mostly depends on the patient's cooperation. Risks include potential compliance issues and the possibility of overuse of the bleaching agent. Results with at-home bleaching techniques tend to remain stable for 1 to 10 years.[132]

RISKS AND COMPLICATIONS ASSOCIATED WITH TOOTH BLEACHING

Risks Associated with Internal Tooth Bleaching

Tooth bleaching may cause localized adverse effects on hard and soft tissues, such as the risk of external cervical resorption, interaction with adhesive bonding systems, and dental material solubility.[10]

Cervical Root Resorption

External or cervical root resorption is a serious complication of whitening procedures with peroxide compounds. Cervical root resorptions were seen in 6% to 8% of cases when 35% hydrogen peroxide was used, and 18% to 25% if the hydrogen peroxide was heat activated.[47,62,63,81,91,124,182] The etiology for external root resorption to occur is complex.[75,81,120,124] It is suggested that a combination of predisposing factors—such as a cementum deficiency exposing dentin, a periodontal ligament injury that is triggering an inflammatory response, or an infection that is sustaining inflammation—has to be present.[17,63,160,219] Cervical resorptions are also often seen in patients who had bleaching treatment at a young age[7,11,63,91,95,124] or who suffered from a traumatic injury.[81,217]

Hydrogen peroxide itself was suggested to be responsible for the induction of the resorptive process.[81] The body can handle hydrogen peroxide effectively at lower concentrations.[79]

Proinflammatory agents activate reduced nicotinamide adenine dinucleotide phosphate oxidase, which produces superoxides that can react with hydrogen peroxide in the presence of inflammation.[77] This may allow the formation of hypochlorous acid, N-chloramines, and reactive hydroxyl ions and cause a resorptive process.[77] Hydrogen peroxide may reach the bone by diffusion via dentinal tubules, cementum, and the periodontal ligament.[77,166,231] Within the bone, the acidic environment induced by the low pH value of hydrogen peroxide at high concentrations may facilitate osteoclastic activity.[63,224] After application to the enamel surface, 25% hydrogen peroxide was also shown to cross enamel and the dentinoenamel junction (DEJ), reaching the dentin.[220]

About 10% of all teeth have a natural defect at the cementoenamel junction, exposing dentin.[205] These cementum

defects, as well as unusual morphology at the CEJ, can favor the penetration of hydrogen peroxide into the cervical area of a tooth.[119,159,182] The placement of 30% hydrogen peroxide in the pulp chamber of teeth with missing parts of the cementum layer resulted in the diffusion of 82% of the bleaching agent.[182] Dentin exposure may also be a result of defects in the cementum layer following traumatic injuries or an incomplete formation of the cementoenamel junction.[144,150] The permeability of the dentin can then facilitate the penetration of bacteria or bacterial endotoxins from an infected root canal system or pulp chambers to the surface of the root, potentially causing inflammatory processes in the periodontal ligament.[92,152] If highly concentrated bleaching agents are used, in particular, 30% to 35% hydrogen peroxide, a diffusion of highly reactive hydroxyl radicals via unprotected dentinal tubules and cemental defects was suggested.[119,182]

Free oxygen radicals are also able to break down constituents of connective tissue, in particular collagen and hyaluronic acid, which may be another likely mechanism responsible for periodontal tissue destruction and root resorptions after internal bleaching.[48] The oxidizing agents were shown to induce dentin protein denaturation,[124] either by local changes in the pH[50,69,150] or by heat.[60,81,144] Pretreatment is with EDTA, a chelating complex binding iron. Heat activation of 30% to 35% hydrogen peroxide is the characteristic step of the thermocatalytic method. It may result in widening of the dentinal tubules, allowing for a diffusion of free radicals into the dentin[165,181] and an enhancement of resorptive processes.[181] The hydroxyl radicals released from hydrogen peroxide are extremely reactive and have been shown to degrade components of connective tissue.[48] As a consequence, the thermocatalytic technique is nowadays disfavored due to the high risk of external root resorption.

The potential for cervical resorption may be minimized by using sodium perborate with water instead of hydrogen peroxide for internal bleaching techniques, because similar acceptable outcomes have been reported[184] and because it did not cause cervical resorption, even 1 year after bleaching.[144] Sodium perborate–water suspensions were also shown to be less toxic to periodontal ligament cells than 30% hydrogen peroxide or sodium perborate mixed with 30% hydrogen peroxide.[115,181] Moreover, a strong association was found between tooth discoloration related to blood components and an increased presence of hydroxyl radicals.[48]

Treatment of cervical resorption may range from simple fillings to extraction, depending on the severity of the resorptive defect. An early detection of a resorptive process increases the chances of avoiding unnecessary tooth loss, because the prognosis for cases with advanced resorptions is doubtful.[51] Evaluation by means of a CBCT may greatly enhance the ability for correct treatment planning.[55] If resorptions are related to internal bleaching, the placement of calcium hydroxide into the root canal space has been suggested[63] to change the low pH present in inflammatory osteolytic processes characteristic for hard tissue resorption.[147] Reparative hard tissue formation was suggested to take place following this treatment.[218] Some cervical resorption can be repaired with direct restorations, such as composite resin or glass ionomer–composite compomers (e.g., Geristore, DenMat, Lompoc, CA). This treatment requires a surgical exposure of the defect, followed by degranulation by curettage and the application of 90% trichloroacetic acid to remove remnant tissues prior to adhesive restorations.[61,149] Patients should be informed about the potential for gingival recession if the surgical access requires a full thickness flap in the anterior area.[55,69] Rapid orthodontic extrusion in combination with fiberotomy and restoration was suggested for resorptions with a substantial subcrestal component.[90,127]

The free radicals released by peroxides can cause chemical burns and tissue sloughing on gingiva, mucosa, or other oral soft tissues. This may occur during the internal bleaching procedure in the dental chair during both walking bleach or thermocatalytic technique appointments after a patient has left the office if a walking bleach technique is used. In any case, prevention is the best cure, and avoiding accidents is the priority. In general, the use of higher concentrations of peroxides, such as 30% to 35% hydrogen peroxide, in particular in liquid form, is more dangerous than the use of a mixed paste or gel of sodium carbamide peroxides that have lower effective hydrogen peroxide concentrations and can be used more controlled. However, in the dental office great care has to be taken so that the bleaching agents do not leak through the rubber dam and all excessive bleaching material is carefully removed after the end of the procedure (see details in Walking Bleach Clinical Protocol). For emergency situations, clinicians should have vitamin E on hand, because this tough antioxidant reverses the strong oxidation processes on oral soft tissues and minimizes damage (see details in Power Bleaching Clinical Protocol). To avoid out-of-office accidents, it must be assured that the temporary filling material is sealing tightly and is placed in an adequate thickness to cover the bleaching agent. Patients should be advised to return immediately after a temporary restoration starts to fail or wash out.

Enamel and Dentin Damage

A number of in vitro studies reported changes in enamel microhardness and morphology,[22,37,142,154,175,177,237] as well as in the cementum.[213,239] It has been suggested that peroxide components alter the proportions of organic to inorganic hard tissue components.[83,92,135,169,213] A treatment with 10% carbamide peroxide and 7.5% hydrogen peroxide did alter the enamel surface micromorphology, but not its microhardness.[187] Hydrogen peroxide demonstrated a different chemical affinity to each specific dental tissue, rather than just to diffuse through interprismatic spaces into the dentinal tubules when applied to the enamel surface.[220] It was also shown to modify the organic compounds of dentin.[220]

At least in vital teeth, however, these changes appear not to be permanent[14,68] and can be reduced by the application of fluoride before or during remineralization.[31,68] The bleached enamel surface may show an increased porosity and slight erosion when observed under scanning electron microscopy (SEM). These changes were mostly seen when acidic prerinses or bleaching gels with a low pH had been applied.[222] One study found no differences between bleached and unbleached human enamel over a 6-month period when a 10% carbamide peroxide gel was used.[89] No significant clinical evidence of negative effects on enamel by professionally administered at-home bleaching techniques was seen. A few case reports described significant enamel damage after over-the-counter products had been applied by patients, possibly the result of overuse.[46]

Inhibition of Adhesive Bonding

Polymerization and bonding strength of composite resins to dentin and enamel are temporarily compromised by the oxygen

released during a bleaching process.[13,52,202,209,211] Scanning electron microscope images have shown an increased porosity of the enamel after bleaching.[211] This may present a clinical issue in terms of leaking restorations with the potential for caries activity and rediscoloration. Several remedial solutions were suggested, including rinsing the cavity with sodium hypochlorite,[180] which, however, was demonstrated to have similar effects on bonding, alcohol,[105] chlorhexidine, catalase, and sodium ascorbate.[41,107,125] Clinicians are generally advised to wait for 2 to 3 weeks prior to placing a permanent adhesive restoration to allow time to reverse the effects and have all remnants of hydrogen peroxide removed from the pulp chamber.[41]

Risks Associated with External Tooth Bleaching

External tooth bleaching (including professional at-home tray bleaching techniques) is, generally speaking, a safe procedure that allows tooth whitening to be retained for several years.[132] Nevertheless, concerns have been raised since the introduction of external bleaching,[88,137-140] mostly related to the caustic effects of free oxygen radicals that may cause tissue damage in oral soft and hard tissues. The reaction with proteins, lipids, and nucleic acids may eventually lead to cell damage. At-home external bleaching did not demonstrate significant long-term complications if 10% carbamide peroxide was used as the bleaching agent. However, since at-home bleaching does not give the practitioner control over the patient's behavior, higher concentrations of carbamide peroxide than recommended may be used and could more likely cause damage to the gingival and periodontal tissues.[93] In general, caution is advised in regard to the quality of product, techniques used, and treatment rendered.

Tooth Sensitivity

The presence of hypersensitivity is an indication of inflammatory changes in the dental pulp.[139] Histologically, however, few pulps have demonstrated actual signs of inflammation after external bleaching with hydrogen peroxide gels.[114] Nevertheless, changes in sensitivity after external bleaching of vital teeth have been reported in up to 50% of the teeth.[88,136] Most of the time the change in sensitivity is mild to moderate and is transient over a period of 2 to 3 days.[103,133,168] In the case of at-home bleaching, the incidence of hypersensitivity increases with the frequency of changing the bleaching trays, particularly if they are changed more than once daily.[133] For the best immediate remediation, the bleaching periods should be shortened. Both topical fluoridation and desensitizing toothpaste may aid in reducing the hypersensitivity after bleaching.

Hydrogen peroxide that is released from the bleaching trays or from the gel during power bleaching may reach the pulp chamber via craze lines, enamel defects, as well as enamel and dentin cracks.[28,43,71,171] However, it was shown that 50,000 µg of hydrogen peroxide are required to inhibit pulpal enzymes.[79] From bleaching gels containing 12% carbamide peroxide, less than 30 µg of hydrogen peroxide were shown to reach the pulp chamber after tray applications for up to 7 hours. Therefore, at least for at-home external bleaching, it is unlikely to create long-term or significant damage. Nevertheless, to avoid complications, active bleaching should be avoided whenever restorations with ill-adapting margins or exposed dentin areas are present. It has been suggested that desensitizers be used in addition to the bleaching gel. Caution should also be applied regarding children and adolescents due to the larger pulpal volume present in immature, respectively younger teeth.[129]

Gingival Irritation

The most commonly observed adverse effect after external bleaching is gingival irritation, which may be associated with an increase in tooth sensitivity.[131,183,188] Most of the gingival irritations are mild to moderate and disappear after 2 to 3 days without causing significant discomfort for the patient. For in-office bleaching, these issues are mostly related to soft tissue exposures to excessive bleaching gel or liquid hydrogen peroxide in amounts less than necessary to cause severe discomfort or tissue damage. However, when a patient reports tissue irritation, the soft tissues should be checked immediately. Warning signs other than the patient's sensation are air bubbles rising from the gingival margins. The area should be copiously rinsed without delay. A vitamin E preparation should be on hand to serve as an emergency dressing that will provide an immediate antioxidative effect. If an at-home technique is used, gingival irritations may be related to badly adapting trays, and the issue should be resolved after correcting the defective trays. As for gingival hypersensitivity, the increase of gingival irritation is related to the frequency of changing the gel in the custom trays. For more severe cases, topical anesthesia, limited movement, and good oral hygiene can increase the speed of soft tissue healing.

Mercury Release from Amalgam Restorations

Several studies have reported an increased mercury release from amalgam restorations after the application of bleaching agents, in particular carbamide peroxide.[176,179] Although mercury is toxic and can cause damage in larger doses, no health implications due to the induced release of mercury by tooth bleaching has been reported.

PROGNOSIS OF BLEACHING

Most studies addressing the prognosis of internal bleaching refer to the immediate postoperative whitening result.[4,7,11,95,99,145,160] A long-term follow-up of teeth bleached with the thermocatalytic technique reported an 80% success rate after 1 year and a 45% success rate after 6 years, confirming the redarkening of bleached teeth in many instances.[57] Discolorations induced by trauma or pulp necrosis appear to have a good prognosis of around 95% that bleaching reaches the desired result, whereas discolorations due to medications or restorations have a much less successful outcome.[158] In general, discoloration caused by restorative materials has an uncertain prognosis,[225] particularly if metallic ions such as silver, mercury, copper, or iodine are involved. Although some authors disagree,[1,30,100] there may be a higher possibility for successful bleaching in younger patients due to the wider open dentinal tubuli when compared to older patients.[2,94,160] Gray or light yellow discolorations may be easier to bleach than other discolorations.[1] Well-sealing composite restorations are recommended to prevent renewed discoloration.[1] External bleaching may show color regressions after 1 to 3 years.[33]

CHAPTER 28

Understanding and Managing the Fearful Dental Patient

HENRIETTA L. LOGAN | ELLEN B. BYRNE

CHAPTER OUTLINE

Anxiety and Fear
Mechanisms
Intervariability and Intravariability in Responses
Variability in Stress Response
Variability in Pain Response
Management of Pain and Anxiety
Patient Communication
Behavioral Interventions
Pharmacologic Management of Fear
Summary

The hand froze as she started to dial, almost as if some other life form had seized control of her body. She stood there for what seemed like minutes before she could bring herself to dial the number. Her heart was beating faster—she just couldn't do it. As she fumbled to disconnect, she heard a cheery voice on the other end of the line: "Dr. Rodriq's office, dentistry with a personal touch. May I help you?" She muttered under her breath, "I can't do it now. I'll try tomorrow."

This scenario is familiar to many people. The mere act of making a dental appointment requires greater courage than they can summon up, and except when oral pain becomes unbearable, pursuing dental treatment is out of the question.[80]

Many fears are regarded as socially unacceptable. Dental fear, however, is widely accepted and carries little social stigma. Several studies have confirmed that dental anxiety and fear are common among the general U.S. population and are a worldwide problem.[68,69,75] About 50% of adults in the United States report some dental fear, and 8% to 12% are fearful enough that simply making a dental appointment is problematic.[84] Although women account for more than half of fearful patients, clinicians should not assume that the men they treat as patients are without dental fear and anxiety. Men may not express their fears as openly as women, but exaggerated emotions, such as anger or impatience, may be masking their dental fear.[33] As the fictional scenario demonstrates, many clinicians have attempted to make their practices inviting by presenting a warm and friendly image to the patient who calls. Yet data show that in the United States, the rate of dental anxiety or fear has remained stable during the past 50 years.[83]

Worldwide, the prevalence of dental phobia (an extreme form of fear) is also common. In Australian adults, the level of dental fear ranges from 10% to 14%,[31] whereas in Iceland, Taiwan, and Japan, the percentages of adult respondents who reported at least some dental fear were 21%, 50%, and 82%, respectively.[25,72,77] Studies of children have shown considerable global variation in the prevalence, with some estimates as high as 43%.[30] Given the international prevalence and universal acceptance of dental fear and anxiety, it is impossible for any clinician to avoid fearful patients. Consequently, it is worth the clinician's time and energy to understand the nuances of dental fear and anxiety.[4] This chapter presents general information about fear and anxiety, including proposed mechanisms, and highlights individual differences in response and management strategies. It begins with a section describing the biologic and psychological characteristics of anxiety and fear.

ANXIETY AND FEAR

Anxiety and fear play an adaptive role as an alarm in response to danger. Both are crucial and adaptive components of the overall behavioral and autonomic stress response. In response to dangerous situations that threaten to disturb homeostasis, some biologic systems are activated and others are inhibited in a largely predictable manner. A short-term reaction proportional to the challenge elicits an appropriate response (often escape and avoidance) and is of fundamental importance as a survival strategy. However, this survival strategy taxes the patient's resources, and stress-induced dysregulation may result in a diverse set of health risks ranging from increased susceptibility to viral infection[13,14,89] and activation of latent virus[7,58] to impaired wound healing after surgery[63] and increased mortality.[10]

Anxiety and fear lie at the interface of neurobiology and psychology and are controlled by a highly complex system of both inhibitory and facilitatory mechanisms. These stress mechanisms are dynamic and redundant.[70] Their purposes include maintaining an appropriate degree of emotion under nonthreatening conditions; efficiently responding to potential threats; producing behavioral responses, such as "fight or flight"; and, finally, allowing the patient to rapidly return to

"baseline" after the danger has passed. Authors have attempted to make a distinction between anxiety and fear, and for the purposes of this chapter, those distinctions may be helpful in understanding dental patients' responses to actual and potential treatment.[69,91]

Fear is described as an individual's physiologic and emotional response to a perceived immediate and identifiable threat or danger. It is accompanied by an unpleasant cognitive or affective state of impending doom marked by physiologic changes involving the sympathetic branch of the autonomic nervous system (e.g., hyperventilation, enlarged pupils, gastrointestinal upset, changes in salivary flow, elevated catecholamines) and overt behavior that may involve pacing, shaking, combativeness, or attempts to escape the situation.

Anxiety may or may not differ in the degree of physiologic and emotional arousal compared with fear, but the source of the threat is typically ambiguous, ill defined, and not immediate. Using this paradigm, the emotional and physiologic response a patient reports when imagining a dental appointment would be classified as anxiety, whereas the elevated psychological and physiologic arousal of a patient receiving an injection of local anesthetic while seated in a dental chair would be characterized as fear.

Dental phobia is a special case of dental fear, characterized as a consistent and persistent fear that interferes with a person's social life or role functioning and often leads to avoidance of dental treatment of almost any type. Although the distinction between anxiety, fear, and phobia is useful to consider, most patients do not make such a distinction; consequently, the clinician should be aware that the terms are often used interchangeably.

For most people, the level of anxiety and fear expressed is commensurate with the level of danger or threat present, and the individual quickly adapts to the threatening event, either through reassessment of the level of danger or development of more effective coping skills. For most dental patients, the level of threat from treatment is balanced by the potential to benefit from maintaining good oral health, leading the patient to seek and receive treatment. For others, the fear may be disproportionate to the level of threat, and the individual's behavior is perceived by an outsider to be maladaptive (avoiding treatment until the last moment). For still others, the anxiety experienced is paralyzing with respect to the stimulus and persists in the absence of threats, producing high levels of intrusive thoughts and memories.[21] At its most extreme, this reaction qualifies as a phobia, and the avoidance is of such a proportion that it produces extreme distress and may provoke an immediate and intense anxiety response at the mere mention of the word *dental*.

MECHANISMS

The paradox, that the systems activated by stress-inducing stimuli cannot only protect and facilitate, but also damage the body, was recognized nearly 70 years ago.[26] Since that time, the interactive roles of the autonomic nervous system, the hypothalamic-pituitary-adrenal axis, and the cardiovascular, metabolic, and immune systems during stressful responses have been documented, and the price of the continual accommodation to stress has been characterized.[65]

The stress system coordinates the generalized stress response, which has both central nervous system and peripheral components. The main elements of the stress system's central components, which are located in the brainstem and the hypothalamus, include the arginine vasopressin neurons of the paraventricular nuclei of the hypothalamus; the parvocellular neurons of corticotrophin-releasing hormone; the corticotrophin-releasing hormone neurons of the paragigantocellular and parabrachial nuclei of the medulla and the locus ceruleus; and other, largely noradrenergic cell groups in the medulla and pons (LC/NE). (The reader is referred to an excellent paper by Charmandari et al.[9] for details of the endocrinology of the stress response.)

INTERVARIABILITY AND INTRAVARIABILITY IN RESPONSES

Variability in Stress Response

The stress system receives and integrates a diversity of inputs; these arrive through distinct pathways arising from the individual's unique biology, psychology, and environment. Activation of the stress system is remarkably similar across species, but individual differences do exist that arise from variations in genetics and individual experiences. The knowledge resulting from research into the effects of stressful responding is far-reaching and shows associations across a broad range of health conditions, including wound healing[82]; the severity of infectious diseases[14,59]; inflammatory response[60]; chronic diseases such as cancer[85]; and pain levels.[20,71,73,93]

For instance, psychological stress has been shown to impair human wound healing in a number of well-controlled studies. In one study,[46] the investigators placed 3.5-mm punch biopsy experimental wounds on the arms of chronically stressed caregivers of patients with Alzheimer's disease, in addition to well-matched controls, to study dermal wound healing. In the Alzheimer caregivers group, healing of standardized wounds took an average of 24% longer, with group differences in wound size appearing within the first week of healing. The ability to mount an inflammatory response was tested using an ex vivo endotoxin-stimulated interleukin 1 beta (IL-1β) gene expression assay in whole blood. Alzheimer caregivers produced significantly less IL-1 than did the controls. These results indicate that stress begins to have an impact in the early phases of wound repair, specifically the inflammatory phase, resulting in delayed wound closure. In an oral wound model, with wounds placed 3 days before examinations, dental students healed an average of 40% slower than did the same students with wounds made during summer vacation, and the differences were quite reliable. No student healed as rapidly during examinations as during vacation.[63] These data show that an event as transient, predictable, and relatively benign as examination stress may have significant consequences for wound healing, even in young adults.[62]

It seems quite likely that similar phenomena would be found in fearful dental patients after surgery, but no study to date has tested the question. It is beyond the scope of this chapter to review this important body of work,* but two important factors largely determine individual responses to potentially stressful situations: the way a person perceives the situation and the person's general state of health, which is

*References 11, 40, 42, 44, 47, and 88.

influenced by both genetic factors and lifestyle.[66] Under this paradigm, it is not surprising that both interindividual and intraindividual differences exist in response to potentially aversive stimuli.[23] Nowhere are variations in an individual's response to a stressor more apparent than in a dental office. The following section describes one highly relevant dental outcome that has been shown to be influenced by fear, anxiety, and stress and that exhibits remarkable interindividual variability.

Variability in Pain Response

Two patients with comparable dental disease may report vastly different levels of pain associated with their disease and treatment. One patient may be distressed and report high levels of pain. The other may seem less bothered by the problem and report low to moderate levels of pain. Is one patient an outlier and the other typical? Or are both legitimate expressions of the individual's experience?

The role of these individual differences in the response to stress is complex, and the part these differences play in pain perceptions is only partially understood. Investigators showed that experimentally induced anxiety led to increased pain reactivity, whereas high levels of fear led to decreased pain.[79] Whether the dental setting produces fear or anxiety is not clear, but within the dental care context, patients may have worried for days about a scheduled treatment, resulting in elevated levels of autonomic arousal and high levels of anxiety. This elevated arousal may produce heightened levels of plasma catecholamines, which in laboratory studies have been shown to lower the pain threshold and tolerance.[8] It is not surprising that many highly anxious patients show elevated levels of pain reactivity during dental treatment compared with less anxious patients.[49] Therefore, clinicians should anticipate that anxious patients will have more sensory and affective distress during dental treatment than less anxious patients and treat them accordingly.[61]

A body of literature shows that pain is strongly influenced by factors that include the person's affective, cognitive, and psychosocial history and social learning (see also Chapter 4). One study[56] demonstrated that patients' perception of pain was associated with the amount of personal control they believed they would have during dental treatment, coupled with the amount of control they wished to have. Dental patients with the largest discrepancy between the amount of control they desired and the amount they believed was available were at greatest risk for elevated levels of expected, experienced, and recalled pain during dental treatment.[36] *Catastrophizing,* a form of coping characterized by expecting the worst, predicts greater severity of postoperative pain; it has been linked with both experimental pain sensitivity and clinical pain symptoms.[45] In addition, negative mood predicts greater severity of acute pain and is related to greater pain sensitivity.[37,57]

Negative mood also influences the level of pain that is recalled. Overall, pain is remembered inaccurately and becomes exaggerated over time, with the amount of exaggeration strongly influenced by the intensity of the negative emotions at the time of the painful encounter. Moreover, the elevated recall of pain influences the level of pain experienced at a second painful encounter, such as in dental treatment.[35] These research findings reinforce the significance of efforts to reduce a patient's level of negative emotion before dental treatment.

Increasing evidence indicates that women with high levels of dental fear are more likely to have a history of sexual or physical abuse (or both) than other women. The current estimate of childhood sexual abuse in the general U.S. population is 5.8% to 34% for women and 2% to 11% for men, which is considered by many to be a conservative estimate.[29,94] The sheer number of patients who have experienced sexual abuse strongly suggests that clinicians frequently treat sexually abused patients, and a greater understanding of the impact of abuse on dental attitudes and reactions may help both the patient and clinician to form an effective treatment partnership.

A study of sexually abused European women who were categorized by whether they had been exposed to sexual touching, intercourse, or oral penetration showed that women in the oral penetration group scored significantly higher on dental fear than women in the other two groups.[95] In addition, women with a history of childhood sexual abuse and high levels of dental fear considered interpersonal factors related to the clinician as more important than did women with high levels of dental fear but without a history of childhood sexual abuse. These important interpersonal factors included not feeling that the clinician could be trusted and not feeling in control.[96] It is not hard to understand the parallel between some elements of abuse and receiving dental care, including discomfort and pain, in addition to a reluctance by abused patients to believe that the clinician can be trusted.[87]

From a more general perspective, one study[28] found that a self-reported history of physical or sexual abuse among a nonclinical sample was associated with increased pain complaints and lower perceived health status. Not surprisingly, health care utilization and psychological distress, including the tendency to catastrophize about upcoming events, was greater among women with an abuse history compared with other women.[28] The clinical implications of the association between sexual abuse and dental fear are that clinicians should be prepared to talk to their patients about sexual and physical abuse and the influence of that abuse on receiving dental care.

Fear of pain differs greatly among dental patients and is associated with elevated levels of anxiety.[93] Of particular concern to the clinician is the finding that anxious patients tend to be more fearful of dental pain *after* they experience a procedure than before, whereas less anxious patients tend to report less fear of pain after the procedure has been experienced. For highly anxious dental patients specifically, experiencing treatment tends to make their fear of pain even greater.[93] Individual differences in pain response may correlate to individual biological changes, which may be evaluated objectively using techniques such as functional magnetic resonance imaging (fMRI). Using neural imaging, researchers in one study[73] found that fear of pain predicted activation of the right lateral orbital prefrontal cortex during a heat pain task. This region of the brain has been linked to attempts by fearful individuals to regulate pain by determining how much threat the stimulus represents. This phenomenon of assessing the primary threat level, in conjunction with the coping resources available, is well documented in dental patients[4,15,54] and, in conjunction with recent research using fMRI, provides biologic evidence to support behavioral observation that differences in pain perception are true representations of the individual's experience.[73]

Although a variety of cultural, psychological, and physiologic factors contribute to variability in both clinical and experimental contexts, the role of genetic factors in human pain sensitivity is increasingly recognized. The most dramatic manifestation of individual variations in pain response is congenital insensitivity to pain, caused by single mutations of the *NTRK1* gene. This well-documented genetic defect, which causes pain insensitivity by influencing tyrosine kinase, the receptor for nerve growth factor, underscores the role of individual genes in the reaction to painful stimuli.

One study[48] evaluated genetic influences on variability in human pain sensitivity associated with gender, ethnicity, and temperament. Loci in the vanilloid receptor subtype 1 gene *(TRPV1)*, delta opioid receptor subtype 1 gene *(OPRD1)*, and catecholamine *O*-methyltransferase gene *(COMT)* were genotyped using 5′ nuclease assays. These researchers demonstrated that gender, ethnicity, and temperament contribute to individual variation in thermal and cold pain sensitivity by interacting with *TRPV1* and *OPRD1* single-nucleotide polymorphisms. Another study[24] found that the *COMT* gene was related to experimental pain sensitivity and the risk of developing temporomandibular pain and disease (TMD).

In a fascinating study,[78] 207 cancer patients receiving morphine treatment were genotyped with respect to the Val158Met polymorphism. The study compared the morphine doses, serum concentrations of morphine, and morphine metabolites between the genotype groups. Patients with the Val/Val genotype (n = 44) needed more morphine (155 mg ± 100 mg/24 h; n = 96) and the Met/Met genotype (95 ± 99 mg/24 h; n = 67) ($P = 0.025$). This difference was not explained by other factors, such as the duration of morphine treatment, performance status, time since diagnosis, perceived pain intensity, adverse symptoms, or time until death. These results show that genetic variation in the *COMT* gene may contribute to variability in the efficacy of morphine in cancer pain treatment.

Further evidence has emerged of a genetic basis for differences in patients' response to pain control agents. One study[71] demonstrated a significant link between the melanocortin-1 *MC1R* gene sequence, pain tolerance, and the efficacy of morphine-6-glucuronide in both humans and laboratory animals. In addition, the distinctive molecular processes associated with different types of pain and changes in gene expression over time support the idea that heterogeneous responses to pain stimulus are typical, and "one size fits all" attempts at pain management are unrealistic. It follows that failure to achieve anesthesia in some dental patients may reflect real anatomic and genetic differences. Limited research on the effectiveness of local anesthetic agents has been conducted in the past 50 years, and almost none has focused on individual differences in genetic composition and anatomic structure. One in seven patients reports inadequate anesthesia when the teeth are stimulated with a drill, even after administration of local anesthetic[69]; therefore, it may be time to launch research into the impact on drug efficacy of individual differences in genetic composition.[90]

Brain imaging studies provide additional support for the need to adapt to individual differences in pain mechanism. One study[12] used fMRI to evaluate cerebral responses and, through this approach, confirmed that identical experimental pain stimuli produced different activation in pain-related regions of the cortex. These differences systematically varied in subjects who were sensitive to the pain and those who were not.[12] This study provides additional and persuasive evidence that individual differences in pain responses reflect actual variability in the experience of pain. Incorporating pain management strategies into dental treatment, with the understanding that individual differences in pain response are rooted in true biologic, psychological, and social differences, will lead to better outcomes for patients and less stress for clinicians.

Considerable evidence has been presented supporting the existence of differences among individuals in their responses to dental treatment. It follows that a single management approach for anxious patients is less effective than adapting the strategy to the needs of the individual patient. In the next section, a few selected strategies are outlined, with special emphasis on tailoring communication to the fearful patient.

MANAGEMENT OF PAIN AND ANXIETY

Patient Communication

Individualizing clinician-patient communication, so as to identify, acknowledge, and reassure a distressed patient, is one of the most effective anxiety-reducing strategies available to the dental team. This is a three-pronged strategy involving (1) establishment of rapport with the patient, (2) use of a standard interview protocol, and (3) use of effective nonverbal communication. Each of the prongs of communication requires a dialog with the patient, rather than either of two extremes—one-sided listening to the patient, or a monologue by the clinician that does not provide opportunities for the patient to comfortably speak up. For most patients, having the clinician listen attentively sets a context for building a trusting clinician-patient relationship.

Establishing Rapport

Fearful patients often cite poor communication with the clinician as a factor in maintaining anxiety. In particular, patients report that they do not believe their clinician adequately listens to their concerns.[34] Accurate diagnostic information is the foundation of any treatment, but to obtain that information, the clinician must first develop a trusting relationship with the patient so that a free exchange of information is possible. The first step in building a trusting relationship with a fearful patient is to develop rapport.

Rapport development can begin in the first few minutes of getting acquainted. In fact, because many first impressions are unconsciously made, the clinician may be wise to carefully consider patients' first impressions of the dental provider and his or her staff. There is probably no better way to make a positive first impression than to demonstrate a sincere and genuine interest in the patient. What is the first question the patient is asked by the staff? Often, it concerns the payment policy of the practice and how the patient will be paying. Although it is essential to know about the patient's financial status, making that the first question the patient hears may immediately set an impersonal tone. Research shows that the clinician who initially talks about nondental topics is more likely to be perceived by the patient as friendly, and *friendly clinicians are more likely to have satisfied patients*.[3] An important exception to the use of nondental topics to establish rapport is the patient who immediately initiates conversation about dental-related issues associated with his or her fear. Failing to respond to such an initiative may suggest to the patient that the clinician is avoiding the topic of fear or lacks compassion.

The clinician should also be aware of the impression he or she is making when addressing the patient. The use of a first name assumes or implies a familiarity not all patients are comfortable with. Because the manner in which we address each other frequently sets the context for future interactions, dental providers and their staff should be cautious and sensitive to the individual needs of the patient. Addressing the patient as Mr., Mrs., or Ms. demonstrates respect, and this form of address should be used unless the patient has expressed a preference for use of his or her first name. Older patients and fearful patients may be offended if younger clinicians or staff members address them by their first name. Developing rapport and trust may require additional time and attention with the fearful patient, who is already on guard. It is worth the effort, however, because satisfied, formerly fearful patients become excellent ambassadors for the dental practice. Another effective tool with anxious patients is active and engaged listening. In the following paragraphs, the challenge of listening to a distraught patient in a busy practice is discussed.

Listening

Listening is sometimes viewed as analogous to sending an audio signal to a receiver that faithfully reproduces the signal as it was transmitted; however, listening is not a passive act. Anxious and fearful patients may express their feelings to the clinician or staff in the form of anger and blame. Rather than reacting to the patient's anger, the clinician should show reflective listening. Reflective listening is an effective way to respond to anger, often defusing the exchange regardless of the cause of the anger. When people are angry, one of their primary goals is to convey their feelings to the listener. If a patient is expressing strong emotions, he or she cannot listen very well, so it is best not to offer advice at that moment. Both patients and clinicians listen through a filter of biases and prejudices that influence their interpretation of what is being said. In this kind of interaction, it is especially important that the clinician not assume that he or she understands what the patient is saying or how the patient "feels." Clinicians should encourage the patient to explain expressed fear with statements such as, "It sounds like you have very strong feelings about what happened. I want to be sure that I understand. Please go on." This gives the patient an opportunity to clarify, and the clinician has demonstrated that the emotional content or tone of the concern is being heard.

Strong feelings do not vanish just because they are ignored; they do diminish in intensity and lose their sharp edges when the listener accepts them with respect and understanding and allows the patient to express these feelings. Often the best initial step for either the clinician or the staff member is to *LISTEN!* Once the nature of the problem has been clarified and the patient's strong emotions have diminished, the usual techniques for effective communication can be used, such as open-ended questions with appropriate follow-up questions based on the content and tone of the message. ***Developing a dialog of trust between the clinician and the patient is necessary and cannot be delegated to a staff member.***

Building Empathy

Fearful patients are sensitive to any communication that can be interpreted as belittling or disrespectful. This includes dental jargon the patient does not understand or terms the clinician or staff members do not clearly explain. Fearful patients may be insulted by a statement such as, "There is no reason for you to be afraid," when the patient is convinced there are abundant reasons for fear. The more empathetic the clinician can be, the more likely it is that the fearful patient will accept treatment. The term *empathy* refers to the capacity and willingness to understand a situation from the other person's point of view and communicate that understanding to the person.[19] This is not the same as sympathizing, which can widen the gap between patient and provider and has been shown to be counterproductive in establishing a therapeutic alliance.[52] Instead, reflecting back but not parroting what the patient has said can help the clinician show empathy. For example, if the patient says that he or she hates going to the dentist, a reflective statement might be, "Sounds like you have had some unpleasant experiences with dentists in the past." The patient may elaborate, and at the appropriate time, the clinician can offer reassurance by saying that he or she will do whatever can be done to make the treatment as comfortable as possible. Once a clinician has developed a good rapport with the patient, the rest of the patient's visit is more likely to go smoothly. The clinician will also find that a good rapport with the patient facilitates a smooth standard interview and future treatment. After a trusting relationship has been established, the patient is more likely to accept the moments in which the clinician is distracted as a forgivable event and not take it as a personal insult or lack of interest.

Demonstrating clinical empathy can be more of a challenge in a diverse society. Clinicians frequently treat patients from ethnic, racial, and cultural groups different from their own. It is unreasonable to expect that clinicians can identify or understand what it is like to be from another ethnoracial cultural group. It is still possible, however, to demonstrate clinical empathy if empathy is understood as a feedback loop much like hypothesis testing.[19] Successive cycles of conversation establishing what the patient believes about the nature of dental disease and what needs to be done can allow the patient and clinician to move closer to a shared understanding about an acceptable course of treatment. If nothing else, the clinician's honest attempt to understand the patient's perspective facilitates trust. Trust cannot be earned if the patient feels a lack of concern from the clinician.

Using a Standard Interview Protocol

The use of a standard interview protocol facilitates the dialog with distressed patients. Not infrequently, the anxious patient becomes sidetracked by the emotion-driven recollection of past dental experience, and the responses to questions in the patient history meander, lacking logic and clarity. To keep the interview on track and in professional focus, the clinician may need to gently, smoothly, and efficiently return to the standard protocol and format for the information-gathering process. This may be accomplished by using a statement such as, "I am very interested in that part of your experience, but to be sure we have enough time, please tell me about … Remind me later, and we will return to what you were starting to tell me." Similarly, it may become necessary to pause and deal with the patient's fear in the middle of the interview.

The use of a standard set of questions allows the clinician to concentrate on the patient and the response to each verbal question, confident that all relevant information will be gathered. Depending on the patient's comfort level and curiosity, it is often useful for the clinician to provide a rationale for

particular questions or requests for specific information. The rationale need not be long or detailed but should clearly establish, in lay language, why obtaining the information is in the patient's best interest. Stressed or fearful patients are frequently not attentive to the details of a message, so it is a good practice for the clinician to verify clarity and understanding by summarizing each phase of the interview. The clinician may wish to say, "Sometimes my statements are pretty confusing. [A little personal joke can help make the point, such as a reference to the clinician trying to clarify with his or her teenager what time to come home.] Because much of what we are going to talk about is important if I am to provide optimum care for you, I may ask you to repeat what you think I said just to reassure myself that I am being clear." Patients usually respond positively to such an approach.

Another helpful portion of the standard interview protocol is a question already established on most patient medical/dental health history questionnaires, which is, "Are you anxious about receiving dental treatment?" The question provides two benefits for the patient: It allows the patient to verbalize his or her anxieties, and it also reassures the patient that the clinician is aware he or she may be anxious about the visit. The answer to the question also provides a benefit to the clinician; if the patient responds positively, a series of follow-up questions regarding the patient's perception of the cause or causes of the anxiety can lead to fruitful revelation of specific adverse issues, materials, and techniques. This knowledge can then be very helpful in strategizing how treatment will be planned and carried out to mitigate the patient's aversion and anxiety.

The type of questions the clinician uses in talking with a fearful patient can influence the degree of satisfaction with the interaction for both. For example, if the fearful patient is not talkative, the clinician should consider whether responses could be encouraged through use of more open-ended questions. If the patient is talking excessively, closed questions help the clinician control the interview. Incomplete or inaccurate information may result from questions that lead patients to an answer they believe the clinician is seeking. For example, "I don't suppose there have been any changes in your medications," may suggest to the patient that the clinician does not want to be bothered with any new information. A mix of open and closed questions produces the most effective interview and facilitates an ongoing dialog. Effective communication, however, is not based solely on words. Nonverbal communication can be an effective strategy in building an empathetic and effective relationship with a patient. The following section describes an approach many clinicians find helpful, beginning with silence, which is rarely thought of as an important communication tool.

Using Nonverbal Strategies

There is a strong tendency in the commercial model of health care to think that giving advice and providing treatment is the sole task of the clinician. Periods of silence are often avoided, but silence can be a useful tool when listening to any patient, especially a frightened one. Conversely, good care cannot be provided without spending the time to build a trusting relationship between the patient and the clinician. The silence may feel a bit clumsy or uncomfortable, but patients often report that they are not given adequate time to respond to the clinician's questions. This is especially true with older patients who may need a bit more time to understand what is being said or asked of them. Giving the patient adequate time to collect his or her thoughts and avoiding the tendency to comment too quickly gives the impression that the patient is the focus of attention at that moment. It also helps if eye contact is maintained with the patient; a nod of the head shows that the message is being heard and is important. Permitting the silence to continue may encourage the patient to provide additional relevant information that would have otherwise been missed. Within limits, the clinician should encourage the fearful patient to talk more rather than less.

The clinician's physical orientation toward the patient also provides important messages about the level of interest in what the patient is saying. It is unlikely the patient will continue talking if the clinician appears not to care about what is being said. Making direct eye contact and nodding as the patient speaks can be affirming and can serve as encouragement for more conversation. During the interview, it is most effective for the clinician to face the patient, with the chair at about the same level as the patient's chair. These initial moments are often the time when the fearful patient assesses the clinician's trustworthiness and the extent to which expressed concerns are being taken seriously.

In Western culture, eye contact is the principal means of demonstrating involvement with another human being. Eye contact should be steady and frequent (without staring). Glancing elsewhere is acceptable, but the patient's face should be the focus of the clinician's attention. The clinician may take notes, but it is important to reestablish eye contact after each note is taken to convey the impression that what the patient is saying is important. Showing care in this way is one avenue of demonstrating clinical empathy. Patients are very sensitive to discordant messages between our words of caring and aspects of nonverbal communication, such as eye contact. Maintaining eye contact until the patient has stopped speaking provides a powerful statement of respect and concern.

The fearful patient is best served if the context in which care is received is based on mutual respect and concern. Many fearful patients have not received routine preventive care and may have extensive treatment needs, including some requiring complex, invasive treatment. If so, the patient will need reassurance that the clinician will make every effort to provide comfortable treatment.

No promises should be made that the treatment will be painless or free of discomfort. Pain-free dentistry is not a promise that can always be kept. It is also important to acknowledge the patient's feelings. Acknowledgment does not represent endorsement; it simply confirms that what the patient said was heard. During treatment, frequently expressing sincere interest in the patient's level of comfort and keeping the patient informed of progress helps relieve anxiety. The expression of concern should be sincere, not automatic.

As part of the framework for care of a fearful patient, the clinician should work quickly and systematically without appearing hurried. Planning ahead and informing the patient about the next step can be reassuring. Keeping promises made to the patient maintains the patient's trust. Such promises may include the length of the appointment or the frequency of breaks. Being honest about what is and is not realistic helps both the clinician and the patient. Fearful patients appreciate a frequent review of what has been accomplished, what remains to be completed, and any unanticipated deviations from the

original plan. Setting a context of predictability is important to most patients, but with fearful patients, the appearance of predictability projects organization and control.[22] The basis of trust often rests in the patient's sense of personal control.

Research has shown that fear about dental care increases when the fearful patient wants control during treatment and believes he or she will not have it.[56] A sense of personal control can be provided through information, predictable sequences, and choices about the treatment and the treatment process. One strategy that returns some level of control to the patient involves inviting the individual to raise a hand when he or she would like to take a timeout. It should not be surprising if a patient tests the clinician's willingness to give up control during the treatment by frequently raising a hand. Other options may include giving patients a choice of music to listen to during treatment, which implies control over the environment.[2,39] (See de Jongh et al.[22] and Logan and Marek[55] for reviews of individualized dental anxiety management strategies.)

Patients who manage their apprehension about dental treatment often have identified coping strategies that have worked well for them in the past. Fearful patients may not have such well-defined strategies. Asking about preferred coping strategies and helping the patient identify one that usually works has proven useful in reducing anxiety.[54] Dental anxiety can also be managed with conscious sedation techniques,[67] but it is important to remember that these agents do not treat anxiety, they only facilitate treatment. When conscious sedation techniques are used, they are most effective when combined with behavioral interventions.[43,53] (See de Jongh et al.[22] for a review of individualized management strategies for dental anxiety.)

In short, if anxiety reduction is to be possible, a trusting relationship needs to be in place whereby (1) the patient's feelings of anxiety are acknowledged, (2) a safe and secure environment is in place, and (3) the patient believes that nothing will happen that the patient and clinician have not agreed on.[22] In addition to the strategies described before, numerous other behavioral interventions are available. Although no one strategy has emerged as best, most have shown that dental anxiety is treatable, and the effects of the behavioral treatment are long lasting.[50] Next, four interventions with particular relevance to dental care are highlighted in somewhat greater detail.

Behavioral Interventions

Distraction

Distraction as an anxiety-reducing strategy has broad appeal because of the ease of use. Music represents one of the simplest distraction techniques to use and is particularly effective if the patient selects the music and listens over individual headphones. Regardless of their anxiety level, patients often report that they prefer to have music in the background because music makes them more comfortable.[3] In a randomized clinical study, patients who listened to music during dental treatment reported less pain, less discomfort, and a greater sense of personal control.[2] Thus music can be both distracting and, under certain conditions of choice, provide the patient with a sense of control.

Portions of the office environment can also divert a patient's attention. It has often been reported that interesting artwork, decor, and tropical fish tanks are useful in distracting the patient from feared stimuli.[3] Some clinicians have used video games or a television set in the operatory as an effective and comforting distraction for anxious patients.[16,32] Manual distraction-stimulating devices have also been used during injection of dental anesthetics to reduce dental anxiety.[92] The clinician should be aware that simple distraction techniques may be ineffective if the perceived intensity of dental pain is too high.[5] Distraction is largely effective in the short-term management of anxiety but less effective for long-term behavior change.

Relaxation

The goal of relaxation is to achieve both muscular and mental relaxation. Research shows that relaxation is an effective method of reducing patient anxiety.[17,18] Deep breathing coupled with muscle relaxation can be effective in stress reduction. Many fearful adults tend to hold their breath during basic procedures such as applying a rubber dam, giving injections, or forming impressions. When the person's blood becomes poorly oxygenated because of an insufficient amount of fresh air entering the lungs, states of anxiety, depression, and fatigue arise, contributing to the already stressful situation. Deep breathing exercises to help reduce this unwanted stress can consist of as little as 2 to 4 minutes of breathing in deeply, holding the breath, and then exhaling completely. Demonstrating for patients that deep breathing is something they can do on their own provides a new sense of control, in addition to the calming effects from the breathing techniques. It may even be helpful to attach a heart rate monitor so that both clinician and patient can assess this aspect of stress arousal and success in controlling it.

Pausing during the procedure and suggesting that the patient briefly repeat the deep breathing techniques can be helpful. Muscle relaxation is also very useful in calming the patient. This method includes repeated tensing and relaxing of specific muscle groups in the body. Breathing and muscle techniques can be combined by tensing the muscles while breathing in and relaxing them while breathing out. Practicing this rhythmic coordination of relaxation techniques quickly and effectively improves the patient's ability to relax.[69] Periodic reinforcement of muscle relaxation during treatment helps the patient regain composure. Pausing during the procedure and suggesting that the patient take several slow, deep breaths can also be useful. For some fearful patients, the mere act of deeply inhaling and exhaling completely can help dispel negative reactions to receiving care. Some caution should be used in attempting to combine music and relaxation therapy because some types of music may have unanticipated effects on the patient and may actually increase autonomic arousal.

Hypnosis and Guided Imagery

Hypnosis is a guided, self-controlled state of mind in which concentration and focus are directed inward. An altered level of consciousness is reached, similar to "zoning out" while daydreaming or reading a book.[86] Guided imagery is a form of mild hypnosis that can be useful with fearful patients.[6] It produces a light trance from which patients easily awaken, and the procedure is less time-consuming for the clinician than guiding patients into a deep hypnotic state. Asking the patient to focus on a place in which he or she feels very relaxed, comfortable, or safe is a good starting point for guided imagery and can be effectively combined with relaxation training.[81]

Information about appropriate images can be gathered during the examination process. Current research shows that patients have reduced pain and distress when they themselves choose the place to be imagined. The patient should be asked to choose imagery that is associated with little movement so that movements do not interfere with the provision of care. During guided imagery, the patient achieves an altered state similar to daydreaming or focused attention. By focusing on a calm and safe scene, positive emotions are elicited that can block or mitigate the anxiety arising from the dental treatment. An analysis of imagery topics chosen by patients shows that the topics were highly individual; this further supports the efficacy of guiding patients to a "safe and comfortable place" of their own choosing.[27,53] Guided imagery is effective in managing pain during outpatient procedures and can be delivered by the dental team without disrupting the workflow in the patient care setting.[6,51]

In the past, the success of hypnosis was believed to depend on the hypnotizability of the subject and was associated with a specific "phobic" portion of the population.[38] More recently, researchers have shown that nearly all patients are equally able to engage in imagery during invasive outpatient procedures, and the imagery has resulted in reduced pain and anxiety.[51] Although nearly all patients are equally susceptible to hypnotism, their attitudes, motivations, and fears from common misconceptions may interfere with or impede their willingness to engage in a hypnotic state.[27] The most successful conditions involving hypnotism in the clinical setting include a well-trained hypnotherapist and a patient who is highly motivated to overcome a problem.[1,14] *For most mildly or moderately anxious patients, the most effective management strategy for the clinician is taking time, actively listening to the patient's concerns and fears, and emphasizing the building of a trusting relationship between the patient and the clinician.*

For more serious cases, deep breathing techniques and hypnosis or guided imagery are among the most useful. The effectiveness of hypnosis in treating dental fear has been demonstrated.[38] Hypnosis, however, requires specialized training and experience, so a brief "how to" belies the complexity of the strategy. For clinicians who are interested in training in hypnosis, resources can be accessed through the Internet[74] or through other printed materials.[69] Information about training in the specific area may be available through the local dental society or mental health center.

Referral to a Mental Health Professional

In extreme cases, refining the dialog and using previously mentioned strategies are inadequate to reduce the patient's distress and fear. The clinician may want to exercise the option to refer a fearful patient to a mental health worker for professional counseling and therapy. This decision may depend on the clinician's own skills and interests in working with fearful patients. One criterion used for referral is whether the fear imposes a significant barrier to successful completion of care. If this is the case, referral may be warranted. If a therapist's name is not readily available, a call to a county or state psychological or psychiatric association will yield the names of professionals who specialize in anxiety disorders. If the patient is currently in therapy, it is appropriate to ask the patient's permission to speak with the therapist. If the patient gives permission to contact the therapist, the clinician should consider maintaining an ongoing dialog with the therapist during the course of dental treatment. The following are questions the dental provider and the therapist may discuss.

- Do adjustments need to be made in the sequence of the dental treatment plan?
- Do adjustments need to be made in the anxiety management strategies as the treatment progresses?
- Should new anxiety treatments be tried?

Based on the conversation with the therapist, the clinician can decide whether further referral is necessary or if the patient is being treated adequately for his or her dental fear. If the patient's dental fear and anxiety do not subside, other measures may be needed, including pharmacotherapy. As with all treatment, careful documentation of the anxiety treatment is important. The dental team should be reminded to assiduously adhere to the standards established by the Health Insurance Portability and Accountability Act (HIPAA) in discussing the patient's care among themselves and in sharing information unless directly relevant to provision of dental care.

PHARMACOLOGIC MANAGEMENT OF FEAR

If clinician-patient dialog is not adequate to calm the fearful patient, sedative-hypnotic drugs that treat anxiety and insomnia may be an option. Agents used to treat anxiety are known as *antianxiety agents* or *anxiolytics*. An older term is "tranquilizer." Agents used to promote sleep are known was *hypnotics*. The benzodiazepines are the most commonly prescribed group of drugs used to treat anxiety. This class of drugs has four distinct effects: anxiolytic, anticonvulsant, muscle relaxant, and sedative-hypnotic. The distinction between an anxiolytic effect and a hypnotic effect is often a matter of dose or length of action. Lower doses relieve anxiety, whereas higher doses induce sleep. In addition to these actions, the benzodiazepines are known for producing anterograde amnesia.

The benzodiazepines are by far the largest and most important group of drugs used as anxiolytic and hypnotic agents. The antianxiety and calming effect of this class of compounds was discovered in the late 1950s. The basic 7-membered ring can be modified to alter half-life, number of active metabolites, overall duration of action, and therapeutic use.

The benzodiazepines act selectively on gamma-aminobutyric acid A ($GABA_A$) receptors throughout the central nervous system. The benzodiazepines work by enhancing the inhibitory effects of GABA. Short-term use of these medications is generally considered safe and effective; however, long-term use is controversial because of the potential for tolerance and dependence, cognitive impairment, and falls, especially in the elderly or when these drugs are combined with opioids.[41]

The many different benzodiazepines vary in potency, speed of metabolism associated with half-life, number of active metabolites, and approved indications (Table 28-1).

These drugs are classified as U.S. Food and Drug Administration (FDA) Pregnancy Category D or X, depending on the drug. They should not be used in pregnant patients because the risk outweighs the benefit; potential harm to the unborn has been demonstrated.[64]

The benzodiazepines are one of the few classes of drugs with a commercially available competitive antagonist, romazicon (Flumazenil). This drug, which is administered by

TABLE 28-1
Frequently Prescribed Benzodiazepines

Drug Name	Half-Life (Hours)
Alprazolam (Xanax, generics)	12-15
Chlordiazepoxide (Librium, generics)	>100 with active metabolites
Clonazepam (Klonopin, generics)	20-50
Clorazepate (Tranxene, generics)	>100
Diazepam (Valium, generics)	>100
Estazolam	10-24
Eszopiclone (Lunesta, generics)	6
Flurazepam (Dalmane, generics)	>100
Lorazepam (Ativan, generics)	10-20
Oxazepam (generics)	5-14
Temazepam (Restoril, generics)	3.5-18.4
Triazolam (Halcion, generics)	1.5-5.5
Zaleplon (Sonata)	1
Zolpidem (Ambien, generics)	2.5[76]

injection, is used to reverse excess sedation after a benzodiazepine has been used for diagnostic or therapeutic procedures or in the case of an overdose. Romazicon's short half-life requires multiple dosing and careful monitoring of the patient to ensure that resedation does not occur.

Because all benzodiazepines have essentially equivalent pharmacologic actions, selection is largely based on the difference in the course of action. For example, if a patient needs medication to accelerate falling asleep, a benzodiazepine with a rapid onset is preferable. For treatment of anxiety and fear for a dental appointment, a shorter acting agent, such as lorazepam, triazolam, or alprazolam, may be preferable.

SUMMARY

Individual patients differ dramatically in how they respond to dental treatment. These differences arise from multiple biologic, psychological, and social sources, which are influenced by both genetic factors and lifestyle. How successfully a clinician adapts to these differences by tailoring treatment options depends on the depth of his or her understanding of the way a patient perceives the situation and the person's general state of health. Incorporating this understanding into the clinician-patient dialog can produce improved clinical outcomes.

Summary

ENDODONTIC RECORD EXCELLENCE

Importance

Endodontic therapy records serve as an important map to document and guide the clinician's journey down the correct diagnostic and treatment path. Documentation is essential to attaining endodontic excellence.

The dental record must contain sufficient information to identify the patient, support the diagnosis, justify the treatment, and document the course and result of treatment, and it should be designed to protect the patient's welfare. Records also are fundamental means of communication among health care professionals.

Content

Endodontic treatment records should include the following information:

1. Name of patient
2. Date of visit
3. Medical (periodically updated) and dental history
4. Allergies and adverse drug reactions
5. Chief complaints
6. Radiographs of diagnostic quality
7. Pulpal and periodontal diagnostic tests performed
8. Clinical examination findings
9. Differential diagnoses and final diagnosis
10. Treatment plan
11. Prognosis
12. Referrals, including patient refusals (if any)
13. Communications with other health care providers
14. Progress notes (including complications)
15. Completion notes
16. Canceled or missed appointments and stated reasons
17. Emergency treatment
18. Patient concerns and dissatisfactions
19. Planned follow-ups
20. Drug and laboratory prescriptions
21. Patient noncompliance
22. Consent and informed refusal forms
23. Accounting ledger
24. Recall notifications
25. Name or initials of author for each treatment entry
26. E-mail address of patient
27. Emergency contact persons, addresses, and phone numbers
28. Patient phone numbers including home, work, and cell
29. Log of records and radiographs received or sent

Function

Dental records should document the following information:

1. Course of therapy by recorded diagnosis including differential diagnoses, informed consent or refusal, treatment, and prognosis
2. Communications among the treating clinician, other health care providers, consultants, subsequent treating practitioners, and third-party carriers
3. Necessity and reasonableness of diagnosis and treatment capable of peer review and dental insurance carrier evaluation
4. Standard of care compliance
5. Adverse reactions or events with explanation
6. Follow-up comments to medical history–positive responses

Patient Information Form

A patient information form provides essential data for patient identification and office communication, which should be updated periodically (Fig. 29-1). The patient's name; home, business, and e-mail addresses; and telephone and fax numbers are needed to contact the patient for scheduling purposes and inquire about postoperative sequelae.[178] Location information about the patient's spouse, relative, or a close friend who can be notified in an emergency is also suggested. In the event the patient is a minor, the responsible parent or guardian should provide the information. Questions about dental insurance and financial responsibility are included on the form to avoid any later misunderstandings and help fulfill federal requirements of the Truth in Lending law, applicable if four or more

FIG. 29-1 Patient information form.

installment payments are arranged (whether or not there are interest or late-payment charges).[104]

Medical Health History

The clinician should thoroughly review the patient's past and present health status before proceeding so that dental treatment can be safely initiated. Health questionnaires open avenues for discussion about problems of major organ systems and important biochemical mechanisms, such as blood coagulation, allergy, immunocompromised status, need for antibiotic prophylaxis, and disease susceptibility. The clinician may request that the patient be examined by a physician or undergo laboratory testing under medical supervision to determine whether a suspected medical problem may require attention before endodontic therapy proceeds or if drug sensitivity or an allergy mandates treatment modifications.[43,165,188] Knowledge about current medications, medical therapy, and the name and address of the treating physician is essential.

Medical histories must be updated periodically (or at least annually or sooner as the need arises). The patient should be asked to review the previous and current medical history (Fig. 29-2). If no changes are necessary, the patient should date and sign the history form. If any changes occurred, the patient should identify each updated medical change, the date, and sign the form where indicated for medical update information. Periodically the patient should provide an entirely new updated form rather than changing data on the old form. Earlier medical histories should be retained in the chart for future reference. If physician communication for treatment occurs, the clinician should record these contacts. In addition, the clinician should

TELL US ABOUT YOUR MEDICAL HISTORY

First Name: _____ Last Name: _____

How would you describe your health? Please circle one. Excellent Good Fair Poor

When did you have your last physical examination? _____

Are you currently being treated for any illness or medical condition? Yes ____ No ____

If yes, please describe: _____

_____

Who is treating you for this condition? _____

Have you ever had any kind of surgery? Yes ____ No ____

When did you have this surgery? _____

What type of surgery did you have? _____

Have you ever had any trouble with prolonged bleeding after surgery? Yes ____ No ____
Do you wear a pacemaker or any other kind of prosthetic device? Yes ____ No ____
Are you taking any medication or drugs at this time? Yes ____ No ____
Have you ever taken Fen-phen and/or Redux (diet drugs)? Yes ____ No ____
What medications, drugs, or herbs are you taking?

_____

Why are you taking these medications? _____

_____

Have you ever had a reaction or complication to a local anesthetic or drug (like penicillin)? Yes ____ No ____

If yes, please explain: _____

Please circle any present or past illness you now have or had in the past:

FIG. 29-2 Medical history form.

verify physician approvals for treatment by fax, with verification of receipt or letter or preferably both, and retain copies in the chart.

Updating the medical history requires the practitioner to be apprised of changes in the patient's medical condition and any new medications the patient is taking, including over-the-counter or herbal medications or supplements.[257] A patient untrained in medical science may not appreciate the fact that new medications may suggest new diseases or changes in existing disease status. For instance, certain regurgitating valvular heart diseases may require antibiotic prophylaxis.[334] New medications may also cause a synergistic effect with other medications the patient is using or another treating clinician is prescribing.

Clinicians who pass the buck by claiming, "Oh it was my secretary or my new assistant—I could do nothing about it," are nonetheless legally liable for their staff's actions or inactions.[335] A clinician exclusively relying on staff members to obtain medical histories in a waiting room full of patients is making a mistake. Instead, the clinician must check and then follow up regarding the accuracy of the histories. Training and monitoring staff are duties clinicians cannot afford to ignore. President Harry Truman's sage advice, "The buck stops here," applies to treating clinicians who overdelegate to nonclinician staff members who lack the requisite dental education for adequate medical history follow-up.

Dental History

The dental history should include past dental difficulties, name and address of current or most recent treating clinician, chief complaint (including onset, duration, frequency, type, and

TELL US ABOUT YOUR DENTAL SYMPTOMS

FIG. 29-3 Dental history record.

intensity of any pain or numbness), relevant prior dental treatment, and attitude regarding teeth retention. Positive responses suggest further patient consultation and consideration for obtaining records (by written release) for elucidation from the patient's previous or present treating clinician.[227] After receiving positive responses, the clinician may also wish to obtain prior and concurrent treaters' radiographs for current comparison with any progressive changes (Fig. 29-3).

Diagnostic and Progress Records

Diagnostic and progress records often combine fill-in and check-off types of forms. Fill-in or essay forms allow greater latitude of response to a question, resulting in a more detailed description. However, one drawback is that these forms are open to oversights unless a clinician is conscientious in following up with further clinical information.

Using only an essay-type health history is insufficient. Often a patient may not appreciate the significance of important symptoms. A check-off format is efficient and more practical. Forms with questions that reveal pertinent data alert the clinician to medical or dental conditions that warrant further evaluation or consultation.[43] Moreover, such records can document any missing medical information the patient failed to provide orally. At the end of the check-off portion of the medical history, an essay question allows the patient to provide any omitted pertinent medical information or elaborate on check-marked items.[273,286]

Electronic Records

Electronic records represent current methodology for recording patient information (see Chapter 30 for details).[307] Several safeguards are essential for their use. First, patient

confidentiality and security must be protected. Consider using AES encryption with at least 2048 bit key. Be certain that only the clinician and authorized staff view patient data in conformance with the Health Insurance Portability and Accountability Act (HIPAA) security standards, effective April 2005.[149] Second, data backup of patient records, including digital radiographs and account ledgers, should be stored off site. The entire hard drive should be periodically backed up for additional protection, which can be accomplished with cloud technology autosave backup systems.[94] Multiple copies of the backup data should be stored in more than one geographic location, and fault protection such as RAID level 1 or 5 should be installed to prevent data loss.

Radiographs

Radiographs are essential for diagnosis and also serve as additional documentation of the patient's pretreatment condition. A panographic radiograph is not diagnostically accurate for endodontics and therefore should be used only as a screening device (see Chapter 2).[143,271,344] Diagnostic-quality periapical plain film or digital radiographs are essential aids for diagnosis, for working films (e.g., measuring the length of root canals, fitting gutta-percha cones), to verify the final fill, and for follow-up comparisons at recall examinations. Therefore, the clinician should retake any radiographs that lack diagnostic quality. Retain all radiographs including working films.

Digital radiography is recommended because it increases endodontic efficiency at the chair. Also images may be forwarded via e-mail to either the patient or another clinician. No developing time is needed, so procedural radiographs can be viewed instantly and approved or retaken with little time in between (no downtime is required to wait for a film to exit the film processor). Newer digital x-rays with improved sensor technology use high-resolution charged coupling device (CCD) chips, rather than complementary metal-oxide semiconductor (CMOS) technology, and provide close-up zooming with improved image quality as described in Chapters 3 and 30.

Three-dimensional (3D) cone-beam computerized tomography (CBCT) imaging has greater information compared with conventional radiography. Conventional periapical radiographs do not facilitate accurate predictions in the preoperative assessment for the potential perforation of the maxillary sinus. CBCT has greatly aided the diagnosis of pain sources caused by root fractures or incompletely filled, overfilled, or missed extra canals that two-dimensional (2D) periapical imaging may obscure.*

According to the U.S. Food and Drug Administration (FDA), switching from D to E speed results in a 30% to 40% reduction in radiation exposure. F-speed film reduces exposure 20% to 50% compared to E-speed film, without compromising diagnostic quality.[19] Digital imaging reduces radiation dose by 40% to 60%.[5,124]

A rectangular collimator decreases the radiation dose by up to fivefold compared with a circular one.[126] Radiographic equipment should provide rectangular collimation for exposure of periapical and bitewing radiographs.

Evaluation and Differential Diagnosis

Diagnosis includes evaluating pertinent history of the current problem, clinical examination, pulpal testing, periodontal probe charting, and recorded radiographic results. If therapy is indicated, the reasons should be discussed with the patient in an organized way. When other factors affect the prognosis (e.g., strategic importance, restorability of the tooth, or proximity to vital structures), the clinician should consider further consultation with the referring clinician or specialists, including a prosthodontist, periodontist, or radiologist with CBCT imaging, before initiating endodontic treatment.

Diagnosis is essential in treatment decisions. Recommending extractions for undiagnosed pain etiology is generally contraindicated. Chronic idiopathic orofacial pain warrants referrals and consultation with other health care professionals, lest wholesale extractions worsen the patient's dental state and not relieve pain (see Chapter 17).[7] For instance, in a long-term follow-up study of patients with chronic facial pain and without a recognizable odontologic pathosis, some patients were subsequently diagnosed with maladies ranging from cracked-tooth syndrome to medication-mediated illnesses.[7] Accordingly, referral to other specialists is essential, lest a patient be misdiagnosed with idiopathic or atypical facial pain when instead the pain etiology was misdiagnosed.[238,255]

About 5.3% of patients have postendodontic pain 6 months or more after nonsurgical and surgical endodontic treatment. Nonodontogenic pain may account for about 57% to 64% of the total causes of postendodontic pain that persists after 6 months. Therefore, of patients being treated with endodontic procedures, about 3.4% (64% of 5.3%) will have posttreatment pain that arises from a nonodontogenic cause.[41,237]

Fig. 29-4, *A* and *B*, demonstrates the advantage of CBCT 3D imaging compared to 2D imaging. In *A*, the nail appears inside the cranium, contrasted with *B*, which shows the nail taped outside the skull.

Diagnostic Tests

Sound endodontics begins with a proper diagnosis. Otherwise, unnecessary or risky treatment with a compromised prognosis follows. Generally, as described in greater detail in Chapter 1, the following endodontic tests should be performed to arrive at a correct and accurate endodontic diagnosis:

1. Percussion
2. Thermal testing
3. Electrical testing (optional)
4. Palpation
5. Mobility
6. Periodontal assessment (pockets, mobility, furcations, gingival recession)

Both positive and negative pulpal testing results should be recorded. Juries, peer-review committees, and insurance consultants often disbelieve unrecorded test results. Uncharted test findings may be regarded as never having been done. Consequently, reasonable clinicians should record all testing results, both positive and negative. An evaluation of the temporomandibular apparatus is necessary to diagnose or rule out temporomandibular disorders (TMDs).

Treatment Plan

Treatment records should contain a written plan that considers all aspects of the patient's oral health. Treatment plans should be coordinated, preferably in writing, with other concurrent or jointly treating clinicians. For instance, endodontic treatment will probably fail if underlying periodontal pathosis is ignored or untreated. Thus, the clinician should assess the patient's

*References 20, 75, 97, 157, 169, 201, 204.

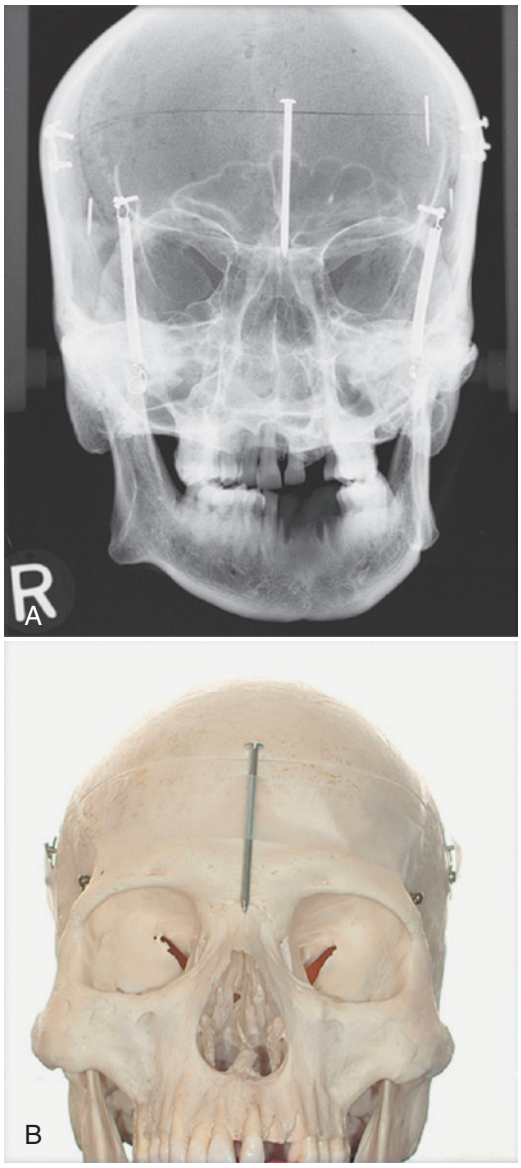

FIG. 29-4 A, Nail inside cranium? B, Nail in same patient as in (A), showing nail taped to outside of skull. Alas, poor Yorick!

entire dentition and not just a single root canal system. The clinician should also recommend a periodontal consultation to both the patient and the referring clinician if periodontal therapy is required. The patient should approve the treatment plan. Remember the maxim: If you fail to plan, plan to fail.

Examination

After gathering the dental and medical history, findings obtained from the various phases of the clinical and radiographic examinations are recorded as shown in Figure 29-5. Lists in each category afford the clinician a systematic format for recording details pertinent to an accurate diagnosis. Appropriate descriptions are circled, followed by the necessary notations in the accompanying spaces. Tabular arrangement allows easier recording and comparison of diagnostic test data acquired from one tooth on different dates or from different teeth on the same visit. A pain intensity index (i.e., 0 to 10) or pain classification (i.e., mild +, moderate ++, severe +++) should be used to differentiate diagnostic test results.

Diagnosis

Careful analysis of accumulated examination data should result in the determination of an accurate pulpal and periapical diagnosis. Clinical conditions and the probable etiologic factors for the presenting problem are circled. Alternative modalities of therapy are considered and analyzed. The recommended treatment plan is circled, followed by a prognostic assessment of the intended therapeutic course.

Patient Consultation

Patients should be advised of each diagnosis and should consent to the treatment plan before therapy is instituted. Consultation should include an explanation of reasonable alternative treatment approaches and rationales and treatment consequences of each alternative therapy, including risks from nontreatment or delayed treatment that may affect the outcome of intended therapy. This discussion is documented by completing the checklist items.

Treatment

All treatment provided on a given date is documented by placing a checkmark (✓) within the designated procedural category. Only the most frequent retreatment procedures are included for tabulation. Descriptions of occasional procedures or explanatory treatment remarks should be entered in writing. A separate dated entry should be made for each patient visit, phone call, e-mail message, and fax communication (e.g., consultations with the patient or other clinicians) or correspondence (e.g., biopsy report, treatment completion letters).

Individual root canal lengths are recorded by (1) circling the corresponding anatomic designation and the method of length determination (e.g., radiograph or electronic measuring device), (2) writing the measurement (in millimeters), and (3) indicating the reference point. For any medication prescribed, refilled, or dispensed, the treatment record should show the date and type of drug (including dose, quantity, and instructions for use) in the treatment table under the heading "Rx." Figure 29-6 also shows a sample medication log. Periodic recall intervals, dates, and findings are entered in the spaces provided.

If the scope of the examination or treatment is intentionally limited, such as a screening examination or emergency endodontic therapy, the limited scope of the visit should be recorded. Otherwise, the chart appears as if the examination were superficial and treatment incomplete. If a suspicious apical lesion requires subsequent reevaluation, the clinician should record the future reevaluation date and differential diagnosis—for example, "Small apical lesion on #28. Reevaluate for changes in 2 months. Also, check for any root fractures." If this is not done, it appears (on the chart) as if the clinician ignored potential pathosis, such as suspected root fracture. A soft-tissue examination (including cancer check) is a standard part of any complete dental examination. E-mail, prescriptions, and correspondence should be documented with hard copies in the chart unless virtually all treatment records are stored in electronic format.[191,307]

Informed Consent Form

After endodontic diagnosis, the benefits, risks, treatment plan, and alternatives to endodontic treatment—including any patient refusal of recommended treatment and consequences of refused treatment—should be presented to the patient or the

patient's guardian. This will document acceptance or rejection of treatment recommendations. The patient or guardian, along with a witness (who can be a staff member), should sign and date the consent form. Any informed-consent video should similarly be noted, if viewed. Subsequent changes in the proposed treatment plan should also be discussed and initialed by the patient to indicate continued acceptance and acknowledge the patient's understanding of any newly disclosed risks, alternatives, or referrals.

Despite a patient's confirmed signature on an informed consent form, a jury is free to decide that the patient never read the informed consent form's content before signing. For instance, the patient may claim it was impossible to have read the consent form, because he or she did not have reading glasses when signing and no clinician ever explained the form contents. Another frequent factual scenario is when the patient claims the staff stated it was a standard consent form that was a mere procedural formality requiring patient signature, rather than a detailed informed consent form. Consequently, numerous legal cases have been lost at trial on the issue of inadequate informed consent despite a signed patient consent form.

FIG. 29-6 Medication log.

To obviate a patient's claim that no explanation ever occurred, a patient questionnaire can additionally be used. Patients can be instructed that unless they score 100%, proposed procedures will not be done (because patient understanding is imperative and essential for cooperation, including postoperative care). To be effective, the patient questionnaire should be relatively short and simple (Fig. 29-7). Also, the patient should be given an opportunity to correct any incorrect answers after the clinician reviews with the patient the reasons why the patient answered incorrectly. Note that the majority of answers are false. This precludes a patient from guessing the correct answer by assuming that all test questions are necessarily true.

Treatment Record: Endodontic Chart

A suggested chart is presented in Figure 29-8 to facilitate recording of information pertinent to the diagnosis, recommendations, and treatment of the endodontic patient. Systematic acquisition and arrangement of data from the patient questionnaire, along with clinical and radiographic examinations and careful recording of treatment performed, expedites accurate diagnosis and maximizes clinician efficiency. Suggested chart format and use are described in the sections that follow.

General Patient Data

Patient name, address, phone numbers, referring clinician, and chief complaint are printed or typed in the corresponding space at the patient's initial office visit. The patient's appointment and financial record are divided into two parts as follows:

1. The treating clinician or staff completes the first portion after the diagnosis and treatment plan have been formulated and presented to the patient. Tooth number and quoted fee are posted. The treatment plan is recorded by circling the appropriate description. Under "Special Instructions," specific treatment requests by the referring clinician are circled. Details of planned adjunctive procedures (e.g., hemisection, root resection) may be written in the adjacent space, along with information from the patient data section. The clinician can then use this information for general reference during future treatment. The secretary or treatment coordinator can also use this information when scheduling appointments and establishing financial arrangements.
2. Business personnel complete the second portion. Financial agreements, third-party coverage, account status, and appointment data (including the day, date, and scheduled procedure) are recorded.

ENDODONTIC INFORMED CONSENT QUESTIONNAIRE

In order to help your understanding of endodontic benefits, risks, and alternatives, please answer the following questions by checking the true box if the statement is correct and the false box if the statement is incorrect. In the event that your answers suggest the need for further explanation, Dr. Cohen will review root canal treatment (and options) with you and answer any questions.

Please feel free to ask questions so that you may feel comfortable with your understanding of the surgical endodontic procedure on tooth number 19 and your consent to endodontic surgery.

	True	False
1. Endodontic surgical success is guaranteed.	☐	☐
2. Since endodontic surgery is carefully done, there is no chance of any infection occurring after surgery.	☐	☐
3. As with any surgical procedure involving the human body, there are associated risks. One of these risks is numbness of the lower lip or chin on the side that the surgery is done. Any numbness is usually temporary but, on rare occasions, it can be permanent.	☐	☐
4. Daily oral hygiene care after endodontic surgery is unnecessary.	☐	☐
5. Dr. Cohen is unavailable for emergency calls after business hours.	☐	☐

I understand that I may ask Dr. Cohen any question I may have regarding endodontics at any time. Dr. Cohen has answered all of my questions, if any, to my satisfaction.

Date: _____ Patient's signature _____ Witness

FIG. 29-7 True/false endodontic informed consent form.

Either the clinician or the assistant may complete portions of the diagnosis and treatment sections, but *the clinician should review and approve all entries*.

Dental History

Chief complaint should include whether the patient is symptomatic at the time of examination or in the recent past and what medications the patient is currently taking for pain relief. Narrative facts regarding the presenting problem are then recorded. Additional details of the chief complaint obtained during successive questioning are recorded by circling the applicable word within each symptom parameter. The pain intensity index (i.e., 0 to 10) or pain classification (i.e., mild +, moderate ++, severe +++) should be registered alongside the appropriate description. For accurate assessment of the effects of prior dental treatment pertaining to the examination site, a summarized account of these procedures should be documented. In addition, all pretreatment signs and symptoms should be described. It is essential that the patient comprehend all communications with the clinician and staff. If there is any language comprehension difficulty, the clinician should ask the patient whether he or she understands completely the language the clinician is speaking. To verify patient comprehension, the clinician should ask the patient to repeat important information that has been conveyed. A clinician- or patient-provided interpreter may be necessary if language problems exist.

Medical History

More medical history information is obtained from a patient-administered questionnaire than from the clinician obtaining

an oral history solely from the patient.[43,286] Maximum information is obtained if the clinician reviews with the patient the written health history form the patient has completed.

Information (e.g., personal physician's name, address, and phone number; patient's age; date of last medical examination) is recorded for reference. The clinician can obtain a detailed medical history by completing a survey of common diseases and disorders along with a comprehensive review of corresponding organ systems and related pathosis. Specific entities that have affected the patient are circled. Essential remarks regarding these entries (e.g., details of consultations with the patient's physician) should be documented on an attached blank sheet with dated treatment notes attached to the back of the chart (see Fig. 29-2). A review of the patient's medical status (including recent or current conditions, treatments, and medications) completes the medical history. Updated medical histories that the patient signs or initials should be done at least annually and at reevaluation visits.

Excessive alcohol consumption can contribute to a higher incidence of restoration corrosion from chronic regurgitation and vomiting from gastritis associated with alcohol abuse.[139] Corrosion can lead to coronal marginal leakage predisposing to endodontic failure.[305] Accordingly, medical histories should include histories of gastric reflux disease, bulimia with associated habitual vomiting, gastritis, and excessive alcohol intake.

Periodontal Disease

Nearly half of American adults older than age 30 years have periodontal disease.[241] Periodontal disease was higher in men

Each tooth undergoing endodontic therapy (and adjacent teeth) should be probed with a calibrated periodontal instrument to obtain six measurements per tooth. Pockets of 4 mm or greater should be recorded on the patient's chart. If no pockets exist, WNL (within normal limits) or a similar abbreviation should be noted. Mobility should also be charted and classified class I, II, or III. Gingival recession, furcations, and mucogingival deficiencies should also be recorded.[9,10]

A clinician who treats with endodontic success but ignores loss of periodontal attachment may misdiagnose or fail to appreciate the risk of failure because of poor periodontal prognosis. It bears repeating that the endodontic treating clinician should not assume an adequate periodontal evaluation has been performed by another clinician or the referring clinician. Instead, an independent periodontal evaluation should be done with a calibrated periodontal probe and results recorded before initiating endodontics, including noting absence of pockets or within normal limits.

If clinically significant periodontal disease is present, the endodontic treating clinician should consult with the restorative clinician to determine whether the periodontal disease will be properly treated or referred to a periodontist in conjunction with endodontic treatment. A patient should be advised of any compromise of the endodontically treated tooth's periodontal status to comply with required informed consent disclosure.

Drug History

A current drug history, both written and oral, is necessary to alert the clinician to any potential for interaction between any newly prescribed drugs and any other medication, supplements, or over-the-counter medication the patient is already taking.

In patients aged 57 through 85, 40% potentially are at risk of a major drug reaction—half involving various prescription medications and the other half involving anticoagulant drug reactions. About half of prescription users also concurrently take over-the-counter medications plus dietary supplements.[190,235]

Risks of drug interactions or side effects incidence may not be discovered or appreciated in premarket research-controlled drug trials for newly marketed drugs, despite FDA approval. For example, rofecoxib (Vioxx) was withdrawn from the market in September 2004 after increased incidences of myocardial infarcts and strokes manifested in a postmarket research study of 2600 patients. Merck's voluntary recall followed an FDA researcher's claim that the FDA tried to ostracize and intimidate him after he raised safety concerns over Vioxx.[33] Currently, pharmaceutical manufacturers budget more for marketing than research and development.[121] Some drug manufacturers have suppressed publication of adverse research.[55,208,337] The Patient Protection and Affordable Care Act of 2010 (Section 6002) requires drug companies to disclose payments to medical/dental professionals who tout their drugs in seminars or publications and receive compensation greater than $500.[245]

For newly marketed drugs, the small number of premarket patients studied may lack sufficient statistical power to expose serious side effects that occur infrequently but are nonetheless life threatening.[337] For instance, mibefradil (Posicor) was withdrawn from the market after 1 year because it increased plasma concentrations of 25 other co-administered drugs, including erythromycin.[235,239] In another example, the popular prescription nighttime heartburn drug Propulsid (cisapride) was linked to 70 deaths and more than 270 significant negative reactions.[328] Other examples include the risk of esophageal cancer with bisphosphonate[337,341] and bisphosphonate-associated osteonecrosis.[92,287] In 2008, the FDA added a black box warning label for Levaquin-associated risks of tendonitis (www.levaquin.com/levaquin/medication).

Preoperative and Postoperative Radiographs

Pretreatment, midtreatment, and posttreatment radiographs or digital images are essential for endodontic diagnosis and treatment:

1. A current, pretreatment, interpretable periapical radiograph of adequate diagnostic quality is mandatory.
2. Measurement films or digital images are necessary to verify canal length (which can be supplemented with an electronic canal-measuring device) and the apical extent of the gutta-percha fill to the radiographic apex.
3. Posttreatment radiographs are essential for determining the adequacy of the endodontic seal or if further treatment is necessary (see Chapter 8).

Digital Radiography

Digital radiographic endodontic applications are ever increasing in accuracy.[142] The standard of care does not currently require digital imaging, because traditional silver halide radiographic film is a reasonable alternative. When there is more than one reasonably acceptable practice modality, a clinician who chooses either modality meets the standard of care. Figure 29-9, *A*, represents a distal open margin on tooth #30 (shown digitally) that is not evident in part *B* with plain-film radiography.

Advertised claims of 80% reduction in radiation with direct digital radiography (rather than film) assume the following[53,142]:

1. Ultraspeed D-speed film is used. (Ektaspeed E-speed film and the newer F-speed film reduce radiation 50% and 60%, respectively, while producing images of comparable quality to D speed.)[4]
2. No rectangular collimation is used, which reduces exposure another 30%.
3. No extra radiographs are taken to compensate for a smaller area. For instance, a 2 charged-coupling device (CCD) sensor has an active area smaller than size 1 film and may require an extra image with additional radiation exposure.

A digital x-ray image should never be modified to "enhance" the radiographic appearance of the original image. X-ray modification can be detected. In litigation, it can prove devastating to the clinician's defense because the clinician's credibility of events or recorded entries are not believable, particularly if the radiograph is Photoshopped.

Periapical (PA) radiography is limited to only two dimensions. Newer 3D imaging systems for dental radiology use x-ray beams that are cone shaped. Cone-beam computed tomography can provide a more nearly accurate diagnosis.[75,122,157] In Figure 29-10, *A* to *C*, the PA does not show the transported canal and extent of short fill, which is more evident in the CBCT. Each CBCT scan produces three image views: axial, coronal, and sagittal.

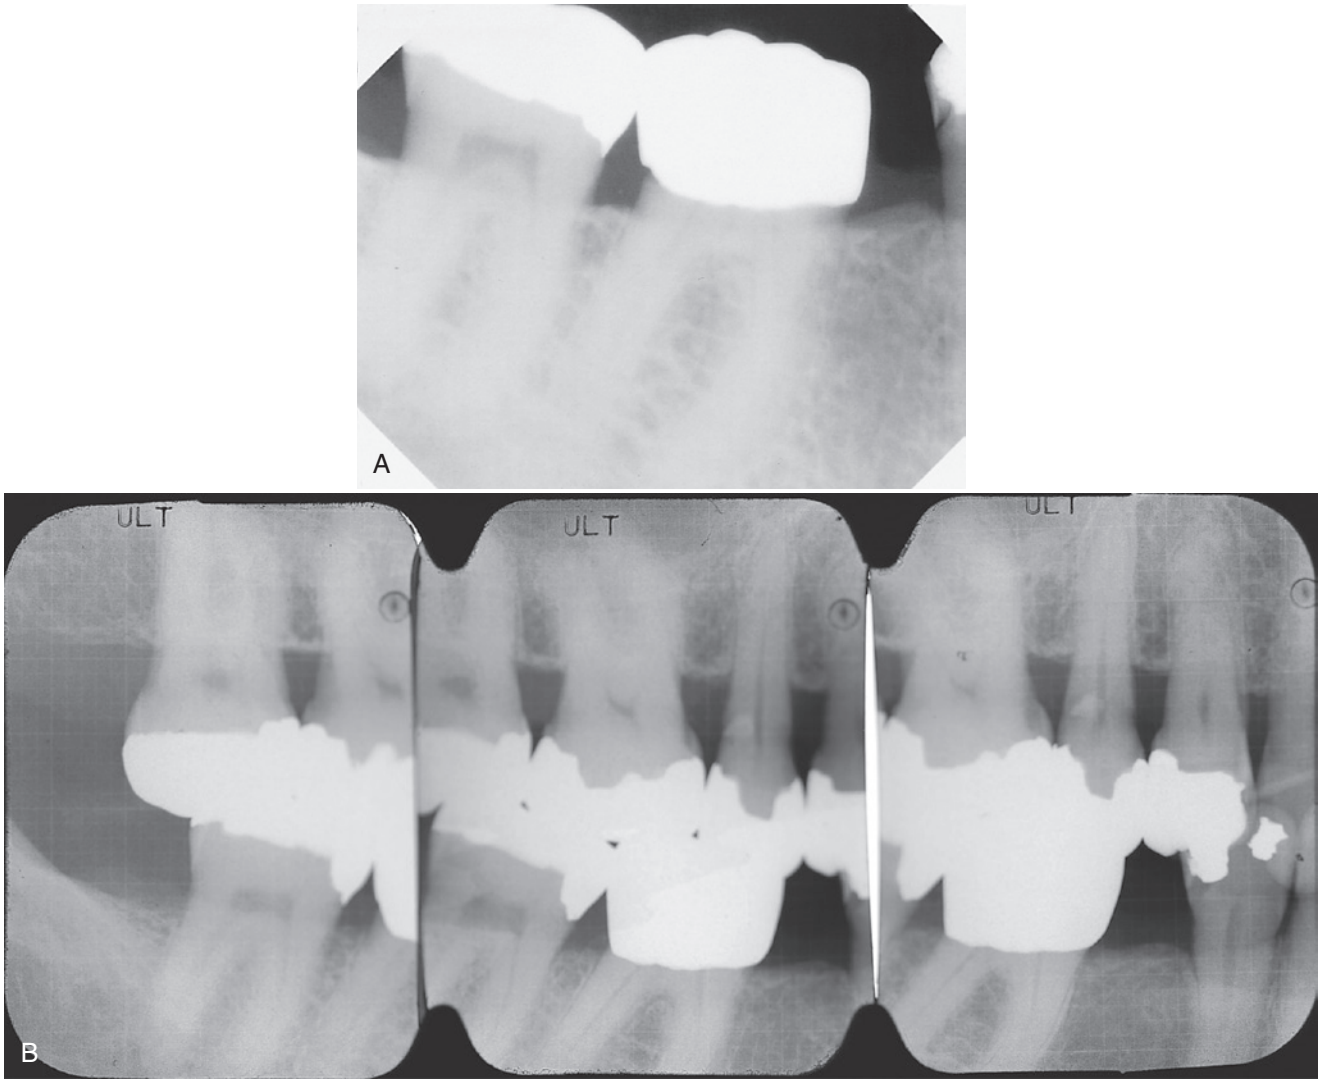

FIG. 29-9 **A,** Distal open margin on tooth #30 (shown digitally). **B,** Distal open margin on tooth #30 not evident with plain-film radiography.

Radiation Safety

The American Dental Association (ADA) Council on Scientific Affairs recommends the dentist recognize the importance of keeping radiation exposure as low as reasonably achievable (ALARA). Accordingly, CBCT imaging should not be performed for screening purposes but rather for specific diagnostic and treatment usage.[20]

The Food and Drug Administration provides recommendations for dental cone-beam computed tomography.[99] The American Academy of Oral and Maxillofacial Radiology provides indicated use of the CBCT for implant placement.[317] In the future, magnetic resonance imaging (MRI) may supplant or augment CBCT because its imaging quality equals and in certain instances surpasses that of CBCT.[189]

Children have greater radiosensitivity because of developing cells in their young bodies. Thus, CBCT imaging radiation dosage should be considered for young patients in assessing the need for a CBCT.

Computed tomography (CT) scans enable evaluation of the true extent of lesions and their spatial relationship to important anatomic landmarks.[97] Figure 29-11, *A* to *C*, shows a bifid inferior alveolar nerve canal (IANC) that is not apparent on Panorexes. CT scans may provide information important for retreatment decisions, especially apical surgery. CBCT[75,201,204] showed significantly more lesions than PA radiography, including expansion of lesions into the maxillary sinus, sinus membrane thickening, and missed canals; PA radiography missed 34% of these lesions.[201,204] Artificial bone defects in the antral surface were not detected with PA radiography. Because of overlapping roots, only 1 out of 14 furcation defects in upper molars were seen on PA radiography, but CT scans were able to identify all furcal defects. Second molars proved to be the most difficult for detecting lesions with PA radiography alone. Twenty-three teeth with lesions expanding into the maxillary sinus were detected by CBCT, of which only two teeth were seen with PA radiography. Thirty-five teeth with membrane thickening were identified with CBCT, of which 16 teeth were also detected with PA radiography. Fifteen teeth with missing canals were detected with CBCT, of which only four teeth were identified with PA radiography. In a study that compared the efficacy of PA radiography and CBCT in detecting periapical lesions in

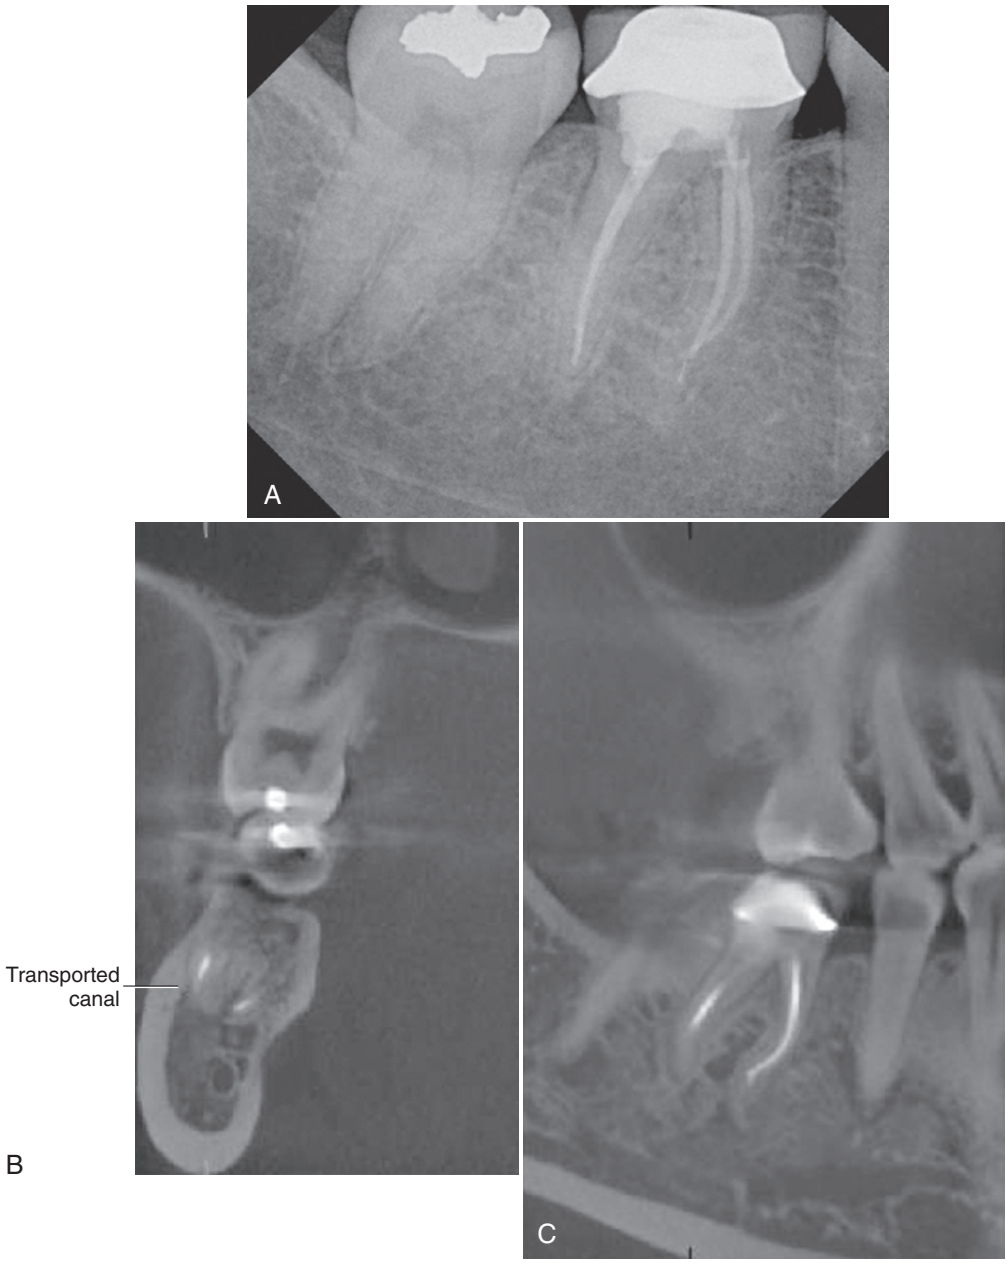

FIG. 29-10 A, Periapical (PA) view, which does not show full extent of transported and short-filled canal. Both deficiencies evident in B and C with cone-beam computed tomography (CBCT). B, CBCT Accuitomo of transported canal. C, CBCT Accuitomo of short-filled canal.

maxillary premolars and molars for apical surgery,[204] Lofthag-Hansen showed that 38% of maxillary posterior teeth lesions were undetected by PA radiography, despite the fact that an additional different angulated PA radiograph was taken.[201] Lesions associated with apices near the sinus floor had a higher probability of being missed with PA than lesions associated with apices located away from or overlapping the sinus floor. Expansion of the lesion into the maxillary sinus, thickening of the sinus membrane, missed canals, and presence of apicomarginal communications were more frequently detected with CBCT than with PA radiography.[201]

Apicomarginal communication is an important predictor for the success rate of apical surgery, including evidence of undetected vertical fractures necessitating extraction; 83% of apicomarginal communications were not seen with PA radiography in the Lofthag-Hansen study.

If the radiograph shows a small distance between the periapical lesion and the sinus floor when the bony wall is thin, there is a high probability that an oral antral communication (OAC) can result, unless skillful care avoids sinus penetration during apical surgery. CBCT also allows the clinician to study the topography of the bony defect and assess whether the use of guided tissue membranes would be beneficial. Precise morphometric assessment of osseous relationships to the sinus is often inadequate with periapical radiography. Thus, CBCT is invaluable in treatment planning for apical surgery, as 70% of cases studied revealed clinically relevant information not found in PA radiography.[204]

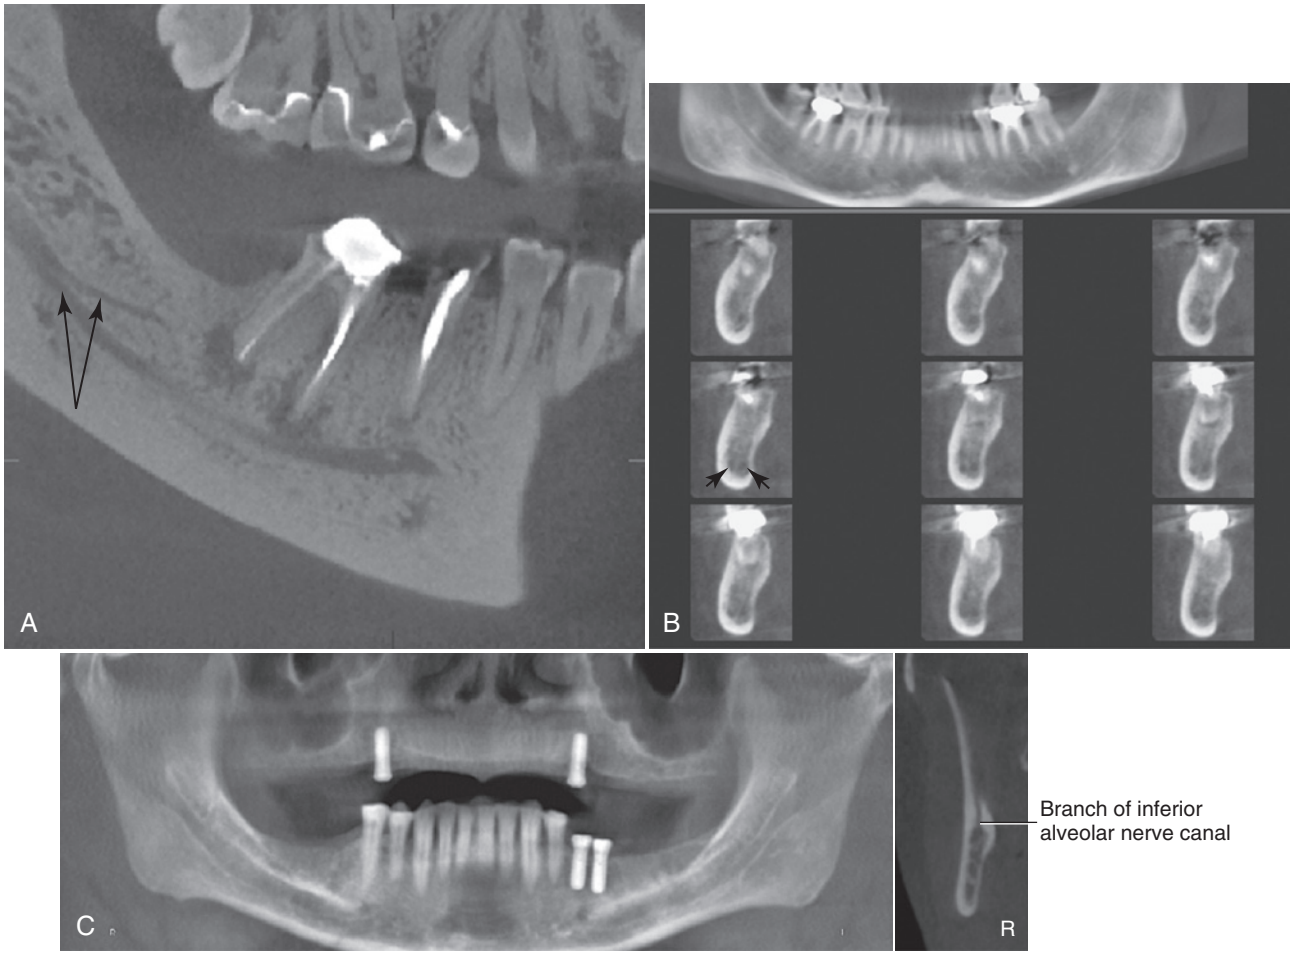

FIG. 29-11 A, Bifid inferior alveolar nerve canal (IANC) visible with cone-beam computed tomography (CBCT). B, Bifid canal visible with CBCT but not shown on Panorex. C, Branch of IANC apparent on CBCT but not shown on Panorex. (Courtesy Gurminder Sidhu, DDS, MS.)

The probability of detecting lesions with PA alone was limited for teeth with apices in close contact with the floor of the maxillary sinus, for molars (in particular second molars), and when bone thickness between lesion and sinus was less than or equal to 1 mm. Findings of lesion expansion into the sinus, sinus membrane thickening, missed canals, and presence of apicomarginal defects are more frequently diagnosed with CBCT than PA.[75,204]

ENDODONTICS AND HEART DISEASE

Associations between chronic infections such as periodontal diseases and coronary heart disease (CHD) have been suggested.[280] Conversely, supporting evidence linking root canal–filled teeth or teeth with periapical disease to CHD is lacking.[119]

If a patient's medical history shows valvular heart defects with regurgitation, the clinician should consult with the patient's physician to determine the necessity of antibiotic prophylaxis against infective endocarditis in accordance with current American Heart Association (AHA) guidelines.[334] If the physician does not appear knowledgeable about those guidelines, the clinician should provide a copy of the guidelines to the physician. If the physician advises deviation from AHA guidelines, the clinician should inquire why the physician feels that this is appropriate. The clinician should also record any discussions with the physician in the patient's chart and confirm the discussion and the physician's recommendation in writing (by fax and letter to the physician).

Communications with the physician should be specific, because dental treatment risks, such as overextension of files or filling material sealants that occur nonsurgically and may enter the bloodstream, may not be fully understood or appreciated. A sample format is shown in Figure 29-12.

Abbreviations

Abbreviated records can be frustrating if the clinician is unable to decipher one's own or other clinicians' handwritten entries, so the clinician should use standard or easily understood abbreviations. Pencil entries are legally valid, but ink entries are less vulnerable to a plaintiff's claim of erasure or alteration. A short pencil is better than a long memory; records remember, but patients and clinicians may forget.

A sample of a completed endodontic chart (Fig. 29-13) illustrates its proper use. Box 29-1 lists a key to the abbreviations.

Computerized Treatment Records

Clinicians are increasingly using computerized record storage as described in this chapter.[282] To avoid a claim of record falsification, whatever computer system is used should be able to

Dear Physician:

Your patient requires potentially invasive dental treatment that will likely result in transient bacteremia. Does the patient have a heart valve defect that increases the risk of infective endocarditis? If so, please advise of the diagnosed defect and recommended prophylactic antibiotics and dose for endodontic treatment or surgery with potential to invade the bloodstream. If you require the patient to have a current cardiac evaluation or echocardiogram to provide an answer, please advise both me and the patient, preferably in writing. Please also advise if your recommendation is in accordance with the enclosed American Heart Association current guidelines concerning bacterial endocarditis relating to dental treatment.

Thank you for your anticipated cooperation.

(Enclosure: current AHA guidelines)

demonstrate that records indicating earlier treatment were not recently falsified. Software technology, such as the "write only read memory" (WORM) system, used to identify computer data tampering, is not foolproof because it cannot detect tampering where an entire disk of recent origin has been substituted for an earlier version. Periodically, a hard copy of computer data should be printed out, hand initialed, dated in ink, and stored in the chart to provide written verification of the computer records if the office is a virtual paperless office.[307]

Health Information Technology for Economic and Clinical Health (HITECH) Act Pitfalls

Affected patients must be notified if there is a breach in the electronic record storage system.[148] Electronic records have the following pitfalls:

- Data entry in the wrong patient record
- Incorrect data entry in the patient record

Incorrectly entered information or information that was not entered at all was reported as the cause of the majority of errors. The absence of an undecipherable scrawl is designed to reduce errors. Whether the result of fat fingers or providers pushed for time, mistakes will still occasionally occur. Some of the things that make paperless electronic records desirable—transparency, the ability of more people to view the same information, and more immediate accessibility—may cause any electronic record mistakes risk to be amplified.

Health Insurance Portability and Accountability Act (HIPAA)

The Department of Health and Human Services' Security and Electronic Signature Standards rule is part of the Health Insurance Portability and Accountability Act (HIPAA) of 1996. This act emphasizes the safeguarding of clinicians' health care information and permits a patient to obtain a copy of the requesting patient's records. Most states have authorized digital electronic signatures as binding for most contracts and orders. Digital signatures with electronic transactions are authorized by the Third Millennium Electronic Commerce Act (also called the Electronic Signature in Global and National Commerce Act).[323]

Pertinent HIPAA requirements follow:

1. Original records and radiographs should not be released but only copies provided to the patient. A reasonable copying charge may be requested before or after release of the copies.
2. A patient may amend health information in the chart that the patient believes to be incorrect or incomplete. The clinician may respond to the patient's proposed chart amendments.
3. Notice of office privacy practices should be provided to the patient, and the patient should acknowledge receipt in writing.
4. If privacy rights are violated, the patient can file a grievance with the secretary of the Department of Health and Human Services. Patients cannot be penalized for complaining.
5. Confidential dental and medical information may be shared with other clinicians, based on a need to know.
6. All e-mail communications between clinician and patient must use a secure network and be stored on a secure server.[282]

Record Size

Although there is little harm in recording too much information, there is great danger in recording too little. Standard $8\frac{1}{2} \times 11$ inch or larger clinical records possess the advantage of providing the treating clinician adequate space for clinical notes.

Identity of Entry Author

Either a clinician or an auxiliary can chart clinical entries unless state law indicates otherwise. Some states require clinicians and assistants to sign or initial each treatment entry.[58] What is important is that the correct clinical information is recorded. Each person who makes a clinical chart entry should record the date and initial the entry. Otherwise, the author's identity may be forgotten if the individual who recorded the entry is needed in a legal proceeding. For instance, initialing the entry makes it easier to identify the particular clinician or auxiliary who, after the original recording, is now employed elsewhere. A separate log of clinician and staff initials should be created and stored for later comparison to identify the entrant's initials (see Fig. 29-13).

BOX 29-1

Standard Abbreviation Key

Ab	=	Antibiotic

Temp	=	Temporary restoration
Test	=	Test file
Tx	=	Treatment
WNL	=	Within normal limits

Patient Record Request

Patient requests for record transfers or copies must be honored. It is unethical to refuse to transfer patient records, on the patient's request, to another treating clinician.[18] Moreover, refusing to provide patient records is illegal in some states, subjecting the clinician to discipline and fines should the records not be provided to the patient upon written request, even if the balance is outstanding.[62]

Patient education pamphlets may be used in litigation as evidence that a patient was properly informed and given endodontic alternatives but instead chose extraction. Such pamphlets include the American Dental Association's (ADA's) *Your Teeth Can Be Saved by Endodontic Root Canal Treatment* and the American Association of Endodontists' (AAE's) *Your Guide to Endodontic Treatment, Your Guide to Endodontic Retreatment,* and *Your Guide to Endodontic Surgery*. The clinician should indicate in the patient's chart which particular pamphlets the patient was provided or which video was shown, because this may prove useful should the patient later deny being informed of endodontic alternatives.

Patient Education Materials

The use of educational materials may improve health behavior, enhance patient satisfaction, and facilitate the consultation processes. Consequently, the patient is better informed if patient questions are answered after prompting with informative educational materials.

Postoperative Instructions

It is unlikely a patient will remember oral postoperative instructions unless accompanied with written instructions. After endodontic procedures, the patient may be sedated or affected by analgesic drugs. Accordingly, written postoperative instructions are beneficial. Emergency phone numbers to contact the treating clinician should be included on the form. Written instructions reduce postoperative morbidity and pain and improve patient compliance.[6] Document that both written and oral postoperative instructions were provided. If treating in close proximity to the IANC, place a precaution, such as seen in Figure 29-14, in the postoperative instruction sheet.

> If numbness persists the next morning or suddenly within three days following root canal treatment, immediately telephone our office so we may treat or refer to another specialist to surgically remove any root canal filling material overfill impinging upon the sensory jaw nerve, causing altered sensation to the lip and/or chin.

FIG. 29-14 Postoperative instruction sheet.

Recording Referrals

Every clinician, including the endodontic specialist, has a duty to refer under appropriate circumstances. If consultations with additional experts or specialists become necessary, referrals should be recorded lest they be forgotten or refused. Carbonless, two-part referral cards allow the clinician to provide an original referral slip to the patient while retaining a copy for the patient's chart. The clinician or staff member should document the fact that the original referral card was given or mailed to the patient and record the name of the person who provided the referral card and the date on which it was provided. A copy of the referral card should also be sent to the referred doctor. If the patient fails to keep the referral appointment, this copy will provide proof that a referral was made. The clinician should request that the patient and the referred clinician report back if the referral appointment is canceled. Staff should calendar to verify that the referral consultation occurred.

Dental Fees Related to Quality Care

The link between health care fees and the quality of health care remains unclear.[156]

Record Correction

Records must be complete, accurate, legible, and dated. All diagnoses, treatments, and referrals should be recorded. Chart additions may expand, correct, define, modify, or clarify (as long as they are currently dated to indicate a belated entry).

To correct an entry, the clinician should draw a line through (but not erase or obscure) the erroneous entry. The correction should then be written on the next available line and dated. Handwriting and ink experts use ink chemical tags, age dating, and infrared technology to prove falsified additions, deletions, or substitutions. If records are proved to be falsified, the clinician may be subject to punitive damages in civil litigation. In addition, the clinician may be subject to license revocation for intentional misconduct.[58] Professional liability insurance policies may defend but will usually not indemnify punitive damages if the clinician is found to have committed fraud or deceit.[56,57,61,77] In addition, insurance carriers may deny renewal of professional liability coverage to a clinician who fraudulently alters dental records.

If an erroneous entry occurs, the clinician should add another entry dated as a late entry to demonstrate later corrected information. Figure 29-15 gives an example of the proper method of belated record correction.

When patient records have been requested or subpoenaed, it is wise to refrain from examining in detail prior to copying to avoid the temptation to clarify or belatedly add an entry. Alteration of clinical records is a cause of large settlements because the clinician's credibility is suspect. Also the jury may be similarly instructed. For instance, California Jury Instruction 204 regarding "Willful Suppression of Evidence" states as follows:

You may consider whether one party intentionally concealed or destroyed evidence. If you decide that a party did so, you may decide that the evidence would have been unfavorable to that party.

- 10-13-15-Corrected entry for 10-12-15. (Entry should have recorded): Hot, cold, and percussion tests plus one. Recommend re-evaluation in 24 hours and repeat pulpal tests. Next visit scheduled 10/13/15 at 9 a.m.

FIG. 29-15 Belated record correction.

Spoliation

Spoliation is the destruction or significant alteration of evidence, or the failure to preserve property for another's use as evidence, in pending or reasonably foreseeable litigation under Fed. R. Civ. P. 37(b)(2)(C).[103]

Spoliation occurs when the wrongdoer alters, changes, or substitutes dental records in an attempt to defeat a civil lawsuit.[64,322] It is far easier to defend a dental negligence lawsuit with poor records compared to attempting to justifiably defend altered (falsified) records. A jury and/or a judge will likely conclude the clinician acted with consciousness of guilt for falsifying records compared with excusing staff clerical oversight if records are poorly maintained. Dental records, like all business records, deserve accuracy and completeness.

Questioned document experts utilize ink age dating, examine watermarks, or apply infrared techniques to ascertain substituted pages and additions or deletions in records, including prior erasures, entries underneath whiteouts, and indentations made when one page is overwritten on another page. Infrared technique analyzes these patterns of indentations underneath the altered pages that detect belated second entries. In one case, the defendant clinician claimed a written referral was made to a specialist in 1998, but the patient refused the referral. During litigation, the patient denied the referral and subpoenaed records of the print shop where the specialist's referral forms were printed. These subpoenaed records proved the carbon copy of the form used for the purported 1998 referral was instead first printed in 2000, which was 2 years after the alleged specialist referral was made (Fig. 29-16, *A* and *B*).

In another example, altered records were detected in nine different entries in one medical negligence case involving an undiagnosed malignancy. The physician's carrier subsequently settled for $1 million. Also, the defendant personally paid a separate fine to the court. As part of the settlement, the defendant authored an article for the Washington Medical Association detailing why records falsification is wrong.[29]

Records are subjected to (1) audits by insurance carriers for documentation that treatment was performed, (2) review by peer review committees, and (3) subpoena by state licensing boards or agencies for disciplinary proceedings. Accordingly, falsified records expose the clinician not only to civil liability for professional negligence but also to criminal penalties for criminal offenses, such as insurance fraud.[64,313,318,322,323]

Deliberate record alteration with intent to deceive may also subject the clinician to licensing[58] and ethical discipline as well as punitive damages for deceitful misconduct. Insurance carriers may defend but not indemnify a verdict for intentional material alteration of dental records done with intent to deceive.

Digital radiography may have dental advantages, but because the digital images originally may be computer manipulated, they may be legally suspect as altered.[168,313] Therefore, hard copies of the digital images may also be printed and dated in ink to show the informational baseline upon which the clinician based diagnostic or therapeutic decisions. This also protects against computer glitches, such as disk drive crashes, electrical power surges, computer viruses, and operator delete errors.

B

FIG. 29-16 A, Falsified records with belated entry of year of referral. B, Falsified records.

In one instance, a judgment of $641,541.65 was awarded for negligently designed and prepared veneers and crowns. The dentist claimed she spilled Diet Coke on her records, which entailed inspection with a questioned document expert. Also the claim that a flood of muddy water caused the dentist to discard her study models was refuted by showing that the models could have been easily washed and preserved.[324]

False Claims

Performing or billing for unnecessary endodontic therapy, such as prophylactic endodontic therapy with every crown preparation, subjects the clinician to fraud. In non–pulpal exposure crown preparation, the likely incidence of subsequent endodontic therapy is approximately 3%. Therefore, performing prophylactic endodontics on the other 97% of patients represents unnecessary and therefore fraudulent treatment. Excessive unnecessary treatment also ethically violates the Hippocratic oath of "primum non nocere" ("first, do no harm").

The Federal False Claims Act carries both civil and general penalties of treble damages, fines, and attorneys' fees for fraudulently billing government programs, such as the Civilian Health and Medical Program of the Uniformed Services (CHAMPUS) or Medicare. Fines between $5000 and $10,000 per claim form apply if the U.S. mail was used for a false-claim submission. If any portion of the claimed treatment was fraudulently misrepresented, even if a small minority, a violation results.[322] Fraudulent intent need not be conclusively proved. Reckless disregard for the accuracy of submitted data is all that is necessary to obtain a federal criminal conviction or prove civil wrongdoing.[314]

LEGAL RESPONSIBILITIES

Malpractice Claims

More than 42% of physicians have been sued over the course of their careers. Before reaching the age of 40, more than half of obstetricians/gynecologists have already been sued. About 90% of general surgeons age 55 and over have been sued.[22]

Incidence of Negligence

Medical errors or adverse events are estimated to occur in almost one out of four patient visits to a family practitioner.[270]

A U.S. government study of the Institute of Medicine found that 152,000 avoidable deaths occur annually because of medical negligence.[118,120] In this government study, injury from medical care occurred in 3.7% of hospital admissions. Some 58% of these injuries were concluded to be preventable, and 13.6% were fatal injuries. The actual fatality numbers may be underestimated, because calculations were based solely on hospital chart review.

Malpractice Prophylaxis: Importance of Records

Good clinicians keep good records. Records represent the single most critical evidence a clinician can present in court as confirmation that an accurate diagnosis, proper planned treatment, and informed consent were provided.

Prevention is the goal of modern dental care. Competent endodontic treatment performed within the requisite standard of care not only saves endodontically treated teeth but also helps prevent a lawsuit for professional negligence. Thus, sound and carefully applied endodontic principles protect both patient and clinician. Prudent practices reduce avoidable and unreasonable risks associated with imprudent or careless endodontic diagnosis or therapy.

Not all examples of negligent endodontic treatment are included in this chapter, because the myriad of malpractice incidents far exceeds its scope and length. Rather, only select examples are elucidated for educational purposes.

Standard of Care

Good endodontic practice, as defined by the courts, is the standard of reasonable care that reasonably careful clinicians legally are required to comply. The standard of care does not require perfection. Instead, the legal standard is the reasonable degree of skill, knowledge, and care ordinarily possessed and exercised by reasonably careful clinicians under similar circumstances.[172]

Although the standard of care is flexible to accommodate individual variations in treatment, it is objectively tested based on what a reasonable clinician would do. Reasonable conduct represents a minimum standard required for legal due care. Reasonable care is care based on reasoning supported by sound science such as evidence-based peer-reviewed literature. Additional precautionary steps that rise above this minimal floor of reasonableness and ascend to achieve ideal care are laudable but not legally mandated. Again, the standard of care does not require perfection; nor does it require ideal endodontics. Nevertheless, prudent clinicians should always strive to achieve a higher level of care than barely or minimally adequate care. Excellent clinicians always strive to do their best and practice endodontics at the highest level. Some have criticized this concept by contending that average care is below average, because 49% of clinicians represent a minority compared to the majority of clinicians. Careful clinicians should strive to avoid the mediocrity of minimally acceptable care and instead zealously pursue a goal of endodontic excellence. Endodontists set the standard of care in endodontics. Accordingly, a general dentist and endodontist must each meet the same standard of care.

The written policies and procedures of a clinician, institution, or organization may be used as evidence of standard of care. An expert may consider these the appropriate standard of care in testifying about alleged breaches of standard of care on that issue. For instance, an expert may rely upon AAE's 1998 position paper on paraformaldehyde-containing root canal filling materials as substandard practice, as well as the fact that all U.S. dental schools teach that toxic paraformaldehyde substances should not be used for adult patients as a root canal obturant.

Negligent errors are unintended acts, either of omission or commission. Some errors do not lead to patient injury if intercepted. Failure to mitigate factors that contribute to errors or near misses may combine with human fallibilities of mood, inattention, carelessness, and forgetfulness to cause error repetition or a future more serious injury.

In deep-sea oil exploration (e.g., Deepwater Horizon) and nuclear power (e.g., the Fukushima Daiichi Power Plant) obtained oil and nuclear power presumed safely but paid a great human and environmental cost because of inadequate safety precautions. (The difference in dental care is that dental disasters are usually episodes of patient suffering or a single death rather than a single episode with many injuries and multiple deaths.)

We all make mistakes. The biggest mistake we make is not to learn from these errors. Our responsibility is to recognize our error, discuss the adverse event with the injured patient and colleagues, and follow up with prevention strategies.[187]

An example of error prevention through shared learning from the mistakes of others is Radiology Events and Discrepancies (READ). READ is structured as a confidential, educational resource to encourage learning from events and discrepancies with the goal of promoting improved patient safety.[86]

Useful lessons are thus learned from incidents/discrepancies that result in adverse consequences. As clinicians, we learn from the mistakes of others. By encouraging a reflective approach to adverse events, radiologists are encouraged to become keenly critical self-observers. For example, a "miss" is noted when an abnormality is radiographically visible but not detected at the time of reporting.

The READ submission form is accessible online via the READ website. Radiologists are encouraged to submit reports and safety-related events that have occurred in their practice. Submitted reports must be anonymized to assure the reporter's identity remains confidential. The READ panel reviews all reports and learning points identified. To ensure patient confidentiality, the event is "disidentified" by changing age and sex along with other alterations to preserve confidentiality. After publication, all material relating to the case is destroyed. A story is thus created based on a real event, which is published for shared learning. A "lessons learned" conclusion provides instructions to prevent future risks.

Standards of Care: Generalist versus Endodontist

A general practitioner performing treatment ordinarily performed exclusively by specialists—such as apical endodontic surgery, periodontal surgical grafting, or full bony impaction surgery—will be held to the specialist's standard of care.[131,132] To avoid performing treatment that is below the specialist's standard, a generalist should refer to a specialist rather than perform procedures that are beyond the general practitioner's training or competency. The three levels of clinical skill are (1) competency or beginning level, (2) proficiency, and (3) mastery.

To err is human. Even specialists may not always know what they believe they know.[98,179] Approximately 80% of general practitioners in the United States provide some endodontic therapy. Endodontic expansion into the realm of the generalist can be linked to (1) refinements in root canal preparation and improved obturation (i.e., packing) techniques currently taught in dental schools, (2) continuing education courses, and (3) significant improvements in the armamentarium of instruments, equipment, and materials available to all clinicians to optimize efficiencies in endodontics.

The AAE's Guidelines Case Difficulty Assessment Form and Guidelines provide a road map for when a generalist should treat or refer to an endodontist. Levels of difficulty range from minimal to moderate and high difficulty (Fig. 29-17). General dentists are competent to treat cases of minimal difficulty. Experienced general dentists may treat the moderate-difficulty cases but should refer high-difficulty patients.

Ethical Guidelines

The ADA's Code of Ethics guides conduct that distinguishes the dental profession from a trade by placing patient service paramount and profit secondary.[122] Section 5 of the ADA Code of Ethics regarding veracity ("truthfulness") states, "Professionals have a duty to be honest and trustworthy in their dealings with people." Accordingly, both ethically and legally,[159] clinicians are obligated to communicate truthfully and without deception to patients. Announcements to the public must be truthful so that the average person is not materially misled. Truth in dentistry is the rule and not the exception.[122]

Section 5.I of the ADA Code of Ethics provides the following:

> General Practitioner Announcement … general clinicians who wish to announce the services available in their practices are permitted to announce the availability of those services so long as they avoid any communications that express or imply specialization.

Thus, clinicians should not misrepresent or overstate the facts of their training and competence in any way that would be false or misleading in any material or significant manner to the public or their peers. General clinicians should avoid false and misleading self-representation regarding endodontic "superiority." Implying credentials that the generalist lacks misrepresents a general clinician's endodontic skill and knowledge as equivalent to a board-eligible or board-certified endodontist. A generalist's 30-year experience may be little more than 1 year's experience repeated 30 times. Every state has specific laws governing advertising. Consult your state's law, because each state deals differently with specialty announcements.

Telephone directory listings are organized into categories based on types of procedure, such as endodontics. Generalists must also state in such ads that endodontic services are being provided by general clinicians. The public is entitled to be informed of the distinction between an endodontist specialist and a generalist, although each provides endodontics. Only an ADA-recognized board-eligible or board-certified clinician is entitled to represent him or herself as an endodontist. With this distinction in mind, the ADA-recognized endodontic specialty organization is titled the American Association of Endodontists, not the American Association of Endodontics.

Standard of Care for Endodontics

Endodontists set the standard for routine endodontics. Therefore, if the endodontist's standard of care cannot be met, such as the need for microscopy or apical surgery, the generalist should refer the patient to an endodontist.[76,131,132,183]

Endodontists should not forget their general dentist training. Even though a patient may be referred for a specific procedure or undertaking, the endodontist should not overlook sound biologic principles inherent in the overall treatment. A specialist may also be held liable for relying solely on the information referral card or radiographs of the referring clinician if the diagnosis or therapeutic recommendations prove incorrect, unnecessary, or the referral card lists the wrong tooth for treatment. Therefore, conduct a "time-out" with patient and staff to verify which tooth is to be treated.[167]

Figure 29-18 demonstrates a general clinician's radiograph showing apparent complete endodontic fill within the canal space, whereas Figure 29-19 demonstrates an endodontist's radiograph showing a transported canal. This difference is explained by radiographic quality and angulation. Taking radiographs at different angles improves radiographic accuracy.[201,204]

Endodontists should not provide rubber-stamp treatment to whatever the clinician refers or recommends. Without performing an independent examination, the endodontist risks misdiagnosis and resulting incorrect treatment. Prevention of misdiagnosis or incorrect treatment requires an accurate medical and dental history preceding a clinical examination (not only of the specific tooth or teeth involved but also of the general oral condition). Obvious problems such as oral lesions, periodontitis, or gross decay should be noted in the chart and the patient advised regarding a referral for further examination, testing, or another specialist's consultation.

Radiographs from the referring clinician should be reviewed for completeness, clarity, and diagnostic accuracy. An endodontist should expose a new radiograph to verify current status before treatment and only use the referring clinician's radiograph for historical comparison. Unfortunately, the referring clinician may surreptitiously forward a pretreatment film with the referred patient, rather than the referring clinician's own posttreatment film depicting a perforation or broken file that necessitated the referral. This may occur whenever an errant clinician attempts to fraudulently conceal negligently performed endodontic treatment in an attempt to shift blame for bungled treatment to the endodontist. In such cases, a valuable lesson is learned when the endodontist exposes independent pretreatment radiographs, rather than relying exclusively on the referring clinician's radiographs to determine current status of endodontic treatment.

Poor oral hygiene may contribute to periodontal disease. In such cases, endodontic treatment may be compromised unless the associated periodontal condition, along with the tooth being treated endodontically, is brought under periodontal disease control, including any crown-lengthening needs (see Chapter 25 for more information). Referral to a periodontist may be necessary before or contemporaneous with completion of endodontic treatment.

In summary, it is necessary for the endodontist to do the following:

1. Be alert to any contributory medical or dental condition within the operative area of endodontic treatment that can affect treatment.

Guidelines for Using the AAE Endodontic Case Difficulty Assessment Form

The AAE designed the Endodontic Case Difficulty Assessment Form for use in endodontic curricula. The Assessment Form makes case selection more efficient, more consistent and easier to document. Dentists may also choose to use the Assessment Form to help with referral decision making and record keeping.

Conditions listed in this form should be considered potential risk factors that may complicate treatment and adversely affect the outcome. Levels of difficulty are sets of conditions that may not be controllable by the dentist. Risk factors can influence the ability to provide care at a consistently predictable level and impact the appropriate provision of care and quality assurance.

The Assessment Form enables a practitioner to assign a level of difficulty to a particular case.

LEVELS OF DIFFICULTY

MINIMAL DIFFICULTY	Preoperative condition indicates routine complexity (uncomplicated). These types of cases would exhibit only those factors listed in the MINIMAL DIFFICULTY category. Achieving a predictable treatment outcome should be attainable by a competent practitioner with limited experience.
MODERATE DIFFICULTY	Preoperative condition is complicated, exhibiting one or more patient or treatment factors listed in the MODERATE DIFFICULTY category. Achieving a predictable treatment outcome will be challenging for a competent, experienced practitioner.
HIGH DIFFICULTY	Preoperative condition is exceptionally complicated, exhibiting several factors listed in the MODERATE DIFFICULTY category or at least one in the HIGH DIFFICULTY category. Achieving a predictable treatment outcome will be challenging for even the most experienced practitioner with an extensive history of favorable outcomes.

Review your assessment of each case to determine the level of difficulty. If the level of difficulty exceeds your experience and comfort, you might consider referral to an endodontist.

The contribution of the Canadian Academy of Endodontics and others to the development of this form is gratefully acknowledged.

The AAE Endodontic Case Difficulty Assessment Form is designed to aid the practitioner in determining appropriate case disposition. The American Association of Endodontists neither expressly nor implicitly warrants any positive results associated with the use of this form. This form may be reproduced but may not be amended or altered in any way.

FIG. 29-17 American Association of Endodontists (AAE) Endodontic Case Difficulty Assessment Form and Guidelines.

AAE Endodontic Case Difficulty Assessment Form

Criteria and Subcriteria	Minimal Difficulty	Moderate Difficulty	High Difficulty
A. PATIENT CONSIDERATIONS			
Medical history	☐ No medical problem (ASA Class 1*)	☐ One or more medical problems (ASA Class 2*)	☐ Complex medical history/serious illness/disability (ASA Classes 3-5*)
Anesthesia	☐ No history of anesthesia problems	☐ Vasoconstrictor intolerance	☐ Difficulty achieving anesthesia
Patient disposition	☐ Cooperative and compliant	☐ Anxious but cooperative	☐ Uncooperative
Ability to open mouth	☐ No limitation	☐ Slight limitation in opening	☐ Significant limitation in opening
Gag reflex	☐ None	☐ Gags occasionally with radiographs/treatment	☐ Extreme gag reflex which has compromised past dental care
Emergency condition	☐ Minimum pain or swelling	☐ Moderate pain or swelling	☐ Severe pain or swelling
B. DIAGNOSTIC AND TREATMENT CONSIDERATIONS			
Diagnosis	☐ Signs and symptoms consistent with recognized pulpal and periapical conditions	☐ Extensive differential diagnosis of usual signs and symptoms required	☐ Confusing and complex signs and symptoms: difficult diagnosis ☐ History of chronic oral/facial pain
Radiographic difficulties	☐ Minimal difficulty obtaining/interpreting radiographs	☐ Moderate difficulty obtaining/interpreting radiographs (*e.g.*, high floor of mouth, narrow or low palatal vault, presence of tori)	☐ Extreme difficulty obtaining/interpreting radiographs (*e.g.*, superimposed anatomical structures)
Position in the arch	☐ Anterior/premolar ☐ Slight inclination (<10°) ☐ Slight rotation (<10°)	☐ 1st molar ☐ Moderate inclination (10-30°) ☐ Moderate rotation (10-30°)	☐ 2nd or 3rd molar ☐ Extreme inclination (>30°) ☐ Extreme rotation (>30°)
Tooth isolation	☐ Routine rubber dam placement	☐ Simple pretreatment modification required for rubber dam isolation	☐ Extensive pretreatment modification required for rubber dam isolation
Crown morphology	☐ Normal original crown morphology	☐ Full coverage restoration ☐ Porcelain restoration ☐ Bridge abutment ☐ Moderate deviation from normal tooth/root form (*e.g.*, taurodontism, microdens) ☐ Teeth with extensive coronal destruction	☐ Restoration does not reflect original anatomy/alignment ☐ Significant deviation from normal tooth/root form (*e.g.*, fusion, dens in dente)
Canal and root morphology	☐ Slight or no curvature (<10°) ☐ Closed apex (<1 mm in diameter)	☐ Moderate curvature (10-30°) ☐ Crown axis differs moderately from root axis. Apical opening 1-1.5 mm in diameter	☐ Extreme curvature (>30°) or S-shaped curve ☐ Mandibular premolar or anterior with 2 roots ☐ Maxillary premolar with 3 roots ☐ Canal divides in the middle or apical third ☐ Very long tooth (>25 mm) ☐ Open apex (>1.5 mm in diameter)
Radiographic appearance of canal(s)	☐ Canal(s) visible and not reduced in size	☐ Canal(s) and chamber visible but reduced in size ☐ Pulp stones	☐ Indistinct canal path ☐ Canal(s) not visible
Resorption	☐ No resorption evident	☐ Minimal apical resorption	☐ Extensive apical resorption ☐ Internal resorption ☐ External resorption
C. ADDITIONAL CONSIDERATIONS			
Trauma history	☐ Uncomplicated crown fracture of mature or immature teeth	☐ Complicated crown fracture of mature teeth ☐ Subluxation	☐ Complicated crown fracture of immature teeth ☐ Horizontal root fracture ☐ Alveolar fracture ☐ Intrusive, extrusive or lateral luxation ☐ Avulsion
Endodontic treatment history	☐ No previous treatment	☐ Previous access without complications	☐ Previous access with complications (*e.g.*, perforation, non-negotiated canal, ledge, separated instrument) ☐ Previous surgical or nonsurgical endodontic treatment completed
Periodontal-endodontic condition	☐ None or mild periodontal disease	☐ Concurrent moderate periodontal disease	☐ Concurrent severe periodontal disease ☐ Cracked teeth with periodontal complications ☐ Combined endodontic/periodontic lesion ☐ Root amputation prior to endodontic treatment

*American Society of Anesthesiologists (ASA) Classification System

Class 1: No systemic illness. Patient healthy.
Class 2: Patient with mild degree of systemic illness, but without functional restrictions, *e.g.*, well-controlled hypertension.
Class 3: Patient with severe degree of systemic illness which limits activities, but does not immobilize the patient.
Class 4: Patient with severe systemic illness that immobilizes and is sometimes life threatening.
Class 5: Patient will not survive more than 24 hours whether or not surgical intervention takes place.

FIG. 29-17, cont'd

FIG. 29-18 A general clinician's radiograph that ostensibly shows a complete endodontic fill within the root canal space.

FIG. 29-19 Endodontist's radiograph demonstrating a transported canal.

2. Undertake an independent diagnostic and radiographic examination of the treatment area and treatment plan rather than relying solely on the referring clinician.
3. Perform a general dental examination (at least a screening) to diagnose any hard- and soft-tissue pathosis.
4. Evaluate status and prognosis of adjacent and opposing teeth.
5. Advise the referring clinician and patient of pertinent findings.

Ordinary Care Equals Prudent Care

Ordinary is commonly understood (outside its legal context) to mean "lacking in excellence" or "being of poor or mediocre quality."[217] As expressed in the context of actions for negligence, however, ordinary care has assumed a technical legal definition that differs somewhat from its common meaning. The eighth edition of *Black's Law Dictionary* describes ordinary care as "that degree which persons of ordinary care and prudence are accustomed to use or employ … that is, reasonable care."[46]

FIG. 29-20 Implant "harpooned" inferior alveolar nerve canal.

In adopting this distinction, the courts have defined *ordinary care* as "that degree of care which people ordinarily prudent could be reasonably expected to exercise under circumstances of a given case."[108] It has been equated with the reasonable care and prudence exercised by ordinarily prudent clinicians under similar circumstances.[136,265] It is not extraordinary or ideal care. Thus, ordinary care is not average care but instead equates with prudently careful care. Stated otherwise, average care may be below the average of what all reasonable clinicians should practice.

Although the standard required of a professional cannot be only that of the most highly skilled practitioner, neither can it be limited to the arithmetic-average member of the profession, because those who possess somewhat less than median skill may still be competent and qualified to treat.[265] By such an illogical definition of average care, half of all clinicians would automatically fall short of the mark and be negligent as a matter of law. As one court explained, "We are not permitted to aggregate into a common class the quacks, the young men who have not practiced, the old ones who have dropped out of practice, the good, and the very best, and then strike an average between them."[281] Thus, the standard of care equates with reasonable care and not average care.

Customary Practice versus Negligence

Customary practice may constitute evidence of the standard of care, but it is not the only determinant. Moreover, if the customary practice constitutes negligence, it is not considered reasonable (although or even if customarily practiced by a majority of clinicians).[38] Rather, the reasonably careful clinician is the standard of care and not an average or mediocre practitioner. For instance, a majority of clinicians did not perform biologic testing of the dental unit water lines despite ADA recommendations to do so.[220,222] However, careful clinicians did follow the ADA's recommendation (Box 29-2 and Fig. 29-20).

Merely because a majority of clinicians in a community practice a particular method does not establish it as the standard of care if the practice is unreasonable or imprudent.[38] Ultimately, the courts determine what constitutes reasonable practice by considering available dental knowledge and

BOX 29-2

Typical Examples of Negligent Customs

- Failing to probe and record periodontal pockets
- Failing to take diagnostic-quality radiographs
- Failing to refer patients for complicated procedures
- Failing to use aseptic practices such as gloves, facemasks, and sterile fluids for surgery
- Failing to use rubber dams for root canal therapy
- Failing to install or periodically check valves in dental units to prevent water retraction, suck-back, and cross-contamination
- Failing to do thermal pulp testing as an aid to diagnosing pulpal disease (see Chapter 1)
- Failing to discontinue quaternary ammonium chloride–based products for precleaning or disinfection of environmental surfaces
- Failing to use a microscope for fractured file retrieval and periradicular surgery
- Failure to include CAMBRA in a comprehensive new patient exam
- Failure to use CBCT technology to guide implant placement when placement is in close proximity to the IANC (see Fig. 29-21 for implant "harpooning" of IANC)
- Not informing CT radiation risks to patient[171]

CAMBRA, caries management by risk assessment; *CBCT,* cone-beam computed tomography; *IANC,* inferior alveolar nerve canal.

evaluating the relative risks versus benefits of a particular procedure.

Again, the law does not require dental perfection.[311] Instead, the legal yardstick by which prudent conduct is measured is what a reasonably prudent clinician should do under the same or similar circumstances, regardless of how many or how few clinicians conform to this standard.

In one case, it was not customary practice in the state of Washington for ophthalmologists to test patients under 40 years old for glaucoma, because the incidence was only 1 in 25,000 patients. Nevertheless, the Supreme Court of Washington state held that the defendant ophthalmologist was negligent as a matter of law, irrespective of customary medical practice, as a negligent customary practice is no defense.[150,213]

Little excuse exists for failing to routinely probe and chart periodontal pockets before rendering endodontic therapy, no matter how many other clinicians in the community may fail to do so. The benefit of probing for periodontal disease substantially outweighs the virtually nonexistent risk of conducting this valuable diagnostic procedure. A legal defense likely to invoke a jury's wrath is to claim that a necessary diagnostic or prophylactic procedure is "too time consuming," when dental and medical patient health are placed at risk if not done. If the benefit outweighs the risk, a reasonable clinician complying with the standard of care should opt for the beneficial diagnostic test or treatment. For instance, the Accuitomo and Kodak 9000 CBCT may prove an invaluable benefit for diagnosing the etiology and source of endodontic pain when compared to the relatively low radiation risk. Thus, the CBCT diagnostic benefit outweighs the radiation risk if a differential diagnosis cannot accurately rule in or rule out a final diagnosis.[203]

Another example of negligent customary practice includes a majority of general dentists not using a rubber dam for all root canal therapy despite virtually all endodontists who do so. The AAE's 2010 Position Statement mandates that "tooth isolation using the dental dam is the standard of care; it is integral and essential for any nonsurgical endodontic treatment."

A further instance of a customary but nevertheless negligent practice concerns the majority of dentists who did not adhere to CDC guidelines for infection control.

Health Maintenance Organization Care versus Standard of Care

Reasonably careful or prudent practitioners (not insurance carriers) set the standard of care. Third-party payers may limit reimbursement but should not limit access to quality care. Clinicians have an affirmative duty on behalf of patients to appeal insurance carrier care denial decisions and, in some states, are protected against retaliation.[332] The clinician who complies (without protest) with restrictive limitations or denials imposed by a third-party payer when sound judgment dictates otherwise cannot avoid ultimate responsibility for the patient's care.[332]

Although dental insurance companies do not set the standard of care, insurance carriers may contractually limit dental benefits. Therefore, a clinician is obligated to inform patients of their dental needs, regardless of carrier reimbursement. Patients may then elect to pay out of pocket for noncovered treatment or decline uninsured services. Informed choice is uninformed if the clinician fails to provide patients with all reasonable options and alternatives.[209] Follow the adage to not x-ray the patient's pocket book or wallet to determine what options the patient should be presented. Instead offer the patient all reasonable treatment options.

Notwithstanding that an insurance carrier denies endodontic therapy or limits endodontics to only certain clinical conditions, a prudent clinician must nevertheless, both legally and ethically, provide an informed consent option to the patient that a tooth may be endodontically treated and retained rather than extracted.[71,220,288,303,346] The California Dental Association's Dental Patient Bill of Rights advises patients that "You have the right to ask your clinician to explain all treatment options regardless of coverage or cost."[60]

Clinicians may agree to a discounted fee with a health maintenance organization (HMO) carrier but must never discount the quality of care provided. Peer reviews and the courts

recognize only one standard of care. A lower, double, or different standard of care for reduced-fee HMO plans is not legally recognized. Expediency should not be exercised at the expense of quality patient care. Section 3 of the ADA Code of Ethics affirms, "Managed care contract obligations do not excuse clinicians from their ethical duty to put the patient's welfare first."

An Illinois appellate court held that a clinician may be sued for injuries a patient experiences as a result of the clinician's failure to disclose a contractual arrangement with the patient's HMO that creates financial incentives to minimize diagnostic tests and referrals to specialists. The court recognized a distinct cause of action for breach of fiduciary duty for failure to disclose these types of financial incentives.[232] In reaching its conclusion, the court cited an American Medical Association (AMA) ethics opinion that stated that a clinician must ensure that a patient is aware of financial incentives through which health insurers limit diagnostic tests and treatment options.

Managed care organizations use a variety of strategies to influence the practice styles of providers. One of the most controversial of these methods is the use of financial incentives designed to limit referrals to specialists. Such financial incentives usually take the form of bonus payments drawn from surpluses in risk pools funded by "withholds." These funds are deducted from the primary care provider's base payments or otherwise reserved under contracts in which the care provider bears financial risk. Such bonuses are based on referral limitations.[140] Conversely, the federal Patient Protection and Affordable Care Act compensates based on the quality of care rather than the quantity.[244]

Plans that delay treatment approval, resulting in endodontic complications or tooth nontreatability, may be subject to liability.[233,303] HMO carriers have not always succeeded in arguing that the 1974 Employee Retirement Income Security Act (ERISA) preempts state law for dental negligence claims against entities who administrate health care benefits to an ERISA plan and shift blame to the clinician.[248]

Capitation systems have a built-in incentive to undertreat, delay, or discourage treatment and access to care. For the HMO-paid clinician, the patient may be perceived as a threat to profits. Thus, capitation creates incentives that can transform clinicians from the patient's advocate to the patient's adversary.

Although clinicians seem like double agents serving two masters (i.e., managed care carriers and patients), the law is clear that the clinician must always act in the patient's best interest, because the clinician owes a fiduciary obligation to the patient. Should the carrier deny requested care, the clinician is legally obligated to appeal the decision to protect the patient's dental health.[332] A patient's best interest is always paramount, both legally and ethically, to a clinician's financial interest.[122,333]

Although profitable to insurance carriers, the success of denying or limiting benefits has created an era of rightfully indignant patients and frustrated clinicians. Consequently, the clinician must guard against patient disappointment with limited insurance benefits by explaining that although insurance carriers determine coverage under their patients' insurance policy, carriers do not set the standard of care. Regardless of how much or how little is covered by the patient's insurance carrier, prudent and reasonably careful clinicians set the standard of care. Providing less than necessary care because of insurance carriers' dictates may explain resulting deficient endodontics but does not excuse such conduct. Moreover, the legal doctrine of informed consent mandates the patient be informed of alternative therapy choices that the patient may pay privately even though the HMO denies approval for alternative therapies. Follow the maxim: Do not x-ray a patient's pocketbook. Reasonable informed consent is premised on patient choice and not cost alone.

Employment Law

An employer may fire an employee for a bad reason or no reason at all, as long as termination was not done for discriminatory reasons.[236,326]

Dental Negligence Defined

Dental negligence is defined as a violation of the standard of care (i.e., an act or omission that a reasonably careful or prudent clinician under similar circumstances would not have done).[172] *Negligence* is equated with carelessness or inattentiveness.[179] *Malpractice* is a lay term for such professional negligence. Dental negligence occurs for two reasons:

1. A clinician does not possess a reasonable degree of education and training to act prudently.
2. Despite reasonable schooling, additional training, and continuing education, the clinician acts with unreasonable carelessness or imprudently fails to act as a reasonably careful clinician would act.

One simple test to determine if an adverse outcome results from negligence is to ask the following question: Was the treatment result reasonably avoidable? If the answer is yes, it is probably malpractice. If the answer is no, it is instead an unfortunate maloccurrence that resulted despite reasonable care attempts.

Locality Rule

The locality rule, which provides for a different standard of care in different communities, is rapidly becoming outdated. Originating in the 19th century, the rule was designed to acknowledge differences in facilities, training, and equipment between rural and urban communities.[198,347]

The trend across the United States is to move from a locally based standard to a statewide standard, at least for generalists. For endodontists, a national standard of care is applied, as the AAE Board is national in scope.[290] Because of nationally published endodontic literature, advances in Internet communication, continuing education courses, and reasonably available transportation for patients, no disparity generally exists between rural and urban endodontic standards. A current exception may be the limited geographic availability of specific cone-beam CT technology such as the Accuitomo or Kodak 9000. Their higher resolution provides superior radiographic endodontic diagnosis compared with 2D imaging and even other CBCT devices. As CBCT machine pricing is lowered and availability increases, the locality rule may be broadened beyond a local community for CBCT technology. On the other hand, time is critical during the first 48 hours of symptomatic numbness if an endodontic overfill enters the IANC.[254] In such instances, a referral to a distant CBCT facility may be required to assess the need for immediate microsurgical removal or instead obtain, at the very least, a medical CT in the local geographic area if a CBCT facility is unavailable.*

*References 75, 97, 157, 169, 201, 204.

A clinician should provide reasonably careful endodontic care to a patient regardless of treatment locality. Rather than focusing on different standards for different communities, more important considerations include knowledge of endodontic advances in the field gained with continuing education to utilize improved diagnostics, instrumentation, and therapeutic interventions.

The locality rule has two major drawbacks. In areas with small populations, clinicians may be reluctant to testify as expert witnesses against other local clinicians. Also, the locality rule allows a small group of clinicians in an area to establish a local standard of care inferior to what the law requires of larger urban areas. Peer-reviewed publications are available to all clinicians in print and online. Clinicians can easily travel great distances to attend continuing education courses or attend webcasts in their own office. Blaming technologic ignorance on a clinician's rural location is inexcusable with modern media, computer technology, continuing education courses, and travel ease.

Continuing Education

Continuing education should not add new skills at the expense of compromising or eliminating core clinical values. A prudent practitioner should be cautious adding a new methodology that is counterintuitive to basic biomechanical principles.[224] As a general maxim, don't be the first or the last to adopt new technology.

A clinician is legally obligated to maintain current knowledge in the field of endodontics. If not, the clinician may have only 1 year of knowledge (repeated 30 times) during the span of a 30-year career. By not maintaining continuing education knowledge and updating clinical skills, a clinician may unreasonably condemn otherwise salvageable teeth because of inadequate diagnosis or treatment.

Scientific Research Evaluation

In evaluating scientific research, the clinician should remember that epidemiologic data of risk factors are not always equivalent to etiology. Thus, *epidemiology* is not a synonym for *etiology*. The scientific community has never exclusively relied on epidemiology as the accepted method of evaluating cause-and-effect relationships in an effort to make clinical decisions. Accordingly, clinicians should not consider only one class of data to supply ultimate proof when conducting an evaluation. Instead, clinicians should consider the strength of any study to be related to the presence and contributing cause of other cofactors.[137,239,240,253] The unusual characteristics of a particular patient can place the patient at higher risk than the average patient.[153]

New products and procedures are often introduced faster than epidemiologic and toxicologic studies are implemented to evaluate their potential risks. Academic medical/dental centers are facing severe pressure on their reimbursement for health care services and postgraduate education. This creates the need to examine additional sources of revenue to fund their tripartite mission of education, research, and patient-care delivery. Reduced government spending for research has resulted in proprietary interests (with proprietary goals) funding more research.[147] Since 1984, the *New England Journal of Medicine*'s policy has been to refuse publication of research done by those with financial ties to drug makers. But in 1999, the journal admitted conflicts in nearly half of the drug studies published since 1997.[26] The next year, the retiring editor of the *New England Journal of Medicine* concluded that despite tax-supported privileges and extraordinary pharmaceutical industry profits, the best interests of society were not always served. A public trust more accountable to science was needed.[27]

Evidence-Based Endodontics

Although much emphasis is currently placed on evidence-based medicine and dentistry, most clinical practices are not based on data derived from randomized clinical trials.[240] It is virtually impossible to conduct a trial to test the validity of every possible patient-management option. Many therapeutic choices are so compelling that a test would be unethical; others are so trivial that a test might not be worth the time or effort. Clinicians do not always practice in conformity to evidence-based research, even when evidence is available from randomized clinical trials. This is because knowing the right answer is only the first step in the process of adopting a new treatment methodology. Many clinicians will not use a new drug simply because supporting research data suggest its efficacy. Instead, identification of the probable mechanism of action is often a prerequisite before adopting a new treatment. Moreover, the test of time may eventually reveal an adverse effect of a particular drug or device (e.g., defects that were not identified before marketing). Even if the new product's research proves beneficial, comparative effectiveness studies with other time-proven and tested products are needed to determine a new product's relative worthiness.[137,196,253,295]

Clinicians should not avoid using certain drugs if the data supporting their use are overwhelming. When the results of a clinical trial conflict with a widely held mechanistic model, many clinicians doubt research-based evidence.[226] However, when the results from well-researched clinical trials become so convincing that the evidence can no longer be ignored, a prudent clinician embraces the new paradigm and discards previously held concepts. Endodontic science advances as disproved older concepts retreat. For example, delaying extractions until after several days of antibiotic use to reduce infection is no longer the accepted practice. Rather, immediate extraction, along with any necessary antibiotics, is the preferred current therapy.[6] Another example is one-visit endodontics, which has been proved to be as effective as two-visit endodontics.[109,225,250]

New Products

New devices that lack definitive research studies should be used cautiously. For instance, high-intensity, wireless, fast-curing lights may generate heat at the wand tip and cause pulpal pathosis. First-generation halogen bulbs require longer composite curing time to achieve polymerization but generate only 400 to 800 mW/cm. Plasma arc bulbs reduce curing time but generate 2000 mW/cm.

Hydron was marketed without long-term clinical testing. Its purported biocompatibility and reduced inflammation portended an improved endodontic drug for obturation. Post-marketing failures resulted from inadequate premarket testing that lacked long-term research. Thus, Hydron's inability to obturate canals with a durable filling material resulted in both clinicians and patients being harmed as postmarket guinea pigs. Hydron's in vitro research did not match in vivo patients' experiences.

Other examples include Endocal 10 (formerly Biocalex 6/9), which proved ineffective. Arsenic to promote devitalization of the pulp resulted in local osteonecrosis. Thermafil metal carriers proved difficult to remove and were replaced with plastic carriers. Advance cement was touted as an improved luting cement for retaining permanent restorations. The high incidence of marginal leakage with Advance resulted in its withdrawal from the market in 2000. A multimillion-dollar class action settlement resulted against the manufacturer on behalf of California clinicians with unsealed margins of crowns cemented with the Advance luting agent.[128]

Older devices, over time and with sufficient patient experience, may manifest adverse events. Overheating with ultrasonic tips for post removal has resulted in teeth and tissue loss (Fig. 29-21). Accordingly, despite insufficient label warnings on some ultrasonic devices, copious water coolant, rest periods, and avoidance of prolonged ultrasonic device use are needed for safe post removal.[90,95,130]

Today's clinician exploring ways to improve the quality and success of endodontic therapy is constantly presented with new dental products and techniques. For prescribing and using drugs or other agents, the ADA's Principles of Ethics, Section 5D, provide this guideline[18]:

> Except for formal investigative studies, dentists shall be obliged to prescribe, dispense, or promote only those devices, drugs and other agents whose complete formulae are available to the dental profession. Dentists shall have the further obligation of not holding out as exclusive any device, agent, method or technique if that representation would be false or misleading in any material respect.

Ethical clinicians should not indiscriminately adopt every new product. Instead, the supporting research should be reviewed, rather than risk the patient's welfare with inadequately tested products or researched products only tested in vitro. Again, don't be the first or the last to adopt new technology.

FDA Approval

Despite FDA approval, some drugs are marketed with fraudulent concealment of the number and nature of adverse event incidents.[10]

FDA Drug Approval

Until 1962, drug companies were allowed to promote their products for any use so long as they were shown to be "safe" for one use. Manufacturers were marketing drugs with serious side effects for minor conditions and to vulnerable populations, resulting in many injuries and deaths. Ineffective drugs were the rule rather than the exception. When a retrospective review of all drugs was conducted after 1962, the National Academy of Sciences found that fully 80% of the uses for which drugs were being promoted could not be shown to be effective. Since 1962, the FDA has required prescription drug manufacturers to demonstrate safety and efficacy with animal and randomly controlled research trials conducted with FDA-approved protocols. FDA "approval" to market new drugs for specific uses is termed *premarket approval* (PMA).

In a new drug application (NDA) to the FDA, findings from many clinical studies are done to assess a new drug's efficacy and safety and to gain the FDA's PMA to market the drug. An NDA judges whether the proposed new drug (1) causes more good than harm (benefit outweighs the risk), (2) is comparatively more effective than already existing marketed drugs, or (3) has unreasonably frequent or severe side effects (risk outweighs the benefit).[35,321]

In 2008, $58 billion in privately funded drug research was approximately twice the basic federal medical research budget and encompassed an estimated 50,000 clinical trials among 2.3 million patients. Medicare drug spending is forecast to grow from $2 billion in 2000 to $153 billion in 2016, a 7550% increase.[247] In 2007, one in seven U.S. residents younger than age 65 skipped prescribed medications because of rising prescription cost.[106,152]

The Pharmaceutical Research and Manufacturers Association of America has created an online database that summarizes

FIG. 29-21 Results of overheating a post with an ultrasonic device during post removal.

clinical study results involving hundreds of prescription medicines. Notwithstanding, the sheer volume of clinical testing has overwhelmed the FDA's ability to independently assess commercial trials and make all test results public. Deceptive marketing, unreported side effects, and hidden payments to medical/dental researchers highlight the gap between the number of clinical trials conducted and the number published.*

Comprehensive clinical data filed with the FDA for gaining market approval of a new drug (PMA) form the basis for safety information that accompanies every prescription label.[113,114] For the first time, under a new federal law[115] effective in 2009, researchers in PMA trials will have to post their basic research results publicly on a federal online registry maintained by the National Library of Medicine. However, new registry regulation will only cover new tests, not tests with poor results done prior to the effective date of the new law. Moreover, findings are not independently FDA verified. Instead, the FDA relies on the manufacturer's submitted trial data research.

Until September 2007, researchers only had to report the start of a clinical trial and were under no federal legal obligation to report the outcome in the FDA's registry or in a peer-reviewed journal. Consequently, clinical data on health risks could be downplayed or benefits extolled selectively in any one of 5200 peer-reviewed biomedical journals.[316,338]

By January 31, 2009, as a voluntary patient guide, the federal registry (www.clinicaltrials.gov) logged 67,000 studies. The results of all drug trials that were ongoing on or after September 27, 2007, must be reported at ClinicalTrials.gov if the products under study have FDA approval. The results for drugs not yet receiving FDA approval do not have to be posted. A deficiency of the current law is that the results of older trials of drugs that were FDA approved before September 27, 2007, and that were no longer the subject of ongoing trials on or after September 27, 2007, do not need to be posted. Such drugs constitute the majority of current prescription drugs. The FDA considers much of the data on clinical trials it receives from sponsors—and its own analyses of these data—to be "confidential commercial information." FDA drug-trial information released to the public is frequently heavily redacted. Redacted disclosure occurs in response to one or multiple requests made under the Freedom of Information Act, but usually only after a prolonged delay. The FDA Amendments Act of 2003, Section 916, institutionalizes this limitation by mandating that the FDA publish on its website key information related to approval of an application for a drug that contains a previously approved active ingredient only after it has received three Freedom of Information Act requests.

In a 2008 University of California, San Francisco (UCSF), study of 164 clinical trials testing 33 different drugs submitted for FDA approval, approximately one in four had yet to be published.[269] Virtually all of the unpublished findings were negative. The UCSF study also reported that in 900 FDA filings involving 90 new drugs, more than half the clinical trials were still unpublished 5 years after the drug had FDA approval. UCSF researchers who reviewed the FDA's regulatory paperwork for dozens of recently FDA-approved (PMA) drugs found that in some clinical trials previously reported to the FDA, when subsequently submitted for publication, conclusions were changed, statistics revised, and outcomes altered to make treatments appear more effective. Among 43 outcomes reported in the FDA filings that did not favor a drug, 20 were never published. In four out of five instances in which the statistical significance of findings were changed from the FDA filing, the published version was more favorable. Positive effects of a new drug were more likely to be submitted for publication than those reporting negative findings. Basic principles of evidence-based practice require the analysis of all data. Publishing only some results but not others undermines the ability to adequately assess a product's safety and efficacy, which is FDA's standard for FDA approval of drugs or devices.

Journals want to sell journals. Companies wish to increase profits. Researchers promote career advancements and seek research funding. Consequently, potential conflicts are pervasive. To offset these temptations, failure to timely report basic data about clinical test results in the federal public registry can subject researchers to fines of $10,000 a day and/or loss of their federal research funding (Public Health Service Act Section 302[J]).[114,338]

In 2009, the Government Accounting Office (GAO) concluded in the GAO's 2009 High-Risk Series, *FDA Oversight of Medical Products*[65]:

> New Laws, the complexity of items submitted to FDA for approval, and the globalization of the medical products industry are challenging FDA's ability to guarantee the safety and effectiveness of drugs, biologic, and medical devices. As a result, the American consumer may not be adequately protected from unsafe and ineffective medical products. FDA needs to improve the data it uses to manage the foreign drug inspection program, do more inspections of foreign establishments that manufacture drugs or medical devices, more systemically review the claims made in drug advertising and promotional material, and ensure that drug sponsors accurately report clinical trial results.

Globalization of clinical research is a relatively recent phenomenon. The number of countries serving as trial sites outside the United States more than doubled in 10 years. Conversely, the proportion of trials conducted in the United States and Western Europe decreased.[127] Clinical testing in developing countries sidesteps stringent FDA regulatory barriers for FDA drug approval.[28]

Wide disparities in education, economic and social standing, and health care systems may jeopardize the rights of research participants in foreign countries. Foreign participants may lack understanding of the investigational nature of therapeutic products or the use of placebo research participant groups. In some places, financial compensation for research participation may exceed participants' annual wages. Standards of health care in developing countries may also allow ethically problematic study designs or clinical research trials that would not be allowed in wealthier countries. In one study, only 56% of the 670 researchers surveyed in developing countries reported that their research had been reviewed by a local institutional review board or health ministry.[158] In another study, 90% of published clinical trials conducted in China in 2004 did not report ethical review of the protocol, and only 18% adequately discussed informed consent.[345]

Developing countries will also not realize the benefits of clinical research trials if the drugs being evaluated do not become readily available for host-country research participants after FDA approval is obtained.[28] The Declaration of Helsinki

*References 27, 181, 196, 216, 256, 269, 274, 284, 295, 316, 337.

includes an expectation that every patient enrolled in a clinical trial should, at the end of the trial, be assured access to the best proven therapy identified in the research study.

Geographically distinct populations can have different genetic profiles; these differences have been shown to be related to the safety and effectiveness of drugs and medical devices. For example, a study of 42 genetic variants associated with pharmacologic response in drug studies showed that more than two thirds had significant differences in frequency between persons of African ancestry and those of European ancestry.[133] Genetic diversity is often not considered in study design and interpretation and in the reporting of trial results.

From fiscal 2002 through 2007, the FDA issued 15 warning letters to foreign companies with serious deficiencies, but the agency only reinspected four of the companies, and then only 2 to 5 years later. Decades ago, most pills consumed in the United States were made here. But like other manufacturing operations, drug plants have been moving to Asia where labor, construction, regulatory, and environmental costs are lower. The world's growing dependency on Chinese drug manufacturers became apparent in the heparin scare. In 2007, Baxter International and APP Pharmaceuticals split the domestic market for heparin, an anticlotting drug needed for surgery and dialysis. When federal drug regulators discovered that Baxter's product had been contaminated by Chinese suppliers, the FDA banned Baxter's product and turned almost exclusively to the one from APP. However, APP also obtained its heparin product from China. Of the 1154 pharmaceutical plants with generic drug application to the FDA in 2007, only 13% were in the United States; 43% were in China, and 39% were in India.[65] Drug labels often claim that the pills are manufactured in the United States, but the listed U.S. plants are often the sites where foreign-made drug powders are pounded into pills and packaged.

Under the Prescription Drug User Fee Act, known as PDUFA, pharmaceutical companies pay the FDA to facilitate their PMA applications. Congress provided PDUFA with added power to impose restrictions on the sale of drugs and enforce regulations requiring that postmarketing surveillance studies be completed in a timely manner rather than delayed or evaded. Notwithstanding PDUFA, in 2008 the FDA was still missing target dates to act on NDAs because the FDA lacks sufficiently adequate staffing to handle PMA applications.[259]

FDA Clearance

The applicant must receive FDA approval of its PMA application prior to marketing the device as FDA approved. PMA approval is based on an FDA determination that the PMA contains sufficient valid scientific evidence to assure that the device is safe and effective for its intended uses.

The FDA lists certain products that are exempt from premarket notification requirements under the Food and Drug Administration Modernization Act of 1997 (the Modernization act),[116] which include the following endodontic products:

- Root canal posts
- Gutta-percha

Adverse Drug Events (ADEs)

Adverse drug events (ADEs) include "injury due to medications."[39] In 1999, the Institute of Medicine identified medication errors as a significant and preventable source of ADEs. Warning labels represent a quick reminder to highlight the most important instructions for the safe and effective use of prescribed medications. In one study, 50% of participants looked directly at the warning labels; 22% did not look at any. The recommendation was to move all of the warnings from the colored stickers to the main, white label.[304] More than 30% of those 65 and older take 10 medications daily.[304]

Primary Medication Nonadherence: Unfilled Prescriptions

Primary medication nonadherence occurs when a noncompliant patient fails to fill a prescription. Up to 25% of children discharged from a hospital with a prescription do not have those prescriptions filled.[348] Other data from emergency departments suggest that the frequency of unfilled prescriptions is between 7% and 35%.[348] Electronic prescriptions are more likely to be filled. When a prescription is electronically prescribed, the patient does not have an opportunity to lose or misplace it. Data suggest that clinicians should explore whether patients actually filled the medication prescribed or were taking it properly when a patient does not appear to be responding adequately to prescribed treatment.[199]

FDA MedWatch

Newly marketed drugs may not list all potential adverse drug reactions or events because of the limited number of patients in research trials before marketing. Therefore, the FDA's MedWatch program encourages clinicians to report known or suspected drug reactions. MedWatch encourages reporting of serious unexpected adverse drug reactions whose nature and severity are inconsistent with or absent from the drug's labeled warnings.[111-113,115,235] Clinician reporting to the FDA is confidential and voluntary. The patient's identity need not be disclosed. Clinicians should contact the FDA by telephone at (800) FDA-1088 or fax at (800) FDA-0178 to obtain the FDA Medical Products Reporting Program (MedWatch) form (FDA form #3500). The back portion of the *Physicians' Desk Reference* (PDR) contains a MedWatch form. Clinicians can also download the MedWatch reporting form at www.fda.gov/medwatch/getforms.htm; request the form by mail via MedWatch, 5600 Fishers Lane, Rockville, Maryland 20852-9787; and report suspected drug interactions, reactions, or adverse product events at www.fda.gov/medwatch/report.htm. Other electronic drug databases are available to report and access important drug interaction information.[340] For FDA-approved safety-related drug labeling online, see www.fda.gov/MedWatch.

Adverse drug reactions are injuries occurring when drugs are administered at usual doses. These reactions represent the primary focus of regulatory agencies and postmarketing surveillance. An adverse drug event suggests medication prescribing or dispensing errors that compromise patient safety. Unfortunately, clinicians report only between 1% and 5% of adverse drug incidents to the FDA, because clinician reporting is voluntary.[184] On the other hand, drug manufacturers must report known adverse drug incidents to the FDA.[113]

Clinicians should document adverse drug reactions not only in the progress notes but also in the allergy section of the chart in order to assess whether future use of the same drug is contraindicated and to prevent a harmful recurrence. Predictable adverse drug reactions that manifest should also be recorded as consideration for future disuse of the involved particular drug.

The Weber effect is a known phenomenon in the epidemiology literature in which the number of spontaneously reported adverse events for a drug tends to peak around the second year after a drug's initial marketing.[80] The influence of the Weber effect suggests that an increase in adverse events may be attributed to epidemiologic reporting bias, which may not reflect a true difference in adverse events.[80]

Compounding Pharmacies

More than 500 cases of fungal meningitis including 44 fatalities were attributed to injectable steroid solutions prepared by the New England Compounding Center (NECC), which subsequently filed for bankruptcy.[297]

Contamination is only one of five categories of risk associated with compounding pharmacies. The other four are subpotency, superpotency, overmedication, and medication replacement.[47]

Many patients received sterile injections for back and joint pain for procedures that lack high-quality evidence-based efficacy.[299] FDA-approved methylprednisolone acetate is sold by Pfizer and two generics companies. NECC's version did not contain preservatives, which avoided the FDA's regulatory process.

Compounding involves the preparation of medications on prescription to meet unique patient health care needs that cannot be met with commercially manufactured and marketed drug products. Compounding includes providing different strengths of a drug with different nonactive excipients for allergy patients or creating dosage forms that are more palatable for a patient. Compounding pharmacies and pharmacists work directly with the prescribing dentist to create customized personalized medication solutions for patients in doses and formulations that the pharmaceutical industry does not manufacture.

The Food and Drug Administration Modernization Act (FDAMA), enacted November 21, 1997, amended the Federal Food, Drug, and Cosmetic Act relating to the regulation of food, drugs, devices, and biologic products. FDAMA exempted individualized compounded drug products from the rigid federal current goods manufacturing practices. Under federal law, drugs that are not manufactured in conformity with federal current goods manufacturing practices are deemed to be "adulterated" under 21 U.S.C. 351(a)(2)(B) and subject to federal sanction. FDAMA, 21 U.S.C. 351(a)(2)(B) does not apply to a drug product compounded by a licensed pharmacist in a state-licensed pharmacy for an identified individual patient with a valid prescription order—or in limited quantities before receipt of the valid prescription order.[299]

Federal law prohibits compounding of drugs previously removed from the market because such drug products, or one or more of their components, have been found to be unsafe or ineffective. Compounding drugs that are copies of a commercially available drug product is also prohibited.

After the 1937 sulfanilamide disaster that killed more than 100 people, Congress passed the Food, Drug, and Cosmetic Act (FDCA), requiring drugs to be safe and properly labeled. In 1962, a requirement was introduced for proof of drug efficacy through "adequate and well-controlled investigations," in response to thalidomide's fatal side effects causing impaired limb development.

Traditional compounding pharmacies are not registered with the FDA as drug manufacturers. The FDA does not approve compounding pharmacy prescriptions before marketing. Nor does the FDA require compounding pharmacies to report adverse events. Instead, state law generally controls recordkeeping, certifications, and licensing for compounding pharmacies.

Dietary Supplements

The Dietary Supplements Health and Education (DSHE) Act allows dietary supplements to be sold directly to consumers without any oversight or FDA regulation. In response to intense lobbying by the multibillion-dollar dietary supplement industry, Congress in 1994 exempted these products from FDA regulation.[190,205,342] Products may contain amounts claimed, but they need not, and nothing can prevent their sale if they do not. For example, an analysis of ginseng[205] products showed no ginseng at all in some products. The DSHE Act places the burden of proof for dietary supplements' safety on the FDA and not the manufacturer. As a result, consumers of herbal supplements must depend on self-regulation within the industry for assurance of product quality, consistency, potency, and purity.[164,342] An understaffed and overworked FDA can hardly be expected to be a vigorous enforcer.

An herbal product label can state the way the product is intended to affect "the structure or function" of the body but cannot claim its use for a specific disease. Manufacturers thus use creative language that complies technically with the statute but generally is confusing or deceptive.[205]

A current medication history form should include over-the-counter, herbal, and illicit drugs, many of which have the potential for synergistic or antagonistic interaction with clinician-prescribed drugs.[342] Ma-huang, or ephedra, a major component of many weight loss supplements, has been associated with more than 800 adverse health effects, including the death of major league baseball player Steve Bechler. Ephedra is an amphetamine-like compound with the potential for overstimulating the central nervous system and heart. Ephedra/ma-huang has been associated with 54 deaths, primarily involving cranial hemorrhage or stroke.[42,146] A Los Angeles police officer who experienced a crippling stroke after taking an ephedra-based energy supplement, Dymetradrine Xtreme, was awarded $4.1 million.[32] The retail storeowner had read but disregarded 30 journal articles warning of strokes, heart attacks, seizures, and other ailments associated with the drug. The stroke occurred before the FDA banned ephedra from sale in April 2004. Nonetheless, Internet sales proliferated.[300]

Echinacea increases potential for liver damage when used with steroids. Gingko biloba and feverfew interfere with anticoagulants such as warfarin (Coumadin).[74] Dong quai root, willow bark, goldenseal, guarana, horse chestnut, and bilberry tablets/supplements also have antiplatelet properties.[300] Ginseng may cause rapid heartbeat or high blood pressure in some individuals, as well as coagulation disruption. Vitamin E has antiplatelet properties and inhibits vital clot formation. Gingko and selenium are powerful anticoagulants, three times stronger than vitamin E. In 1998, California investigators found about one third of 260 imported Asian drugs were either spiked with unlisted drugs or contained mercury, lead, or arsenic. In 2009, the FDA warned of 70 weight-loss pills containing potentially harmful drugs unlisted on their labels.

The formulations for herbal supplements—or *botanicals*, as they are correctly called—such as St. John's wort and

Echinacea are often complex, highly variable, and impure. Many are toxic, carcinogenic, or otherwise dangerous. Side effects include blood-clotting abnormalities, high blood pressure, life-threatening allergic reactions, abnormal heart rhythms, exacerbation of autoimmune diseases, and interference with life-saving prescription drugs.

The American Society of Anesthesiologists has warned patients to stop taking herbal supplements at least 2 weeks before surgery to avoid dangerous interactions with anesthesia.

Congress exempted supplements from oversight under a 1994 law that prevents federal regulators from requiring manufacturer's proof that botanicals are safe or effective, or even that dosage information on the label is correct. In 1999, the FDA allowed manufacturers to make dubious health claims, such as for products to treat conditions such as premenstrual syndrome and acne, although only a few botanicals have proved to be efficacious for anything.

Negligence Per Se

Violation of a health safety statute constitutes negligence per se if the patient was in the class of persons the statute was designed to protect.[292] Compliance with a health safety statute does not conclusively establish due care, because regulations require only minimal care and not (necessarily) prudent care or what the law regards as due care.[79,308]

Prescription Drugs

Clinicians should exercise extreme caution when administering or prescribing dangerous drugs. For sedative or narcotic drugs, cautionary directions should be written on prescriptions, and the pharmacist should place these directions on the prescription container as a patient reminder. For example, for the appropriate drugs, the clinician should prepare a prescription rubber stamp or obtain preprinted prescriptions that state the following:

> Do not drive or operate dangerous machinery after taking medication because drowsiness is likely to occur. Alcohol, sedative, or tranquilizing drugs will cause drowsiness if taken in combination with this prescribed drug.

The ADA and American Medical Association (AMA) provide prescription drug warning pads. Clinicians should document each drug information form provided with the prescription in the patient's chart.

Overuse of antibiotics risks resistant-strain development and side effects. Studies demonstrate generally no increased therapeutic efficiency of endodontic therapy with antibiotics when performed in the absence of facial swelling.[327] Unless persistent infections occur or compelling systemic reasons exist (e.g., uncontrolled diabetes, antibiotic prophylaxis necessary because of mitral valve regurgitation), antibiotics should not be prescribed prophylactically.[163,227] Neither pain nor localized swelling alone justifies antibiotics. However, extraoral swelling, cellulitis, or lymphadenopathy may require surgical drainage, antibiotics, or both. The U.S. Centers for Disease Control and Prevention (CDC) estimates about one third of all antibiotic outpatient prescriptions are unnecessary.[12]

Product liability may result when the manufacturer provides inadequate hazard warnings for safe use of its product. Product contraindications should be identified (Fig. 29-22).

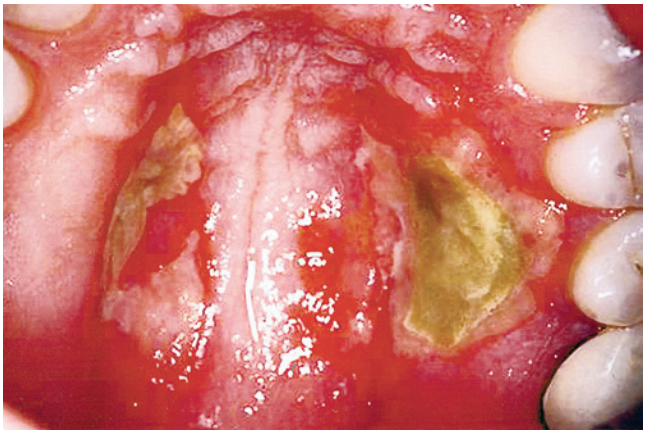

FIG. 29-22 Excessive local anesthetic resulting in palatal tissue sloughing with AMSA (wand) injection.

Ability to Foresee Unreasonable Risk

Each endodontic procedure has a variable degree of inherent risk. The standard of care requires that the clinician avoid unreasonable risks that may harm the patient. Treatment is deemed negligent when a reasonably careful clinician would have foreseen some unreasonable risk of harm to the patient. Failure to follow the dictates of sound endodontic practice increases the risk of negligently induced deleterious results. Accordingly, prophylactic endodontic practice is designed to prevent foreseeable or reasonably avoidable injury risks. Foreseeability connotes predictability.

It is not necessary that the exact injuries that occur be foreseeable. Nor is it necessary to foresee the precise manner or circumstances under which injuries are inflicted. It is enough that a reasonably prudent clinician would foresee that injuries of the same general type would likely result in the absence of adequate safeguards.[265]

Consent

Simple consent occurs when the clinician makes the treatment decision unilaterally and obtains the patient's consent without offering the patient a choice. Conversely, informed consent is a joint decisional process whether to proceed with treatment or not. Unconsented treatment constitutes a battery in legal parlance.

Patients are legally empowered to decide for themselves when substantial competing risks are involved with each separate treatment choice. A patient's therapeutic choice is particularly apt when there is no professional consensus for the best treatment. For instance, different implant systems exist with arguably different risks for each. A decision to proceed with an immediate implant versus waiting for osseointegration before initiating restorations requires that a risk-versus-benefit analysis be provided to the patient. Such decisions should include comparative peer-reviewed longevity research results compared with newer short-term immediate implant research. The benefits of immediate implant placement are attractive to both patient and clinician. To fairly compare researched implant survivability studies, the variables should similarly be controlled for each study, such as whether the implants are placed in native bone, socket size, and shape.

Emergency endodontic treatment often requires that the patient be provided pain relief. Acute pain clouds the patient's

decisional process; palliative treatment provides immediate pain relief so that on a return visit, the patient can rationally decide among treatment choices. With ample time, the patient can rationally decide and compare choices such as completion of endodontics and a crown versus extraction followed by an implant with crown. Also, an extraction that may result in progressive alveolar ridge bone loss and the need for bone grafting are considerations the clinician should explain to the patient.

Patient choices may be influenced by cost, convenience, time off work, travel needs, aesthetics, or a myriad of other reasons. The clinician plants the seeds of the decisional tree, but the patient decides which branch of the tree should be followed.

Informed Consent Principles

The legal doctrine of informed consent requires that the patient be advised of reasonably foreseeable material risks of endodontic therapy, the nature of the treatment, reasonable alternatives, and the consequences of nontreatment.[71,173,221] This doctrine is based on the legal principle that, as individuals, patients have the right to do with their own bodies as they see fit, including the right to prematurely lose teeth regardless of recommended dental treatment. Once the clinician has informed the patient of the diagnosis, treatment risks, prognosis, and nontreatment risks, as well as recommendations for corrective treatment or alternative therapy, the patient has the right to decide how, when, or if to proceed. An adult of sound mind is entitled to elect to do nothing about existing endodontic disease. Rather than elect corrective treatment, the patient may elect to suffer nontreatment consequences, including present or future tooth loss or apical abscess.

To be legally effective, a patient's consent to treatment involving potentially serious injury complications must include informed consent. Accordingly, a clinician has a fiduciary duty to disclose all material or essential information necessary for the patient to make a decision.[71,173,221] The scope of a clinician's duty to disclose information is measured by the amount of knowledge a reasonable patient requires to make an informed choice. Material information is the disclosure a clinician knows (or should know) would be regarded as significant by a reasonable person in the patient's position who must decide whether to accept or reject a recommended endodontic procedure.

If a clinician fails to reasonably disclose information that would make a reasonable person in the patient's position decline the procedure, the clinician may be liable should an undisclosed risk manifest. Beyond the foregoing minimal disclosure, a clinician must also reveal such additional information as a skilled practitioner of good standing would provide under similar circumstances.

The personal bond between clinician and patient has long been considered an essential element of the therapeutic environment. Information is empowering. Laws requiring informed consent place patients on a closer footing with their clinicians. In addition to the transfer of information in both directions, bonding takes place when the clinician and patient engage in a conversation of length and substance. Canned disclosure displaces this human interaction. One of the surest safeguards clinicians can have against malpractice litigation is the bond of personal relationship forged with their patients.[273]

Informed Consent

Adequate informed consent requires that a patient be informed of the ABC's—the alternatives, benefits, and complications—of a proposed treatment, along with the pros and cons of the alternative therapies or options.[71,173,221] A patient has a right to be informed of these ABC's from the treating clinician and not solely from an informed consent form or by a front office staff person who lacks a dental license. Informed consent must be presented in layperson's language, so that the patient can appreciate and understand what the treatment risks are.

A patient cannot legally consent to negligent care.[315] Accordingly, informed consent applies only to treatment that complies within the standard of care. If the clinician is reasonably careful during treatment but an untoward result occurs, the clinician is not liable if the patient was forewarned of the potentially unavoidable risk prior to treatment.

A reasonably unavoidable risk that manifests during treatment represents a maloccurrence and not malpractice. For example, a small percentage of endodontic failures occur for non-negligent reasons. The clinician should be sensitive to the patient's feelings of disappointment. When endodontics fails, regardless of cause, it is a 100% failure rate for the patient. On the other hand, if the risk was reasonably avoidable, then informed consent does not apply to reasonably avoidable risks.

Patient treatment refusals should be documented. Some states require informed refusal disclosures advising the patient about the consequences of refusing treatment or diagnostic modalities.

Informed Consent Application

Informed consent is a flexible standard that considers reasonably foreseeable consequences, depending on the clinical situation present both before and during treatment. For instance, a fractured or separated endodontic instrument left in the root canal creates the possibility of root canal failure or impaired success (depending on whether the fracture occurred in the coronal, middle [least favorable], or apical third of the root canal). The clinician must advise the patient of the relative risk of future failure and suggest treatment alternatives to correct the problem. An adequately informed patient can better make an intelligent choice among apicoectomy, referral to an endodontist utilizing microscopy for attempted retrieval, or periodic radiographic observation at recall visits.[76,183,197] In Figure 29-23, the clinician overinstrumented and perforated the inferior alveolar nerve (IAN), causing both a permanent dysesthesia and paresthesia. The clinician should have immediately referred the patient to an endodontist for attempted gutta-percha retrieval before the endodontic sealant containing eugenol set, which caused more deleterious chemical injury to the IAN. If retrieval was unsuccessful, the patient should have then been referred to a microsurgeon within 48 hours from occurrence for optimal opportunity to prevent chemical cytotoxic injury to the IAN.[262]

Adequate disclosure includes clinical judgment and experience, which assesses current research and applies it to the clinical needs of each patient. Today's advance may be tomorrow's retreat if materials, devices, or instruments lacking adequate long-term study of safety and efficacy predictably fail. For instance, the one-component bonding agent is more technique sensitive than its two-component predecessor. This is because the one-component agent contains acetone that desiccates the tooth surface and requires a moist surface to

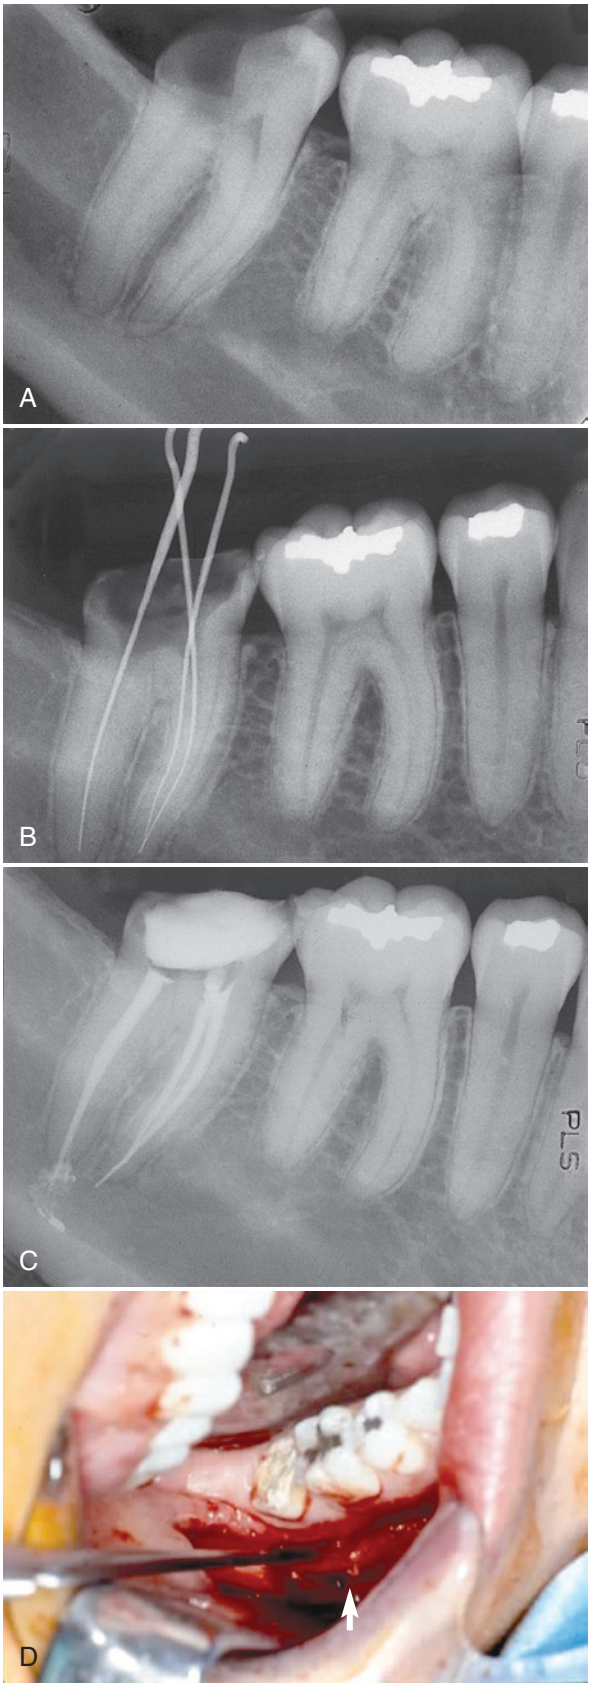

FIG. 29-23 A, Preoperative radiograph. B, Measuring film without a rubber dam. C, Postoperative radiograph. This is probably due to file overinstrumentation. (Courtesy Anthony Pogrel, DDS, MD.)

avoid postoperative sensitivity. Long-term testing before marketing would have revealed that the two-step system is more reliable and forgiving.[312] Reasonable clinicians do not sacrifice patient safety for speed and profit and then compensate with desensitizing agents. Clinicians should be sensitive to limited research on new products or devices lest the patient be the injured guinea pig patient with products that were inadequately tested before marketing.

Material disclosure concerns whether the patient was provided sufficient information for a reasonable patient to achieve a general understanding of the proposed treatment or procedure. This disclosure includes information concerning any dentally acceptable alternatives, any predictable risks of serious injury, and any likely consequences should the patient refuse the proposed therapy. The standard to be applied is whether a reasonable person in the patient's position would have consented to the procedure or treatment in question if adequately informed of all significant perils.[66] Informed consent applies only to inherent risks of non-negligent treatment, because a patient's consent to negligent treatment is voidable as being contrary to public policy.[315] Accordingly, a patient who refuses necessary diagnostic radiographs should be refused treatment.

If warnings are limited to some risks but not others, some courts have held that the patient can recover for all surgical injuries including warned risks.[160]

Endodontic Informed Consent

If the practitioner's own statistical experience varies significantly from national statistics, using statistics presented in national literature regarding success rates for endodontic procedures is considered insufficient disclosure and does not fulfill the legal requirements of informed consent (Fig. 29-24).[145,291]

Among specialists, the reported incidence of treatment complications in endodontics is relatively low. Based on a Southwest Endodontic Society retrospective study, a reasonable endodontist or a practitioner with similar abilities should disclose the following facts to patients[288]:

1. Endodontic therapy cannot be guaranteed.
2. Although endodontic therapy is usually successful, a small percentage of teeth are lost due to complications or treatment failure, despite competent endodontic care.
3. Slight overextending or underfilling of root canals occurs in 2% to 4% of cases, which may contribute to treatment failure.
4. Slight to moderate transient postoperative pain may occur. Severe postoperative pain rarely occurs.
5. Irreparable damage to the existing crown or restoration secondary to endodontic treatment is uncommon after the access opening is restored.

Video-Informed Consent

Animated video-informed consent shown to the patient is a dynamic method of providing informed consent. Because the

INFORMED CONSENT

We are concerned not only about your dental health and endodontic treatment needs, but also about your right as a patient to make the treatment decision that you feel is best for you. Our commitment to you is to provide you with detailed and complete information about your dental needs as we diagnose them. We will share our diagnostic processes with you, and we invite and welcome all of your questions regarding our treatment.

Towards this aim of a mutual sharing of information, we feel it is important to advise you of the reasonably foreseeable risks of endodontic therapy. The following is important information you should consider to aid your treatment decision.

- Root canal therapy is a procedure designed to retain a tooth that may otherwise require extraction. Root canal therapy has a very high degree of success. However, it is a biological procedure, and results cannot therefore be guaranteed.
- Approximately 5% to 10% of teeth that have undergone nonsurgical root canal therapy may require retreatment or root-end surgery.
- Despite our best efforts, approximately 5% of endodontically treated teeth may fail and require extraction.
- Final restoration (crown) of the tooth that has undergone root canal therapy is essential to root canal success and retention of the tooth. A final restoration should be completed within 30 days of root canal therapy. This restoration should be done by your restorative dentist.

Signature of Patient (or Parent) _____ Date _____

video-informed consent is considered part of the clinician's records, in the event the patient disputes having ever been advised of (1) the nature of endodontic disease, (2) the availability of endodontic specialists, or (3) the relative indications for nonsurgical versus surgical endodontic care, the videotape can be played back to the jury as proof that the patient was informed. It is doubtful a jury would believe a forgetful patient who admits having previously viewed the videotape, because the videotape refreshes the stream of memories that may have otherwise faded into the unconscious.

A patient viewing the videotape is more likely to understand the informed consent disclosure of a technical procedure, particularly if the video contains illustrated animation. After viewing the videotape and discussing its contents with the clinician, the patient should sign a video consent form to verify that the video was viewed and all the patient's questions were answered.

Alternative Technique Choices

Currently taught methodologies include filling the root canal with the lateral compaction method or using vertical warm gutta-percha carrier delivery systems, such as heat-transfer units for warm gutta-percha.[197] Each technique has zealous advocates. Both methods are reasonable and acceptable choices, and each method conforms to the standard of care. The choice of techniques changes as new products are introduced and scientific research is conducted. The vertical warm gutta-percha technique promises to deliver improved flow to fill lateral canals and is likely to predominate in the 21st century as the preferred methodology. Nonetheless, lateral

compaction has a long-term proven track record, particularly with less-experienced practitioners, and is less technique sensitive. Regenerative endodontics will have greater utilization as this scientific application increases.[16]

Restorative Informed Consent

Patient choices for restorations may discount longevity and elect instead aesthetics. In one study, amalgams lasted 15 years, composites 6 years, and conventional glass isomers 7 years.[116] Shorter-term restorations' longevity increases the frequency of restoration replacement and increased potential for endodontic therapy with each replacement. Nevertheless, it is the patient's treatment choice after the clinician first explains relative risks, benefits, and alternatives.

Different Schools of Thought

After the clinician advises treatment, if other reasonable clinicians would disagree or if there are other respectable schools of thought on the correct treatment, this material information should be disclosed to the patient.[325,346] For example, there may be two schools of thought concerning the optimal treatment for retrofilling and apicoectomy. One school posits that a retrograde with mineral trioxide aggregate (MTA) or Biodentine is the appropriate procedure, whereas another school asserts that retrograde with Super EBA is a reasonable choice.[343] One can assume further that an explanation of these two different methods of treatment constitutes material information for the purposes of informed consent. The mere fact that there is a disagreement within the relevant endodontic community does not establish that the selection of one procedure as opposed to the other constitutes negligent endodontic therapy. Because competent endodontists regularly use both procedures, a patient would have a difficult time proving dental negligence (i.e., that the endodontist failed "to have the knowledge and skill ordinarily possessed, and to use the care and skill ordinarily used, by reputable specialists practicing in the same field and in the same or a similar locality and under similar circumstances"). Moreover, neither school of thought possesses long-term clinical research results to prognosticate apical sealant insolubility rates in an 18-year-old patient with an additional 60-year life expectancy.[293] Long-term durability depends on an insoluble seal to reduce the risk of bacterial leakage.[66,228] Figure 29-25 represents a preoperative and postoperative radiograph of a successful apicoectomy and retrograde in a 14-year-old.

On the other hand, the specialist would have a duty under the previous hypothetical circumstances to disclose the two recognized schools of treatment so that the patient could be sufficiently informed to make the final personal decision. An endodontist, being the expert, appreciates the risks inherent

in the procedure prescribed, the risks of a decision not to undergo the treatment, and the probability of a successful outcome of the treatment. Once this information has been disclosed, this aspect of the endodontist's expert function has been performed. The weighing of these risks against the individual subjective fears and hopes of the patient is not an expert skill. This evaluation and decision constitute a nondental judgment reserved for the patient alone.[71,173] In this hypothetical situation, failure to disclose such material information would deprive the patient of the opportunity to weigh the risks versus the benefit. Consequently, the clinician would have failed in the duty of disclosure, which the doctrine of informed consent requires.

When improved technology offers clearly superior results, it no longer becomes a patient choice issue but rather a requisite requirement to fulfill the standard of care. Apical microsurgery with ultrasonic tips for retrofilling exemplifies improved technology and the current standard of practice. Likewise, apical retrogrades should be done with MTA and not with amalgam.[66] Finally, microscopic endodontics represents the current standard of care for apical surgery or fractured instrument retrieval.[76,86,166,183,197]

Avoiding Patient Claims

If a clinician fails to obtain adequate informed consent, a plaintiff can recover damages (even in the absence of any negligent treatment) should the patient testify that performed treatment would have been refused if the clinician had provided information concerning possible risks. Therefore, discussions of treatment risks with the patient should be documented. Informed consent forms are very helpful, although not legally mandated. A jury may believe that the patient was informed orally although the patient's attorney may argue that if it is not documented it did not happen. Equally, if not more important than consent forms, is a chart notation indicating that the clinician discussed informed-consent risks and alternatives (and that the patient understood and accepted this information).

Patients may mentally block out frightening information. Trauma and a potent anesthetic agent can create retrograde amnesia. Therefore, clinicians must document (in the patient's chart) any risks, benefits, alternatives, and consequences of nontreatment provided to the alert patient before sedation.

Clinicians should follow only the patient-authorized and consented treatment plan. If an emergency precludes advising treatment risks to the minor patient, lack of informed consent may be defensible as implied consent (because no reasonable parent would refuse necessary emergency treatment).

The following example demonstrates how a clinician should record any recommended treatment the patient has refused and the reason for refusal:

> Patient refused endodontic referral for consultation with endodontist (Dr. Goodguy) because husband was laid off work last month and cannot afford treatment. After Dr. G. provided explanation, patient states she understands detrimental delay risks but is willing to assume these risks.

Patients may initial any referral refusal on the chart. Although patient signature is not mandatory, it will enhance the clinician's credibility should the patient later dispute a referral was made.

Reasonable familiarity with a new product or technique is required before it is used. In addition, a patient is entitled to know the clinician's personal experience with a particular modality because the patient has a right to choose between reasonable alternatives or to seek care from a clinician who has more extensive experience with a particular modality or new product. A clinician who fails to obtain informed consent may be liable for injury caused by a product or instrument. The fact that the clinician followed the manufacturer's instructions is no defense if the clinician did not provide adequate information concerning a product or instrument risk (to permit the patient to intelligently weigh the disclosed information and choose among treatment options).

Referrals to Other Specialists

Every clinician, including specialists, will at some time need to refer a patient to another specialist for treatment to comply with the standard of care required of a reasonably careful clinician.[123]

Generally, if the referral takes place within the same dental practice, the legal doctrine of respondeat superior ("let the master answer") may be applicable. Under this doctrine, a clinician is liable for the dental negligence of a person acting as his or her agent, employee, or partner.[264] Liability is determined by whether the principal clinician controls the agent clinician's activities or methodology, regardless of whether such control is actually exercised.

If the referral is made (even within the same physical environment) to an "independent contractor" endodontist who does not diagnose or treat under the direction or supervision of the referring clinician, and that referring clinician has no right of control as to the mode of performing the treatment, the principle of agency and responsibility for the acts of another does not apply.[223] The legal test for agency is the principal's right to control, regardless if the control is exercised over the agent. However, if the independent contractor or referring clinician in the same practice does not provide adequate notice of this independent relationship to the patient, the independent contractor will still be liable under the legal doctrine of ostensible agency. Thus, despite an independent contractor agreement, a patient can legally infer the so-called independent clinician is instead an employee, because neither clinician in the group practice disclosed an independent contractor relationship to the patient.

To ensure that the referred clinician is not considered the agent of the referring clinician within the same facility, fees for the referred clinician should not be set by the referring clinician nor should the fees be divided equally or shared based on some other arrangement. Also, the referred clinician should bill separately and exercise independent diagnostic and therapeutic judgment. The patient should be advised that the referred clinician is independent of the referring clinician. Otherwise, the referred clinician or specialist may be regarded or inferred to be the ostensible agent of the referring clinician in the same office although not intended. The legal test for agency is how the facts or circumstances appear to a reasonable patient, regardless of the clinician's understanding or written contract intent that the other treating clinician is to be considered an independent contractor. Thus, agency may be actual in fact or, alternatively, ostensible (i.e., implied by circumstantial conduct).[174]

Surgical versus Nonsurgical Endodontics

Litigation to determine whether nonsurgical or surgical endodontics was the proper treatment choice will not be decided by any one clinician, the ADA, the AAE, or the ablest of judges. Rather, after considering all the evidence and the opinions of experts, a jury of the patient's peers will decide the disputed matter. Depending on the individual case, the jury may decide that either a combination of nonsurgical and surgical endodontic therapy, rather than one method exclusively, should have been attempted. The jury may also decide that the patient should have been advised of the availability of such alternative therapy. Similarly, the jury may determine that apical surgery should have been done microscopically rather than macroscopically, depending on expert testimony regarding the relative advantages of each method or upon presenting clinical circumstances (e.g., suspected calcification, viewing a separated instrument).

Microscopic Endodontics

Microscopic endodontics improves posture and reduces neck and back fatigue.[25] Identification of microfractures in teeth[76,183,197,230] and removal of diseased dental tissue are easier and more accurate when done microscopically.

> The operating microscope is an indispensable tool for state-of-the-art endodontic treatment. The specialty practice should not be without a microscope; this instrument is useful in all phases of endodontic treatment from diagnosis to placement of the final restoration.[166]

Microscope

A 2007 survey of 1091 endodontists indicated that 90% of endodontists have access to and use the OM in their practice, a dramatic increase from 52% in use in 1999.[15] The 2012 AAE Position Statement is that the microscope is an integral and important part of the performance of modern endodontic techniques.[15]

According to the AAE, microscope benefits are as follows:

- Locating hidden canals obstructed by calcifications or reduced in size
- Removing materials such as solid obturation materials (silver points and carrier-based materials), posts, or separated files
- Removing canal obstructions
- Assisting in access preparation to avoid unnecessary destruction of mineralized tissue
- Repairing perforations
- Locating cracks and fractures that not clinically visible or palpable with an endodontic explorer
- Facilitating all aspects of endodontic surgery, particularly in root-end resection and placement of retrofilling material
- Photographic documentation enhancement
- Ergonomic benefit[15]

Magnification

The modern approach to periradicular surgery (PRS) is through magnification, illumination, and microsurgery. Prognosis is greatly improved when these techniques are employed. Although loupes are helpful, improved illumination and magnification of the surgical operating microscope are essential for PRS. Microscopy provides a more detailed examination of the root apex anatomic features such as isthmuses, accessory canals, fracture cracks, and crazing. Failure to shape, clean, and fill the root canal system is acknowledged as the main reason for failure of root canal treatment. The same principle applies to apical surgery. A disadvantage of MTA for retrograde sealant is handling and placement. MTA is hydrophilic and requires moisture to set with up to 3 hours of setting time. Newer agents to replace MTA include Biodentine, containing tricalcium silicate.

Root canal systems have much greater complexity at the level of root resection than previously recognized. At least 3 mm of the root apex should be removed to ensure successful retrograde obturation of all portals of exit. Angle of resection should be close to horizontal.

Floor of the sinus may be only 1 or 2 mm above root apices of the posterior dentition. Accordingly, the risk of sinus perforation increases when apical pathosis is present. Care must be taken to prevent debris from entering the sinus during maxillary posterior root canal therapy.

Separated Instruments

The risk of broken files can be reduced if all hand and rotary nickel and titanium (NiTi) cleaning and shaping files are not resterilized and reused but are discarded after single-tooth use. Efficiency also increases, because approximately 50% of cutting efficiency is lost after initial use. Episodes of broken instruments will be dramatically reduced and nearly eliminated when files are used correctly and discarded after single-tooth use. Breakage increases sharply when hand or rotary shaping files are reused. Therefore, the clinician should discard rotary instruments after a single-use visit. Chair and staff time efficiency, along with improved safety, dictates single-visit use of files.[228]

The clinician should save broken or defective instruments (e.g., a file that was broken inside a canal) (Fig. 29-26). The instrument manufacturer may be liable because the product was defective, rather than the clinician being liable for dental negligence.[266] Electron microscopy spectrographic analysis can determine if manufacturing defects with contaminants caused the break, rather than the clinician excessively stressing the instrument.

Equipment and Supplies

Equipment should be kept in good repair by checking and following the manufacturer's recommended maintenance schedule. The clinician should carefully read the manufacturer's instruction warnings on instruments and inform staff of any important points. Infection control in operating dental equipment is mandatory, such as updating and maintaining dental units with check valves to prevent water retraction or suck-back.[70] The clinician should inspect check valves monthly and change clogged valves immediately.[287] Water retraction testers, at no charge to the clinician, are available from some manufacturers (A-dec [Newberg, OR], for instance). The clinician or a staff member should also disassemble the unit's handpiece, run water through the line for a few seconds, and then stop. If a bubble of water is visible at the end of the water hose holes, the check valve is operating properly. If a bubble of water is not visible, water may be sucked back because of an absent or clogged check valve. An absent or clogged check valve is a source of cross-contamination, so it is important for the clinician or staff to perform weekly spore testing of the autoclave and monthly bacteriologic testing of water lines.[17] The

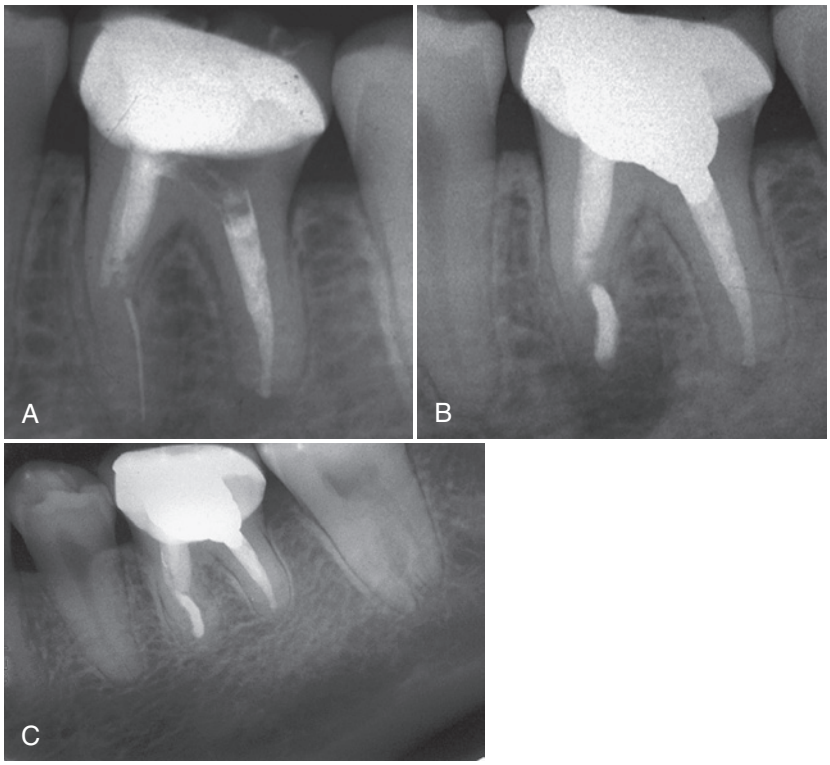

FIG. 29-26 A, Nickel-titanium file broken inside the mesiobuccal canal of the mandibular first molar. B, Due to patient discomfort, the segment was surgically removed and mineral trioxide aggregate (MTA) was used as root-filling material. C, Periapical radiograph 2½ years posttreatment shows complete healing. (From Torabinejad M, Walton RE: *Endodontics: principles and practice,* ed 4, St. Louis, 2009, Saunders/Elsevier.)

clinician or staff should consider using filters and should flush dental-unit water lines between patients and also daily with FDA-approved chemical disinfectants to reduce water tubing biofilm. Some chemical disinfectants claim improved cost effectiveness by increasing handpiece and bur longevity concomitant with water-line purging or with continual use during treatment. Currently available water line delivery systems, such as AquaSept, provide for safe water delivery or coolant to the handpiece or sonic scaler with autoclavable tubing. Figure 29-27 shows a student who was burned by an inadequately maintained handpiece that overheated. This case settled for $280,000.

Clinician's Liability for Staff's Acts or Omissions

A clinician is liable for the acts or omissions of the clinician's staff under the doctrine of respondeat superior ("let the master answer"). This is termed *vicarious liability,* which means that the clinician is responsible not because of personal wrongdoing but because the clinician assumes legal responsibility for the conduct of employees and agents who act in the course and scope of their employment.

The clinician should instruct the staff in advising patients regarding posttreatment complaints. For example, if the staff ignores signs of infection, such as difficulty in swallowing or breathing or elevated temperature, and dismisses the patient's complaints as normal postoperative swelling, the clinician may be held liable for injury to the patient, such as delayed cellulitis, diagnosis or treatment of Ludwig's angina, brain abscess, or other serious complications.

A clinician must be cautious when delegating responsibilities and give clear instructions to ensure that staff members properly represent the clinician and the chosen practice methods. Auxiliaries should not be allowed to practice beyond their competency level or license. For example, in states where assistant-placed restorations are legally permissible, the clinician should check any assistant-placed restoration before patient dismissal. Staff members should not make final diagnoses or handle patient clinical complaints without the clinician's involvement and consultation. Staff should be instructed to ask appropriate questions and relay the patient's answers to the clinician so the clinician can adequately determine what should be done.

Abandonment

Once endodontic treatment is initiated, the clinician is legally obligated to complete the treatment regardless of the patient's payment of any outstanding balance. This requirement is posited on the legal premise that any person who attempts to rescue another from harm must reasonably complete the rescue with beneficial intervention unless another rescuer (i.e., clinician) is willing to assume the undertaking.[69,195] Another view is that should a patient be placed in a position of danger unless further treatment is performed, the clinician must institute reasonable therapeutic measures to ensure that adverse consequences do not result.[212,296]

A clinician performing endodontic therapy should have reasonable means of communicating with patients after regular office hours to avoid a claim for abandonment. A recorded message is inadequate if the clinician fails to check for recorded messages frequently. Therefore, answering services, pagers, or cell phones is required by the standard of care.

If the clinician providing endodontic therapy is away from the office for an extended period, a substitute on-call clinician should be available for any endodontic emergency and to answer patients' emergency calls. The endodontic treating clinician should arrange in advance for emergency service with

FIG. 29-27 A, Before injury. B-D, A clarinetist music student was burned by an inadequately maintained handpiece that overheated. This lawsuit was settled for $280,000.

a covering clinician. Leaving a name on the office answering machine or with the answering service without first determining the availability of the covering clinician is a mistake.

To avoid an abandonment claim, several prophylactic measures apply:

1. No legal duty requires a clinician to accept all patients for treatment. A private practice clinician may legally refuse to treat a new patient, despite severe pain or infection, except on the grounds of race or disability.[49,329] If treatment is limited to emergency measures only, the clinician must advise the patient that only temporary emergency endodontic therapy is being provided and that endodontic treatment is incomplete. The clinician should record this information in the patient's chart. For example:

   > Emergency palliative treatment only. Patient advised endodontic treatment of tooth #8 needs to be completed, either here or with another clinician. Explained complications likely if not soon completed, including infection recurrence, tooth loss, or both.

   The patient should also be asked to acknowledge that treatment is limited to the existing emergency by endorsing an informed consent to emergency endodontics statement as follows:

   > I agree to emergency endodontic treatment of my tooth #8 and have been advised that (1) emergency treatment is for temporary relief of pain and (2) further root canal treatment of tooth #8 after emergency treatment is necessary to avoid further complications, including, but not limited to, pain, infection, swelling, tooth fracture, abscess, or tooth loss.

2. No legal duty requires a clinician to continue treating former patients on recalls or subsequent emergency care once treatment is complete. Thus, completion of endodontic treatment for tooth #19 does not legally obligate the clinician to initiate endodontic therapy for tooth #3 if endodontic disease of #3 began months after the clinician completed treatment of tooth #19.
3. Any patient may be discharged from a practice for any arbitrary reason, except on the grounds of race or disability, so long as all initiated treatment is completed. Accordingly, a former patient who evokes memories of a "frictional" relationship, who is financially irresponsible, or who arrives at the office after an absence of several years with an acute

apical abscess in a site where previous care was not rendered may legally be refused treatment.
4. It is not considered abandonment if a patient is given reasonable notice to seek endodontic treatment with another clinician, and the patient is willing to seek endodontic services elsewhere.[229] Thus, if rapport with the patient dissolves, the clinician should not hesitate to suggest that the patient would be better served if any remaining endodontic treatment were performed by a different clinician.

The clinician may discontinue treatment, provided it is not done at a time when the patient's dental health will be jeopardized (e.g., in the middle of treatment). To discontinue treatment, the clinician should do the following:
1. Notify the patient of the plan to discontinue treatment after a certain date.
2. Allow enough time for the patient to obtain care with another clinician, usually 30 days.
3. Offer to make emergency service available during the interim 30 days until a new clinician is obtained.
4. Provide diagnostic-quality records, copies of radiographs, and other pertinent clinical information in transfer records to the new treating clinician.
5. Allow the patient to select a new clinician or suggest referral by the local dental society if a referral service exists.
6. Document all of this in the patient's records, including a copy of a certified letter sent to the patient notifying discontinuance of further treatment.

Expert Testimony

The standard of care a clinician must possess and exercise is particularly within the knowledge of dental experts. However, there are occasional exceptions where the conduct involved is within the common knowledge of laypersons, in which case expert testimony is not required. In determining whether expert testimony is required to establish negligence, one California court commented: "The correct rule on the necessity of expert testimony has been summarized by Bob Dylan: 'You don't need a weatherman to know which way the wind blows.'"[170]

Incorrectly operating on the contralateral side because of mismounted radiographs or marking the wrong tooth on an endodontic referral card is an example of negligent conduct within the common knowledge of laypersons for which expert testimony is not required. The tort of battery results from unconsented treatment.

Increasingly, courts act as gatekeepers regarding the admissibility of scientific expert testimony. Anecdotal comparisons appear compelling, but such evidence may be judicially excluded in the courtroom. Some experts rely solely on their skill for experience-based observation, rather than research testing of risk factors, such as occurs with epidemiologic research.

The U.S. Supreme Court (in the Daubert four-factors checklist[78]) held that in federal court an expert's testimony may be reliably admitted into evidence based on the following:
1. Whether the expert's technique or theory may be tested or refuted
2. Whether the technique or theory has been the subject of peer review or publication
3. Known or potential rate of technique error
4. Degree of acceptance of a theory or technique within the relevant scientific community

Courts determine whether testimony is based on the application of scientific principle or clinical experience. In general, courts are flexible and adaptable in determining whether a bright line separates scientific and unsupported nonscientific evidence. Often technical and specialized knowledge gained through continuing education and scientific journals, rather than an expert performing the research, is considered sufficient.

State courts are not bound to follow the Federal Rules of Evidence, but many do comply.[30] Nonetheless, U.S. Supreme Court decisions influence state courts that consider placing limitations on expert testimony. State court trial judges may either be more liberal or more restrictive in admitting expert witness testimony. If the trial court judge denies admission of scientific evidence as unreliable, untrustworthy, or irrelevant, the result may be to preclude an expert offering any opinion. On the other hand, the court may admit such evidence and instruct the jury members that they may consider the scientific basis for the expert opinions and give such evidence the evidentiary weight it deserves.

In *Weisgram v. Marley Co.*,[330] the U.S. Supreme Court held that under Federal Rule of Civil Procedure 50(a), either a district (trial) court or a court of appeals may enter judgment for defendant, notwithstanding the plaintiff's verdict, if either court determines that admitted expert testimony was unreliable and inadmissible under *Daubert v. Merrell Dow Pharmaceuticals, Inc.*[78]

National Practitioner Data Bank

Insurance carriers are obligated to report all settlements to the National Practitioner Data Bank. These data are only accessible to hospitals for staff privilege credentialing and state licensing boards but not individual patients.

Medical negligence occurring in hospitals is too often underreported.[81] The Public Citizens' Health Research Group reports that more than half of U.S. hospitals have never reported an adverse incident to the National Practitioner Data Bank, an incredulous occurrence rate.[72]

Professional Negligence Incidence

In 2011, health care spending totaled $2.7 trillion, or 17.9% of the gross domestic product. Total spending for doctors' services was $541.4 billion.[65]

Harvard School of Public Health found that 97% of claims involving medical injury are meritorious.[251] A survey of federal judges found that 85% believed frivolous lawsuits were not a problem. Juries are more likely to rule in favor of a defendant than judges.[193,320]

Tort filings in state courts, which constitute only 6% of all filings, declined by 21% over the decade 1997-2006.[231] Tort actions in U.S. district courts also dropped 21% (2003-2007).[320] Medical malpractice filings dropped 8% during this period. Contract cases, on the other hand, which are more likely to involve businesses, increased 23% over the same time period.[193,231]

A 2003 GAO report submitted to Congress found that malpractice awards are only one factor contributing to increases in premiums for medical professional liability insurance.[302] Other factors cited include falling investment returns for insurance companies and normal business cycles. The report concluded that assertions that insurance premiums are driving clinicians out of business and making health care inaccessible were "not substantiated or did not affect access to health care on a widespread basis." The GAO report also stated that it is

not possible to prepare a full analysis of the issue because comprehensive insurance data are not available.

Because malpractice premiums account for about 1% of health care spending, imposing caps in liability cases would therefore have essentially no impact on the cost of health care. Evidence that this unnecessary remedy for a perceived but absent wrong is the National Association of Insurance Commissioners' data from 1995 to 2000, which show new medical malpractice claims declined.

The existing civil liability system permits each state the autonomy to regulate the resolution of professional liability actions within its borders. This is a hallmark of our American justice system.

The popular image holds that jurors are overly sympathetic to patients with unfortunate dental outcomes, regardless of whether anyone is to blame. However, research on juror attitudes demonstrates the opposite. Thus, weak cases seldom succeed despite serious injuries.[34,302]

On any given day, even the best clinician may make a negligent mistake. About 5% of clinicians account for the majority of all malpractice claims, according to reports filed with the National Practitioner Data Bank. Among clinicians who have settled five or more malpractice claims, only 13.3% have been subject to professional discipline, according to the Public Citizens' Health Research Group's analysis of the data. About 45% of otolaryngologists admit medical errors in all phases of their practice. However, even this proportion of clinicians reporting medical errors is underestimated.[272] One study estimated the number of fatal medical errors doubled in the preceding 3 years.[81]

Managed Care and the Employment Retirement Income Security Act

Ten states passed managed care liability laws that permit patients to sue managed care organizations for damages resulting from delayed or refusing authorization for treatment the clinician recommended as medically necessary. A U.S. Supreme Court decision nullified those state laws for the 140 million Americans covered by health plans that are regulated by the Employment Retirement Income Security Act of 1974 (ERISA).[1] ERISA restrictions do not apply to government employees' dental insurance.

MALPRACTICE INCIDENTS

What to Do If You Are Sued

If served with a summons or complaint, call your carrier immediately. Your carrier will assign an attorney. Be candid with the attorney. You will be asked to provide and interpret your dental records. Assemble all available records regarding your patient's treatment and review them thoroughly with your attorney prior to your deposition. Cell and office phone records can confirm calls to the patient, pharmacy, or specialists.

Screw Posts

Screw posts represent a restorative anachronism. The risk of root fracture is too great compared with the benefit, particularly when reasonable and superior passive alternatives exist (see Chapter 22). Even if the screw post is initially placed passively, the temptation to turn the screw is too great, considering human nature. Therefore, screw posts are not a reasonable and prudent treatment choice.[68]

Paresthesia Prevention

Endodontic surgery in the vicinity of the mandibular canal or mental foramen carries with it the significant risk of irreversible injury to the inferior alveolar or mental nerve. Consequently, the clinician must advise the patient in lay terms of the risk of temporary or permanent anesthesia or paresthesia before any surgery near these structures is performed. To document that adequate informed consent was provided, the clinician should have the patient execute a written informed consent form confirming that the patient was so advised. Informed consent is no defense if the surgery was negligently chosen or performed, because informed consent only applies to non-negligent treatment risks. CBCT imaging has greatly reduced if not eliminated entirely the likelihood of IANC perforation. CBCT provides diagnostic guidance before therapy. Also, a final diagnosis with CBCT can confirm or rule out IANC penetration post treatment to facilitate prompt removal of foreign materials that have penetrated into the IANC. Also sealants can chemically leak through the paper-thin porous (5% to 10%) IANC cortical borders even if the initial overfill only reaches but does not penetrate the underlying IANC. Delayed onset of paresthesia or dysesthesia up to 4 days can occur with sealant chemicals such as eugenol or resin components.

A clinician initiating root canal therapy on a mandibular posterior tooth must have (1) an awareness of the vital neurovascular bundle containing the IAN, which commonly approximates the ends of these roots, and (2) a diagnostic-quality image that accurately demonstrates both crestal borders of the IANC. Should the radiograph only demonstrate one border of the IANC, it is highly likely the evident border is the inferior crest of the IANC and not the superior crest.[206] If endodontics is done without adequate diagnostic radiographs, the patient is placed at great risk if there is anatomic variation or vital neural bundles lie in close proximity to these roots.[110,180,206,289,336] Also be mindful that as the IAN ascends toward the mental foramen, the IAN may have an anterior loop before exiting the mental foramen.[138,175,176,277] Overfilling or overinstrumentation of the root ends can cause traumatic or chemical injury to the IAN bundle, resulting in potentially permanent altered or total loss of sensation from paresthesia (partial numbness), anesthesia (total anesthesia), or dysesthesia (burning pain).[261]

The risk of overfills containing toxic materials causing irreversible neuropathies results from (1) inadequate imaging of the proximity of both borders of the IANC (Fig. 29-28, *A* to *C*), (2) inadequate measurements during cone measurement, (3) not limiting filling materials to within the confines of the shaped root canal space, and (4) not utilizing CBCT when instrumenting or performing surgery adjacent to vital structures such as the IANC and maxillary sinus.

The eugenol component of the root canal sealer part of the overfill is known to be cytotoxic. Consequently, endodontic overfill of the root apex is capable of producing not only mechanical damage[219] but also chemical injury. Accordingly, a prompt microsurgery referral to remove the injurious materials from the IAN inside the IANC nerve space before overfill material toxins are chemically set is mandatory.[254] Better yet is to take precautions to prevent *any* significant injurious overfill.

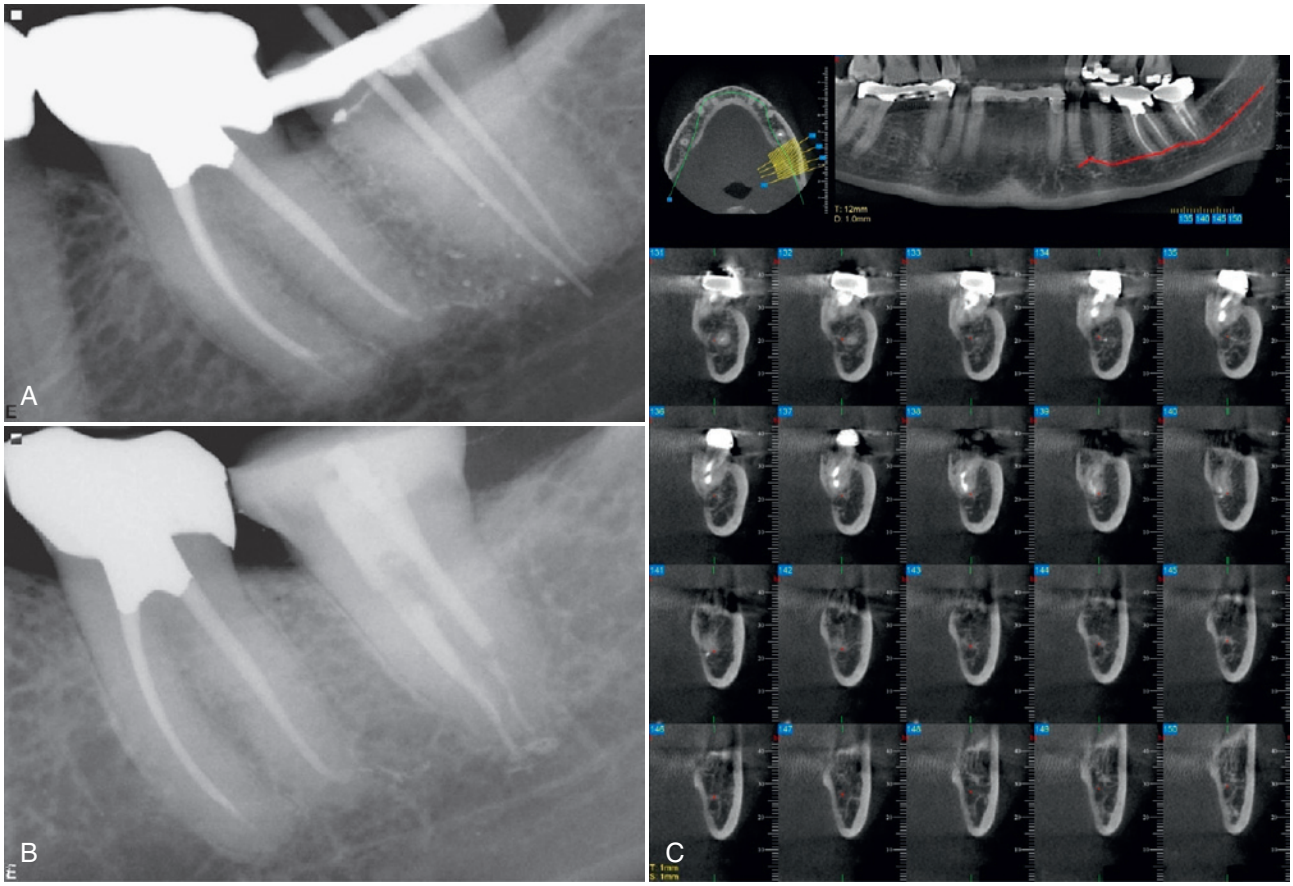

FIG. 29-28 A, Unclear periapical radiograph shows both cortical borders of inferior alveolar nerve canal (IANC). B, Cones placed into IANC, showing measurements beyond apices. C, Overfill into IANC better shown on cone-beam computed tomography (CBCT) than periapicals of A and B.

The use of electronic measuring devices such as an electronic apex locator is standard technology for accuracy when working deep within the root canal system. Combined with diagnostic quality radiographs, an apex locator helps provide accurate length readings. If it is determined that the apex is in extremely close proximity to the IANC, extra precaution must be taken to prevent overextension of instruments or materials including slightly short fills and apical packing techniques.

Precise measurements during cleaning, shaping, and obturation compacting stages of endodontics minimize significant overfill incidents. Obturating filling materials with sealants may be not only toxic to nerve cells but also create a mechanical pressure injury to the nerve cells themselves. Immediate microsurgical referral should be done on a stat basis within the first 48 hours of neuropathic symptoms for retrieval of any overfill materials that "harpoon" the IANC to protect against irreversible neuropathies (see Fig. 29-30, *C*, presented later).[254]

Serious mechanical and chemical injury to the IAN results from a lack of recognition of the overfill piercing the IANC or disregard for neuropathic symptoms the patient reports any time between 4 hours and 4 days postoperatively that are consistent with neurologic deficits such as paresthesia or burning pain dysesthesia.

Referral to an oral surgeon/microsurgeon is time dependent. Pogrel's study demonstrated complete reversal of neuropathic symptoms secondary to overfill if microsurgery was done within 48 hours.[254] Two thirds of Pogrel's patients gained significant improvement if microsurgery was done within 3 months of IAN overfill injuries. Delaying expeditious referral to a microsurgeon for removal of overfilled materials progressively worsens the toxic effects of the chemical injury over time. Delaying microsurgical referral risks permanent injury, owing to the time-dependent 48-hour window for complete reversal or within several weeks to greatly diminish the cytotoxic effects of overfill errors.

Microsurgical delay will close the window of opportunity to prevent permanent neurologic deficits of altered sensation, with resulting persistent chronic pain, numbness, and painful burning symptoms that extrusion overfills into the IANC can cause. Stat referral for microsurgical removal of paraformaldehyde-containing root canal filling materials and sealants is even more critically time dependent because of the greater toxicity and mummifying effects of these powders when mixed into pastes (e.g., N2 and RC2B). Risks include anaphylactic shock.[50,125,144,192]

For needed stat referrals, the referring clinician should phone, fax, and e-mail the microsurgeon. Patients lack the expertise to promptly obtain critically time-dependent referrals. When time is of the essence, the clinician and staff must assume direct responsibility to assure the stat referral to a microsurgeon is promptly appointed. Remind the patient that microsurgical delay is detrimental to corrective care.

Sealant Overfills

Neurotoxic and compressive effects of sealants are the most frequent causes of paresthesia after endodontic overfill.[129,185,262]

Additionally created injuries occur to the maxillary division of the trigeminal nerve or into the maxillary sinus membranes when sealants or bleach is extruded through maxillary teeth. Obturation and sealant materials should be used cautiously in all circumstances, especially in teeth in close proximity to the inferior alveolar nerve canal and maxillary sinus.

Use of syringes for applying endodontic scalers such as the Lentulo spiral require extra precaution when application is done in close proximity to neural structures because precise control is compromised.

Short fills contribute to apical infections and may cause temporary paresthesia. Paresthesia reversal can occur with retreatment gaining improved cleaning, shaping, and obturation to the anatomic apex.[3]

Standard of care requires that the clinician avoid unreasonable risks to prevent potentially serious or permanent harm to the patient. Treatment is negligent when a reasonably careful clinician should have foreseen and prevented unreasonable patient harm risks.

Treatment Failure

A clinician should not guarantee treatment success. It is foolish to assure the patient of a perfect result.[67] Endodontic failures may occasionally occur despite adequate endodontic care.[161,311] Nevertheless, negligent contributing factors to endodontic failures include perforation, missed or transported canal, uninstrumented portion of a root canal, bacterial infiltrates by way of a leaky coronal restoration contaminating the root canal filling,[66,293,298] overextension errors, and inadequate isolation of the tooth from salivary contaminants during instrumentation due to lack of a rubber dam.

Successful root canal treatment requires the prevention of microorganism toxins from the oral flora penetrating through the root canal system into the periapical tissues. Inadequate obturation of the root canal system is the most frequent cause of failure. Either coronal or apical leakage adversely affects success.[84,85,298]

Failing endodontics that necessitate endodontic disassembly should first be considered for a nonsurgical option because it is less invasive and therefore represents risk reduction. The clinician should first evaluate for coronal leakage, fractures, missed canals, silver point corrosion, and incomplete obturation. Root canal systems can then be recleaned, or correctly transported and then thoroughly disinfected, reshaped, and packed in three dimensions to avoid apical surgery by providing instead adequate coronal, lateral, and apical seal nonsurgically.

To avoid claims based on failed endodontics, the patient should be advised in advance of treatment of the inherent (but relatively small) risk of failure (i.e., about 5% to 10%). It may be adequate to advise the patient of the high statistical probability of success in endodontics if the clinical condition of the tooth and the clinician's past success rate warrant such representation.[145,291] Clinicians should avoid quoting the national success rate of endodontics when (1) the patient's tooth is of questionable endodontic and periodontal status and (2) the clinician is known to have an unusually high endodontic failure rate. A rate that varies markedly from national statistics suggests referral to an endodontist.

An endodontic treating clinician is also liable for failure to disclose evidence of other pathosis in the quadrant being treated. The patient should be advised of any periodontal disease that adversely affects the prognosis of abutment teeth for partial dentures, bridges, or an implant with a need for grafting if the endodontically treated tooth is lost. A clinician should also advise of cysts, fractures, or lesions of suspected neoplasms. In addition, the clinician must be careful not to ignore any evident pathosis that if untreated may adversely affect the dental or medical health of the patient. Again, a clinician who fails to plan treatment properly is planning for treatment failure.

The doctrine of informed consent protects both the clinician and the patient so that there will be no surprises or patient disappointment if a non-negligent adverse result occurs. Should such a failure or complication occur, the availability of a signed informed consent form can serve as a reminder to the patient that the risk of complications, including failure, was discussed in advance of treatment and that unfortunately the patient's endodontic treatment fell outside the usual 90% or greater root canal therapy success rate.

Full Disclosure

Disclosing a nonharmful mistake will not erode patient confidence. On the contrary, it bolsters trust by reassuring the patient that the dentist is honest and truthful. Increased trust through full transparency mitigates against legal action. Patients who trust their dentist are less likely to bring a malpractice suit. Truthful disclosures, sincere apologies, and appropriate acceptance of responsibility, including reimbursing corrective care, decreases litigation.

Disclosing is ethical and preserves integrity. "No harm, no foul" is a misguided approach. It is the patient's right to be informed of any intervention administered in the course of treatment that *could* have caused harm. On the other hand, major errors must be prudently disclosed to the patient for the sake of transparency, trust, integrity, and ethical responsibility.

Slips of the Drill

A slip of the drill, like a slip of the tongue, may be unintentional. Nevertheless, it can cause harm. When a cut tongue or lip occurs, it is usually the result of operator error. To paraquote Alexander Pope, "to err is human, to forgive, divine." To increase the likelihood that a patient will forego filing suit because of a cut lip or tongue, the clinician should follow these steps:

1. Inform the patient that the clinician regrets having injured the patient. This is not a legal admission of guilt in 29 states with "I'm sorry" protective statutes, but rather an admission that the clinician is a compassionate human being. In 2005, federal legislation to apply "I'm sorry" to all 50 states was proposed. The Senate bill sponsored by senators Clinton and Obama did not pass in Congress.
2. Repair the injured tissues or refer the patient to an oral or plastic surgeon, depending on the extent of the injury and whether a plastic revision is necessary if scarring is likely.
3. Advise the patient that the clinician will pay the bill for the referred treatment of the oral or plastic surgeon. Request the oral or plastic surgeon to send the bill directly to the clinician for payment. Send the oral or plastic surgeon's bill to the clinician's professional liability carrier. Some carriers will pay the claim under the medical payments provisions

of the general liability policy for an "accident" rather than as a malpractice incident compensable under the professional liability policy. Call the patient periodically to check on healing, recovery, and any follow-up plastic or other surgeries.

Fear Factor

U.S. Centers for Disease Control and Prevention's National Center for Health Statistics report that cost is the overriding factor preventing adults from seeking dental care. Fear is the second reason for delayed dental care. Medicaid recipients were at five times greater risk for worse dental health than those with private coverage. Adults on Medicaid were twice as likely to have not visited a dentist in more than 5 years.[319]

Dental fear may result in patients delaying or avoiding dental care.[199] Frequent cancellations and missed appointments are characteristically associated with fearful dental patients. Although it is ordinarily a defense of contributory negligence if patients do not follow a clinician's treatment recommendations, the patient's advocate may contend that the defendant clinician negligently failed to diagnose a fearful patient. Fearful patients tend to avoid dental treatment because they believe it may exacerbate a prior traumatic dental experience. Referral to clinicians who specialize in treating fearful patients should be considered to facilitate comprehensive dental treatment and to avoid future emergency endodontic care because of repeatedly canceled treatment visits.

Dental anxiety and finances are the two most important barriers to patients obtaining regular dental care. Fearful dental patients avoid necessary treatment, delay recalls, and are reluctant to undergo painful procedures. Therefore, it is essential that such patients be identified for proper management or referral for fear-reduction therapy. A patient who experiences intense anxiety in the dental chair, together with a history of avoiding dental care, suggests a diagnosis of dental phobia. Fearful dental patients fear loss of control during clinical treatment and require reassurance and reaffirmation that they have the power to halt the procedure by raising a hand or using another appropriate gesture. After trust is gained, additional procedures may be performed.

In addition to desensitizing techniques, the use of proven topical-anesthesia delivery systems helps to ensure a relatively painless injection of local anesthetics. Topical-anesthetic patches and oral-anesthetic rinses may prove a valuable aid for pain management of the fearful patient.

The use of psychological questionnaires, such as the Dental Anxiety Scale or the Modified Dental Anxiety Scale, may help to identify such individuals.[154] These simple questionnaires are short, quick, and easy to complete, and users are provided with cutoff scores that help the clinician identify patients who have psychological special needs. In this way, the clinician will be in a position to assist the dentally anxious or dentally phobic patient in accessing dental health care.

Leakage

Long-term seal of the root canal system is determined apically by the sealer and coronally by the final restoration.[36,134,228,293] Root canal–filled teeth should be permanently restored without undue delay to prevent leakage contamination of the previously obturated canal system, because varying canal shapes from round to oval prevent a 100% seal.[84,85,202] Bonded seals covering the canal surfaces should be used to control any leakage after compaction until a permanent restoration is cemented.[305] Besides an adequate coronal sealing, an adequate apical sealer should be well adhered to the canal walls.

The endodontic goal is to prevent bacterial contamination of the periradicular tissue by predictably providing adequately cleaned, shaped, and filled root canal systems. Any residual bacteria should be entombed in the root canal filling. A bacteria-tight apical seal should be designed to last long term with sealed portals to prevent reentry of microorganisms, which cause reentry recontamination and lead to endodontic failure.[84,298] Younger patients are more susceptible to bacterial penetration inside dentin tubules and thus recurring infections.[177]

Electrosurgery

Electrosurgery can cause problems if mishandled. Damage to the oral cavity caused by improper use of electrosurgical devices consists primarily of gingival necrosis, osteonecrosis, sloughing adjacent to the surgical field, and pulpal necrosis of affected teeth.

All equipment should be properly maintained and certified to meet the American National Standard (ADA specification no. 44 on electrical safety standards). Current equipment should be checked to see that units meet these standards and that electrical cords and other components are in good repair. Electrical receptacles should meet the requirements of the National Electrical Code for circuit grounding and ground fault protection. During use, the dispersive electrode plate should be well away from metal parts of the dental chair and the patient's clothing, because skin contact can cause burns. Use of plastic mirrors, saliva ejectors, and evacuator tips is strongly recommended.

Implant Risk Factors

Patient risk factors such as grinding teeth or diabetes increase the odds of implant failure.[166] Higher implant failure rates occur with surgeons who have less than 5 years of implant experience.[166]

Fluoride Varnish for Caries Prevention

In 2006, the ADA Council on Scientific Affairs published evidence-based research with fluoride recommendations for caries prevention. The ADA recommends that fluoride varnish treatments for at-risk patients should be done between two to four times annually, depending on risk classification.

If fluoride trays are used, trays are effective only when used for 4 minutes. One-minute foam or gel fluoride treatments are ineffective.

One of many benefits of fluoride varnish is very little systemic exposure, which does not require daily patient compliance compared to fluoride trays. Fluoride varnish containing 5% sodium fluoride with 22,600 ppm fluoride ions help occlude dentin tubules and aid remineralization.

Xerostomia and Diet

A common side effect of cancer treatment is diminished saliva production, which increases the risk of dental demineralization, caries, and candidiasis. Milk may help because it moisturizes, lubricates, and buffers acids while contributing to enamel remineralization. Demineralization aggravated by a chronic lack of saliva may result in osteoradionecrosis. Therefore, diseased teeth should be treated prior to cancer therapy.

DNA preserved in calcified bacteria on the teeth of ancient human skeletons has shed light on the health consequences of the evolving diet and behavior from the Stone Age to the present.[3] Composition of oral bacteria changed markedly with the introduction of farming and again around 150 years ago. With the introduction of processed sugar and flour in the Industrial Revolution, the diversity in oral bacteria dramatically decreased, allowing domination by caries-causing strains. As a result, the modern mouth basically exists in a permanent disease state.

Reasonable versus Unreasonable Errors in Judgment

Although a clinician is legally responsible for unreasonable errors in judgment, mistakes occasionally happen despite adherence to the standards of reasonable care. A mistake does not prove malpractice unless the mistake is caused by a malpractice error or omission.[141] For example, accessory or fourth canals on molar teeth are frequently difficult to locate and may tax the best clinicians. Failure to locate an accessory or fourth canal does not conclusively constitute an unreasonable error of judgment. Rather, this may represent a reasonable error of judgment in the performance of endodontics. Nevertheless, if the additional canal could have been diagnosed radiographically with diagnostic quality radiographs at different angles, the existence of a fourth canal should have been considered. Instrument and seal the extra canal for successful obturation.

Incorrect Tooth Treatment

A reasonable, non-negligent mistake in judgment may occur because the clinician has difficulty localizing the source of endodontic pain. Vital pulps may on occasion be sacrificed in an attempt to diagnose the pain source, but it is unreasonable and therefore inexcusable to treat the wrong tooth if it is inadequately tested with pulp tests, misidentified on the referral slip, or if radiographs are mounted or read incorrectly. Also, treating large numbers of teeth endodontically (e.g., an entire quadrant) when attempting to localize chronic pain suggests pain is probably not of pulpal origin, and other differential diagnoses should be ruled out including atypical facial pain, referred pain, or TMD pain.

If the wrong tooth is treated because of an unreasonable mistake in judgment, the clinician should be compassionate, waive payment for all endodontic treatment, and offer to pay the fee for crowning the unnecessarily treated tooth.

Post Retrieval

Ultrasonic instruments will vibrate and loosen the cement around posts.[68] The clinician can avoid overheating the post by proceeding slowly with a water coolant, periodically resting for cool down, and checking the post temperature periodically to be reasonably certain overheating is not occurring.[96,130,230] Figure 29-21 demonstrates what happened when an endodontist negligently overheated the post during attempted removal, causing tissue necrosis, bone loss, need for augmentation procedures, irreversible pulpitis in an adjacent tooth, and the loss of two teeth.[252]

Broken Files

Leaving broken files behind without referring the patient to an endodontist for attempted microscopic retrieval and not advising the patient of leakage potential may constitute fraudulent concealment (Figs. 29-29 and 29-30). Patients should be informed of such mishaps for (1) referral consultation or treatment; (2) advising the patient, who on his or her own may seek a second opinion; or (3) disclosure, so as to return if a flare-up occurs.

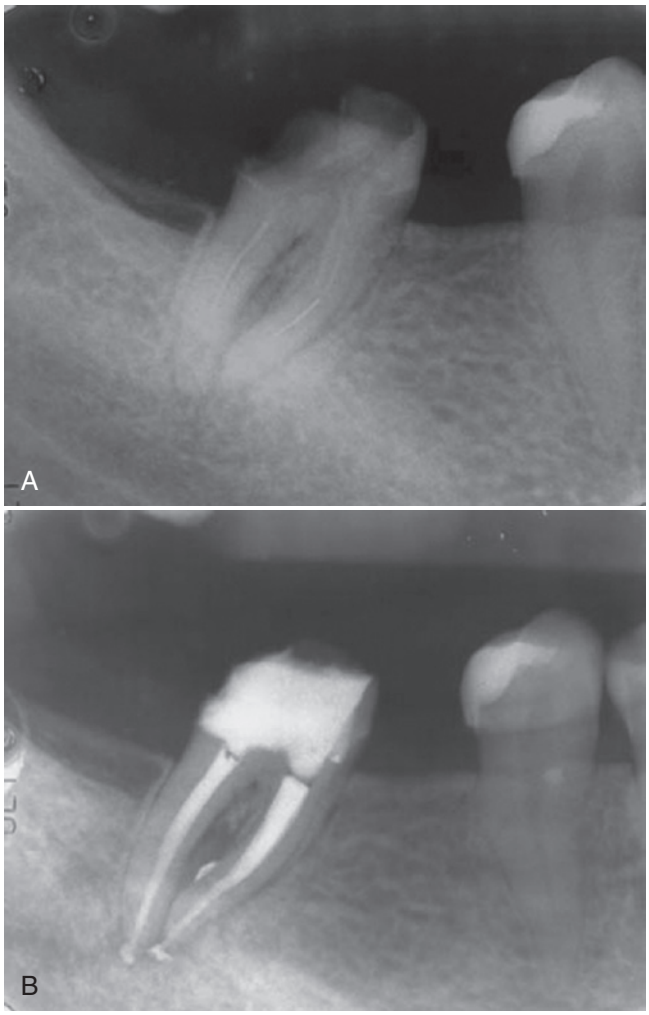

FIG. 29-29 A, Tooth #31 with three separated files, one in each canal. K-files used for cleaning canals and also obturation (1996). B, No apparent radiographic changes in 1998.

Swallowing or Aspirating an Endodontic Instrument

Use of a rubber dam in endodontics is mandatory.[14,294] Even if the endodontically treated tooth is broken down and cannot be clamped, a rubber dam, regardless of required modification, should be used in all instances (see Chapter 5). Not only is microbial contamination reduced with the use of a rubber dam, but the risk of a patient's aspirating or swallowing an endodontic instrument is eliminated (Fig. 29-31). Accordingly, if a patient swallows or aspirates a file, it is likely because of the clinician's failure to observe the standard of care. If a swallowing or inhalation incident does occur, the clinician should do the following:

1. Advise the patient that the clinician regrets and is sorry about what occurred.

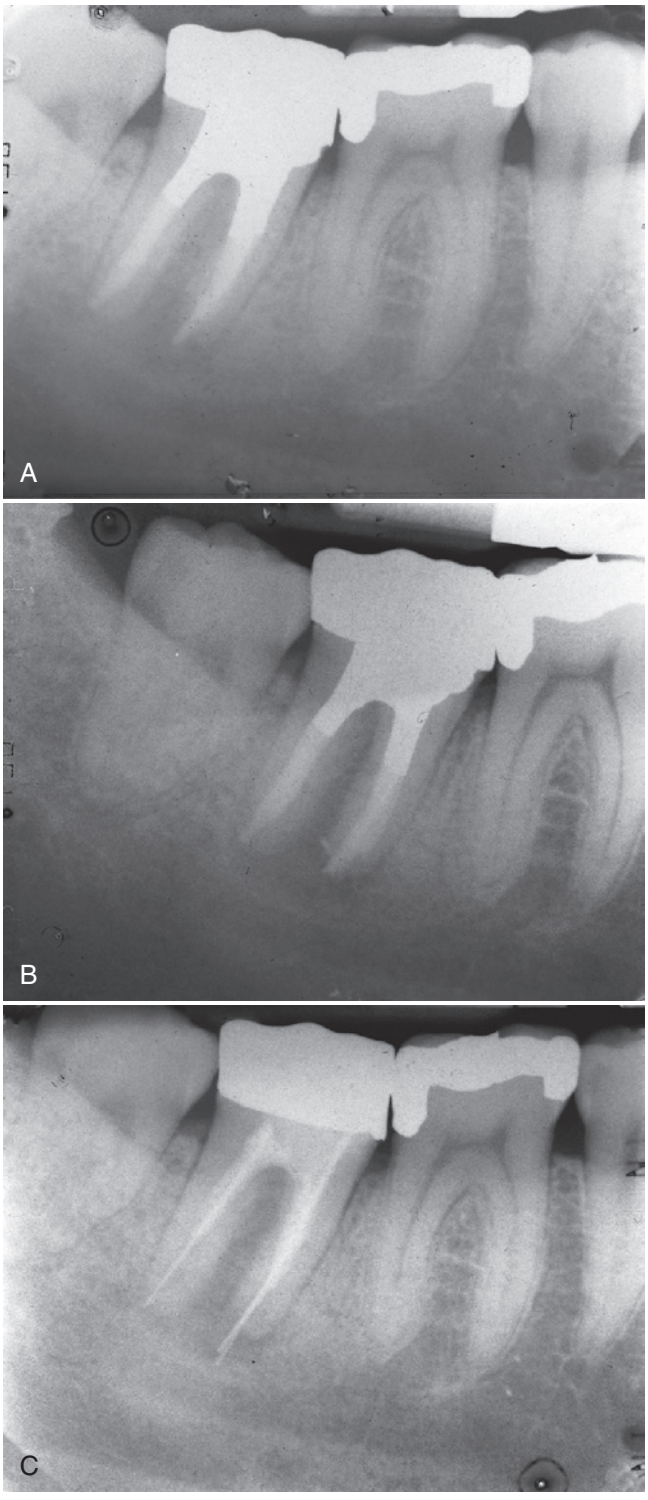

FIG. 29-30 A, Apical radiolucent changes with draining 9-mm buccal abscess (August 2003). B, Endodontist retreatment (August 2003). C, Successful retreatment with no buccal pocket (September 2003). (Courtesy James YS Ho, DMD.)

2. Refer the patient for immediate medical care, including radiographic imaging, to determine if the instrument is lodged in the bronchus, esophagus, or stomach so that appropriate medical measures are taken promptly to remove it.
3. Offer to pay for the patient's out-of-pocket medical expenses and wage loss. Some professional liability policies will cover the incident as "medical payment" for an accident and not as a malpractice claim.

FIG. 29-31 Swallowed endodontic instrument demonstrates the wisdom of using a rubber dam.

Overextensions and Overfills

A common error in utilizing periapical or Panorex imaging is presuming that when only one cortical border of the IANC is visible, the sole visible border is the superior border. Instead, virtually always when only one cortical border is clearly visible, it is the inferior cortical border.[206] (See Fig. 29-30, *B*, periapical, which may appear to show only one cortical border, and Fig. 29-30, *C*, a clearer CBCT image of the same area showing both cortical borders.)

Misassumption of the IANC borders results in mismeasurement of the IANC location. Because the IANC is approximately 3 mm in diameter, misassuming the sole observable cortical canal border to be the superior border (rather than the inferior border) can result in an imprudent treatment decision to delay microsurgery if overfill occurs and belated CBCT confirms an overfill inside the IANC. In Fig. 29-30, *B*, the defendant endodontist misdiagnosed the overfill as being superior to the IANC rather than inside the IAN canal. Resultant permanent paresthesia occurred from watching and waiting for sensory return rather than referring to a microsurgeon for a stat microsurgical removal.

A slight overextension of root canal filling with conventional obturation or sealants can occur without violating the standard of care if not in close proximity to the IANC or sinus (see Chapters 2 and 29). Gross overfill usually indicates faulty technique. Fig. 29-32, *A* and *B*, illustrates gross overfill of calcium hydroxide, causing permanent paresthesia. Nevertheless, so long as the overextension is not in contact with vital structures such as the IANC or sinuses, permanent harm is unlikely. An exception is paraformaldehyde-containing

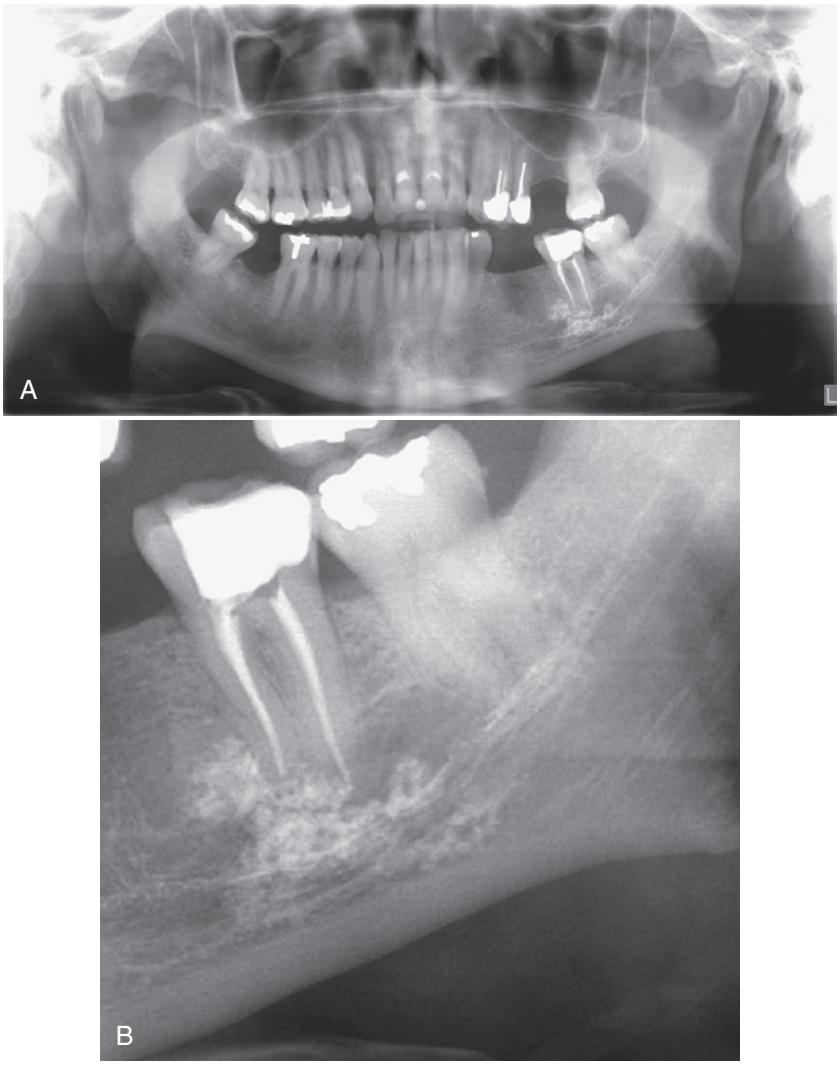

FIG. 29-32 A-B, Calcium hydroxide overfill, causing permanent paresthesia.

sealants, which cause a neurotoxic chemical burn type of injury that chemically diffuses through bone and soft tissue spaces.

If, however, postoperative pain is foreseeable as a result of overextension, the patient should be advised with postoperative written instructions of the likelihood of postoperative discomfort or paresthesia because of suspected contact of the sealant material with surrounding vital structures. A note should be made on the patient's chart of the overextension should symptoms later manifest. The clinician should observe with close follow-up visits and patient phone calls that evening, the next morning, and the following 3 days to rule out postoperative persistent numbness or dysesthesia pain resulting from any overfill. Slight overextensions with inert conventional endodontic sealers, such as gutta-percha with Grossman's sealant, can repair themselves and produce no irreversible changes if done without direct contact with the sinus or IANC or indirectly through chemical leakage and seepage beyond the initial area of operation.

Overextending the root canal filling material risks permanent consequences if the underlying IAN is initially "harpooned" with files. A portal of entry into the IANC results from overinstrumentation penetration. Flexible gutta-percha alone probably will not penetrate beyond the mature root into the IANC or other vital structures without prior excessive instrument perforation into the IANC.

Mental foramen distances can be overestimated on the panoramic radiograph. Panoramic radiography may show more deviation (+0.6 mm) from the perioperative measurement.[110,289] Paraformaldehyde-containing sealants can create cytotoxic chemical destruction of the IAN if placed in close proximity to, even though not directly contacting, the underlying IAN (see reference, Sargenti Opposition Society [SOS]).[278] On the other hand, conventional obturators and sealants usually require coming closer to contact with the IAN before resulting permanent anesthesia, paresthesia, or dysesthesia occurs (Fig. 29-33). Consequently, the incidence of permanent sequelae with conventional filling materials is lower than the greater cytotoxic potential with paraformaldehyde-containing sealants.[234] Because of the higher risks associated with paraformaldehyde-containing endodontic materials, use of N2, RC2B, or similar toxic pastes is contraindicated and violates the standard of care.[11] Permanent injury risk is substantially less likely with traditional eugenol-containing filling materials, less toxic chemicals than paraformaldehyde, which destroys and mummifies nerve tissues. When safer, less risky alternative

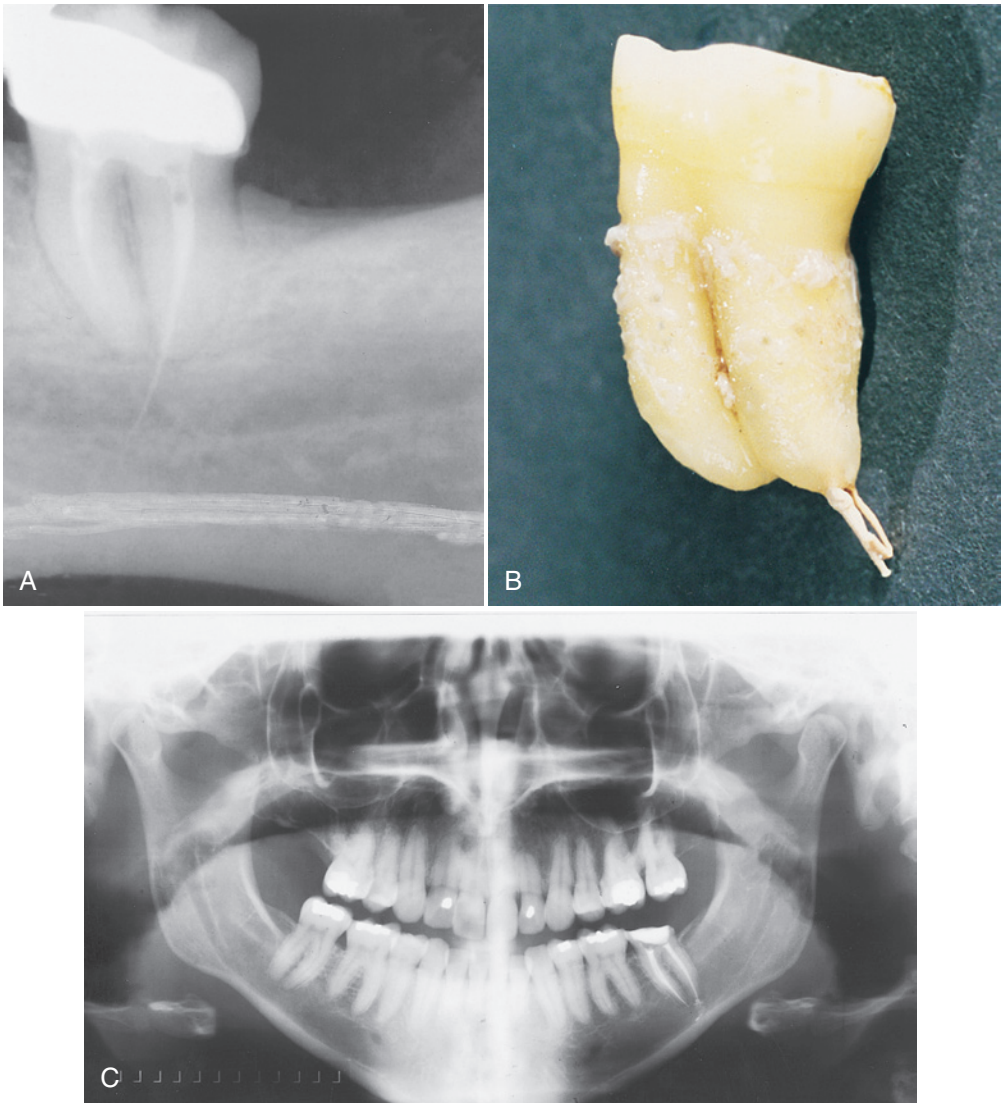

FIG. 29-33 A-C, Overextended gutta-percha and extracted tooth with gutta-percha intact.

effective therapy exists, it is unreasonable (and substandard) to elect an unsafe alternative methodology. Also, the doctrine of informed consent is highly relevant because it is contrary to public policy to request a patient to assume inherently dangerous treatment risks that are reasonably avoidable with safer and more predictable methodologies. When the risk exceeds the benefits, such risks are regarded as negligent and thus should be avoided and not undertaken.

Any significant overextension should be considered for immediate retreatment by attempted retrieval of overextended gutta-percha and sealant.[135] The clinician also has the option of immediately referring the patient to an endodontist for retrieval before the sealant sets. Conventional filling agents such as gutta-percha do not penetrate the cortical walls of the IANC unless probably preceded by prior penetration with overinstrumentation. This principle can apply to sinus perforation. If despite local anesthesia, the patient feels an electric shock during mandibular molar or premolar instrumentation, this may be a warning sign that the IAN was pierced with endodontic files. If this occurs, the root canal should not be filled; instead, periapical radiographs at different angles should be exposed with instruments in place to confirm whether any IAN penetration resulted. Removal of gutta-percha and sealants that have entered the IANC should be attempted as soon as possible (preferably no later than within the first 24 hours).[254] The eugenol component of the sealant causes an inflammatory reaction in a constricted space, which is best relieved by retrieval. If retrieval fails, a decortication microsurgical procedure with an oral surgeon is indicated at the earliest possible time (preferably within the first 24 hours) owing not only to eugenol chemical toxicity but also eugenol reaction with gutta-percha, which causes expansion and thus a mechanical compression ischemic injury.[219,254]

Compartment Syndrome

Inflammatory edema that compresses and compromises blood supply to soft tissues and nerves in limited spaces with resulting ischemia is termed *compartment syndrome*.[285,339] Compartment syndromes are a group of conditions that result from increased pressure within a limited anatomic space, acutely compromising the circulation and ultimately threatening the function of the tissue within that space. Compartment syndrome occurs from an elevation of the interstitial pressure in a closed osseofascial compartment that results in microvascular compromise.

The pathophysiology of compartment syndrome is an insult to normal local tissue homeostasis that results in increased tissue pressure, decreased capillary blood flow, and local tissue necrosis caused by oxygen deprivation. Compartment syndrome is caused by localized hemorrhage or postischemic swelling. The pathophysiology of compartment syndrome is a consequence of closure of small vessels. Increased compartment pressure increases the pressure on the walls of arterioles within the compartment. Increased local pressure also occludes small veins, resulting in venous hypertension within the compartment. The arteriovenous gradient in the region of the pressurized tissue becomes insufficient for tissue perfusion.

The clinician should have a high index of suspicion whenever a nerve is located inside a closed bony compartment where nerve injury within the surrounding neurovascular bundle has the potential for bleeding or swelling. Compartment syndromes are characterized by pain beyond what should be experienced from the initial injury. Also, diminished sensation may be noted in the distribution of the nerve within a compartment that is being compressed, such as the IAN, which is enclosed by bone on all sides.

Root canal followed by root resection without an adequate retrograde restoration will likely fail. Open drainage is no longer recommended. Dissect out subapical granulation tissue cleanly and without damage to vital structures. Caution should be taken when granulation tissues are attached to vital anatomic structures such as neurovascular bundles or sinus linings. A potential for recontamination exists unless the root apex is removed. Apical resection of 3 mm will remove potential problems. This resection will additionally permit inspection. A straight fissure bur design with appropriate air venting is recommended rather than a conventional air rotor to prevent air emphysema.

Currently preferred methodology utilizes specifically designed ultrasonic tips inserted into a piezoelectric ultrasonic handpiece. Amalgam is no longer recommended as a material for root-end filling. MTA and newer silicate trioxide materials are recommended.[243]

Periradicular Surgery (PRS)

Accessing mandibular posterior teeth can generate increased heat during removal of significant quantities of bone to gain apical access. Thus, copious coolants must be applied to avoid risking injury to adjacent structures. Molar teeth surgical access should avoid the facial artery as it crosses the border of the mandible adjacent to the first molar.

Avoiding the Inferior Alveolar Nerve Canal

When placing implants or performing apicoectomies in close proximity to the mental foramen in the bicuspid region, the clinician should consider the anterior loop of the IAN.[277] The IAN ascends as it approaches the mental foramen, compared with the IAN's more inferior location in the molar region. The IANC varies from buccal to lingual as it courses the length of the mandible. Thus, CBCT imaging aids in assessing the IANC location for planning implant placement or apical surgery[75,97] (Fig.29-34, *A* to *C*[138]; this Los Angeles case settled for $915,000, with permanent dysesthesia).

Figure 29-35 illustrates avoidance of the IANC to demonstrate that IANC penetration with the implant or drill is a preventable adverse event.

Mental Nerve Injuries

The mental nerve, as the terminal branch of the IAN, is at risk during elevation of the mandibular mucoperiosteum. Careful flap design and elevation are important to avoid mental nerve injury while working on the buccal surface of the mandible in the region of the mental foramen.[207] In performing incision and drainage in the region of the mental foramen, a diagnostically accurate radiograph is necessary to avoid incising through the course of the mental nerve.[84,180]

When carrying out periradicular surgery (PRS) in the mandibule, consideration must be given to the path of the inferior dental nerve bundle in the mandibular canal, which lies in close proximity to the root apices.[277] Be aware of the position of the mental nerve exiting through the mental foramen. A shallow sulcus, coupled with a prominent mandibular protuberance, together with the lingual inclination of the roots may make access to the root apices difficult. Approximately 40% of lower incisors have two root canals, which may preclude adequate resection and retrograde filling of the root apex, which may ultimately lead to treatment failure.

Local Anesthesia: Septocaine

Septocaine and Articaine are not suitable for an inferior dental nerve block due to the potential increased risk of paresthesia and nerve damage.[91]

Implant versus Endodontics

A natural tooth with its periodontal support, function, and proprioception is superior to an implant-retained restoration. Whenever reasonably feasible, teeth should be retained.

Reasonable clinicians may differ in recommending extraction versus periradicular surgery depending on location near vital structures and clinical conditions. Extraction of the diseased tooth and placement of a dental implant has a better long-term prognosis and thus should be the treatment of choice is one author's conclusion.[275] Conversely, every reasonable effort should be made to retain the natural tooth with its periodontal support, function, and proprioception. Thus, an implant-retained restoration should be considered as the last possible treatment option as concluded by other clinicians.[24,73,310]

Infraocclusion of the implant restoration in teenage patients with residual craniofacial growth occurs as the adjacent teeth erupt. Therefore, delay implant placement until dental and skeletal maturation occurs.[309]

Aesthetics is an important outcome for patients receiving implant-supported restorations. To achieve this outcome, patients require good bone volume and quality, as well as soft-tissue height. Following extraction, the alveolar bone resorbs vertically, as well as horizontally (buccolingually). Socket preservation intervention grafting may aid in reducing the bony dimensional changes after tooth extraction but ridge resorption is not completely prevented. Intervention techniques including autografts, allografts, xenografts, guided bone regeneration (GBR) and growth factors accomplish varying degrees of success in maintaining the anatomic dimensions of the alveolus before implantation.[54]

Current Use of Silver Points

Based on what has been known for more than 3 decades, use of silver points in lieu of gutta-percha or other conventional endodontic filling materials represents a departure from the

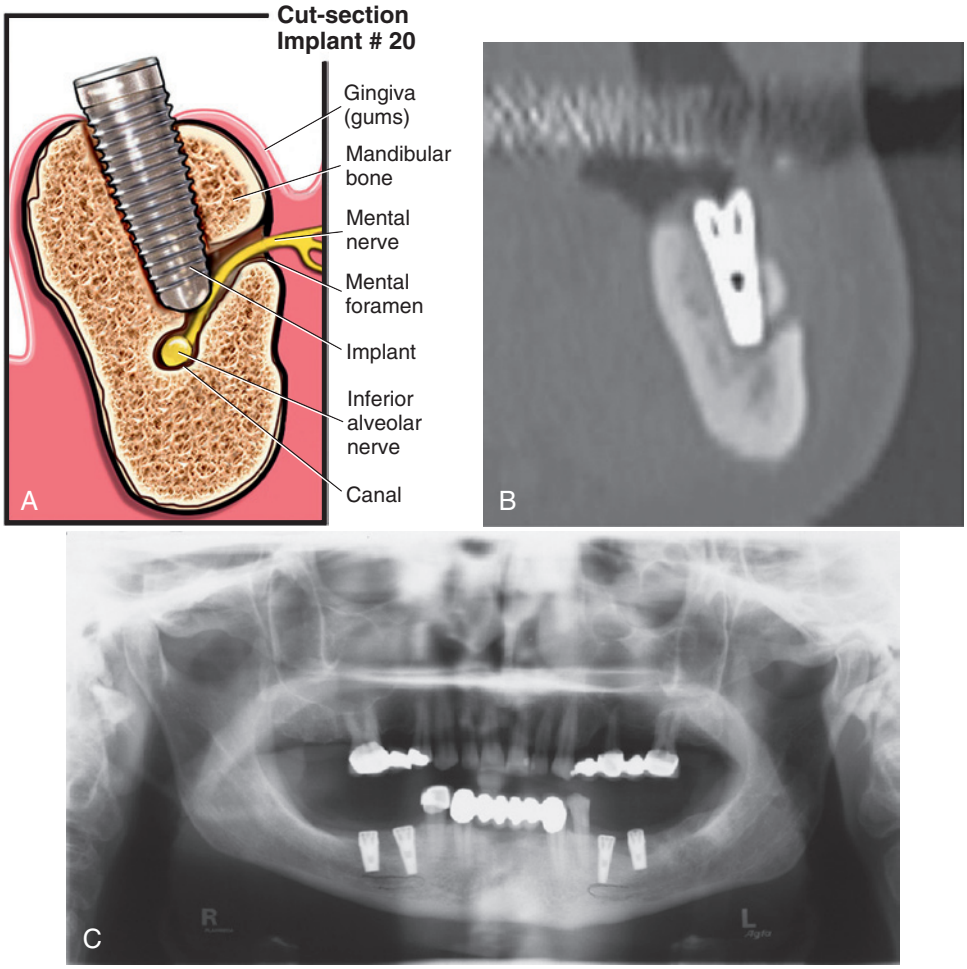

FIG. 29-34 A, Illustration showing implant placed into ascending inferior alveolar nerve canal (IANC). B, Cone-beam computed tomography (CBCT) image of implant into ascending IANC. Settlement of $915,000. C, Implant into IANC; immediate postoperative Panorex image. Same patient but with CBCT image.

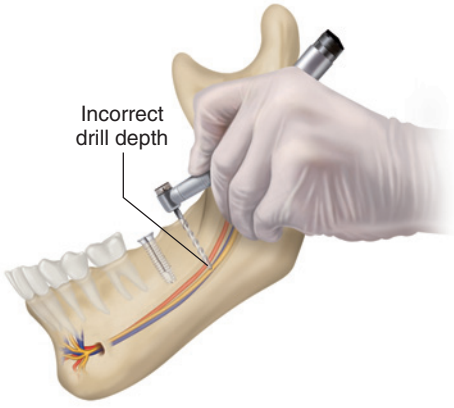

FIG. 29-35 Medicolegal implant image.

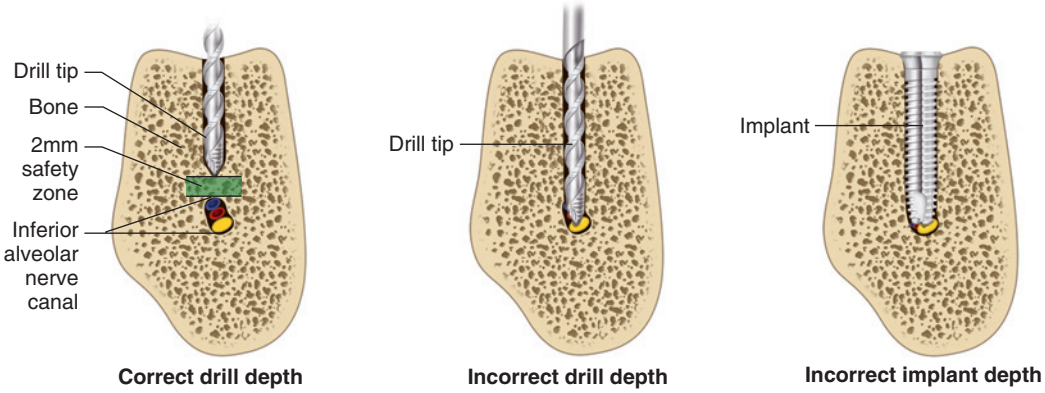

current standard of care.[13] This is because silver points corrode in time, and a tight 3D apical seal is lost. Figure 29-36, *A* to *C*, represents gross overextension with a silver point that ultimately caused the loss of tooth #14 as a result of endodontic failure.

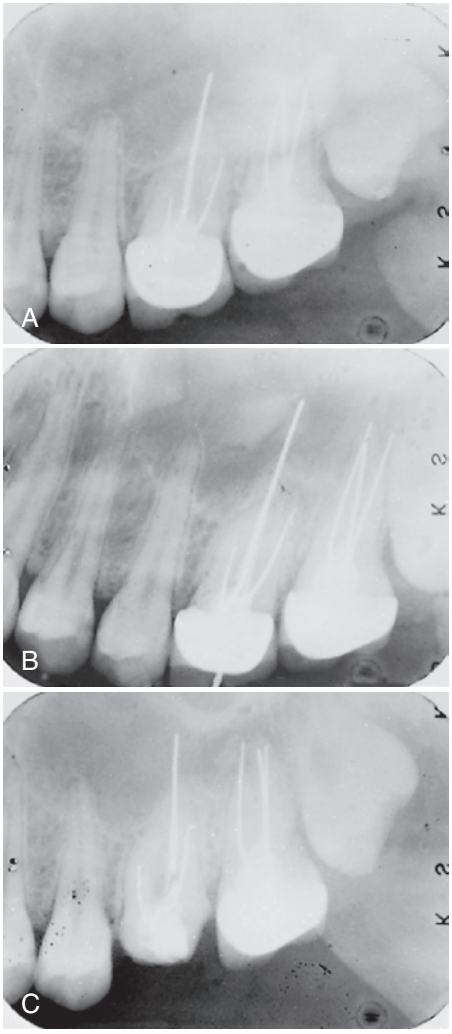

FIG. 29-36 Gross overfill into sinus with a silver point, which ultimately caused sinusitis and loss of tooth #14 as a result of endodontic failure.

The AAE Position Statement does not recommend the prophylactic revision of silver point obturation, unless there is clear evidence of endodontic pathosis or if the silver points complicate proper restoration of the tooth.[13]

N2 (Sargenti Paste)

Dental literature reports that permanent paresthesias are associated with gross overfilling with paraformaldehyde sealant (N2) (Fig. 29-37).[200,234] Current use of paraformaldehyde-containing endodontic sealants is not merely the result of a philosophic difference between two respectable schools of thought. Rather, the distinction is between the reasonable and prudent school of thought that advocates conservative conventional endodontics and the imprudent and radical school of paraformaldehyde providers who unreasonably risk permanent, deleterious injury with N2 overextensions. Regardless of the small number of clinicians professing to use N2, it is cytotoxically unsafe and should be avoided. A customary negligent practice by some clinicians is no defense to safe and prudent practice, which the standard of care requires. No matter how few or how many do it wrong, this never makes it right.

The AAE recommends against the use of paraformaldehyde-containing materials as they have proved to be both unsafe and ineffective. Accordingly, the use of such materials is below the standard of care for endodontic treatment.[11]

Four years after her settlement, a Sargenti paste overfill patient wrote about her persistent dysesthesia as follows:

> I have been in a pain cycle that is almost unbearable. I fully understand why the closest God given disease to what I suffer, trigeminal neuralgia, is nicknamed the suicide disease. There are days where that option enters my mind but I believe that suicide is a sin and will land me in an eternal life worse than what I was trying to escape.

Clinicians may be liable for fraudulent concealment, intentional misrepresentation, or co-conspiracy if they discovered that a previous clinician's negligence is the cause of dental disease and both the prior clinician and subsequent treater concealed the prior clinician's negligence. For instance, if a gross overextension of a paraformaldehyde packing or sealant is evident radiographically and the patient reports that another

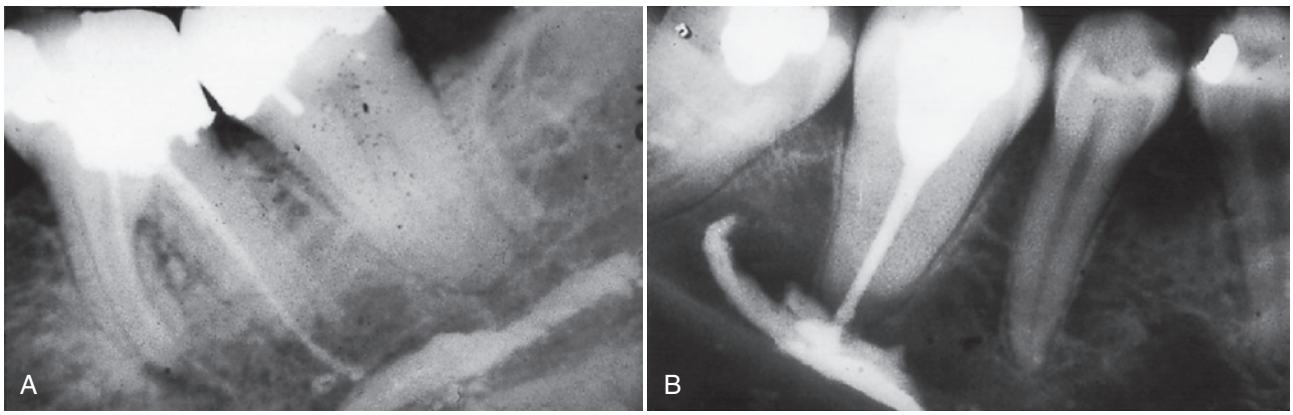

FIG. 29-37 **A and B,** Overextensions of Sargenti paste filling the inferior alveolar nerve canal. Both cases could have been avoided if the practitioners had selected a conventional sealing material and used a technique that emphasizes length control.

clinician caused the overfill (that resulted in permanent lip and chin anesthesia), subsequent treating clinicians may be liable for fraudulent concealment if they misinform the patient that the anesthesia will probably disappear shortly and that using N2 merely reflects a philosophic difference rather than substandard practice. Some clinicians who differ on therapies regard such differences as controversial. The difference between standard of care and substandard practice is not controversial but rather an indisputable difference between right and wrong. For instance, quackery based on pseudoscience is not controversial. Instead it is fraudulent practice.[37,224] Likewise, if the radiographs indicate sealant is inside the IANC and the patient complains of persistent anesthesia, the patient should not be told to wait for return of sensation. The clinician should refer the patient immediately for microsurgical consultation for decortication and decompression surgery.[263]

The Federal Food, Drug, and Cosmetic Act prohibits interstate shipment of an unapproved drug or individual components used to compound the drug.[100] On February 12, 1993, the FDA dental advisory panel confirmed that N2's safety and effectiveness remain unproven. N2 may not be shipped interstate or distributed intrastate if any of the N2 ingredients were acquired interstate. Mail-order shipments of N2 from out-of-state pharmacies in quantities greater than for single-patient use are considered a bulk sales order rather than a prescription, thus violating FDA regulations.[63] A San Francisco jury awarded punitive damages against an N2-distributing New York pharmacy for knowingly shipping N2 in violation of FDA regulations, done with deliberate disregard for patient safety.[162]

Defective Restorations

Marginal gaps greater than 50 µm lead to cement dissolution and cause 10% of crown failures within 7 years after cementation. Dull or worn explorers substantially increase the likelihood of nondetection of open margins. A sharp explorer can detect margin defects as small as a 35-µm opening.[36] Accordingly, a sharp clinician should utilize a sharp explorer to detect open margins. Open crown margins contribute to endodontic failure and should be avoided (see Chapter 22).

Restoration Marginal Integrity

A pathologic apical lesion will resolve when the origin of infection is eradicated, the root canal system effectively sealed, and a satisfactory coronal restoration placed. Many clinical studies report a high success rate for nonsurgical root canal treatment (NSRCT) of greater than 90%.

PROPHYLACTIC ENDODONTIC PRACTICE

Malpractice Prophylaxis

Most negligently injured patients do not sue.[51] Nonetheless, litigation serves a prophylactic purpose because litigation fears make some clinicians more careful and help promote professional guidelines. For example, after the American Society of Anesthesiologists adopted practice guidelines to reduce patient harm, deaths and professional liability premiums decreased dramatically.[252,283]

One-Visit versus Two-Visit Endodontics

One visit endodontics, if done well, will allow disinfection of the canals and obturation without risk of recontamination through the coronal seal between visits. Treatment of apical periodontitis with signs or symptoms of a beginning lesion is determined by the sound judgment choice of the clinician. Either one or two visits will comply with the endodontic standard of care.[242]

Prevention of Orthopedic Joint Infections

Available evidence is insufficient to recommend prophylactic antibiotics for dental procedures in persons with joint replacement, according to the American Academy of Orthopedic Surgeons (AAOS) and the American Dental Association (ADA) clinical practice guidelines.

This new guideline, titled "Prevention of Orthopedic Implant Infection in Patients Undergoing Dental Procedures," replaces the previous AAOS Information Statement, "Antibiotic Prophylaxis for Bacteremia in Patients with Joint Replacement."[8,21]

A collaborative systematic review of the correlation between dental procedures and prosthetic joint infection (PJI) found no direct evidence of a causal link. The new clinical practice guidelines were developed using the published AAOS development process, which meets or exceeds recommended Institute of Medicine standards for the development of systematic reviews and clinical practice guidelines.

Research showed that invasive dental procedures, with or without antibiotics, did not increase the odds of developing a prosthetic joint infection.

Clinical practice guidelines include three specific recommendations:

1. Practitioners should consider changing their customary practice of prescribing prophylactic antibiotics to patients with prosthetic joints undergoing dental procedures. This recommendation is based on limited evidence that dental procedures are unrelated to PJI.
2. There is no direct evidence that the use of oral topical antimicrobials before dental procedures will prevent PJI. This is an inconclusive recommendation. The guidelines' authors were unable to recommend for or against the use of topical oral antimicrobials in patients with prosthetic joint implants or other orthopedic implants
3. Good oral hygiene should be maintained. This is the only consensus recommendation in the new guideline.

Potential adverse effect of routine prophylactic antibiotic use may include increased bacterial resistance, allergic reactions, diarrhea, and death.

Immunocompromised patients may be at greater risk for implant infections. Antibiotic use might be considered in this group.

Immunocompromised patients include patients with diabetes mellitus type 1 and type 2, autoimmune diseases, post–organ transplants, chemotherapy, bone marrow transplants, HIV positive status, chronic steroid use, obesity, hemophilia, malnutrition, tobacco or alcohol use, leukemia or other cancers, radiation therapy history, immunomodulated therapy, or the elderly.

Disclosure Errors

Should dental negligence harm a patient, then full disclosure, including accepting the clinician's responsibility along with providing an apology and explanation, results in the best

outcome for the clinician and patient. Also, assurance of efforts to prevent a recurrence results in greater patient satisfaction and retains trust with the disclosing clinician to sustain a continuing clinician-patient relationship. Patients want to be told of treatment errors, regardless of whether the error can be corrected. One study in which there was full disclosure of negligently caused therapeutic errors resulted in only one patient thereafter seeking legal advice.[210] In the same study, patients paradoxically acknowledged, "It is realistic to expect that doctors will make errors. … Patients have a right to expect that their doctors will not make errors." Nonetheless, virtually all patients concluded, "Patients should be able to trust their doctors to give them the right care." As noted earlier, apologetic expressions of sorrow or empathy for a patient's injuries are barred in evidence from being construed as admissions of fault in 29 states.[182] Protecting the patient's best interest includes telling the patient when negligent errors occur.

Future of Antibiotics and Resistance

Clinical signs, symptoms, and outcomes of infection result as much from the host response to the microbe as from the direct effects of the microbe itself. The speed with which antibiotic resistance spreads is driven by microbial exposure to all antibiotics, whether appropriately prescribed or not. Even if all appropriate antibiotic use were eliminated, antibiotic-resistant infections would still occur (albeit at lower frequency). Widespread antibiotic resistance was recently discovered among bacteria found in underground caves that had been geologically isolated from the surface of the planet for 4 million years.[45] Resistance was found even to synthetic antibiotics that did not exist on earth until the 20th century. To slow the spread of resistance in order to prolong the useful lives of currently available antibiotics, careful clinicians should prevent infections from occurring in the first place.

In 2009, more than 3 million kilograms of antibiotics were administered to human patients in the United States alone. In 2010, a staggering 13 million kilograms were administered to animals, the majority to promote the growth of livestock.[297]

Temporomandibular Disorders

Occlusal prematurities can trigger temporomandibular disorders (TMDs) in patients with a prior TMD history, so during or following endodontic therapy for such a patient, it is essential that temporary and final restorations not open the bite or significantly alter existing occlusion.[194] Hyperocclusion is a potential TMD trigger that can result from open bite or on a contralateral side, when a terminal abutment tooth is taken out of occlusion.

Patient Rapport

Good patient relations are 15% dependent on the clinician's competency to cure and 85% dependent on the clinician's ability to assure the patient that the treatment being given will be done with the clinician's best judgment and care.

Rapport between clinician and patient reduces the likelihood the patient will sue, despite an adverse result. The clinician can develop rapport by demonstrating genuine interest in the patient and making the patient feel valued. Patients feel important if they are seated in the operatory within a reasonable time after arriving. The longer a patient is kept waiting, the more frustration and animosity build. If the patient cannot be seen within a reasonable time, a staff member should communicate the reason and, if appropriate, offer to reschedule the appointment. Staff or the clinician should telephone the patient at the end of the day after any difficult procedure or surgery to check on the patient's status and remind the patient to follow postoperative instructions. The clinician should record any patient complaints, symptoms, and noncompliance with instructions. The latter can be used as evidence of patient contributory negligence if litigation occurs.

The clinician should remember that the patient lacks the information and expertise to evaluate quality and performance. Patients have their own experiences and perceptions and often rely on lay information when gathering facts about dental procedures and treatment options. However, clinicians should expect some patients (especially those with access to the Internet) to ask technical questions and expect sophisticated responses.[199,246]

Rapport Building Blocks

Sir William Osler advised, "Listen to the patient. He is trying to tell you what's wrong with him." The best communicators listen more than they speak. When they do speak, it is mostly to clarify what the patient has said. Difficult clinician-patient relationships create poor communications. Improved understanding of the patient's complaints fosters better rapport, aids treatment, and reduces the likelihood of litigation.

In discussing the patient's complaints, the clinician should ask, "What do you think is causing the problem?" Otherwise, the clinician may solve the patient's dental problem while failing to solve the patient's perceived problem. Failing to clarify the patient's expectations about diagnoses and recommended treatment leaves the patient with unresolved worries and concerns. For instance, a patient may fear that a retained endodontic file is carcinogenic unless this fear is allayed with a careful explanation that it is not.

Unhurried Visits

Paying full attention to the patient's complaints, making good eye contact, and respectful addressing of the patient will gain rapport, improve communication, and prevent lawsuits. The clinician should avoid questions that require a yes-or-no answer and instead ask what the patient perceives as the problem, rephrase the patient's complaints to prevent miscommunication, and ask if the patient's complaints have been summarized accurately. Summarizing clarifies understanding by repeating important points. The clinician should also ask whether there are any remaining questions. Nonverbal communication is a powerful tool. The clinician should shake hands initially and comfort with an outstretched hand if pain is provoked.

Emotions are the dominant force behind most malpractice claims. Patients who feel misled, betrayed, or abandoned become angry and may seek vindication instead of simply seeking financial compensation. Thus, the clinician should maintain a tactful and courteous approach and be attentive to the patient's needs and complaints. In addition, the clinician should always make sure that communications with the patient are clear, even to the point of being repetitious, by asking if the patient has any questions. The patient should never be abandoned in the middle of a course of treatment. Also, the clinician should always be available to provide

follow-up care. Clinicians should avoid making telephone diagnoses. Instead, recommend an office exam to assess treatment needs.

Good telephone communication is a matter of asking the right questions, such as asking a patient complaining of postoperative swelling if there is difficulty breathing or swallowing, as well as the degree and location of swelling. In cases of suspected infection, clinicians should ask the patient or family member to call back with a temperature reading to verify the patient is afebrile.

Off-the-Cuff Diagnoses

One clinician misdiagnosed a patient's party guest's endodontic problem as "sensitivity caused by gum recession" and recommended a desensitizing toothpaste. Although the conversation took place in a social setting, a lawsuit can result based on an inadequate diagnosis. Suggest instead a thorough office exam with diagnostic-quality radiographs or provide a referral.

Keeping Conversations Professional

Making light of a minor occurrence, such as the dropping of an instrument, with a quip about the clinician's "one drink too many" at lunch may seem funny at the time. However, it may not sound so funny if the patient soberly reiterates the quip to a jury.

The clinician must not let a patient's flattery of the clinician's abilities undermine one's best professional judgment. Heroic measures usually result in treatment failures, dissatisfied patients, and, ultimately, lawsuits for uninformed consent.

A patient dissatisfied with prior treatment that appears adequately performed should prompt the clinician to stop treatment. Young clinicians are more apt to walk into traps involving a patient's request for unreasonable treatment. A compassionate clinician who is able to communicate conscientious concern avoids many malpractice actions. Thus, when an iatrogenic mishap occurs, it behooves the clinician to be frank and forthright with the patient. Moreover, negligence concealment may extend the statute of limitations. Most states with discovery statutes construe *discovery* as the date on which the patient discovered or reasonably suspected the negligent cause of the injury, not the date of the injury itself.[89,117,267,331] Further, belated discovery of injury from another clinician evokes a feeling of betrayal in the patient and destroys rapport that would otherwise dissuade the patient from instituting litigation. Beginning in July 2001, the Joint Commission on Accreditation of Health Care Organizations required hospitals to provide an honest explanation to patients regarding medical mishaps. These standards are designed to prevent errors and reduce medical negligence claim payouts. In 1999, the *Annals of Internal Medicine* concluded that "extreme honesty may be the best policy." A full-disclosure policy in a study involving a hospital in Lexington, Kentucky, showed that this hospital was in the top 25% of claim incidence, but it was also in the bottom 25% of claim payouts ($1.3 million over 7 years).

Fees

Clinicians should clarify fees and payment procedures before initiating treatment. If the dental treatment becomes more extensive than originally planned, the clinician should discuss any increased charges and reasons for those charges with the patient before continuing treatment. Charging for untoward complications, such as extended postoperative visits or retrieving broken instruments, should be resisted.

An overzealous receptionist who places payment pressure on a dissatisfied patient, or a clinician who sues to collect a fee from an already displeased patient, may invite a countersuit for malpractice. Refunding fees or paying for the treatment fee of the subsequent treating clinician is usually much less expensive than 1 week in court and a jury award for a patient's pain and suffering. If clinicians must sue for a fee, they should do so only if treatment is beyond reproach and records substantiate proper diagnosis, treatment, and informed consent options.

Suing for unpaid fees continues to be a proven method for getting countersued for dental malpractice. The client who has paid fees in the past but who stops at some point is either unhappy with the dental service received or short of funds. Dealing with a patient's countersuit takes time, and collection of unpaid fees may prove difficult. The patient being sued may seek an attorney to scrutinize the clinician's records for a potential cross-complaint suit against the clinician who initiated the lawsuit for fee collection.

Some cross-complaints for dental malpractice lack merit, whereas others have genuine merit. Pain, suffering, and lost wages may provide a larger potential patient recovery amount than the clinician's fees in dispute. Whenever possible, clinicians should avoid suing patients for unpaid fees. Before considering suing, the clinician should discuss the fee situation with the patient and consider a payment schedule, fee reduction, or fee waiver.

The amount of money being awarded by juries is increasing. In 1999, a New York City jury awarded $3.5 million against a clinician who had replaced three amalgams with composites. To relieve postoperative sensitivity, endodontics was performed and subsequently failed. Chronic TMD followed the extraction, from which the patient was likely to suffer lifetime pain. In Michigan, two endodontists were disciplined in 2008 for sedation overdose after settling for $3.5 million.[278] In 2008, a Spokane, Washington, jury awarded $14.2 million for unnecessary temporomandibular joint (TMJ) surgery. In Figure 29-38, a Los Angeles jury awarded $2.7 million against a periodontist who "harpooned" the IANC with his implant.

Post Perforation

Post selection is important for minimizing the risk of perforations.[68] Generally, posts should not exceed one third of the mesiodistal width of a tooth, should follow the canal anatomy, and should leave 4 to 5 mm for sealant in the opened post space; this is described more thoroughly in Chapter 22. When a tooth is already crowned, access to the root canal entrance

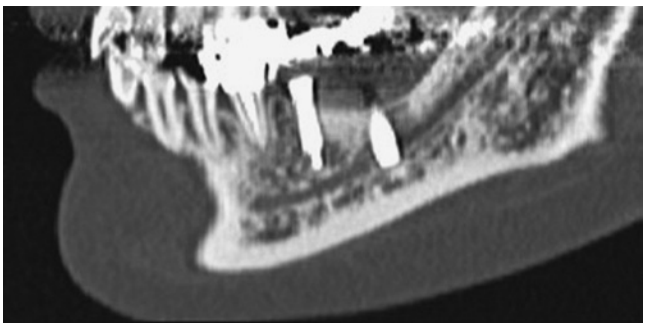

FIG. 29-38 Implant "harpooned" the inferior alveolar nerve canal.

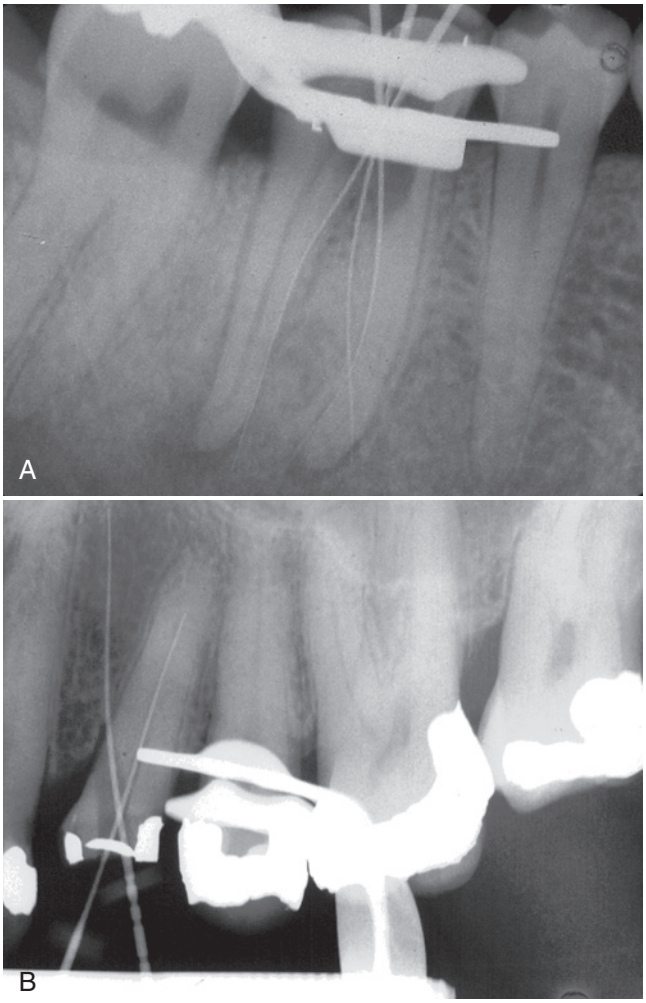

FIG. 29-39 Avoidable perforation. (Courtesy Stephen Cohen, MA, DDS.)

surface should be located before rubber dam placement. This will aid in orienting the root's long axis, which may vary from the prosthetic crown's long axis. Figure 29-39, *A* and *B*, represents an endodontist's perforation of tooth #7 because of difficulty locating the entrance into the root canal apical to the pulp chamber.[107] Figure 29-40 shows a general clinician's misaligned post and perforation of tooth #5.

Ordinarily, a careful clinician performing endodontic therapy should be able to avoid post perforations. If post perforation occurs, early diagnosis and treatment are important. Belated diagnosis and treatment substantially increase the risk of endodontic failure. If the perforation is relatively small (i.e., 1 mm or less) and promptly diagnosed at the time of the post perforation, immediate treatment with intracanal sealants (MTA) or tricalcium silicate in the area of the perforation will probably succeed. However, delayed diagnosis and treatment (beyond 24 to 72 hours) result in bacterial contamination in the area surrounding the perforation. Delayed perforation repair therapy can cause periodontal or endodontic lesions and lateral periodontal abscesses occurring secondary to delayed diagnosis, which usually prognosticate a high failure risk.

Perforation Prevention

Irreversible endodontic complication such as furcation perforation during pulpal chamber access is usually preventable with due care.[228] Furcation perforations are avoided by adhering to basic principles of pulpal chamber removal such as cleaning and shaping in a coronal rather than an apical direction. Innovative bur designs can access the pulp chamber without risking furcation perforation by preventing cutting or ditching of the pulp chamber by use of a non–end-cutting bur.[87]

FIG. 29-40 Post perforation of tooth #5.

Bleach Injury

Because of the varying shapes of the root canal system in the apical third after cleaning, shaping, and obturation, some residual bacteria may remain, which are entombed. Sodium hypochlorite is the usual disinfectant irrigant used to minimize these remaining bacteria.[268] Apical or lateral extrusion occurs when bleach is extruded past the protective apical constriction or through a root perforation. The common denominators of bleach injuries are sudden severe pain and facial swelling.* Because of the clinician's concern for emergency treatment and the patient's pain, further endodontic therapy is deferred and usually not completed at the same visit. However, two cases report that compaction was completed during the same visit, despite a bleach injury.[215,276] One article reports that subsequent flare-up may be related to the original bleach injury.[52]

Prevention of bleach extrusion is done with bleach syringes with safe, side-venting needles constantly moving to prevent hydrostatic pressure buildup from bleach fluid. Sodium hypochlorite is extruded into the periapical tissues during root canal therapy if excessive pressure is placed on the irrigating syringe, resulting in an expression of sodium hypochlorite beyond the apex. Subsequent pain is caused by the solution diffusing into the surrounding bone and soft tissue, causing swelling, tissue necrosis, and paresthesia. Surgery is usually contraindicated, and palliative treatment such as cold compresses accompanied by reassurance that most symptoms will dissipate is usually adequate.[186] However, if the bleach diffuses into vital nerve tissue of the infraorbital or inferior alveolar nerves, permanent paresthesia and occasional dysesthesia may result.[101,214,249,336] Figures 29-41 and 29-42, *A* to *C*, represent bleach injuries secondary to a root canal perforation. Paresthesia persists. Note the periapical film does not show the perforation, but the Accuitomo CBCT does.

*References 2, 101, 186, 214, 249, 260, 268, 336.

FIG. 29-41 Bleach injury.

Bleach Usage

Use of 35% H_2O_2 as a bleaching agent can be clinically adverse in the long term or after recurring bleaching treatments.

Precautions include the following:

- Reduce hydrogen peroxide concentration
- Reduce the time of each application, and increase the time between applications
- Avoid reaction catalysts, such as lamps or lasers

Post-bleaching sensitivity is mostly due to reversible pulpitis that may progress in some cases.

Cores

Incorrect choice of cores can contribute to failure, including fractures. Some manufacturers (e.g., 3M ESPE, St. Paul, MN, for Ketac silver) recommend against use of their core material unless at least two thirds of the tooth remains before buildup. Failure to follow the manufacturer's directions can be considered when an expert determines whether the standard of care was met.

Resin-reinforced post-and-core systems show promise for structurally weakened incisors, but long-term longevity has not been reported. A ferrule or other counter-rotational core design is an important consideration for fracture resistance and retention,[155] although it has not been proved as statistically significant for the resin-reinforced core systems.[279]

Absorbable Hemostatic Agents

Absorbable collagen hemostatic agents should not be placed on or adjacent to peripheral nerves because of the potential for neural injuries, particularly in bony nerve canals.[105,200] Also, as this material is absorbed, its chemotactic properties promote collagen formation and scarring. Compression injuries of peripheral nerves in bony canals can result from expanding scar tissue. FDA adverse incident reports list 11 patients with severe neural defects, including paraplegia secondary to absorbable collagen products placed in the spinal canal for hemorrhage control. Thus, the FDA warned of paralysis from absorbable hemostatic agents.[105,200] Accordingly, after hemorrhage is controlled with hemostatic agents, absorbable collagen agents should not be left in situ or near bony neural spaces. This will avoid having remaining hemostatic material cause swelling, pressure, or migration to adjacent neural tissues. The minimum amount of collagen agents necessary to achieve hemostasis should be used.

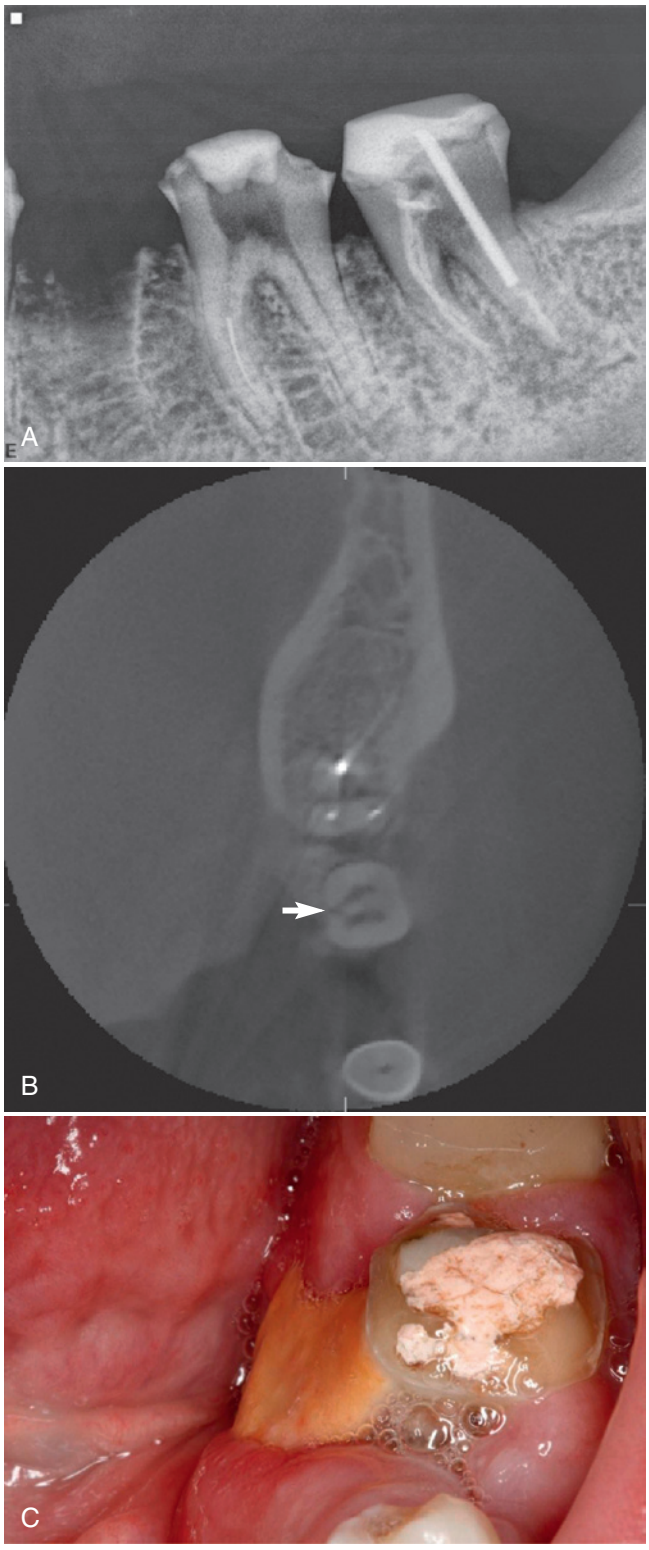

FIG. 29-42 **A**, Periapical tooth #19 showing fractured file but no perforation. **B**, Accuitomo cone-beam computed tomography (CBCT) showing perforation on the lingual side above the tooth #19 furcation. Perforation not evident in periapical view. Image demonstrates Accuitomo accuracy. **C**, Bleach extrusion through tooth #19 perforation, with resultant slough of lingual tissue.

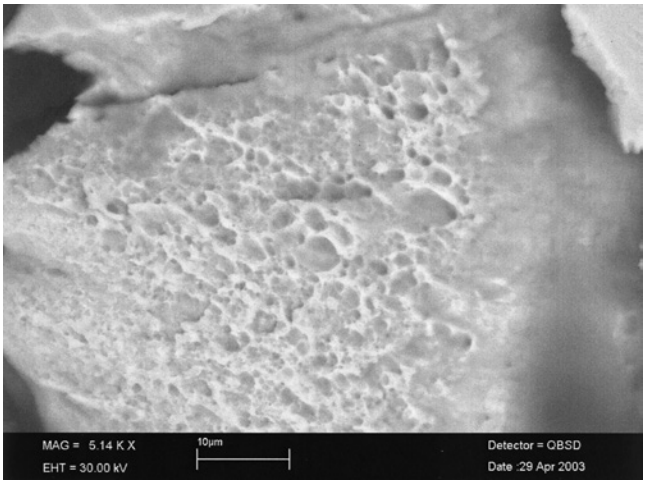

FIG. 29-43 Tensile overload shown in elongated ductile dimple voids.

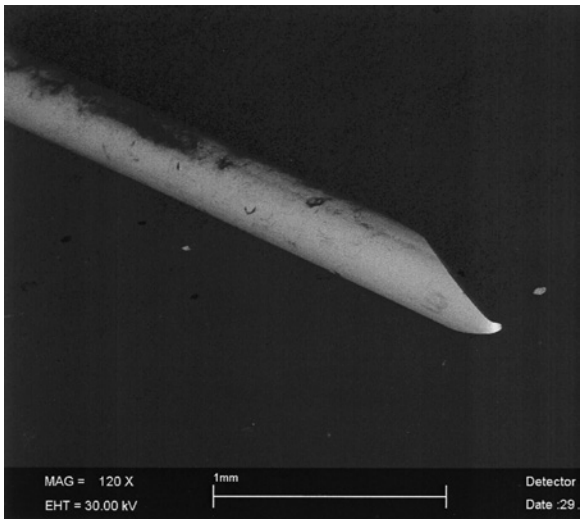

FIG. 29-44 Needle blunting of broken needle tip demonstrating striking hard object (ramus).

Pneumomediastinum (Air Embolus)

When performing endodontic surgery, a surgical handpiece should be used that ventilates air through the back of the handpiece rather than an air turbine that directs air into open tissue spaces. Pneumomediastinum, also known as *mediastinal emphysema,* may result from air embolisms dissecting down the neck facial planes from air forced into the submandibular or sublingual spaces contiguous with neck spaces.[40,301]

Broken Needle

Scanning electron microscopy (SEM) with an energy-dispersive x-ray spectrometer attachment can analyze whether a broken instrument is due to excessive operator trauma or a manufacturing defect. Figure 29-43 represents a combination of low-cycle bending fatigue and tensile overload. Accordingly, the local anesthetic needle likely fractured because of bending deformation as it struck the ramus.

Ductile rupture in metals results from shearing along planes that are oriented at 45 degrees to the tensile stress. Tensile "necking" results from multiple slipping deformations in all the 45-degree planes to the needle axis because of significant overload. Final rupture results from a combination of bending and tension. Figure 29-44 shows the needle tip bent and blunted as it hit a hard object. No manufacturing defects were found. Figure 29-45, *A* and *B*, shows SEM views of the fracture. Figure 29-45, *C*, is a SEM view of the needle fracture taken at the hub side of the fracture. These illustrations demonstrate why longer 25-gauge needles should be used for mandibular blocks rather than shorter 30-gauge needles.[207]

Preventable causes of a broken local anesthesia needle are as follows[207]:

- Use of a 30-gauge needle for mandibular block
- Bending needle
- Insertion of needle to the hub
- Multiple use of the same needle

Sterilization

The nonsurgical use of the dental unit water supply should comply with the Environmental Protection Agency regulatory standard of less than 500 colony-forming units (CFU)/mL.

CDC guidelines require sterile water or sterile solutions for all surgical procedures.[188] Disinfected water from handpieces or ultrasonic devices is no longer acceptable as a water coolant during surgery. Instead, an ultrasonic device that can deliver a sterile irrigant during surgery should be used. Dental unit water lines are available with tubing that can be disposed or autoclaved for surgery. Some ultrasonic devices are also available with disposable tubing to maintain a sterile water coolant delivery system.

Rotary NiTi files likely contain bioburden material that after sterilization may act as a foreign body. Efficiency degradation after sterilization should suggest to the prudent clinician a single-use philosophy.[31]

Digital radiographic devices that contact the oral mucosa region require a combination of barrier protective sheath and chemical disinfection in accordance with prudent manufacturers' directions.[151]

Medication Errors

The FDA has received more than 95,000 reports of medication errors since the year 2000. Medication errors involve the wrong drug, an extra or wrong dose, omission of a drug, or administering a drug by the wrong route or at an incorrect time.[190]

Medication errors are often preventable.[306] Two major sources of errors in prescribing are poor penmanship and the use of error-prone abbreviations. Writing "1.0 mg" can be read as "10 mg" if the decimal point is not clearly visible. The FDA recommends that no trailing zeros be used when denoting doses expressed as whole numbers and that preceding zeros be used whenever a decimal point is needed for a dose that must be administered as a fraction of a whole number (e.g., 1 mg, 0.5 mg). Recent drug label changes can be readily accessed on the National Library of Medicine's DailyMed website.

Posttrauma Therapy

The reader is referred to Chapter 20 for a full discussion of how to treat and manage patients who have sustained a traumatic injury.

Millennium Management of Endodontic Advances

Technologic advances are touted as ideal endodontics. However, the standard of care is a minimal standard of

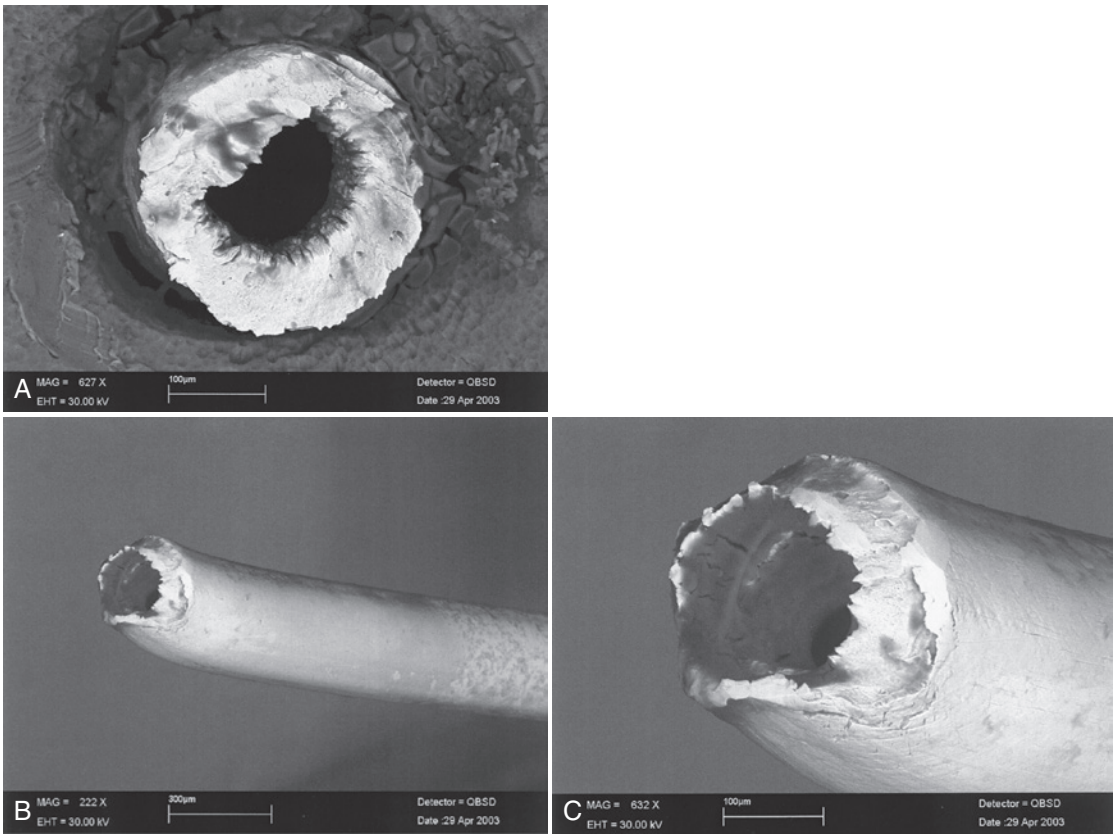

FIG. 29-45 A, Needle fracture with scanning electron microscopy (SEM). B, Needle fracture, side view (SEM). C, Needle fracture at high SEM magnification.

reasonably acceptable practice rather than the perfect ideal. The reasonable and prudent clinician is not required to know and use all the latest technologic advances in endodontics. On the other hand, the reasonable and prudent clinician must keep current with available advances that are generally accepted and proved by research. Microsurgical endodontics is an example of improved endodontic technology; use of magnifying loupes or similar devices may prove inadequate for apical surgery or fractured instrument retrieval compared with microscopes. Therefore, the clinician should adopt proven improvements in the endodontic field. Three-dimensional reconstruction of mandibles can be accomplished with cone-beam volumetric tomography to accurately locate the course of the IANC or mental foramen. Figure 29-46 shows an example of volumetric tomography usage for implant placement or apical surgery.

If studies demonstrate significantly superior results for some alternative to surgical endodontics, the informed consent standard of care may require that the patient be advised of the alternative technique, even if it is more expensive. There may be more than one path to success. So long as the clinician uses reasonably acceptable techniques and informs the patient of reasonable alternatives, the standard of care is met, but clinicians should remember that today's surgical advance may be tomorrow's retreat. For example, temporomandibular joint (TMJ) implants were inadequately tested technology on loading joints and proved virtually 100% disastrous.[102,258] Microscopic apical surgery has gained general acceptance, is performed by the majority of endodontists, and represents the current standard of care.[15,76,166,183]

FIG. 29-46 Cone-beam computed tomography usage for implant placement or apical surgery.

Clinicians should evaluate the quality of peer-reviewed research articles for new products rather than accepting them at face value. A case report amounts to no more than the author's personal experience with one patient. Some authors report a "series" of patients if there are only two patients. A brash conclusion is to state something has occurred time and time again if similar findings were observed with only two or three patients. Valid scientific principles mandate that other competent scientists duplicating a particular research protocol can replicate a test result. If research cannot be duplicated,

sweeping conclusions should not be made. Comparative effectiveness studies should demonstrate not only better results than a placebo but also relatively better results compared with similar marketed products tested under similar clinical conditions.

Statistical Research

Statistical research conclusions may vary, because research protocols may not similarly control variables of population groups studied.[137,253] Discrepancies occur even within trials or among large trials. Meta-analyses of multicenter randomized controlled trials aim to reduce bias by estimating the effect size for outcomes and adverse effects after pooling all qualified research studies. This approach will not assist if the supporting randomized controlled trials are derived from confounded data from heterogeneous trials. Such research results represent an estimate of the average difference in the responses of the tested treatment groups. These differences in results of different centers from various test groups may reflect important distinctions in the clinical conditions of enrolled research subjects. Such distinctions may help identify subgroups of patients harmed by the researched product, although on average, treatment has an overall benefit.[153]

Because most research is currently controlled and sponsored by companies marketing a product, only favorable studies are usually submitted for publication. Literature reviews are prone to publication bias because journal editors are more likely to publish favorable than unfavorable conclusions. The most important use of literature review articles is to develop research questions that ultimately must be tested using a randomized controlled trial. Studies other than randomized controlled trials were the basis for prescribing hormone replacement therapy to millions of women to prevent cardiovascular disease. A randomized controlled trial of this therapy was terminated early because increases in cardiovascular disease and breast cancer were discovered.

Before the 1980s, pharmaceutical industry grants to academic institutions to fund studies by faculty members gave investigators total responsibility to design the study, analyze and interpret the data, write the papers, and decide where and how to report the results. Neither the investigators nor their institutions had other financial connections to sponsoring companies. Drug companies now finance most clinical research on prescription drugs. There is mounting evidence that research is skewed to make drugs look better and safer than research findings warrant.*

Negative results are often not published. For example, a study of 74 clinical trials of antidepressants found that 37 of 38 positive studies were published. Conversely, of 36 negative studies, 33 were either not published or published in a form that conveyed a positive outcome.[316]

Published clinical research is too often biased, usually by designing the studies in ways that will almost inevitably yield favorable results for the sponsor.[216,337] For example, comparative drugs may be administered at a too-low dose so that the sponsor's drug looks more effective, or at a too-high dose so that the sponsor's drug has relatively fewer adverse effects. Bias also takes the form of comparing a new drug with a placebo when the relevant research question is how it compares with an existing drug. A fair comparison would contrast the new drug with an older FDA-approved drug at equivalent doses. As the former editor for two decades of the *New England Journal of Medicine* concluded in a 2008 *JAMA* article, "It is naive to assume bias is only a matter of a few isolated instances. It permeates the entire system. Physicians can no longer rely on the medical literature for valid and reliable information."[27]

Prudent clinicians do not adopt every new technology. Before adoption, such technology must have demonstrated benefits with acceptable levels of risk. It must also be adequately tested, with sufficient numbers of test subjects, over a significant length of time. Because manufacturers too often rush their products to market, newer products may not meet this criterion. Therefore, except for breakthrough technologic changes, a clinician will not likely be judged negligent for failure to adopt each latest device or technique. However, clinicians must keep in mind that in the information technology industry, 1 year is considered several generations, if not an eternity.[44,123] In general, do not be the first or the last to adopt improved technology.

The standard of care usually does not mandate incorporation of every new technology. However, in those states with informed consent laws that are based on what a prudent patient would want to know rather than what prudent clinicians should do, the patient may argue that an alternative technology or technique used by a different clinician would have been chosen had the clinician provided the patient with such information. Microscopic endodontics for broken file retrieval and CBCT to aid apical surgeries and implant placement are pertinent examples of what a reasonable patient would wish to know.[75,157]

Other Clinicians' Substandard Treatment

Clinicians should not be overly protective of blatant examples of another clinician's substandard dental treatment. On discovery of apparent negligent treatment by a previous clinician, the clinician should consider investigation. Begin by obtaining the patient's written authorization for transfer of a copy of the previous clinician's records, including radiographs. If negligence is still suspected after reviewing the records, the clinician should consider talking with the previous clinician to learn the circumstances of what occurred during the patient's past treatment (after obtaining the patient's written consent pursuant to HIPAA).

On discovery of a gross violation of the standard of care, a clinician has an ethical responsibility to report the matter to the local dental society, peer review, dental licensing board, or agency.[18,122] If the patient was misinformed and later discovers patently obvious negligent treatment, the subsequent clinician could arguably be sued as a co-conspirator to fraudulent concealment of the prior clinician's neglect.

Peer Review

If despite good rapport, candid disclosure, and an offer to pay corrective medical or surgical bills the patient is still unsatisfied, the clinician should consider referring the patient to peer review. Peer-review committees award damages for out-of-pocket losses but not for pain and suffering or lost wages. Consequently, even if the committee's decision is adverse to the clinician, the damage award will probably be less than a jury's verdict. If peer review finds for the clinician, the patient may be discouraged from proceeding further with litigation.

DENTAL AUXILIARY CONFIDENTIALITY AGREEMENT

I, _____, have been informed by
(Dental Assistant)
_____, DDS, that all dental, medical, and
(Dentist Name)
financial information concerning patients is confidential.

As a condition of employment, I agree to maintain the confidentiality of all oral and written information, including treatment charts, and to not disclose such information to any unauthorized outside persons, including any family members, except upon request and authorization by the patient, the patient's agent, or supervising dentist.

I understand and agree that breach of this employment agreement shall constitute good cause for my discharge from employment. I acknowledge that I may be personally liable for any violation of a patient's privacy or civil rights including HIPAA committed by me without consent of the patient, or the patient's agent, or approval by above-named dentist.

Date: _____ _____
Signature of Dental Assistant

Witness: _____

FIG. 29-47 Dental auxiliary confidentiality agreement.

Peer review proceedings, including the committee's decision, are not admissible in court.[61] Insurance carriers usually honor and pay a peer-review committee award, because a fair adjudication of the merits has been determined; the award is usually less than a jury would award. Also defense costs, including attorney's fees, are saved with peer review.

Human Immunodeficiency Virus and Endodontics

A clinician may not ethically refuse to treat an HIV-seropositive patient solely because of such diagnosis.[82] Although in the 1980s, no federal law had clearly extended the protection of the handicapped laws to patients with AIDS, federal congressional action in 1990 extended this protection to the dental office setting with the passage of the Americans with Disabilities Act.[23] Many states already offer additional protection under state law.[59,83]

Confidentiality for patients disclosing their HIV status is important. An inadvertent disclosure to an insurance carrier or to other third parties without any need to know may result in cancellation of the patient's health, disability, or life insurance. This cancellation could result in a claim against the clinician whose office disclosed the information without authorization. Therefore, employees should sign the confidentiality agreement shown in Figure 29-47. In signing this agreement, the staff may be alerted to the seriousness and importance of maintaining the confidentiality of patient health histories, because these histories may document AIDS, venereal disease, or other socially stigmatizing diseases.

If a patient requests that the clinician not inform the staff of his or her HIV status, the clinician should refuse to treat that patient. This information is essential to staff members who may come in contact with the infection.[48] An accidental needle stick with HIV-infected blood, which carries a risk of approximately 1 in 250 chances of seroconversion, may occur. Current medical protocol includes prophylactic administration of zidovudine (AZT), either to prevent or to slow the manifestation of AIDS from a deep, penetrating, accidental needle-stick exposure.

Although a treating clinician risks devastating a dental practice by informing patients that the clinician has contracted AIDS, the legal risk of not informing patients is much greater. The health care provider may be required to advise patients of positive HIV test results under the doctrine of informed consent (i.e., advising of a known risk of harm from accidental exposure).[88] Even if an uninformed patient never contracts AIDS, in those states that use a reasonable patient standard for disclosure of material risks of treatment (which could include accidental direct contact such as an unintended cut or needle stick), the patient may decide to bring an action for intentional concealment as a variant of informed consent and seek to recover emotional distress and punitive damages. Conversely, patients may be legally liable for intentionally misrepresenting their health history regarding their HIV status.[51]

SUMMARY

If the clinician performs endodontics within the standard of care as described in this chapter, there should be little concern that a lawsuit for professional negligence will be successful. Prophylactic measures suggested in this chapter should lessen the likelihood of litigation by reducing, if not eliminating, avoidable risks associated with endodontic care.

Both the patient and the clinician benefit from risk reduction.[119] To do it wrong does not take long, but it is far better for the clinician to take the extra precautionary time to do it right. We are in a profession that deserves the public's trust, but only if that trust is earned. Clinicians deservedly earn public trust by providing safe and excellent quality patient care. The best prophylaxis against being sued is to make protecting the patient's best interest our paramount goal. No matter how many others do it wrong, this never makes it right. Our ethical and legal obligation adheres to the identical bedrock principle, which is service to our patients first and foremost.

Customer Service
Marketing
Endodontic Referral Marketing
Leadership
The Endodontic Leader
Summary

Operating a successful endodontic practice requires both excellent clinical *and* management skills (Fig. 30-1). Endodontists are extremely well trained in their clinical specialty, but most do not receive extensive business training prior to becoming a practice owner. This scenario is beginning to change as more in the dental profession recognize the value of practice management skills and the role they play in an endodontist's ability to have a successful and rewarding career.

Endodontists who possess management skills are better positioned to handle the demands of operating an endodontic practice—a business that can generate significant revenue. Historically, there was a time when endodontists could enter practice without strong business skills and enjoy a long, prosperous career, but the business side of endodontics has become more complicated due to the difficult economy.

Young endodontists are leaving dental school and residency with far more debt than even a decade ago. The cost of purchasing or opening an endodontic practice continues to rise. In addition, endodontists face increased competition from other doctors who perform root canal treatments. The success of endodontic practices can also be affected by the development of new clinical techniques or services. For example, some doctors believe that dental implants represent a better treatment option than root canals, depending on the difficulty of saving the infected tooth. As dental implant procedures become easier and more common, this trend may continue to grow.

To meet these and other challenges, endodontists need to supplement their clinical expertise with excellent practice management skills. *Practice management* involves the use of documented systems to achieve superior business results. Effective practice management allows endodontists to provide optimal patient care while creating a highly productive, low-stress office environment. The design and implementation of effective practice management and marketing systems enables endodontists to operate their practices as successful businesses with steady growth and maximum efficiency. Endodontists who can combine excellent clinical skills with strong practice management skills will experience greater practice success (see Fig. 30-1).

ENDODONTIC MANAGEMENT SYSTEMS

Written, documented systems are the basic foundation for all successful operations within an endodontic practice. Step-by-step, reproducible systems enable a practice to consistently operate and be successful as both a provider of patient care and a business enterprise. Documented systems reduce unnecessary stress and allow endodontists to remain chair-side so they can focus on providing exceptional quality of care. As each system is established, every step in that system must be clearly documented and then implemented. Many endodontists fail to establish efficient systems in the early years of a new practice, and inefficient systems can hinder the practice's growth, increasing stress for the doctor and team.

Endodontists should begin their careers by developing and implementing effective practice systems. This way, when an endodontic practice begins to grow, the office has a solid management foundation in place to handle the growth with low stress as well as to reach more challenging goals. If the practice waits until it becomes more established, there is less time to design effective systems, and the endodontist often becomes

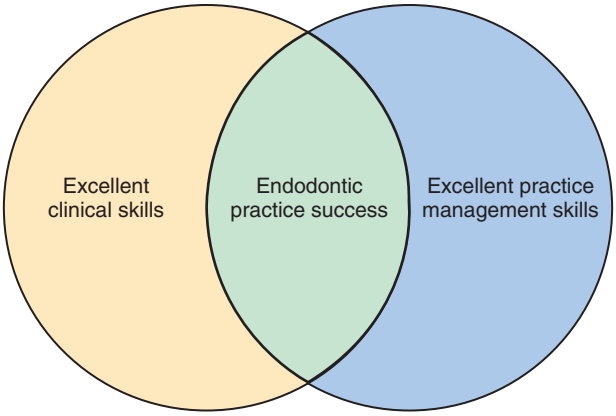

FIG. 30-1 The keys to achieving practice management success.

less motivated to do so owing to an increasingly busy office and other responsibilities in life.

Systems Design

New endodontic practice owners have an excellent opportunity to design systems because the office is nowhere near its capacity. This type of foresight sets the stage for practice growth in the years to come. However, systems should be evaluated and updated throughout an endodontist's career. It will be necessary to replace most major endodontic practice systems on a 5-year cycle to maintain growth and profitability. The reason is that practices regularly outgrow their systems as a result of changes in staff, equipment, technologies, referral relationships, and the economy.

Immersed in the day-to-day pressures of running the practice, evaluating systems can be difficult. Therefore, endodontic practices are well advised to seek outside experts to help them determine the "state of the practice." An in-office practice analysis should include the following:

- First-hand observations of the team and practice operations
- Interviews with the doctor and key team members
- In-depth assessment of all key production indicators
- Thorough evaluation of all practice systems, physical layout, and patient flow

Through such careful analysis, it is possible to accurately determine the effectiveness of practice systems that are in place.

Systems should be designed based on the specific characteristics of each practice. Areas to be considered include the following:

- Days of operation
- Hours of operation
- Number of staff
- Number of patients
- Number of true emergencies
- Average daily patient flow
- Types of procedures offered
- Number of chairs

Effective management systems can make the difference between a successful endo practice and a *highly* successful endodontic practice. Many endodontists cannot fathom how they could see any more patients, produce any more revenue, or work any harder. Yet, there exist similar practices that have much higher production in the same number of days per week with the same number of staff. It is always interesting to reflect on why one endodontic practice can be so much more financially successful than another practice in similar circumstances.

Assuming a sufficient patient flow, the answer always comes down to management systems. It is not about working harder or faster, but it is about creating systems that allow the practice to operate at a specific production and profitability level in a low-stress environment. Key systems and principles for effective endodontic management and marketing include these:

1. Vision
2. Mission
3. Goal setting
4. Target setting
5. Key production indicators
6. Staff training and development
7. Scheduling
8. Customer service

MANAGEMENT

Vision

The first question endodontists should answer before opening or purchasing an endodontic practice is "What kind of endodontic practice do I want to have?" This question requires the endodontist to take some time and identify a vision, which is a description of where the doctor wants the practice to be in 3 years. Whereas some vision statements may reflect a longer period, this shorter time frame works well for most endodontists because it is difficult to predict changes in dentistry, the economy, and other events more than 3 years into the future. In addition, after 3 years, it is time for the doctor to review what has been accomplished and possibly establish a new vision for the practice.

To create a vision statement, the following questions should be answered:

- What location is most suitable for the practice?
- What size should the practice be in 3 years?
- Does the doctor want to be in solo practice or multidoctor practice?
- What working days and hours will be satisfactory for the practice?
- What services will the practice provide?
- Is the intent to have only one practice or to have more than one location?

These are just examples of questions that can stimulate the design of a vision statement.

A vision statement clearly articulates where the practice is going. The length of a vision statement can vary between a short, single paragraph and several paragraphs. It is probably counterproductive to have a multipage vision statement; it will be difficult for both the endodontist and the staff to fully grasp such a lengthy and complex vision.

The vision guides the long-term development and growth of the endo practice. Once the vision statement has been created, it should be shared with the staff on a regular basis. Good leaders always communicate their vision to their staff. When team members understand where the practice is headed, they are empowered to help the endodontist achieve his or her vision. Sharing the vision inspires commitment and participation in achieving the vision. The following are two examples of vision statements.

Short Vision Statement

In 3 years, we will be the leading endodontic practice in the area. We will be known for exceptional quality of care and outstanding customer service. We will grow by 15% per year. Our staff is motivated and committed to continuously improving our management systems and to a lifelong learning process. We strive to meet or exceed our goals in a low-stress work environment.

Long Vision Statement

In 3 years, we will be known in the community for being the most comprehensive and skilled endodontic practice in the area, offering our patients an atmosphere of compassion and comfort.

Our excellent management skills create an environment that is low-stress and productive. We consistently meet our production goals without creating a rushed atmosphere, and our days are fulfilling.

We provide exceptional customer service that consistently generates spontaneous, positive comments. Team members have a clear understanding of their roles and responsibilities. We have developed practice systems that foster a sense of fulfillment and accomplishment for all. In year 3, we will engage an associate doctor.

Mission

Once the vision statement has been created, the next step is the development of a mission statement.

Whereas the vision statement is about where the practice will be in the future, the mission statement is focused on where the practice is today.

Once again, a strong leader has a clear practice mission and shares it with the team. Because of the similar services provided by endodontic practices, many mission statements resemble one another—they talk about quality, patient care, practice services, and customer satisfaction. It is not important to have a mission that differentiates one practice from another, but it *is* essential to have a mission that reflects the doctor's true vision. Here is an example of a mission statement:

> Our endodontic practice is dedicated to delivering quality care to meet the endodontic needs of our patients and referring doctors. We provide exceptional clinical care and customer service in a comfortable, relaxed environment.

One way to keep the mission statement on everyone's mind is to display it prominently in several places throughout the office, as well as on the practice's website. The most powerful reason for displaying the mission statement is to reinforce to the team that the mission is a living document that guides the practice. An added benefit of displaying the mission statement is the opportunity to let patients know that they are important to the practice.

The endodontist should refer to the mission statement on a regular basis. Reinforcing the mission during meetings helps staff members focus on why the practice exists and the difference the team is trying to make in the lives of patients.

Goal Setting

Goal setting represents one of the most important business activities for endodontists. It is critical to achieving success in a doctor's professional and personal life. Once a vision and mission are established, annual goals are the method to make the vision and mission realities. Goal setting is a step-by-step methodology that leads to the achievement of the overall vision. To be effective, a goal must be

1. Written
2. Deadline driven
3. Measurable

Goals that lack these three characteristics cannot be considered goals and are much less likely to be achieved. Be sure that all of the goals are aligned with the practice's vision and mission to achieve the desired results.

The pace of today's endodontic practice forces many doctors to focus on day-to-day operations. In doing so, they cannot see the big picture until many years have gone by. Goal setting and regular goal reviews can help endodontists manage their practice—instead of being managed by it.

Far more than just a motivational concept, goal setting acts as a timeline, benchmark, and directional process to achieve the vision and mission. A vision or mission without specific goals is merely an idea. Endodontists who set goals are much more likely to succeed.

Target Setting

Targets measure whether you are accomplishing your short-term and long-term goals. Each year, endodontists need to set 12 to 15 specific targets to be achieved for the next year. This helps motivate the team to reach goals and drive practice growth. Targets should be reviewed on a weekly basis. For example, if the practice is only collecting 85% of its fees, then the office needs to implement more effective financial procedures to reach the 99% target (if that is the target that has been set).

Sample endodontic targets to achieve include the following:

- Increase practice production by 15% in the next 12 months
- Ensure that 98% of all nonemergency patients are scheduled at all times
- Collect 99% of all money owed to the practice
- Maintain a less than 1% no-show/last-minute cancellation rate

Key Production Indicators

Without data, an endo practice cannot be well managed. To obtain a clear picture of current and potential practice performance, practice goals must be monitored and measured. Key production indicators (KPIs) provide an accurate assessment of the practice's most critical functions, including the following:

- Production
- Collections
- Profit
- Overhead
- New patients
- Accounts receivable
- Number of re-treats versus initial root canal treatments
- Insurance percentages
- Production per hour

These KPIs offer endodontists a starting point for analyzing their practices. Once the information has been collected, weekly measurement and analysis are necessary. Although this may sound arduous, a weekly review should take only a few minutes. Such frequent analyses can bring substantial benefits to the practice.

Evaluating KPIs every week allows endodontists to rapidly identify trends or performance deviations that may be difficult to discern otherwise. With accurate practice data, endodontists are then able to take appropriate actions.

Staff Training and Development

Establishing practice systems will only be effective if team members understand their roles in making those systems work. Training the endodontic team begins with the development of job descriptions that list the skills, responsibilities, and accountabilities for each staff position.

Bear in mind that the majority of staff will be hired without previous endodontic or dental experience and must be trained on the job. Training is specific to each position so that all team members can perform their duties as independently and effectively as possible. During training, it is critical that practices document training policies and procedures so they can be clearly communicated to new staff and regularly reinforced with established team members.

One frequent problem is that many staff members fail to fully understand their job responsibilities and are not held accountable for their performance. As a result, the endodontist will continue to handle numerous responsibilities that should be performed by other team members.

Although this type of behavior may be common in the early stages of an endo practice, endodontists who become effective leaders learn how to delegate appropriate tasks to the team. The goal for all endodontists should be to spend 98% of their workday involved in direct patient care or communication with referring doctors. To reach this goal, it is recommended that endodontists make a list of all activities they perform and which of those responsibilities can be assigned to the staff. This exercise will enable the endodontist to clearly identify which activities should be handled by the doctor only and which should be delegated to the team.

Delegation empowers the team to take ownership of their roles in contributing to practice success. The concept involves giving responsibilities to staff members so that endodontists can concentrate on what they do best. Without delegation, endodontists often carry out numerous responsibilities that can easily be performed by others. To spend more time in direct patient care, endodontists must delegate appropriate responsibilities to specific staff members. In addition, the team should be cross-trained on systems to cover for any illnesses, vacations, or turnover.

Once all team members have achieved a high level of expertise and independence, the endodontic practice can operate at peak performance. Efficiency, professional satisfaction, and quality of care steadily climb to maximum levels. At this stage, endodontists trust their teams to effectively perform their duties with minimal oversight. Best of all, doctors can focus on providing exceptional patient care without distractions and unnecessary stress.

In highly successful endodontic practices, the doctor focuses 98% of working hours strictly on patient care, interdisciplinary treatment, and referring-doctor communication. These practices will typically reach 90% to 100% of their production potential.

Scheduling

Making changes in the area of practice management should begin with a thorough evaluation of the schedule because of its impact on all other major systems. If the schedule is integrated properly with all other endodontic management systems, the practice has the best opportunity to achieve the endodontist's targets.

Schedules are created to achieve specific practice production in a low-stress environment. This means that an endodontic practice must establish a target for annual production and design the schedule accordingly. Each year, endodontic practices should calculate the desired level of growth and create a schedule that allows for that growth. The greatest challenge to increasing production is scheduling inefficiencies that make it all but impossible for the practice to grow.

The following principles are essential when designing the ideal schedule for any endo office.

Schedule for Production

Design the schedule to achieve a specific production target. Endodontic practices are typically capable of growing between 5% and 15% annually. Less than 4% growth represents moving onto a plateau. There are endodontic practices that can grow by as much as 20% to 25% in a single year as optimal systems are implemented.

Scheduling is a quantitative and mathematical activity because time is quantitative and therefore measurable. The schedule should answer questions like these: *How many root canals will we need to perform this year? Will those numbers allow for the production goal to be achieved?* Benchmark these production goals against the hours and days per week the practice is available for patient care, and adjust the schedule accordingly.

Set the Daily Production Target

Setting the daily goal is a reflection of the annual production target. To determine the daily goal, simply take the annual production goal and divide it by the number of days the practice will operate that year. Then build the schedule around this key number. Front desk personnel should become aware that the top practice management priority is to achieve the daily goal. By implementing an excellent scheduling system, they will have a far greater chance of successfully accomplishing this task.

Perform Procedural Time Studies

Many endodontic practices are unrealistic about how much time they actually need for procedures. One common example is for root canals to simply be scheduled for one set length of time, regardless of the level of complexity involved. Performing "procedural time studies" is recommended to determine the exact amount of time needed for each appointment.

During procedural time studies, each type of treatment performed by the office should be measured approximately 10 times to develop an average procedure time. Once these studies are performed and the schedule is updated, most endodontists will usually be able to increase their endodontic workload by using time more efficiently.

Young endodontists should perform procedural time studies once a year for the first 5 years they are in practice. After that, studies can be conducted at less frequent intervals (every 3 to 5 years) to evaluate whether the endodontist has become faster or more efficient in terms of experience, technique, or the use of new technologies in the practice. Procedural time studies play a critical role in building an effective and accurate

schedule, which directly affects the success of the endodontic practice.

Create the Ideal Day

The schedule should be designed to perform larger and more complex appointments in the morning whenever possible. This can be extremely challenging owing to the number of emergencies endodontists see during a normal day. By scheduling larger procedures in the morning, practices can take advantage of the high energy level for both the endodontist and the team earlier in the day. Of course, emergencies will continue to occur, but effectively managing other appointments will better position the practice to handle end-of-day emergencies. Other recommendations for creating the ideal day include the following:

- Handle less complex cases in the early afternoon.
- Perform consults and diagnoses in the midafternoon.
- Schedule all minor procedures, such as posttreatment evaluations, for the end of the day.

Basically, this means that the more difficult or larger cases will occur in the morning when the doctor and team are fresh. As the day goes forward, the doctor and staff have the opportunity to work on less complex cases, such as second visits and patient consultations, with all minor procedures taking place at the end of the day. A highly organized schedule will allow for increased productivity and higher profitability while decreasing stress for the endodontist and the team throughout the day.

Manage Emergencies

No discussion of endodontic scheduling would be complete without focusing on emergency management. Obviously, emergency procedures are a frequent occurrence in endodontic practices. Managing emergencies well requires a combination of referring-doctor management, setting patient expectations, and effective scheduling. The result will be a highly productive, satisfying professional environment for any endodontic practice.

The first step in managing emergencies is to develop a schedule that allows some flexibility. It does not benefit the practice to create a schedule that is 100% maximized without accounting for emergencies. Instead, analyze how many genuine emergencies occur on an average day, and then leave time for that number of emergencies in the schedule. Many high-level endodontic practices will schedule only 80% of their day, leaving time slots for emergencies. The key is to not ignore the time slots and invite every emergency patient to visit the office immediately, but to manage each situation appropriately.

For example, a patient who is in mild discomfort calls at 10 a.m. The practice does not have an opening until noon. If the patient is allowed to come in immediately, the office feels a need to work the patient into the schedule, not only causing stress for the doctor and team but possibly forcing already-scheduled patients to wait longer than expected. If the practice instead schedules the patient in an emergency time slot, there is a much greater opportunity to maintain excellent flow for the day and create a positive customer service experience for every patient. The main point is to provide optimal care and exceptional customer service without disrupting the daily schedule.

The keys to effective emergency management are as follows:

- Evaluate each call from a patient or referring office to determine the level of emergency. Many calls are not true emergencies, and these patients do not need to be seen immediately. Scripting and training can help staff members elicit specific information from patients about the level of discomfort (mild tenderness versus extreme pain) while providing excellent customer service.
- If it is a true emergency, bring the patient in immediately, but still evaluate the schedule to facilitate the overall process. Highly systemized endodontic practices use trained staff to evaluate emergency situations as much as possible, including preliminary assessment and x-rays.
- If the emergency call does not constitute a true emergency, it is important to use effective scripting to move the patient into an emergency time slot that will prevent the appointment from disrupting the entire schedule. This approach can be used with either a referring office or a patient.
- If the practice notices ongoing disruptions from emergencies, it should reevaluate the emergency policy and scripting to create a more effective methodology. Many endodontic practices tell every emergency patient to come in immediately. The problem arises from mistaking high-level customer service with providing immediate treatment. It is much more effective to manage the emergency patient into a time slot reserved for emergencies, unless the patient is experiencing an endodontic problem that necessitates immediate treatment. Staff training is critical for effectively managing emergencies while providing quality customer service.

Scheduling is the single most important system, because it integrates with all other systems. When an effective scheduling system has been established and properly implemented, the practice will immediately see an increase in productivity and a decrease in stress. Most stress in endodontic practices is based on poor scheduling methods that overwhelm the doctor and team and lower customer service. Even though the endodontist and team are actually working harder, profitability will be lower. An efficient schedule enables the endodontic practice to provide a high level of care and customer service to all patients.

Customer Service

Customer service today means much more than just "being nice" to patients. It is a system focused on managing the patient experience from the initial referral to treatment to postoperative care. Outstanding customer service is critical to exceeding patient expectations and building strong relationships with referring doctors.

The majority of endodontic patients are referred to the practice by general dentists. The growth of the endodontic practice therefore depends on the satisfaction and confidence of referring doctors. General dentists want to know that their patients' expectations, as well as their own, are being met. When patients receive excellent clinical treatment and superior customer service, they are likely to provide positive feedback when returning to their general dentist. Positive feedback from patients reinforces the dentist's confidence in the endodontist and leads to continuing referrals.

Developing a customer service system is more complex than simply telling the staff to be nice to patients and referral sources. A customer service system requires that patients consistently receive the same level of responsiveness, caring, and concern from every member of the endodontic practice.

Consistency and quality are at the core of a practice's customer service system.

Although the patient's time in the endodontic practice may be limited, the endodontist must realize that the patient will be returning to the referral source and sharing his or her experience with the referring doctor or the clinician's staff. The patient will also share information about the experience with family, friends, and others. Negative word-of-mouth descriptions about the office will obviously hurt the endodontic practice's reputation within the community.

Patients want to believe they are the practice's *only* priority when they come in for their appointments. Endodontic practices with excellent customer service strive to meet this expectation. If a practice fails to return phone calls quickly, is running late when patients arrive, or does not seem prepared for appointments, patient confidence and trust disappears, as does the patient's perception of quality care.

Endodontic practices should manage expectations by making everything about the patient's treatment plan value based. Do patients fully understand the value of their treatment plans? Do they know exactly what the treatment entails, what the fees are, and why the treatment must be done? Does the patient know the projected outcome? All these questions must be satisfactorily answered before treatment starts.

Endodontic practices have an opportunity to exceed expectations when the following occurs:

- There is complete understanding about why, how, and when endodontic treatment will take place
- Patients have realistic expectations of outcomes
- Patients and referring doctors receive accurate and timely information about the treatment process
- The practice has timely follow-up posttreatment communication with patients

MARKETING

Endodontic Referral Marketing

The business model of an endodontic practice is based on receiving referrals from general dentists and other doctors. There will certainly be the occasional patient who selects an endodontic practice through telephone directories, Internet, social media, or recommendation from a friend, but the majority of endodontic patients will be referred by other doctors. For endodontic practices to reach their true production and profitability potential, an effective referral marketing program should be in place. There are major challenges with implementing a referral marketing program.

Expertise

Referral marketing is a specialized form of marketing. Endodontists are trained doctors with little to no experience or expertise in this type of marketing; most endodontists typically learn about referral marketing through trial and error. This process can be time consuming and costly in terms of missed opportunities.

Time

It is not unusual for endodontists to work 8 hours a day highly focused on providing patient care and managing the practice, with little time to think about referral marketing. This is problematic because effective referral marketing involves not a few sporadic activities but a complete program that must be carried out in a systemized manner to achieve desired results.

Consistency

Inconsistent referral marketing leads to inconsistent referrals. The typical pattern is that if the practice has slowed down, the endodontist will attempt to increase referral marketing until positive results are generated. Once referrals increase, then referral marketing slows down or ceases altogether. This stop-and-start approach to marketing leaves practices more susceptible to the effects of difficult economic conditions, increased competition, and a host of other factors. A consistent referral marketing program is the solution to numerous challenges that face endodontic practices.

Referral marketing should be viewed as a mandatory part of the practice's systems. Referral marketing has two major components:

1. Establishing strong relationships with referring doctors (Fig. 30-2)
2. Designing a consistent marketing program that reaches the doctor's targeted demographic

Establishing Strong Relationships with Referring Doctors

Referral marketing differs from traditional marketing because it is relationship driven. A successful referral marketing program requires positive and consistent contact with referring doctors and offices. It is an investment in time and energy, but when done correctly it can generate a steady influx of referred patients from dentists and other doctors. Communication is critical to establishing and maintaining strong relationships with referring dentists and their teams. Sharing information about mutual patients throughout the treatment process creates a sense of partnership and teamwork that is essential to relationship building. To strengthen relationships with their referral base, endodontists should meet regularly (e.g., quarterly) with their referring doctors. These meetings can be formal or informal occasions, but they provide an opportunity to enhance both the treatment process and the referral relationship.

Designing a Consistent Marketing Program

Building a strong relationship with referring doctors requires more than one or two conversations or meetings a year. By implementing a series of consistent, ongoing marketing strategies that reach referring doctors, endodontists create greater awareness for their practices and services while building and maintaining referral relationships. Referral marketing strategies are selected from areas such as professional relationship, clinical education, social activities, and patient satisfaction. For example, hosting a practice management seminar is a "professional relationship" strategy, and attending a sporting event with a referring doctor is considered a "social activity" strategy. An effective referral marketing program encompasses multiple strategies, resulting in stronger relationships with referring doctors and their teams. The more referrals an endodontist receives, the greater potential for long-term growth and practice success.

LEADERSHIP

Leaders possess many skills, qualities, and attributes that are the result of learning, experience, and self-motivation. Many

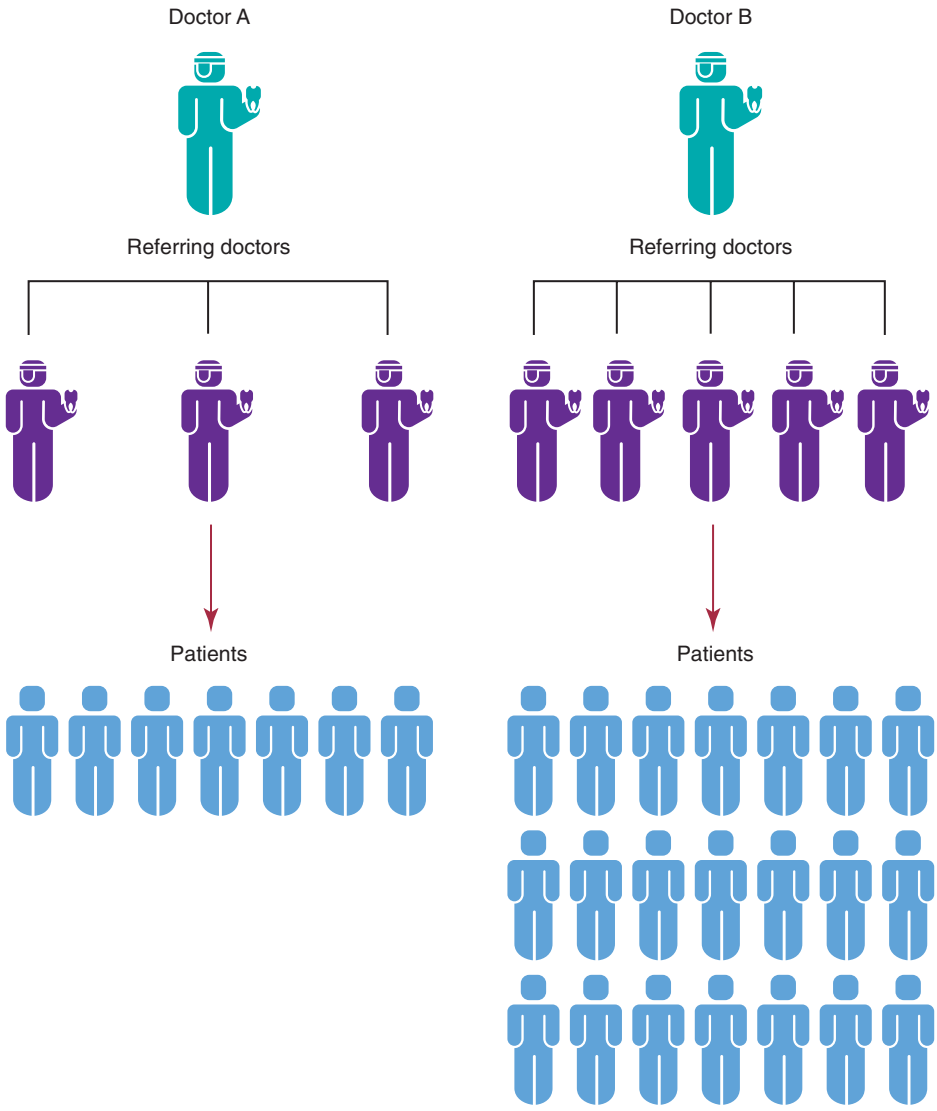

FIG. 30-2 The impact of referral marketing. *Doctor A* does not have a formal referral marketing program in place. *Doctor B* does have a formal referral marketing program in place. The results are dramatic. *Doctor B* has many more referring doctors, who refer more patients for treatment.

people have great ideas or vision, but true leaders are able to implement those ideas or carry out the steps necessary to achieve predetermined goals. They have the ability to inspire others to do their best. The most successful endodontic practices are guided by strong leaders.

Becoming an excellent leader starts with the desire to have an outstanding practice. Most endodontists are highly motivated to be excellent clinicians. Endodontic continuing education is focused mainly on clinical topics, which is appropriate, given that doctors have an obligation to provide the best possible care to patients. This makes it even more important for endodontists to seek out opportunities to develop leadership, business management, and marketing skills.

The Endodontic Leader

As practice owners, endodontists are automatically viewed as leaders by team members. The more leadership skills endodontists master, the better leaders they become. Though not an exhaustive list, the following leadership skills are critical for endodontists.

Interpersonal Communication

Interpersonal skills are the foundation of leadership. Endodontists work with a small group of people in a fairly limited space. Good interpersonal skills are essential for a smoothly functioning office environment. In business, there are many successful "tough" bosses. Even though they may be disliked, they are respected. However, being tough or inflexible is not always the best strategy, especially in dentistry. Few endodontists can be tough leaders in a very small office environment and still expect to have happy team members and a successful practice.

The best practice leaders can motivate their staff, accomplish goals, and earn the respect of team members. Regular morning meetings and monthly staff meetings provide excellent opportunities to communicate with the team, increase awareness of practice challenges and goals, and build stronger interpersonal relationships with team members.

Decision Making

As the CEOs of their practices, endodontists must make business decisions. There are many people who do not progress in

business simply because they vacillate between two choices and fail to make a decision in a timely manner. No matter what the issue, excellent leaders make decisions and trust their instincts, based on analysis, education, and experience. Why? Strong leaders believe in themselves and their knowledge. They are confident that they have the ability to make decisions that are in their best interest and that of their teams.

Motivation

The ability to motivate is one of the most important leadership skills. By earning the trust and respect of the team, the endodontic leader is able to bring together the individuals to achieve shared goals and move toward the practice vision. Many people are not self-motivated. Instead, some external force motivates them. In this case, the external force is the practice leader.

Pursuit of Knowledge

Practice leaders are usually in constant pursuit of knowledge. They want to excel in the management of the endodontic practice and will read, listen, and learn as much as possible about the subject of practice management. Leaders are typically lifelong learners who do not seek knowledge sporadically but take advantage of opportunities to learn new ideas and strategies on an ongoing basis.

Teamwork

An endodontic leader never works on his or her own. These leaders rely on their team to help achieve practice goals. However, many people mistake the concept of being a leader with being a "ruler." The "ruler" approach is not an effective one when working closely with a team whose performance is tied to the ultimate success of the practice. Therefore, endodontic leaders must remember that they are part of a group dynamic. In fact, the practice leader is like the coach of a basketball or football team. He or she creates a game plan, guides the team, and facilitates teamwork.

Time Management

Time is one of the leader's most important assets. Endodontic leaders must not only manage their own schedule but their team's as well. However, good leaders do not micromanage their team. They educate staff members, provide guidance, set expectations, and hold the team accountable for the results.

Successful leaders effectively and efficiently use their time, creating positive outcomes for themselves, their teams, and their practices. Good leaders also eliminate extraneous items from their lives that take time away from achieving their goals.

Leading by Example

The best way to earn the team's respect is to "talk the talk and walk the walk." The way the endodontist behaves will have a significant effect on how the team acts. The professionalism exhibited toward patients, the doctor's attitude and interactions with individual staff members—all of these behaviors send messages to the team. The team is looking to the endodontist for guidance, and the best strategy is to serve as an effective role model. If the team is expected to show up on time, the endodontist cannot stroll in 15 minutes late every day without causing resentment. Good leaders adhere to the rules others are expected to follow.

Leadership is a way of thinking and acting based on desire, skills, training, and specific behaviors. Endodontists who are willing to develop leadership skills will inevitably build better teams with lower turnover and higher efficiency.

FIG. 30-3 Key principles of endodontic practice management.

SUMMARY

Effective practice management involves management and referral marketing systems that enable an endodontic practice to provide outstanding patient care while operating as a successful business enterprise (Fig. 30-3). The number one source of practice stress is the lack of efficient systems. When an endo practice operates year after year without strong systems, the endodontist experiences increased stress and frustration. On the other hand, endodontists who implement documented, high-performance systems enjoy greater satisfaction (and profitability) throughout their careers.

Endodontics is a challenging and rewarding profession. With the right systems, team training, and leadership skills, endodontists can achieve their vision and create a highly successful practice.

COHEN'S PATHWAYS *of the* PULP

THE DEFINITIVE, MARKET-LEADING ENDODONTICS RESOURCE FOR MORE THAN 35 YEARS!

Find the latest evidence-based research and clinical treatments! With chapters written by internationally renowned experts, this comprehensive reference covers the science, theory, and practice of endodontics. Full-color illustrations and detailed radiographs guide you through each step of endodontic care—from diagnosis and treatment planning to proven techniques for managing pulpal and periapical diseases.

THE **PRINT BOOK** OFFERS:

- **23 chapters**—meeting CODA requirements for endodontic dental education—including seven NEW chapters:
  - *Radiographic Interpretation*
  - *Pain Control*
  - *Evaluation of Outcomes*
  - *Root Resorption*
  - *Managing Iatrogenic Endodontic Events*
  - *Cracks and Fractures*
  - *Vital Pulp Therapy*
- **More than 2000 illustrations,** including full-color photos, line art, and radiographs to clearly demonstrate core concepts and reinforce essential techniques.
- **NEW co-editor, Dr. Louis H. Berman,** joins lead editor, Dr. Kenneth M. Hargreaves, for this edition and a respected team of contributors is drawn from dental education programs in the United States, Canada, and Europe.

THE **eBOOK** OFFERS:

- **30 searchable chapters,** including all 23 chapters from the print book—this Expert Consult title lets you search the entire contents of the book on your desktop or mobile device, so you can find clinical answers quickly.
- **Bonus content,** including PowerPoint® lectures, handouts, and review questions. This material is organized to support an entire course in predoctoral endodontics.
- Also included are **video clips** and **case studies** that accelerate clinical decision-making.
