Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment, and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method, and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editor assumes any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

About the Authors

KENNETH M. HARGREAVES

Dr. Hargreaves is Professor and Chair of the Department of Endodontics at the University of Texas Health Science Center at San Antonio. He is a Diplomate of the American Board of Endodontics and maintains a private practice limited to endodontics. He is an active researcher, lecturer, and teacher and serves as the Editor-in-Chief of the Journal of Endodontics. He is principal investigator on several nationally funded grants that combine his interests in pain, pharmacology, and regenerative endodontics. He has received several awards, including a National Institutes of Health MERIT Award for pain research, the AAE Louis I. Grossman Award for cumulative publication of research studies, and two IADR Distinguished Scientist Awards.

LOUIS H. BERMAN

Dr. Berman received his dental degree from the University of Maryland School of Dentistry and his Certificate in Endodontics from The Albert Einstein Medical Center. He is Clinical Associate Professor of Endodontics at the University of Maryland School of Dentistry and a Clinical Instructor and Guest Lecturer at The Albert Einstein Medical Center. He has lectured internationally in the field of endodontics and has published in several peer-reviewed international dental journals as well as co-authoring textbook chapters on numerous topics in various endodontic textbooks. He is past president of the Maryland State Association of Endodontics and is a member of the Journal of Endodontics Scientific Advisory Board. A Diplomate of the American Board of Endodontics and Fellow of the American College of Dentistry, Dr. Berman has been in full-time private practice in Annapolis, Maryland since 1983.

ILAN ROTSTEIN

Dr. Rotstein is Professor and Chair of Endodontics, Orthodontics, and General Practice Residency and Associate Dean at the Herman Ostrow School of Dentistry of the University of Southern California in Los Angeles. He is on the Executive Leadership Team of the School of Dentistry and ambassador member of the University of Southern California.

He has served in leadership roles for various dental organizations, including chair of the International Federation of Endodontic Associations' Research Committee, member on committees of the American Association of Endodontists, European Society of Endodontology, and as scientific reviewer for international endodontic and dental journals. He has also served as president of the Southern California Academy of Endodontists, Israel Endodontic Society, International Association for Dental Research—Israel Division, and chair of the Israel National Board of Diplomates in Endodontics.

Dr. Rotstein has published more than 150 scientific papers and research abstracts in the dental literature as well as chapters in international endodontic textbooks, including *Pathways of the Pulp*, *Ingle's Endodontics*, *Endodontics: Principles and Practice*, *Seltzer and Bender's Dental Pulp*, and *Harty's Endodontics in Clinical Practice*. He has lectured extensively in more than 25 countries throughout 5 continents.

Stephen Cohen
MA, DDS, FICD, FACD

The field of endodontics would be difficult to imagine without *Pathways of the Pulp*. In speaking with colleagues across North America and around the world, it becomes clear that *Pathways* has had an immense, ubiquitous, and persistent impact on endodontics. This enduring contribution to our specialty is due to the genius of Stephen Cohen, who, together with Richard Burns, developed the most distinguished and perpetually updated evidenced-based textbook in our specialty. Their insight was to form a collaboration of the most renowned experts in our field, with expansion of the authorships for each new edition, and with an unwavering emphasis on the art and science of contemporary endodontic therapy. The result was a textbook that is both comprehensive and nuanced, which has transcended 11 editions and 14 languages since 1976. As each edition of *Pathways* evolved, it changed with the times, updating from unquestionable dogma into what was later considered the novel state of the art. Each edition progressed through the decades of endodontics and was inclusive of the next generation of technologies, philosophies, materials, devices, and instruments. As a result, with Steve as the lead editor since its inception, *Pathways of the Pulp* is considered the most comprehensive and innovative endodontic textbook available, literally defining the field of endodontics.

Stephen is an active educator, having lectured for decades around the world and serving as a Clinical Professor of Endodontics at the Arthur A. Dugoni School of Dentistry of the University of the Pacific. His passion for teaching, coupled with his distinctive authoritative voice and his vast scientific and clinical expertise, generates a highly effective combination for educating students on every facet of the endodontic specialty. His steadfast commitment in his authoring and editing of *Pathways of the Pulp* has propelled this textbook into what it is today.

In short, Dr. Stephen Cohen is a renaissance man, being both a practitioner and a teacher, whose breadth of expertise is leveraged by a passionate focus on detail and clarity. Defined by his unquestionable ethics and pursuit of perfection, Stephen's philosophy of learning, teaching, and practicing endodontics can best be summed up in his own words, as he penned in the Introduction of his last edition of *Pathways*:

"As clinicians we must meet this rich convergence of discovery and invention with an equally rich commitment to continuous learning, exposing ourselves to all the science our field has to offer. This is our duty to our founders, this is our responsibility to our patients, and this is our gift to ourselves."

Steve is a pioneer who has transformed the field of endodontics. For the tenth edition of this textbook, we recognized his legacy by renaming this textbook *Cohen's Pathways of the Pulp*. We reinforce our esteem appreciation of him by dedicating this eleventh edition to our mentor and friend, Dr. Stephen Cohen.

New to This Edition

EIGHT NEW CHAPTERS

Chapter 2: Radiographic Interpretation covers imaging modalities, diagnostic tasks in endodontics, three-dimensional imaging, cone beam computed tomography, intraoperative or postoperative assessment of endodontic treatment complications, and more!

Chapter 4: Pain Control looks at two overarching topics: local anesthesia for restorative dentistry and endodontics and analgesics and therapeutic recommendations.

Chapter 11: Evaluation of Outcomes covers the reasons for evaluating treatment outcomes, outcome measurements for endodontic treatment, the outcomes of vital pulp therapy procedures, nonsurgical root canal treatment, nonsurgical retreatment, and surgical retreatment.

Chapter 16: Root Resorption looks at the histological features of root resorption, external inflammatory resorption, external cervical resorption, and internal resorption.

Chapter 19: Managing Iatrogenic Endodontic Events looks at treatment scenarios for eight different iatrogenic events: cervicofacial subcutaneous emphysema, sodium hypochlorite accidents, perforations (nonsurgical), inferior alveolar nerve injury (surgical), sinus perforation, instrument separation, apical extrusion of obturation materials, and ledge formation.

Chapter 21: Cracks and Fractures looks at three categories of cracks and fractures: cracked and fractured cusps, cracked and split teeth, and vertical root fractures, emphasizing the early diagnosis of these conditions.

Chapter 23: Vital Pulp Therapy addresses the living pulp, pulpal response to caries, procedures for generating reparative dentin, indications and materials for vital pulp therapy, MTA applications, treatment recommendations, and more!

Chapter 27: Bleaching Procedures provides a review of internal and external bleaching procedures, their impact on pulpal health/endodontic treatment, with presentations of cases and clinical protocols.

NEW CHAPTER ORGANIZATION

Chapters have been reorganized and grouped into three parts: Part I: *The Core Science of Endodontics*, Part II: *The Advanced Science of Endodontics*, and Part III: *Expanded Clinical Topics*. The seven chapters in Part 1 focus on the core clinical concepts for dental students; the chapters in Parts II and III provide the information that advanced students and endodontic residents and clinicians need to know. In addition, seven additional chapters are included in the online version.

The new organization better reflects the chronology of endodontic treatment.

EXPERT CONSULT

New features included on the Expert Consult site include:

- Seven chapters exclusively online:
  - *Chapter 24: Pediatric Endodontics: Endodontic Treatment for the Primary and Young Dentition*
  - *Chapter 25: Endodontic and Periodontic Interrelationships*
  - *Chapter 26: Effects of Age and Systemic Health on Endodontics*
  - *Chapter 27: Bleaching Procedures*
  - *Chapter 28: Understanding and Managing the Fearful Dental Patient*
  - *Chapter 29: Endodontic Records and Legal Responsibilities*
  - *Chapter 30: Key Principles of Endodontic Practice Management*

- Twelve lecture modules consisting of assigned readings, PowerPoint slides, written objectives for each lecture, and suggested examination questions. Topics covered include:
  - Diagnosis
  - Treatment planning
  - Pain control
  - Isolation
  - Cleaning and shaping
  - Obturation
  - Surgery
  - Assessment of outcomes
  - Pulp biology
  - Pathobiology
  - Emergencies
  - Restoration

- New videos and animations

Introduction

ENDODONTICS: A VIEW OF THE FUTURE

The Editors have had the privilege of "standing on the shoulders" of our generous contributors, enabling us to "look over the horizon" to gain a glimpse at our endodontic future. As we advance into the years ahead, we will incorporate even more refined and accurate improvements in pulpal diagnosis, canal cleaning and disinfection, canal obturation, and surgical enhancements.

In looking more clearly toward our impending endeavors, it becomes important to scrutinize the deficiencies of our past and present. Over the past several decades we have gone from arsenic to sodium hypochlorite, from bird droppings to gutta percha, from hand files to motor-driven files, from culturing to one-visit appointments, from two-dimensional to three-dimensional radiography, and from pulp removal to pulpal regeneration. And still, the clinical and academic controversies are pervasive. So, where will the future of our specialty take us?

With patients living longer and with the inescapable comparison of endodontics to endosseous implants, the demand for endodontic excellence has greatly increased. To that end, we suspect that future evidence-based approaches will continue to question the longevity of successful implant retention, intensifying the need for more predictable endodontic outcomes.

Surprisingly, we still base our diagnosis on a presumed and almost subjective pulpal status. Imagine a future in which endodontic diagnosis could be more objective by non-invasively scanning the pulp tissue. Imagine algorithms built into all digital radiography for interpreting and extrapolating disease processes. CBCT has made a huge impact on endodontic diagnosis, but can we enhance these digital captures with a resolution that would approach micro-computed tomography, and with less radiation? Will non-radiation imaging methods such as MRI (magnetic resonance imaging) leave the dental research clinic to provide a novel solution to address these issues? Will it be CT technology or some other form of detection for dramatically enhancing our guidance during surgical and nonsurgical treatment in order to both maximize our precision and minimize tooth structure and associated tissue removal? Considering the differences in color and consistency of the tissues within the pulp chamber, future technology may permit us to better discriminate these differences and enhance our ability for more precision when negotiating the openings to these canals. And as for clinical visualization: will there be digital or electronic enhancements of conventional loupes? Will 3-D visualization and monitor-based observation change the way we visualize and implement our procedures? During our canal cleaning and shaping, we are lucky if we can debride half of the pulpal tissues within all of the canal ramifications; however, we still use an irrigant that is so toxic by a non-selective mechanism, such that when inadvertently extruded beyond the canal system it can cause severe tissue damage. Our future technology should guide us to obtain the complete removal of organic debris within the pulpal spaces while obtaining complete canal disinfection—and without the potential morbidity from toxic non-selective chemicals. We still use files that can inadvertently separate. The resolution may be in a complete transformation in metallurgy or even the implementation of other non-metal cutting materials. Our obturation material is one of the worst filling materials in dentistry. Hopefully, the future evolution of obturation will lead us to a totally leakage-free, non-neurotoxic, and biocompatible substance that will three-dimensionally expand into *all* microscopic canal ramifications and stop when there is no more space to expand to, being limited to when it reaches the periodontal ligament. Will this obturating material be newly regenerated vital pulp?

Clearly, it is evident that our endodontic future lies in out-of-the-box thinking with the next generation of transformations coming with collaborations not just from within the biological sciences, but rather in conjunction with physicists, chemists, engineers, and a multitude of other great innovative minds. The predictability of endodontics must be incontestable, not just with better technology to guide us toward greater success, but also to better elucidate exactly when endodontics *cannot* be successful. Our future needs to focus on predictability, which will only be achieved by reinventing the wheel with disruptive technologies, rather than persisting with variations and modifications of our current convictions.

As a specialty, we have advanced by leaps and bounds since our inception, but we are still in our infancy with a brilliant future ahead of us. Since 1976 and with 11 editions, *Pathways of the Pulp* has always been about the art and science of endodontics. The dedicated contributing authors have generously given their time to meticulously describe what is considered the state of the art of our specialty. We are hopeful that future editions will guide us toward enhanced endodontic outcomes, with the never-ending pursuit of endodontic excellence.

Contents

PART I: THE CORE SCIENCE OF ENDODONTICS, 1

1 **Diagnosis,** *2*
Louis H. Berman and Ilan Rotstein

2 **Radiographic Interpretation,** *33*
Madhu K. Nair, Martin D. Levin, and Umadevi P. Nair

3 **Case Selection and Treatment Planning,** *71*
Paul A. Rosenberg and Matthew Malek

4 **Pain Control,** *90*
Al Reader, John Nusstein, and Asma Khan

5 **Tooth Morphology, Isolation, and Access,** *130*
James L. Gutmann and Bing Fan

6 **Cleaning and Shaping the Root Canal System,** *209*
Ove A. Peters, Christine I. Peters, and Bettina Basrani

7 **Obturation of the Cleaned and Shaped Root Canal System,** *280*
William Johnson, James C. Kulild, and Franklin Tay

PART II: THE ADVANCED SCIENCE OF ENDODONTICS, 323

8 **Nonsurgical Retreatment,** *324*
Robert S. Roda and Bradley H. Gettleman

9 **Periradicular Surgery,** *387*
Bradford R. Johnson and Mohamed I. Fayad

10 **Regenerative Endodontics,** *447*
Anibal Diogenes, Stéphane Simon, and Alan S. Law

11 **Evaluation of Outcomes,** *474*
Yuan-Ling Ng and Kishor Gulabivala

12 **Structure and Functions of the Dentin-Pulp Complex,** *532*
Inge Fristad and Ellen Berggreen

13 **Pulpal Reactions to Caries and Dental Procedures,** *573*
Ashraf Fouad and Linda G. Levin

14 **Microbiology of Endodontic Infections,** *599*
José F. Siqueira, Jr. and Isabela N. Rôças

15 **Pathobiology of Apical Periodontitis,** *630*
Louis M. Lin and George T.-J. Huang

16 **Root Resorption,** *660*
Shanon Patel, Conor Durack, and Domenico Ricucci

17 **Diagnosis of Nonodontogenic Toothache,** *684*
Donna Mattscheck, Alan S. Law, and Donald R. Nixdorf

18 **Management of Endodontic Emergencies,** *706*
Samuel O. Dorn and Gary Shun-Pan Cheung

19 **Managing Iatrogenic Endodontic Events,** *722*
Yoshitsugu Terauchi

PART III: EXPANDED CLINICAL TOPICS, 757

20 **The Role of Endodontics After Dental Traumatic Injuries,** *758*
Martin Trope, Frederic Barnett, Asgeir Sigurdsson, and Noah Chivian

21 **Cracks and Fractures,** *793*
Zvi Metzger, Louis H. Berman, and Aviad Tamse

22 **Restoration of the Endodontically Treated Tooth,** *818*
Didier Dietschi, Serge Bouillaguet, and Avishai Sadan

23 **Vital Pulp Therapy,** *849*

ART AND SCIENCE OF DIAGNOSIS

Diagnosis is the art and science of detecting and distinguishing deviations from health and the cause and nature thereof.[6] The purpose of a diagnosis is to determine what problem the patient is having and why the patient is having that problem. Ultimately, this will directly relate to what treatment, if any, will be necessary. No appropriate treatment recommendation can be made until all of the *whys* are answered. Therefore, careful data gathering as well as a planned, methodical, and systematic approach to this investigatory process is crucial.

Gathering objective data and obtaining subjective findings are not enough to formulate an accurate clinical diagnosis. The data must be interpreted and processed to determine what information is significant, and what information might be questionable. The facts need to be collected with an active dialogue between the clinician and the patient, with the clinician asking the right questions and carefully interpreting the answers. In essence, the process of determining the existence of an oral pathosis is the culmination of the art and science of making an accurate diagnosis.

The process of making a diagnosis can be divided into five stages:

1. The patient tells the clinician the reasons for seeking advice.
2. The clinician questions the patient about the symptoms and history that led to the visit.
3. The clinician performs objective clinical tests.
4. The clinician correlates the objective findings with the subjective details and creates a tentative list of differential diagnoses.
5. The clinician formulates a definitive diagnosis.

This information is accumulated by means of an organized and systematic approach that requires considerable clinical judgment. The clinician must be able to approach the problem by crafting what questions to ask the patient and how to ask these pertinent questions. Careful listening is paramount to begin painting the picture that details the patient's complaint. These subjective findings combined with results of diagnostic tests provide the critical information needed to establish the diagnosis.

Neither the art nor the science is effective alone. Establishing a differential diagnosis in endodontics requires a unique blend of knowledge, skills, and ability to interpret and interact with a patient in real time. Questioning, listening, testing, interpreting, and finally answering the ultimate question of *why* will lead to an accurate diagnosis and in turn result in a more successful treatment plan.

Chief Complaint

On arrival for a dental consultation, the patient should complete a thorough registration that includes information pertaining to medical and dental history (Figs. 1-1 and 1-2). This should be signed and dated by the patient, as well as initialed by the clinician as verification that all of the submitted information has been reviewed (see Chapter 29 for more information).

The reasons patients give for consulting with a clinician are often as important as the diagnostic tests performed. Their remarks serve as initial important clues that will help the clinician to formulate a correct diagnosis. Without these direct and unbiased comments, objective findings may lead to an incorrect diagnosis. The clinician may find a dental pathosis, but it may not contribute to the pathologic condition that mediates the patient's chief complaint. Investigating these complaints may indicate that the patient's concerns are related to a medical condition or to recent dental treatment. Certain patients may

TELL US ABOUT YOUR SYMPTOMS

LAST NAME _____ **FIRST NAME** _____

1. Are you experiencing any pain at this time? If not, please go to question 6. Yes _____ No _____
2. If yes, can you locate the tooth that is causing the pain? Yes _____ No _____
3. When did you first notice the symptoms? _____
4. Did your symptoms occur suddenly or gradually? _____
5. Please check the frequency and quality of the discomfort, and the number that most closely reflects the intensity of your pain:

LEVEL OF INTENSITY (On a scale of 1 to 10) 1 = Mild 10 = Severe	FREQUENCY	QUALITY
1___2___3___4___5___6___7___8___9___10___	_____ Constant	_____ Sharp
	_____ Intermittent	_____ Dull
	_____ Momentary	_____ Throbbing
	_____ Occasional	

Is there anything you can do to relieve the pain? Yes _____ No _____

If yes, what? _____

Is there anything you can do to cause the pain to increase? Yes _____ No _____

If yes, what? _____

When eating or drinking, is your tooth sensitive to: Heat _____ Cold _____ Sweets _____

Does your tooth hurt when you bite down or chew? Yes _____ No _____

Does it hurt if you press the gum tissue around this tooth? Yes _____ No _____

Does a change in posture (lying down or bending over) cause your tooth to hurt? Yes _____ No _____

6. Do you grind or clench your teeth? Yes _____ No _____
7. If yes, do you wear a night guard? Yes _____ No _____
8. Has a restoration (filling or crown) been placed on this tooth recently? Yes _____ No _____
9. Prior to this appointment, has root canal therapy been initiated on this tooth? Yes _____ No _____
10. Is there anything else we should know about your teeth, gums, or sinuses that would assist us in our diagnosis? _____

Signed: Patient or Parent _____ **Date** _____

FIG. 1-1 Dental history form that also allows the patient to record pain experience in an organized and descriptive manner.

TELL US ABOUT YOUR HEALTH

LAST NAME _____ **FIRST NAME** _____

FIG. 1-2 Succinct, comprehensive medical history form designed to provide insight into systemic conditions that could produce or affect the patient's symptoms, mandate alterations in treatment modality, or change the treatment plan.

even receive initial emergency treatment for pulpal or periapical symptoms in a general hospital.[93] On occasion, the chief complaint is simply that another clinician correctly or incorrectly advised the patient that he or she had a dental problem, with the patient not necessarily having any symptoms or any objective pathosis. Therefore, the clinician must pay close attention to the actual expressed complaint, determine the chronology of events that led to this complaint, and question the patient about other pertinent issues, including medical and dental history. For future reference and in order to ascertain a correct diagnosis, the patient's chief complaint should be properly documented, using *the patient's own words*.

Medical History

The clinician is responsible for taking a proper medical history from every patient who presents for treatment. Numerous examples of medical history forms are available from a variety of sources, or clinicians may choose to customize their own forms. After the form is completed by the patient, or by the parent or guardian in the case of a minor, the clinician should review the responses with the patient, parent, or guardian and then initial the medical history form to indicate that this review has been done. The patient "of record" should be questioned at each treatment visit to determine whether there have been any changes in the patient's medical history or medications. A more thorough and complete update of the patient's medical history should be taken if the patient has not been seen for over a year.[51,52]

Baseline blood pressure and pulse should be recorded for the patient at each treatment visit. Elevation in blood pressure or a rapid pulse rate may indicate an anxious patient who may require a stress reduction protocol, or it may indicate that the patient has hypertension or other cardiovascular health problems. Referral to a physician or medical facility may be indicated. It is imperative that vital signs be gathered at each treatment visit for any patient with a history of major medical problems. The temperature of patients presenting with subjective fever or any signs or symptoms of a dental infection should be taken.[57,80,105]

The clinician should evaluate a patient's response to the health questionnaire from two perspectives: (1) those medical conditions and current medications that will necessitate altering the manner in which dental care will be provided and (2) those medical conditions that may have oral manifestations or mimic dental pathosis.

Patients with serious medical conditions may require either a modification in the manner in which the dental care will be delivered or a modification in the dental treatment plan (Box 1-1). In addition, the clinician should be aware if the patient has any drug allergies or interactions, allergies to dental products, an artificial joint prosthesis, organ transplants, or is taking medications that may negatively interact with common local anesthetics, analgesics, sedatives, and antibiotics.[80] This may seem overwhelming, but it emphasizes the importance of obtaining a thorough and accurate medical history while considering the various medical conditions and dental treatment modifications that may be necessary before dental treatment is provided.

Several medical conditions have oral manifestations, which must be carefully considered when attempting to arrive at an accurate dental diagnosis. Many of the oral soft tissue changes that occur are more related to the medications used to treat the medical condition rather than to the condition itself. More common examples of medication side effects are stomatitis, xerostomia, petechiae, ecchymoses, lichenoid mucosal lesions, and bleeding of the oral soft tissues.[80]

When developing a dental diagnosis, a clinician must also be aware that some medical conditions can have clinical presentations that mimic oral pathologic lesions.[13,28,32,74,80,102,107,133] For example, tuberculosis involvement of the cervical and submandibular lymph nodes can lead to a misdiagnosis of lymph node enlargement secondary to an odontogenic infection. Lymphomas can involve these same lymph nodes.[80] Immunocompromised patients and patients with uncontrolled diabetes mellitus respond poorly to dental treatment and may exhibit recurring abscesses in the oral cavity that must be differentiated from abscesses of dental origin.[43,76,80,83] Patients with iron deficiency anemia, pernicious anemia, and leukemia frequently exhibit paresthesia of the oral soft tissues. This finding may complicate making a diagnosis when other dental pathosis is present in the same area of the oral cavity. Sickle cell anemia has the complicating factor of bone pain, which mimics odontogenic pain, and loss of trabecular bone pattern on radiographs, which can be confused with radiographic lesions of endodontic origin. Multiple myeloma can result in unexplained mobility of teeth. Radiation therapy to the head and neck region can result in increased sensitivity of the teeth and osteoradionecrosis.[80] Trigeminal neuralgia, referred pain from cardiac angina, and multiple sclerosis can also mimic dental pain (see also Chapter 17). Acute maxillary sinusitis is a common condition that may create diagnostic confusion because it may mimic tooth pain in the maxillary posterior quadrant. In this situation the teeth in the quadrant may be extremely sensitive to cold and percussion, thus mimicking the signs and symptoms of pulpitis. This is certainly not a complete list of all the medical entities that can mimic dental disease, but it should alert the clinician that a medical problem could confuse and complicate

BOX 1-1

Medical Conditions That Warrant Modification of Dental Care or Treatment

Cardiovascular: High- and moderate-risk categories of endocarditis, pathologic heart murmurs, hypertension, unstable angina pectoris, recent myocardial infarction, cardiac arrhythmias, poorly managed congestive heart failure[57,80,105]

Pulmonary: Chronic obstructive pulmonary disease, asthma, tuberculosis[80,129]

Gastrointestinal and renal: End-stage renal disease; hemodialysis; viral hepatitis (types B, C, D, and E); alcoholic liver disease; peptic ulcer disease; inflammatory bowel disease; pseudomembranous colitis[25,34,48,80]

Hematologic: Sexually transmitted diseases, HIV and AIDS, diabetes mellitus, adrenal insufficiency, hyperthyroidism and hypothyroidism, pregnancy, bleeding disorders, cancer and leukemia, osteoarthritis and rheumatoid arthritis, systemic lupus erythematosus[35,43,76,80,83,88,100,135]

Neurologic: Cerebrovascular accident, seizure disorders, anxiety, depression and bipolar disorders, presence or history of drug or alcohol abuse, Alzheimer disease, schizophrenia, eating disorders, neuralgias, multiple sclerosis, Parkinson disease[36,44,80]

the diagnosis of dental pathosis; this issue is discussed in more detail in subsequent chapters.

If, at the completion of a thorough dental examination, the subjective, objective, clinical testing and radiographic findings do not result in a diagnosis with an obvious dental origin, then the clinician must consider that an existing medical problem could be the true source of the pathosis. In such instances, a consultation with the patient's physician is always appropriate.

Dental History

The chronology of events that lead up to the chief complaint is recorded as the *dental history*. This information will help guide the clinician as to which diagnostic tests are to be performed. The history should include any past and present symptoms, as well as any procedures or trauma that might have evoked the chief complaint. Proper documentation is imperative. It may be helpful to use a premade form to record the pertinent information obtained during the dental history interview and diagnostic examination. Often a SOAP format is used, with the history and findings documented under the categories of *S*ubjective, *O*bjective, *A*ppraisal, and *P*lan. There are also built-in features within some practice management software packages that allow digital entries into the patient's electronic file for the diagnostic workup (Figs. 1-3 and 1-4).

History of Present Dental Problem

The dialogue between the patient and the clinician should encompass all of the details pertinent to the events that led to the chief complaint. The clinician should direct the conversation in a manner that produces a clear and concise narrative that chronologically depicts all of the necessary information about the patient's symptoms and the development of these symptoms. To help elucidate this information, the patient is first instructed to fill out a dental history form as a part of the patient's office registration. This information will help the clinician decide which approach to use when asking the patient questions. The interview first determines *what is going on* in an effort to determine *why is it going on* for the purpose of eventually determining *what is necessary to resolve the chief complaint*.

Dental History Interview

After starting the interview and determining the nature of the chief complaint, the clinician continues the conversation by documenting the sequence of events that initiated the request for an evaluation. The dental history is divided into five basic directions of questioning: localization, commencement, intensity, provocation and attenuation, and duration.

Localization. "Can you point to the offending tooth?" Often the patient can point to or tap the offending tooth. This is the most fortunate scenario for the clinician because it helps direct the interview toward the events that might have caused any particular pathosis in this tooth. In addition, localization allows subsequent diagnostic tests to focus more on this particular tooth. When the symptoms are not well localized, the diagnosis is a greater challenge.

Commencement. "When did the symptoms first occur?" A patient who is having symptoms often remembers when these symptoms started. Sometimes the patient will even remember the initiating event: it may have been spontaneous in nature; it may have begun after a dental visit for a restoration; trauma may be the etiology, biting on a hard object may have initially produced the symptoms, or the initiating event may have occurred concurrently with other symptoms (sinusitis, headache, chest pain, etc.). However, the clinician should resist the tendency to make a premature diagnosis based on these circumstances. The clinician should not simply assume "guilt by association" but instead should use this information to enhance the overall diagnostic process.

Intensity. "How intense is the pain?" It often helps to quantify how much pain the patient is actually having. The clinician might ask, "On a scale from 1 to 10, with 10 the most severe, how would you rate your symptoms?" Hypothetically, a patient could present with "an uncomfortable sensitivity to cold" or "an annoying pain when chewing" but might rate this "pain" only as a 2 or a 3. These symptoms certainly contrast with the type of symptoms that prevent a patient from sleeping at night. Often the intensity can be subjectively measured by what is necessary for the diminution of pain—for example, acetaminophen versus a narcotic pain reliever. This intensity level may affect the decision to treat or not to treat with endodontic therapy. Pain is now considered a standard vital sign, and documenting pain intensity (scale of 0 to 10) provides a baseline for comparison after treatment.

Provocation and attenuation. "What produces or reduces the symptoms?" Mastication and locally applied temperature changes account for the majority of initiating factors that cause dental pain. The patient may relate that drinking something cold causes the pain or possibly that chewing or biting is the only stimulus that "makes it hurt." The patient might say that the pain is only reproduced on "release from biting." On occasion, a patient may present to the dental office with a cold drink in hand and state that the symptoms can only be *reduced* by bathing the tooth in cold water. Nonprescription pain relievers may relieve some symptoms, whereas narcotic medication may be required to reduce others (see Chapter 4 for more information). Note that patients who are using narcotic as well as non-narcotic (e.g., ibuprofen) analgesics may respond differently to questions and diagnostic tests, thereby altering the validity of diagnostic results. Thus, it is important to know what drugs patients have taken in the previous 4 to 6 hours. These provoking and relieving factors may help the clinician to determine which diagnostic tests should be performed to establish a more objective diagnosis.

Duration. "Do the symptoms subside shortly, or do they linger after they are provoked?" The difference between a cold sensitivity that subsides in a few seconds and one that subsides in minutes may determine whether a clinician repairs a defective restoration or provides endodontic treatment. The duration of symptoms after a stimulating event should be recorded to establish how long the patient felt the sensation in terms of seconds or minutes. Clinicians often first test control teeth (possibly including a contralateral "normal" tooth) to define a "normal" response for the patient; thus, "lingering" pain is apparent when comparing the duration between the control teeth and the suspected tooth.

With the dental history interview complete, the clinician has a better understanding of the patient's chief complaint and can concentrate on making an objective diagnostic evaluation,

although the subjective (and artistic) phase of making a diagnosis is not yet complete and will continue after the more objective testing and scientific phase of the investigatory process.

EXAMINATION AND TESTING

Extraoral Examination

Basic diagnostic protocol suggests that a clinician observe patients as they enter the operatory. Signs of physical limitations may be present, as well as signs of facial asymmetry that result from facial swelling. Visual and palpation examinations of the face and neck are warranted to determine whether swelling is present. Many times a facial swelling can be determined only by palpation when a unilateral "lump or bump" is present. The presence of bilateral swellings may be a normal finding for any given patient; however, it may also be a sign of a systemic disease or the consequence of a developmental event. Palpation allows the clinician to determine whether the swelling is localized or diffuse, firm or fluctuant. These latter findings will play a significant role in determining the appropriate treatment.

Palpation of the cervical and submandibular lymph nodes is an integral part of the examination protocol. If the nodes are found to be firm and tender along with facial swelling and an elevated temperature, there is a high probability that an infection is present. The disease process has moved from a localized area immediately adjacent to the offending tooth to a more widespread systemic involvement.

Extraoral facial swelling of odontogenic origin typically is the result of endodontic etiology because diffuse facial swelling resulting from a periodontal abscess is rare. Swellings of nonodontogenic origin must always be considered in the differential diagnosis, especially if an obvious dental pathosis is not found.[77] This situation is discussed in subsequent chapters.

FIG. 1-6 Buccal space swelling associated with an acute periradicular abscess from the mandibular left second molar.

A subtle visual change such as loss of definition of the nasolabial fold on one side of the nose may be the earliest sign of a canine space infection (Fig. 1-5). Pulpal necrosis and periradicular disease associated with a maxillary canine should be suspected as the source of the problem. Extremely long maxillary central incisors may also be associated with a canine space infection, but most extraoral swellings associated with the maxillary centrals express themselves as a swelling of the upper lip and base of the nose.

If the buccal space becomes involved, the swelling will be extraoral in the area of the posterior cheek (Fig. 1-6). These swellings are generally associated with infections originating from the buccal root apices of the maxillary premolar and molar teeth and the mandibular premolar (Fig. 1-7) and first molar teeth. The mandibular second and third molars may also be involved, but infections associated with these two teeth are just as likely to exit to the lingual where other spaces

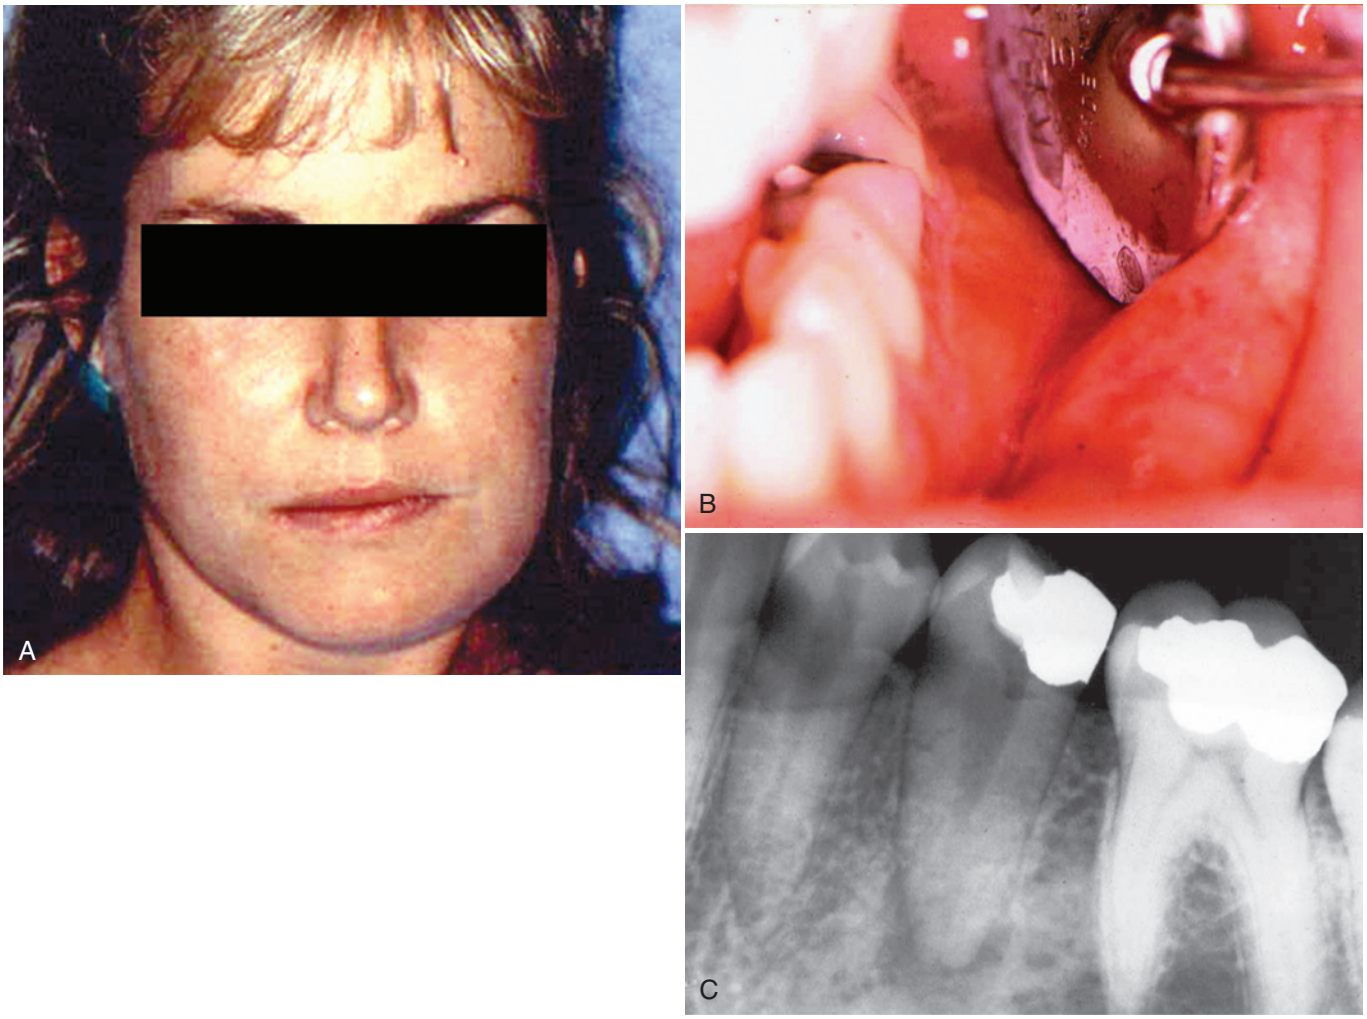

FIG. 1-7 A, Buccal space swelling of the left side of the patient's face. Note the asymmetry of the left side of the face. B, Intraoral view shows swelling present in the left posterior mucobuccal fold. C, This buccal space infection was associated with periradicular disease from the mandibular left second premolar. Note on the radiograph the periradicular radiolucency and large restoration associated with this tooth.

would be involved. For infections associated with these teeth, the root apices of the maxillary teeth must lie superior to the attachment of the buccinator muscle to the maxilla, and the apices of the mandibular teeth must be inferior to the buccinator muscle attachment to the mandible.[77]

Extraoral swelling associated with mandibular incisors will generally exhibit itself in the submental (Fig. 1-8) or submandibular space. Infections associated with any mandibular teeth, which exit the alveolar bone on the lingual and are inferior to the mylohyoid muscle attachment, will be noted as swelling in the submandibular space. Further discussions of fascial space infections may be found in Chapter 14.

Sinus tracts of odontogenic origin may also open through the skin of the face (Figs. 1-9 and 1-10).[2,56,64] These openings in the skin will generally close once the offending tooth is treated and healing occurs. A scar is more likely to be visible on the skin surface in the area of the sinus tract stoma than on the oral mucosal tissues (Fig. 1-10, *C* and *D*). Many patients with extraoral sinus tracts give a history of being treated by general physicians, dermatologists, or plastic surgeons with systemic or topical antibiotics or surgical procedures in

FIG. 1-8 Swelling of the submental space associated with periradicular disease from the mandibular incisors.

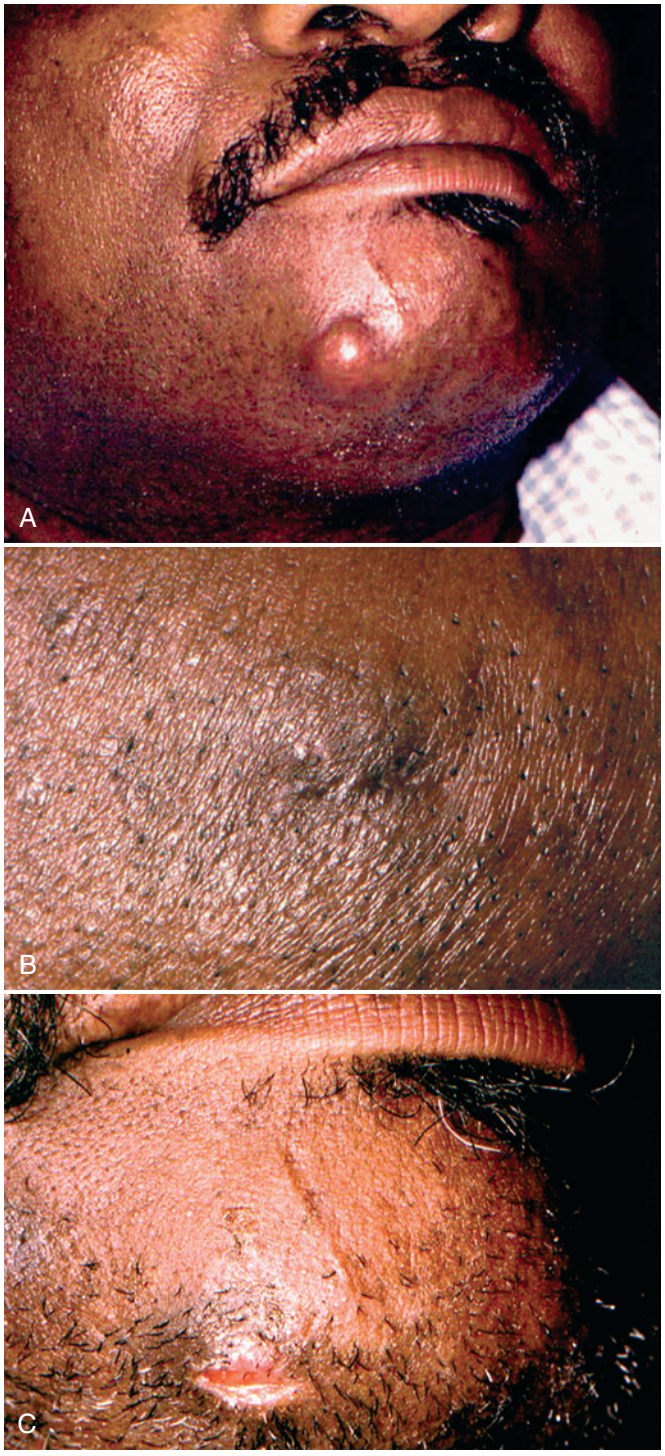

FIG. 1-9 A, Extraoral drainage associated with periradicular disease from the mandibular right canine. Note the parulis on the right anterior side of the face. attempts to heal the extraoral stoma. In these particular cases, after multiple treatment failures, the patients may finally be referred to a dental clinician to determine whether there is a dental cause. Raising the awareness of physicians to such cases will aid in more accurate diagnosis and faster referral to the dentist or endodontist.

Intraoral Examination

The intraoral examination may give the clinician insight as to which intraoral areas may need a more focused evaluation. Any abnormality should be carefully examined for either prevention or early treatment of associated pathosis.[4,30,75,113,110,126] Swelling, localized lymphadenopathy, or a sinus tract should provoke a more detailed assessment of related and proximal intraoral structures.

Soft Tissue Examination

As with any dental examination, there should be a routine evaluation of the intraoral soft tissues. The gingiva and mucosa should be dried with either a low-pressure air syringe or a 2-by-2-inch gauze pad. By retracting the tongue and cheek, all of the soft tissue should be examined for abnormalities in color or texture. Any raised lesions or ulcerations should be documented and, when necessary, evaluated with a biopsy or referral.[82]

Intraoral Swelling

Intraoral swellings should be visualized and palpated to determine whether they are diffuse or localized and whether they are firm or fluctuant. These swellings may be present in the attached gingiva, alveolar mucosa, mucobuccal fold, palate, or sublingual tissues. Other testing methods are required to determine whether the origin is endodontic, periodontic, or a combination of these two or whether it is of nonodontogenic origin.

Swelling in the anterior part of the palate (Fig. 1-11) is most frequently associated with an infection present at the apex of the maxillary lateral incisor or the palatal root of the maxillary first premolar. More than 50% of the maxillary lateral incisor root apices deviate in the distal or palatal directions. A swelling in the posterior palate (Fig. 1-12) is most likely associated with the palatal root of one of the maxillary molars.[77]

Intraoral swelling present in the mucobuccal fold (Fig. 1-13) can result from an infection associated with the apex of the root of any maxillary tooth that exits the alveolar bone on the facial aspect and is inferior to the muscle attachment present in that area of the maxilla (see also Chapter 14). The same is true with the mandibular teeth if the root apices are superior to the level of the muscle attachments and the infection exits the bone on the facial. Intraoral swelling can also occur in the sublingual space if the infection from the root apex spreads to the lingual and exits the alveolar bone superior to the attachment for the mylohyoid muscle. The tongue will be elevated and the swelling will be bilateral because the sublingual space is contiguous with no midline separation. If the infection exits the alveolar bone to the lingual with mandibular molars and is inferior to the attachment of the mylohyoid muscle, the swelling will be noted in the submandibular space. Severe infections involving the maxillary and mandibular molars can extend into the parapharyngeal space, resulting in intraoral swelling of the tonsillar and pharyngeal areas. This can be life threatening if the patient's airway becomes obstructed.[77,80]

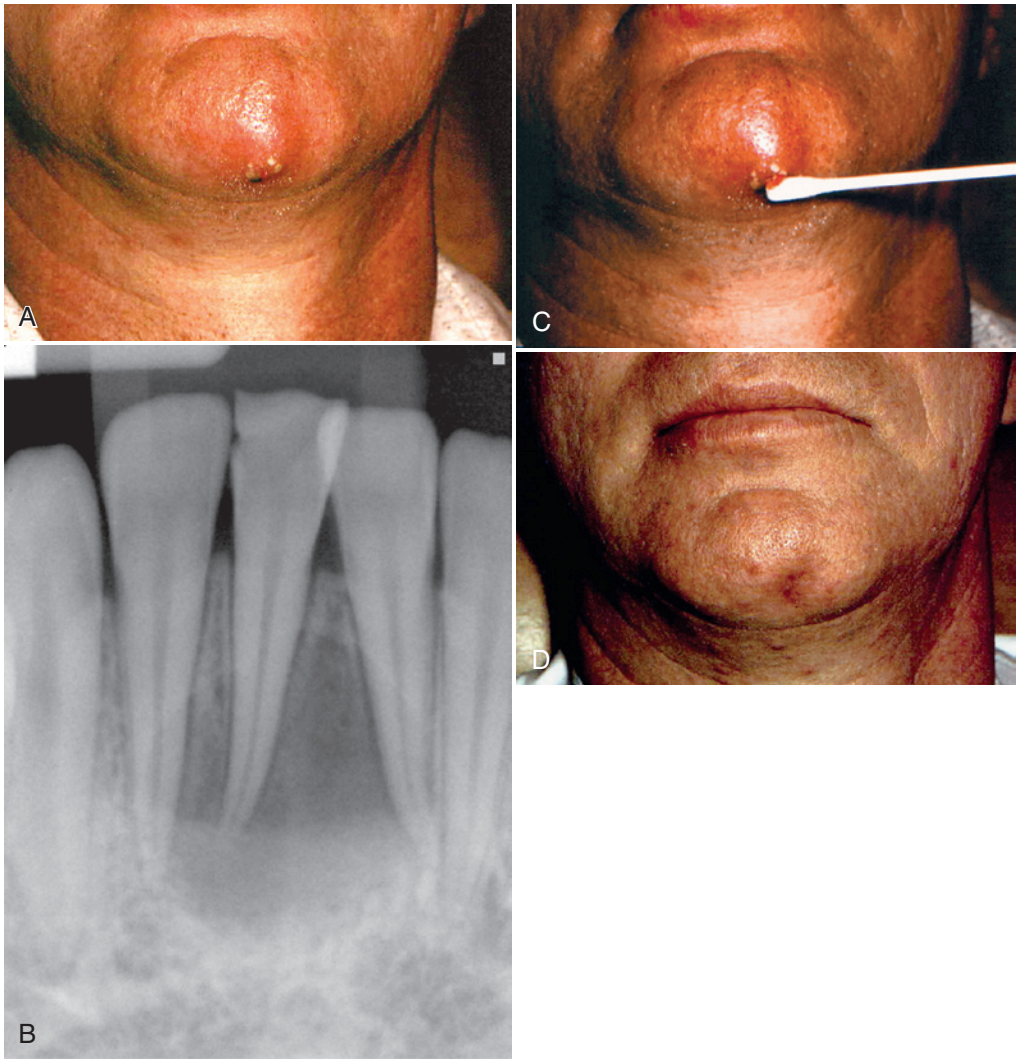

FIG. 1-10 A, Extraoral sinus tract opening onto the skin in the central chin area. B, Radiograph showing large radiolucency associated with the mandibular incisors. C, A culture is obtained from the drainage of the extraoral sinus tract. D, The healed opening of the extraoral sinus tract 1 month after root canal therapy was completed. Note the slight skin concavity in the area of the healed sinus tract.

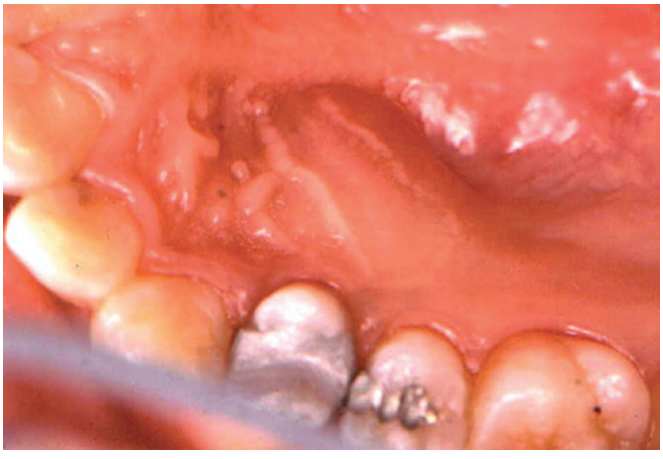

FIG. 1-11 Fluctuant swelling in the anterior palate associated with periradicular disease from the palatal root of the maxillary first premolar.

Intraoral Sinus Tracts

On occasion, a chronic endodontic infection will drain through an intraoral communication to the gingival surface and is known as a *sinus tract*.[12] This pathway, which is sometimes lined with epithelium, extends directly from the source of the infection to a surface opening, or *stoma,* on the attached gingival surface. As previously described, it can also extend extraorally. The term *fistula* is often inappropriately used to describe this type of drainage. The fistula, by definition, is actually an abnormal communication pathway between two internal organs or from one epithelium-lined surface to another epithelium-lined surface.[6]

Histologic studies have found that most sinus tracts are not lined with epithelium throughout their entire length. One study found that only 1 out of the 10 sinus tracts examined were lined with epithelium, whereas the other nine specimens were lined with granulation tissue.[55] Another study, with a larger sample size, found that two thirds of the specimens did not have epithelium extending beyond the level of the surface mucosa rete ridges.[12] The remaining specimens had some

FIG. 1-12 Fluctuant swelling in the posterior palate associated with periradicular disease from the palatal root of the maxillary first molar.

FIG. 1-13 Fluctuant swelling in the mucobuccal fold associated with periradicular disease from the maxillary central incisor.

epithelium that extended from the oral mucosa surface to the periradicular lesion.[12] The presence or absence of an epithelial lining does not seem to prevent closure of the tract as long as the source of the problem is properly diagnosed and adequately treated and the endodontic lesion has healed. Failure of a sinus tract to heal after treatment will necessitate further diagnostic procedures to determine whether other sources of infection are present or whether a misdiagnosis occurred.

In general, a periapical infection that has an associated sinus tract is not painful, although often there is a history of varying magnitudes of discomfort before sinus tract development. Besides providing a conduit for the release of infectious exudate and the subsequent relief of pain, the sinus tract can also provide a useful aid in determining the source of a given infection. Sometimes objective evidence as to the origin of an odontogenic infection is lacking. The stoma of the sinus tract may be located directly adjacent to or at a distant site from the infection. Tracing the sinus tract will provide objectivity in diagnosing the location of the problematic tooth. To trace the sinus tract, a size #25 or #30 gutta-percha cone is threaded into the opening of the sinus tract. Although this may be slightly uncomfortable to the patient, the cone should be inserted until resistance is felt. After a periapical radiograph is exposed, the origin of the sinus tract is determined by following the path taken by the gutta-percha cone (Fig. 1-14). This will direct the clinician to the tooth involved and, more specifically, to the root of the root of the tooth that is the source of the pathosis. Once the causative factors related to the formation of the sinus tract are removed, the stoma and the sinus tract will close within several days.

The stomata of intraoral sinus tracts may open in the alveolar mucosa, in the attached gingiva, or through the furcation or gingival crevice. They may exit through either the facial or the lingual tissues depending on the proximity of the root apices to the cortical bone. If the opening is in the gingival crevice, it is normally present as a narrow defect in one or two isolated areas along the root surface. When a narrow defect is present, the differential diagnosis must include the opening of a periradicular endodontic lesion, a vertical root fracture, or the presence of a developmental groove on the root surface. This type of sinus tract can be differentiated from a primary periodontal lesion because the latter generally presents as a pocket with a broad coronal opening and more generalized alveolar bone loss around the root. Other pulp testing methods may assist in verifying the source of infection.[111,112,121]

Palpation

In the course of the soft tissue examination, the alveolar hard tissues should also be palpated. Emphasis should be placed on detecting any soft tissue swelling or bony expansion, especially noting how it compares with and relates to the adjacent and contralateral tissues. In addition to objective findings, the clinician should question the patient about any areas that feel unusually sensitive during this palpation part of the examination.

A palpation test is performed by applying firm digital pressure to the mucosa covering the roots and apices. The index finger is used to press the mucosa against the underlying cortical bone. This will detect the presence of periradicular abnormalities or specific areas that produce painful response to digital pressure. A positive response to palpation may indicate an active periradicular inflammatory process. This test does not indicate, however, whether the inflammatory process is of endodontic or periodontal origin.

Percussion

Referring back to the patient's chief complaint may indicate the importance of percussion testing for this particular case. If the patient is experiencing acute sensitivity or pain on mastication, this response can typically be duplicated by individually percussing the teeth, which often isolates the symptoms to a particular tooth. Pain to percussion does not indicate that the

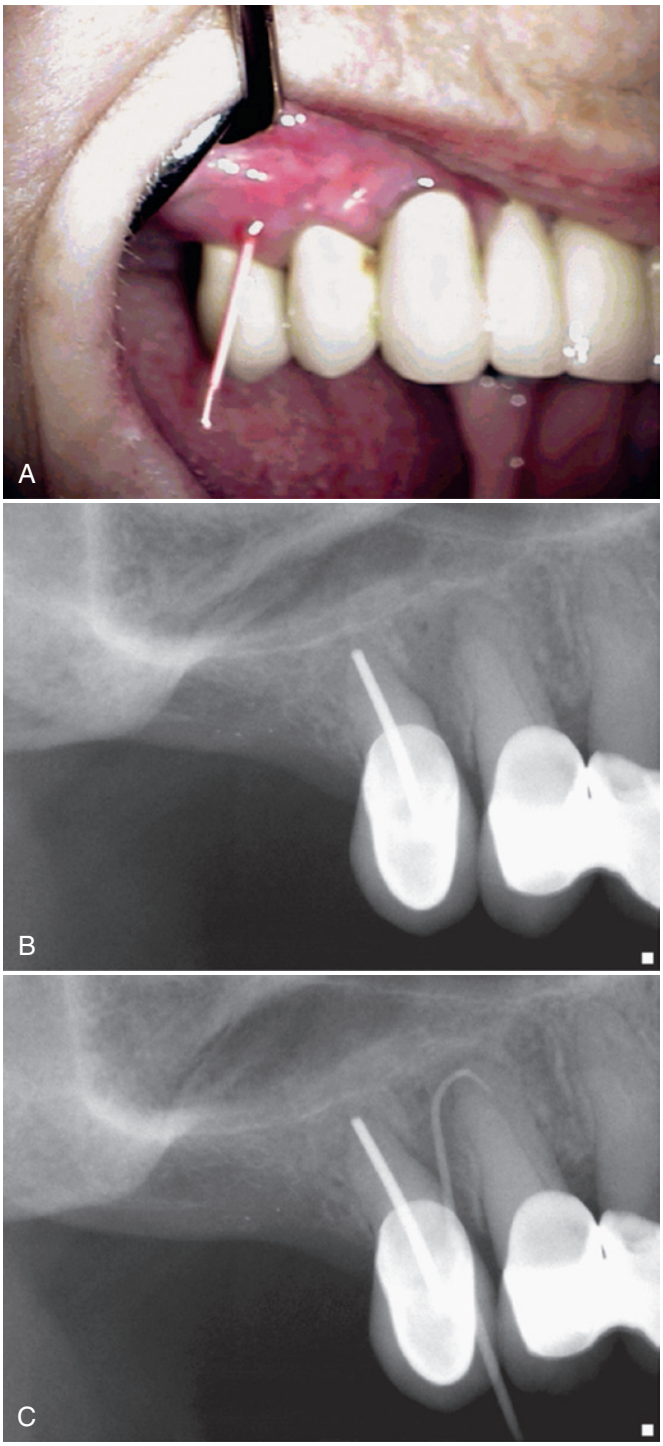

FIG. 1-14 A, To locate the source of an infection, the sinus tract can be traced by threading the stoma with a gutta-percha point. B, Radiograph of the area shows an old root canal in a maxillary second premolar and a questionable radiolucent area associated with the first premolar, with no clear indication of the etiology of the sinus tract. C, After tracing the sinus tract, the gutta-percha is seen to be directed to the source of pathosis, the apex of the maxillary first premolar.

FIG. 1-15 Percussion testing of a tooth, using the back end of a mirror handle.

tooth is vital or nonvital but is rather an indication of inflammation in the periodontal ligament (i.e., symptomatic apical periodontitis). This inflammation may be secondary to physical trauma, occlusal prematurities, periodontal disease, or the extension of pulpal disease into the periodontal ligament space. The indication of where the pain originates is interpreted by the mesencephalic nucleus, receiving its information from proprioceptive nerve receptors. Although subject to debate, the general consensus is that there are relatively few proprioceptors in the dental pulp; however, they are prevalent in the periodontal ligament spaces.[24] This is why it may be difficult for the patient to discriminate the location of dental pain in the earlier stages of pathosis, when only the C fibers are stimulated. Once the disease state extends into the periodontal ligament space, the pain may become more localized for the patient; therefore, the affected tooth will be more identifiable with percussion and mastication testing.

Before percussing any teeth, the clinician should tell the patient what will transpire during this test. Because the presence of acute symptoms may create anxiety and possibly alter the patient's response, properly preparing the patient will lead to more accurate results. The contralateral tooth should first be tested as a control, as should several adjacent teeth that are certain to respond normally. The clinician should advise the patient that the sensation from this tooth is normal and ask to be advised of any tenderness or pain from subsequent teeth.

Percussion is performed by tapping on the incisal or occlusal surfaces of the teeth either with the finger or with a blunt instrument. The testing should initially be done gently, with light pressure being applied digitally with a gloved finger tapping. If the patient cannot detect significant difference between any of the teeth, the test should be repeated using the blunt end of an instrument, like the back end of a mirror handle (Fig. 1-15). The tooth crown is tapped vertically and horizontally. The tooth should first be percussed occlusally, and if the patient discerns no difference, the test should be repeated, percussing the buccal and lingual aspects of the teeth. For any heightened responses, the test should be repeated as necessary to determine that it is accurate and reproducible, and the information should be documented.

Although this test does not disclose the condition of the pulp, it indicates the presence of a periradicular inflammation.

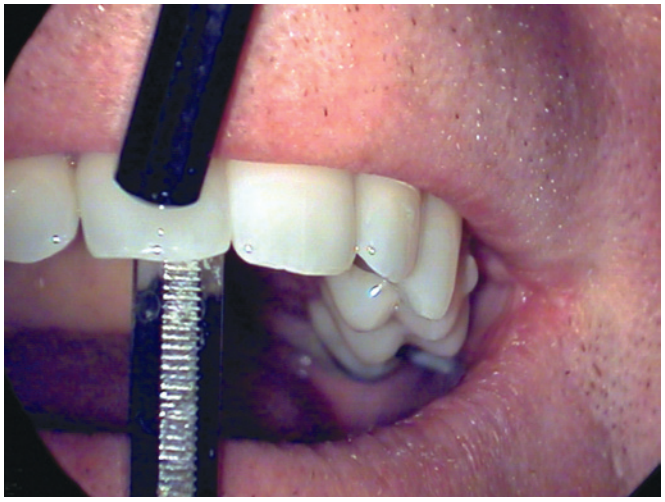

FIG. 1-16 Mobility testing of a tooth, using the back ends of two mirror handles.

BOX 1-2

Recording Tooth Mobility

+1 mobility: The first distinguishable sign of movement greater than normal
+2 mobility: Horizontal tooth movement no greater than 1 mm
+3 mobility: Horizontal tooth movement greater than 1 mm, with or without the visualization of rotation or vertical depressability

BOX 1-3

Recording Furcation Defects

Class I furcation defect: The furcation can be probed but not to a significant depth.
Class II furcation defect: The furcation can be entered into but cannot be probed completely through to the opposite side.
Class III furcation defect: The furcation can be probed completely through to the opposite side.

An abnormal positive response indicates inflammation of the periodontal ligament that may be of either pulpal or periodontal origin. The sensitivity of the proprioceptive fibers in an inflamed periodontal ligament will help identify the location of the pain. This test should be done gently, especially in highly sensitive teeth. It should be repeated several times and compared with control teeth.

Mobility

Like percussion testing, an increase in tooth mobility is not an indication of pulp vitality. It is merely an indication of a compromised periodontal attachment apparatus. This compromise could be the result of acute or chronic physical trauma, occlusal trauma, parafunctional habits, periodontal disease, root fractures, rapid orthodontic movement, or the extension of pulpal disease, specifically an infection, into the periodontal ligament space. Tooth mobility is directly proportional to the integrity of the attachment apparatus or to the extent of inflammation in the periodontal ligament. Often the mobility reverses to normal after the initiating factors are repaired or eliminated. Because determining mobility by simple finger pressure can be visually subjective, the back ends of two mirror handles should be used, one on the buccal aspect and one on the lingual aspect of the tooth (Fig. 1-16). Pressure is applied in a facial-lingual direction as well as in a vertical direction and the tooth mobility is scored (Box 1-2). Any mobility that exceeds +1 should be considered abnormal. However, the teeth should be evaluated on the basis of how mobile they are relative to the adjacent and contralateral teeth.

Periodontal Examination

Periodontal probing is an important part of any intraoral diagnosis. The measurement of periodontal pocket depth is an indication of the depth of the gingival sulcus, which corresponds to the distance between the height of the free gingival margin and the height of the attachment apparatus below. Using a calibrated periodontal probe, the clinician should record the periodontal pocket depths on the mesial, middle, and distal aspects of both the buccal and lingual sides of the tooth, noting the depths in millimeters. The periodontal probe is "stepped" around the long axis of the tooth, progressing in 1-mm increments. Periodontal bone loss that is wide, as determined by a wide span of deep periodontal probings, is generally considered to be of periodontal origin and is typically more generalized in other areas of the mouth. However, isolated areas of vertical bone loss may be of an endodontic origin, specifically from a nonvital tooth whose infection has extended from the periapex to the gingival sulcus. Again, proper pulp testing is imperative, not just for the determination of a diagnosis but also for the development of an accurate prognosis assessment. For example, a periodontal pocket of endodontic origin may resolve after endodontic treatment, but if the tooth was originally vital with an associated deep periodontal pocket, endodontic treatment will not improve the periodontal condition. In addition, as discussed in Chapter 21, a vertical root fracture may often cause a localized narrow periodontal pocket that extends deep down the root surface. Characteristically, the adjacent periodontium is usually within normal limits.

Furcation bone loss can be secondary to periodontal or pulpal disease. The amount of furcation bone loss, as observed both clinically and radiographically, should be documented (Box 1-3). Results of pulp tests (described later) will aid in diagnosis.

Pulp Tests

Pulp testing involves attempting to make a determination of the responsiveness of pulpal sensory neurons.[62,63] The tests involve thermal or electrical stimulation of a tooth in order to obtain a subjective response from the patient (i.e., to determine whether the pulpal nerves are functional), or the tests may involve a more objective approach using devices that detect the integrity of the pulpal vasculature. Unfortunately, the quantitative evaluation of the status of pulp tissue can only be determined histologically, as it has been shown that there is not necessarily a good correlation between the objective clinical signs and symptoms and the pulpal histology.[122,123]

Thermal

Various methods and materials have been used to test the pulp's response to thermal stimuli. The baseline or normal response

to either cold or hot is a patient's report that a sensation is felt but disappears immediately upon removal of the thermal stimulus. Abnormal responses include a lack of response to the stimulus, a lingering or intensification of a painful sensation after the stimulus is removed, or an immediate, excruciatingly painful sensation as soon as the stimulus is placed on the tooth.

Cold testing is the primary pulp testing method used by many clinicians today. It is especially useful for patients presenting with porcelain jacket crowns or porcelain-fused-to-metal crowns where no natural tooth surface (or much metal) is accessible. If a clinician chooses to perform this test with sticks of ice, then the use of a rubber dam is recommended, because melting ice will run onto adjacent teeth and gingiva, yielding potentially false-positive responses.

Frozen carbon dioxide (CO_2), also known as *dry ice* or *carbon dioxide snow*, or *CO_2 stick*, has been found to be reliable in eliciting a positive response if vital pulp tissue is present in the tooth.[46,98,99] One study found that vital teeth would respond to both frozen CO_2 and skin refrigerant, with skin refrigerant producing a slightly quicker response.[66] Frozen carbon dioxide has also been found to be effective in evaluating the pulpal response in teeth with full coverage crowns for which other tests such as electric pulp testing is not possible.[11] For testing purposes, a solid stick of CO_2 is prepared by delivering CO_2 gas into a specially designed plastic cylinder (Fig. 1-17). The resulting CO_2 stick is applied to the facial surface of either the natural tooth structure or crown. Several teeth can be tested with a single CO_2 stick. The teeth should be isolated and the oral soft tissues should be protected with a 2-by-2-inch gauze or cotton roll so the frozen CO_2 will not come into contact with these structures. Because of the extremely cold temperature of the frozen CO_2 (−69°F to −119°F; −56°C to −98°C), burns of the soft tissues can occur. It has been demonstrated on extracted teeth that frozen CO_2 application has resulted in a significantly greater intrapulpal temperature decrease than either skin refrigerant or ice.[11] Also, it appears that the application of CO_2 to teeth does not result in any irreversible damage to the pulp tissues or cause any significant enamel crazing.[61,104]

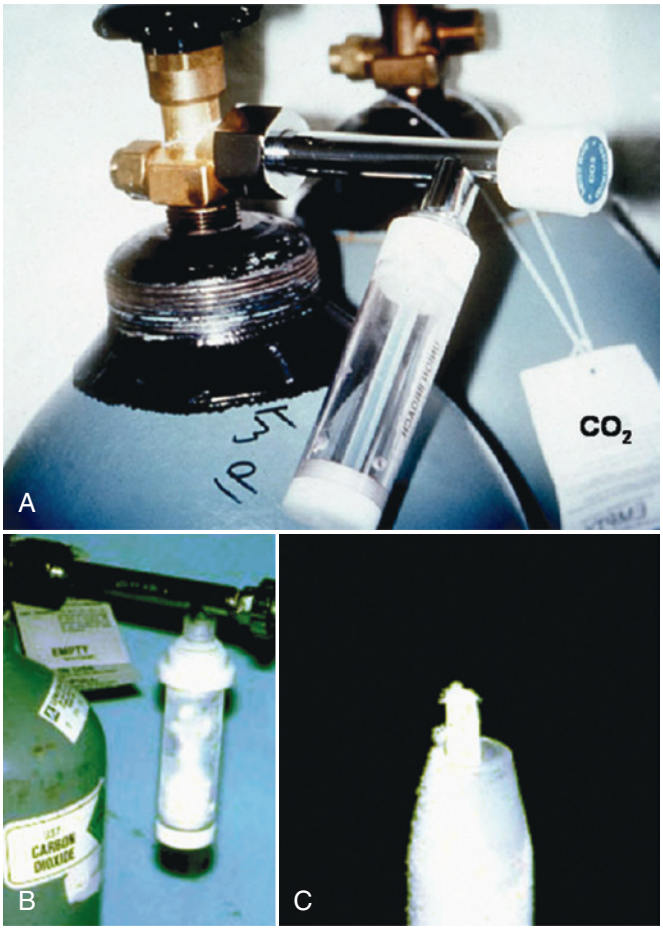

FIG. 1-17 **A,** Carbon dioxide tank with apparatus attached to form solid CO_2 stick/pencil. **B,** CO_2 gas being transformed into a solid stick/pencil. **C,** CO_2 stick/pencil extruded from end of a plastic carrier and ready for use.

The most popular method of performing cold testing is with a refrigerant spray. It is readily available, easy to use, and provides test results that are reproducible, reliable, and equivalent to that of frozen CO_2.[46,66,96,141] One of the current products contains 1,1,1,2-tetrafluoroethane, which has zero ozone depletion potential and is environmentally safe. It has a temperature of −26.2°C.[66] The spray is most effective for testing purposes when it is applied to the tooth on a large #2 cotton pellet (Fig. 1-18). In one study,[65] a significantly lower intrapulpal temperature was achieved when a #2 cotton pellet was dipped or sprayed with the refrigerant compared with the result when a small #4 cotton pellet or cotton applicator was used. The sprayed cotton pellet should be applied to the midfacial area of the tooth or crown. As with any other pulp testing method, adjacent or contralateral "normal" teeth should also be tested to establish a baseline response. It appears that frozen CO_2 and refrigerant spray are superior to other cold testing methods and equivalent or superior to the electric pulp tester for assessing pulp vitality.[11,46] However, one study found that periodontal attachment loss and gingival recession may influence the reported pain response with cold stimuli.[116]

To be most reliable, cold testing should be used in conjunction with an electric pulp tester (described later in this chapter) so that the results from one test will verify the findings of the other test. If a mature, nontraumatized tooth does not respond to both cold testing and electric pulp testing, then the pulp should be considered necrotic.[23,98,141] However, a multirooted tooth, with at least one root containing vital pulp tissue, may respond to a cold test and electric pulp test even if one or more of the roots contain necrotic pulp tissue.[98]

Another thermal testing method involves the use of heat. Heat testing is most useful when a patient's chief complaint is intense dental pain on contact with any hot liquid or food. When a patient is unable to identify which tooth is sensitive, a heat test is appropriate. Starting with the most posterior tooth in that area of the mouth, each tooth is individually isolated with a rubber dam. An irrigating syringe is filled with a liquid (most commonly plain water) that has a temperature similar to that which would cause the painful sensation. The liquid is then expressed from the syringe onto the isolated tooth to determine whether the response is normal or abnormal. The clinician moves forward in the quadrant, isolating each individual tooth until the offending tooth is located. That tooth will exhibit an immediate, intense painful response to the heat. With heat testing, a delayed response may occur, so waiting 10 seconds between each heat test will allow sufficient time for the onset of symptoms. This method can also be used to apply cold water to the entire crown for cases in which cold is the precipitating stimulus.

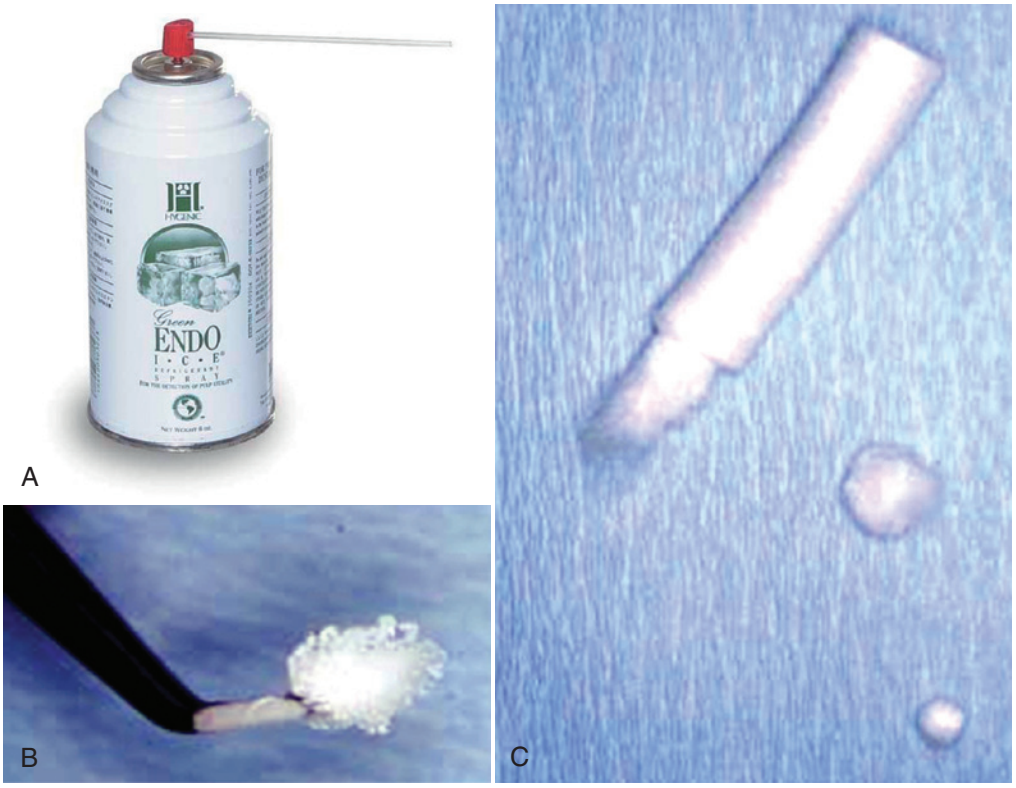

FIG. 1-18 A, Refrigerant spray container. B, A large cotton pellet made of a cotton roll or a ready-made size #2 (large) cotton pellet can be used to apply the refrigerant spray to the tooth surface. The small #4 cotton pellet does not provide as much surface area as the #2 cotton pellet, and therefore should not be used to deliver the refrigerant to the tooth surface. C, A large cotton pellet sprayed with the refrigerant and ready to be applied to the tooth surface. (*A,* Courtesy Coltène/Whaledent, Cuyahoga Falls, OH.)

Another method for heat testing is to apply heated gutta-percha or compound stick to the surface of the tooth. If this method is used, a light layer of lubricant should be placed onto the tooth surface before applying the heated material to prevent the hot gutta-percha or compound from adhering to the dry tooth surface. Heat can also be generated by the friction created when a dry rubber-polishing wheel is run at a high speed against the dry surface of a tooth. However, this latter method is seldom used today and is not recommended. Another approach is the use of electronic heat-testing instruments.[20]

If the heat test confirms the results of other pulp testing procedures, emergency care can then be provided. Often a tooth that is sensitive to heat may also be responsible for some spontaneous pain. The patient may present with cold liquids in hand just to minimize the pain (Fig. 1-19). In such cases, the application of cold to a specific tooth may eliminate the pain and greatly assist in the diagnosis. Typically, a tooth that responds to heat and then is relieved by cold is found to be necrotic.

FIG. 1-19 Irreversible pulpitis associated with the mandibular right second molar. Patient has found that the only way to alleviate the pain is to place a jar filled with ice water against the right side of his face.

Electric

Assessment of pulp neural responses (*vitality*) can also be accomplished by electric pulp testing.[79] Electric pulp testers of different designs and manufacturers have been used for this purpose. Electric pulp testers should be an integral part of any dental practice. It should be noted that the vitality of the pulp is determined by the intactness and health of the vascular supply, not by the status of the pulpal nerve fibers. Even though

BOX 1-4

Potential Common Interpretation Errors of Responses Obtained from Electric Pulp Testing

False-Positive Responses
Partial pulp necrosis
Patient's high anxiety
Ineffective tooth isolation
Contact with metal restorations

False-Negative Responses
Calcific obliterations in the root canals
Recently traumatized teeth
Immature apex
Drugs that increase patient's threshold for pain
Poor contact of pulp tester to tooth

advances are being made with regard to determining the vitality of the pulp on the basis of the blood supply, this technology has not been perfected enough at this time to be used on a routine basis in a clinical setting.

The electric pulp tester has some limitations in providing predictable information about the vitality of the pulp. The response of the pulp to electric testing does not reflect the histologic health or disease status of the pulp.[122,123] A response by the pulp to the electric current only denotes that some viable nerve fibers are present in the pulp and are capable of responding. Numeric readings on the pulp tester have significance only if the number differs significantly from the readings obtained from a control tooth tested on the same patient with the electrode positioned at a similar area on both teeth. However, in most cases, the response is scored as either present or absent. Studies[122,123] have shown that electric pulp test results are most accurate when no response is obtained to any amount of electric current. This lack of response has been found most frequently when a necrotic pulp is present. In addition, false-positive and false-negative responses can occur (Box 1-4), and the clinician must take it into account when formulating the final diagnosis.

The electric pulp tester will not work unless the probe can be placed in contact with or be bridged to the natural tooth structure.[95] With the advent of universal precautions for infection control, the use of rubber gloves prevents the clinician from completing the circuit.[7] Some pulp testers may require the patient to place a finger, or fingers, on the tester probe to complete the electric circuit; however, the use of lip clips is an alternative to having patients hold the tester. Proper use of the electric pulp tester requires the evaluated teeth to be carefully isolated and dried. A control tooth of similar tooth type and location in the arch should be tested first in order to establish a baseline response and to inform the patient as to what a "normal" sensation is. The suspected tooth should be tested at least twice to confirm the results. The tip of the testing probe that will be placed in contact with the tooth structure must be coated with a water- or petroleum-based medium.[86] The most commonly used medium is toothpaste. The coated probe tip is placed in the incisal third of the facial or buccal area of the tooth to be tested.[15] Once the probe is in contact with the tooth, the patient is asked to touch or grasp the tester probe, unless a lip clip is used (Fig. 1-20, *A*). This completes the circuit and initiates the delivery of electric current to the tooth.

FIG. 1-20 A, Electric pulp tester with probe. The probe tip will be coated with a conducive medium such as toothpaste and placed in contact with the tooth surface. The patient will activate the unit by placing a finger on the metal shaft of the probe. B, View of the electric pulp tester control panel; the knob on the front right of the unit controls the rate at which the electric current is delivered to the tooth. The plastic panel on the left front displays the digital numerical reading obtained from the pulp test. The digital scale runs from 0 to 80. (Courtesy SybronEndo, Orange, CA.)

The patient is instructed to remove his or her finger(s) from the probe when a "tingling" or "warming" sensation is felt in the tooth. The readings from the pulp tester are recorded (Fig. 1-20, *B*) and will be evaluated once all the appropriate teeth have been tested by the electric pulp tester and the other pulp testing methods.

If a complete coverage crown or extensive restoration is present, a bridging technique can be attempted to deliver the electric current to any exposed natural tooth structure.[95] The tip of an endodontic explorer is coated with toothpaste or other appropriate medium and placed in contact with the natural tooth structure. The tip of the electric pulp tester probe is coated with a small amount of toothpaste and placed in contact with the side of the explorer. The patient completes the circuit and the testing proceeds as described previously. If no natural tooth structure is available, then an alternative pulp testing method, such as cold, should be used.

One study compared the ability of thermal and electric pulp testing methods to register the presence of vital pulp tissue.[99] The *sensitivity,* which is the ability of a test to identify teeth that are diseased, was 0.83 for the cold test, 0.86 for heat test,

and 0.72 for the electric test. This means the cold test correctly identified 83% of the teeth that had a necrotic pulp, whereas heat tests were correct 86% of the time and electric pulp tests were correct only 72% of the time. This same study evaluated the *specificity* of these three tests. Specificity relates to the ability of a test to identify teeth without disease. Ninety-three percent of teeth with healthy pulps were correctly identified by both the cold and electric pulp tests, whereas only 41% of the teeth with healthy pulps were identified correctly by the heat test. From the results of the testing, it was found that the cold test had an accuracy of 86%, the electric pulp test 81%, and the heat test 71%.

Some studies have indicated there might not be a significant difference between pulp testing results obtained by electric pulp tester and those obtained by the thermal methods.[46,98,99] Cold tests, however, have been shown to be more reliable than electric pulp tests in younger patients with less developed root apices.[5,42,98] This is the reason to verify the results obtained by one testing method and compare them with results obtained by other methods. Until such time that the testing methods used to assess the vascular supply of the pulp become less time consuming and technique sensitive, thermal and electric pulp testing will continue to be the primary methods for determining pulp vitality.

Laser Doppler Flowmetry

Laser Doppler flowmetry (LDF) is a method used to assess blood flow in microvascular systems. Attempts are being made to adapt this technology to assess pulpal blood flow. A diode is used to project an infrared light beam through the crown and pulp chamber of a tooth. The infrared light beam is scattered as it passes through the pulp tissue. The Doppler principle states that the light beam's frequency will shift when hitting moving red blood cells but will remain unshifted as it passes through static tissue. The average Doppler frequency shift will measure the velocity at which the red blood cells are moving.[114]

Several studies[40,60,69,84,114,115,117] have found LDF to be an accurate, reliable, and reproducible method of assessing pulpal blood flow. One of the great advantages of pulp testing with devices such as the LDF is that the collected data are based on objective findings rather than subjective patient responses. As is discussed in Chapter 20, certain luxation injuries will cause inaccuracies in the results of electric and thermal pulp testing. LDF has been shown to be a great indicator for pulpal vitality in these cases.[130] This technology, however, is not being used routinely in the dental practice.

Pulse Oximetry

The pulse oximeter is another noninvasive device (Fig. 1-21). Widely used in medicine, it is designed to measure the oxygen concentration in the blood and the pulse rate. A pulse oximeter works by transmitting two wavelengths of light, red and infrared, through a translucent portion of a patient's body (e.g., a finger, earlobe, or tooth). Some of the light is absorbed as it passes through the tissue; the amount absorbed depends on the ratio of oxygenated to deoxygenated hemoglobin in the blood. On the opposite side of the targeted tissue, a sensor detects the absorbed light. On the basis of the difference between the light emitted and the light received, a microprocessor calculates the pulse rate and oxygen concentration in the blood.[118] The transmission of light to the sensor requires that there be no obstruction from restorations, which can sometimes limit the usefulness of pulse oximetry to test pulp vitality.

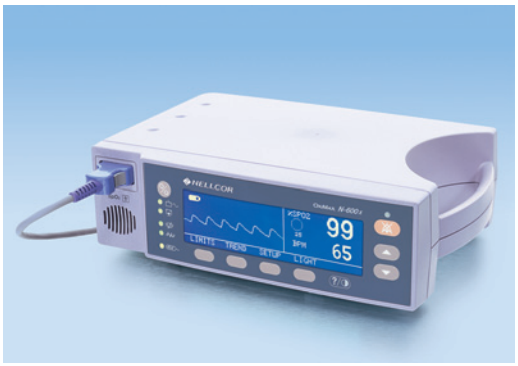

FIG. 1-21 Nellcor OxiMax N-600x pulse oximeter. (Courtesy Nellcor Puritan Bennett, Boulder, CO; now part of Covidien.)

Custom-made sensors have been developed and were found to be more accurate than electric and thermal pulp tests.[31,54] This sensor has been especially useful in evaluating teeth that have been subjected to traumatic injuries, as such teeth tend to present, especially in the short term, with questionable vitality using conventional pulp testing methods.[8,31,53]

Studies regarding the ability of pulse oximetry to diagnose pulp vitality draw various conclusions. Several studies have found pulse oximetry to be a reliable method for assessing pulp vitality.[69,70,118,125,140] Others have stated that in its present form the pulse oximeter may not be predictable in diagnosing pulp vitality.[140] Most of the problems appear to be related to the currently available technology. Some investigators have concluded that the devices used for pulp testing are too cumbersome and complicated to be used on a routine basis in a dental practice.[68,118,140]

Special Tests

Bite Test

Percussion and bite tests are indicated when a patient presents with pain while biting. On occasion, the patient may not know which tooth is sensitive to biting pressure, and percussion and bite tests may help to localize the tooth involved. The tooth may be sensitive to biting when the pulpal pathosis has extended into the periodontal ligament space, creating a *symptomatic apical periodontitis,* or the sensitivity may be present secondary to a crack in the tooth. The clinician can often differentiate between periradicular periodontitis and a cracked tooth or fractured cusp. If periradicular periodontitis is present, the tooth will respond with pain to percussion and biting tests regardless of where the pressure is applied to the coronal part of the tooth. A cracked tooth or fractured cusp will typically elicit pain only when the percussion or bite test is applied in a certain direction to one cusp or section of the tooth.[22,108]

For the bite test to be meaningful, a device should be used that will allow the clinician to apply pressure to individual cusps or areas of the tooth. A variety of devices have been used for bite tests, including cotton tip applicators, toothpicks, orangewood sticks, and rubber polishing wheels. There are several devices specifically designed to perform this test. The Tooth Slooth (Professional Results, Laguna Niguel, CA) (Fig. 1-22) and FracFinder (Hu-Friedy, Oakbrook, IL) are just two of the commercially available devices used for the bite test. As with all pulp tests, adjacent and contralateral teeth should

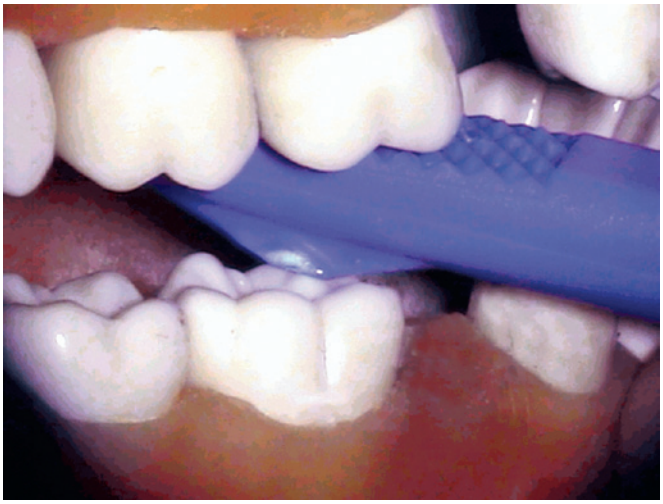

FIG. 1-22 To determine which tooth, or tooth part, is sensitive to mastication, having the patient bite on a specially designed bite stick is often helpful.

be used as controls so that the patient is aware of the "normal" response to these tests. The small cupped-out area on these instruments is placed in contact with the cusp to be tested. The patient is then asked to apply biting pressure with the opposing teeth to the flat surface on the opposite side of the device. The biting pressure should be applied slowly until full closure is achieved. The firm pressure should be applied for a few seconds; the patient is then asked to release the pressure quickly. Each individual cusp on a tooth can be tested in a like manner. The clinician should note whether the pain is elicited during the pressure phase or on quick release of the pressure. A common finding with a fractured cusp or cracked tooth is the frequent presence of pain upon release of biting pressure.

Test Cavity

The test cavity method for assessing pulp vitality is not routinely used since, by definition, it is an invasive irreversible test. This method is used only when all other test methods are deemed impossible or the results of the other tests are inconclusive. An example of a situation in which this method can be used is when the tooth suspected of having pulpal disease has a full coverage crown. If no sound tooth structure is available to use a bridging technique with the electric pulp tester and cold test results are inconclusive, a small class I cavity preparation is made through the occlusal surface of the crown. This is accomplished with a high-speed #1 or #2 round bur with proper air and water coolant. The patient is not anesthetized while this procedure is performed, and the patient is asked to respond if any painful sensation is felt during the drilling procedure. If the patient feels pain once the bur contacts sound dentin, the procedure is terminated and the class I cavity preparation is restored. This sensation signifies only that there is some viable nerve tissue remaining in the pulp, not that the pulp is totally healthy. If the patient fails to feel any sensation when the bur reaches the dentin, this is a good indication that the pulp is necrotic and root canal therapy is indicated.

Staining and Transillumination

To determine the presence of a crack in the surface of a tooth, the application of a stain to the area is often of great assistance. It may be necessary to remove the restoration in the tooth to better visualize a crack or fracture. Methylene blue dye, when painted on the tooth surface with a cotton tip applicator, will penetrate into cracked areas. The excess dye may be removed with a moist application of 70% isopropyl alcohol. The dye will indicate the possible location of the crack.

Transillumination using a bright fiberoptic light probe to the surface of the tooth may be very helpful (Fig. 1-23). Directing a high-intensity light directly on the exterior surface of the tooth at the cementum-enamel junction (CEJ) may reveal the extent of the fracture. Teeth with fractures block transilluminated light. The part of the tooth that is proximal to the light source will absorb this light and glow, whereas the area beyond this fracture will not have light transmitted to it and will show as gray by comparison.[101] Although the presence of a fracture may be evident using dyes and transillumination, the depth of the fracture cannot always be determined.

Selective Anesthesia

When symptoms are not localized or referred, the diagnosis may be challenging. Sometimes the patient may not even be able to specify whether the symptoms are emanating from the maxillary or mandibular arch. In these instances, when pulp testing is inconclusive, *selective anesthesia* may be helpful.

If the patient cannot determine which arch the pain is coming from, then the clinician should first selectively anesthetize the maxillary arch. This should be accomplished by using a periodontal ligament (intraligamentary) injection. The injection is administered to the most posterior tooth in the quadrant of the arch that may be suspected, starting from the distal sulcus. The anesthesia is subsequently administered in an anterior direction, one tooth at a time, until the pain is eliminated. If the pain is not eliminated after an appropriate period of time, then the clinician should similarly repeat this technique on the mandibular teeth below. It should be understood that periodontal ligament injections may anesthetize an adjacent tooth and thus are more useful for identifying the arch rather than the specific tooth.

Radiographic Examination and Interpretation

Intraoral Radiographs

The radiographic interpretation of a potential endodontic pathosis is an integral part of endodontic diagnosis and prognosis assessment. Few diagnostic tests provide as much useful information as dental radiography. For this reason, the clinician is sometimes tempted to prematurely make a definitive diagnosis based solely on radiographic interpretation. However, the image should be used only as one sign, providing important clues in the diagnostic investigation. When not coupled with a proper history and clinical examination and testing, the radiograph alone can lead to a misinterpretation of normality and pathosis (Fig. 1-24). Because treatment planning will ultimately be based on the diagnosis, the potential for inappropriate treatment may frequently exist if the radiograph alone is used for making final diagnosis. The clinician should not subject the patient to unnecessary multiple radiation exposures; two pretreatment images from different angulations are often sufficient. Under extenuating circumstances, however, especially when the diagnosis is difficult, additional exposures may be necessary to determine the presence of multiple roots,

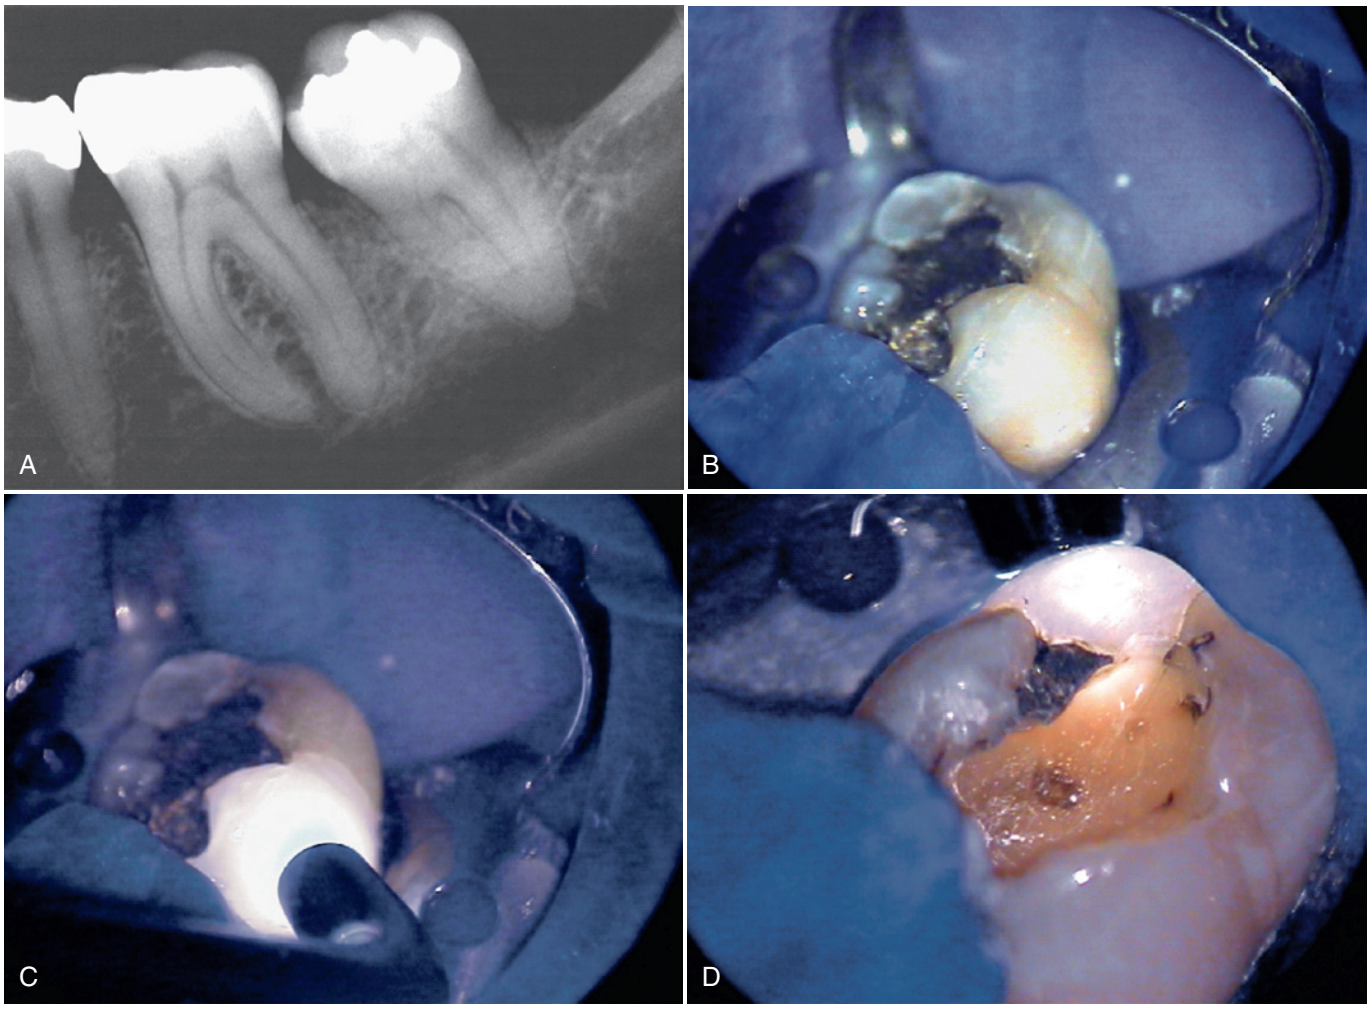

FIG. 1-23 Sometimes there is no clear indication of why a tooth is symptomatic. This radiograph shows a mandibular second molar with a moderately deep restoration **(A)**; the pulp tests nonvital. Without any transillumination, a fracture cannot be detected **(B)**. However, by placing a high-intensity light source on the tooth surface, a root fracture can be observed on the buccal surface **(C)** and the distal-lingual surface **(D)**.

multiple canals, resorptive defects, caries, restoration defects, root fractures, and the extent of root maturation and apical development.

The radiographic appearance of endodontic pathosis can sometimes be highly subjective. In a study by Goldman and colleagues, there was only 50% agreement among interpreters for the radiographic presence of pathosis.[49] When the cases were reevaluated several months later, the same evaluators agreed with their own original diagnosis less than 85% of the time.[50] This further emphasizes the necessity for additional objective diagnostic tests, as well as the importance of obtaining and comparing older radiographs.

For standard two-dimensional radiography, clinicians basically project x-radiation through an object and capture the image on a recording medium, either x-ray film or a digital sensor. Much like casting a shadow from a light source, the image appearance may vary greatly depending on how the radiographic source is directed. Thus, the three-dimensional interpretation of the resulting two-dimensional image requires not only knowledge of normality and pathosis but also advanced knowledge of how the radiograph was exposed. By virtue of "casting a shadow," the anatomic features that are closest to the film (or sensor) will move the least when there is a change in the horizontal or vertical angulation of the radiation source (Fig. 1-25). This may be helpful in determining the existence of additional roots, the location of pathosis, and the unmasking of anatomic structures. Changes in the horizontal or vertical angulation may help elucidate valuable anatomic and pathologic information; it also has the potential to hide important information. An incorrect vertical angulation may cause the buccal roots of a maxillary molar to be masked by the zygomatic arch. An incorrect horizontal angulation may cause roots to overlap with the roots of adjacent teeth, or it may incorrectly create the appearance of a one-rooted tooth, when two roots are actually present.

In general, when endodontic pathosis appears radiographically, it appears as bone loss in the area of the periapex. The pathosis may present merely as a widening or break in the lamina dura—the most consistent radiographic finding when a tooth is nonvital[67]—or it may present as a radiolucent area at the apex of the root or in the alveolar bone adjacent to the exit of a lateral or furcation accessory canal. On occasion there may be no radiographic change at all, even in the presence of a disease process in the alveolar bone.

FIG. 1-24 Radiograph showing what appears to be a mandibular lateral incisor associated with periapical lesion of a nonvital tooth. Although pulp necrosis can be suspected, the tooth tested vital. In this case, the appearance of apical bone loss is secondary to a cementoma.

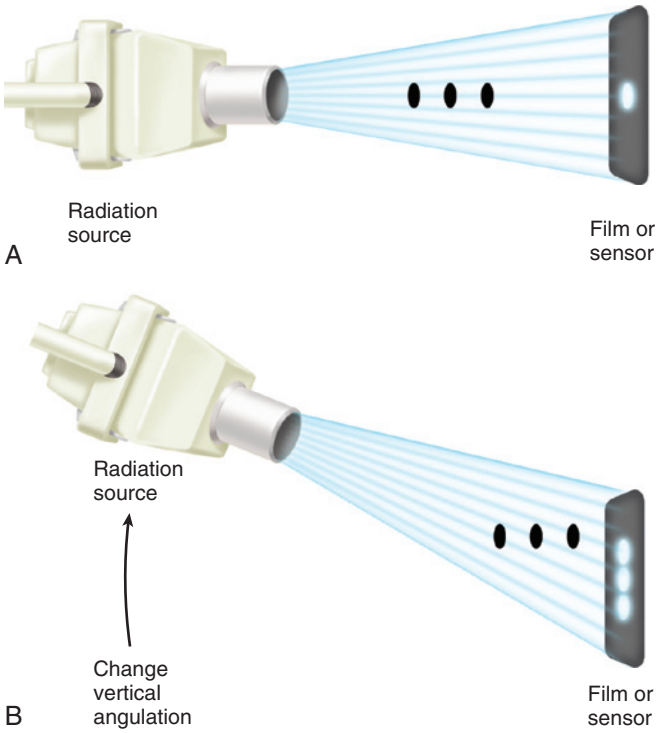

FIG. 1-25 Radiographic images are only two-dimensional, and often it is difficult to discriminate the relative location of overlapping objects. A, When the source of radiation is directly perpendicular to overlapping objects, the image is captured without much separation of the objects. However, when the radiation source is at an angle to offset the overlapping objects, the image is captured with the objects being viewed as separated. B, The object that is closest to the film (or sensor) will move the least, with the object closest to the radiation source appearing farthest away.

Two-dimensional dental radiography has two basic shortcomings: the lack of early detection of pathosis in the cancellous bone, because of the density of the cortical plates, and the influence of the superimposition of anatomic structures. Variability in the radiographic expression of an osseous pathosis has much to do with the relative location of the root of the tooth and how it is oriented with respect to the cortical and cancellous bone. Radiographic changes from bone loss will not be detected if the loss is only in cancellous bone.[16] However, the radiographic evidence of pathosis will be observed once this bone loss extends to the junction of the cortical and cancellous bone. In addition, certain teeth are more prone to exhibit radiographic changes than others, depending on their anatomic location.[17] The radiographic appearance of endodontic pathosis is correlated with the relationship of the periapex of the tooth and its juxtaposition to the cortical-cancellous bone junction. The apices of most anterior and premolar teeth are located close to the cortical-cancellous bone junction. Therefore, periapical pathosis from these teeth is exhibited sooner on the radiograph. By comparison, the distal roots of mandibular first molars and both roots of mandibular second molars are generally positioned more centrally within the cancellous bone, as are maxillary molars, especially the palatal roots. Periapical lesions from these roots must expand more before they reach the cortical-cancellous bone junction and are recognized as radiographic pathosis. For these reasons, it is important not to exclude the possibility of pulpal pathosis in situations in which there are no radiographic changes.

Many factors can influence the quality of the radiographic interpretation, including the ability of the person exposing the radiograph, the quality of the radiographic film, the quality of the exposure source, the quality of the film processing, and the skill with which the film is viewed. Controlling all of these variables can be a difficult challenge but is paramount for obtaining an accurate radiographic interpretation.

Digital Radiography

Digital radiography has been available since the late 1980s and has recently been refined with better hardware and more user-friendly software. It has the ability to capture, view, magnify, enhance, and store radiographic images in an easily reproducible format that does not degrade over time. Significant advantages of digital radiographs over conventional radiographs include lower radiation doses, instant viewing, convenient manipulation, efficient transmission of an image via the Internet, simple duplication; and easy archiving.

Digital radiography uses no x-ray film and requires no chemical processing. Instead, a *sensor* is used to capture the image created by the radiation source. This sensor is either directly or wirelessly attached to a local computer, which interprets this signal and, using specialized software, translates the signal into a two-dimensional digital image that can be displayed, enhanced, and analyzed. The image is stored in the patient's file, typically in a dedicated network server, and can be recalled as needed. Further information about digital radiography may be found in Chapter 2.

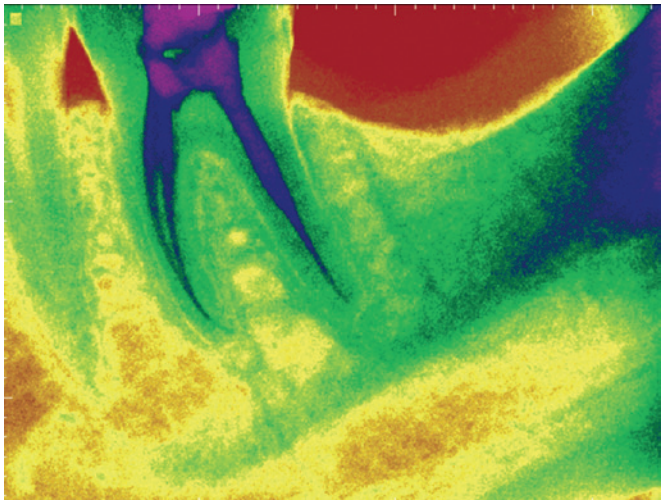

FIG. 1-26 Digital radiography has an advantage over conventional film in that the image can be enhanced and colorized, a useful tool for patient education.

The viewing of a digital radiographic image on a high-resolution monitor allows for rapid and easy interpretation for both the clinician and the patient. The image appears almost instantly, with no potential for image distortion from improper chemical processing. The clinician can magnify different areas on the radiograph and then digitally enhance the image in order to better visualize certain anatomic structures; in some cases the image can even be colorized, a useful tool for patient education (Fig. 1-26).

In the past, x-ray film has had a slightly better resolution than most digital radiography images, at about 16 line pairs per millimeter (lp/mm).[87] Some sensor manufacturers, however, now claim to offer resolutions beyond that of conventional film. Under the best of circumstances, the human eye can see only about 10 lp/mm, which is the lowest resolution for most dental digital radiography systems. Digital sensors are much more sensitive to radiation than conventional x-ray film and thus require 50% to 90% less radiation in order to acquire an image, an important feature for generating greater patient acceptance of dental radiographs.

The diagnostic quality of this expensive technology has been shown to be comparable to, but not necessarily superior to, perfectly exposed and perfectly processed conventional film-based radiography.[39,73,97] Furthermore, it was found that the interpretation of a digital radiograph can be subjective, similar to that of the conventional film.[134] Factors that appear to have the most impact on the interpretation of the image are the years of experience of the examiner and familiarity of the operator with the given digital system.[134]

Cone-Beam Computerized Tomography

Limitations in conventional two-dimensional radiography promulgated a need for three-dimensional imaging, known as *cone-beam computerized tomography* (CBCT) (also known as *cone-beam volumetric tomography* [CBVT]) or as *cone-beam volumetric imaging* [CBVI]. Although a form of this technology has existed since the early 1980s,[106] specific devices for dental use first appeared almost two decades later.[90] Most of these machines are similar to a dental panoramic radiographic device, whereby the patient stands or sits as a cone-shaped

FIG. 1-27 Cone-beam volumetric tomography, using the 3D Accuitomo 80. (Courtesy J. Morita USA, Irvine, CA.)

FIG. 1-28 Cone-beam volumetric tomography has the ability to capture, store, and present radiographic images in various horizontal and vertical planes. (Courtesy J. Morita USA, Irvine, CA.)

radiographic beam is directed to the target area with a reciprocating capturing sensor on the opposite side (Fig. 1-27). The resulting information is digitally reconstructed and interpreted to create an interface whereby the clinician can three-dimensionally interpret "slices" of the patient's tissues in a multitude of planes (Figs. 1-28 and 1-29).[37,33] The survey of the scans can be interpreted immediately after the scan. Various software applications have been used to enable the images to be sent to other clinicians. This is accomplished either in printed format or with portable and transferable software that can be used interactively by another clinician.

In general, many dental applications only require a limited field of vision, confining the study to the maxilla and mandible.

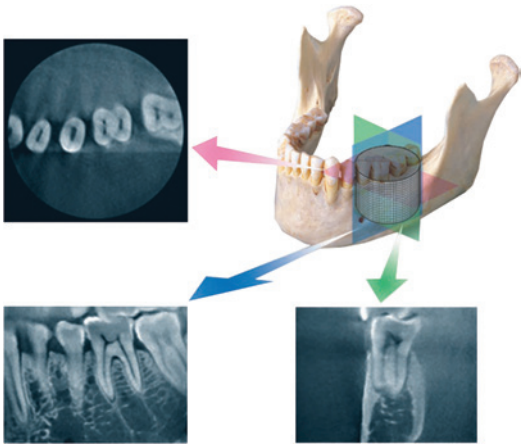

FIG. 1-29 Cone-beam volumetric tomography has the advantage of being able to detect pathosis in the bone or associated with the teeth without the obstruction of anatomic structures. The planes of vision may be axial, sagittal, or coronal. (Courtesy J. Morita USA, Irvine, CA.)

However, many devices have the ability to provide a full field of vision for viewing more regional structures. Clinicians should thoroughly understand the ethical and medical-legal ramifications of doing scans with full fields of view. Incidental nondental findings have been seen from these scans, such as intracranial aneurysms, that when undetected could be life threatening.[91]

The radiation source of CBCT is different from that of conventional two-dimensional dental imaging in that the radiation beam created is conical in shape. Also, conventional digital dental radiography is captured and interpreted as *pixels*, a series of dots that collectively produces an image of the scanned structure. For CBCT, the image is instead captured as a series of three-dimensional pixels, known as *voxels*. Combining these voxels gives a three-dimensional image that can be "sliced" into various planes, allowing for specific evaluations never before possible without a necropsy (Fig. 1-30). One of the advantages of using a device that has a limited field of vision is that the voxel size can be less than half that of a device using a full field of vision, thereby increasing the resolution of the resulting image and providing for a more accurate interpretation of anatomic structures and pathologic conditions. The development of limited field of vision devices has also contributed to decreasing the costs of these relatively expensive machines, making them more practical for dental office use.[41]

Compared with two-dimensional radiographs, CBCT can clearly visualize the interior of the cancellous bone without the superimposition of the cortical bone. Studies show that CBCT is much more predictable and efficient in demonstrating anatomic landmarks, bone density, bone loss, periapical lesions, root fractures, root perforations and root resorptions.[1,21,26,27,38,47,71,78,81,85,92,94,128,131,142]

The superimposition of anatomic structures can also mask the interpretation of alveolar defects. Specifically, the maxillary sinus, zygoma, incisive canal and foramen, nasal bone, orbit, mandibular oblique ridge, mental foramen, mandibular mentalis, sublingual salivary glands, tori, and the overlap of adjacent roots may either obscure bone loss or mimic bone loss, making an accurate interpretation of conventional radiography sometimes difficult or impossible. Several studies have

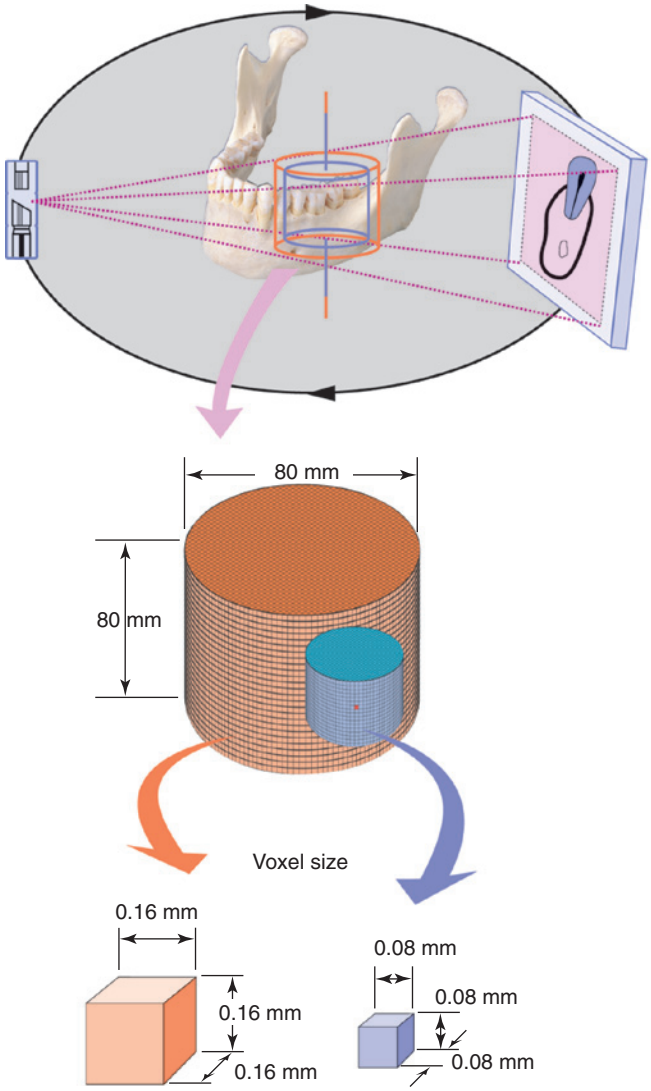

FIG. 1-30 The radiation source in cone-beam volumetric tomography is conical. The receiving sensor captures the image as "voxels," or three-dimensional pixels of information, allowing digital interpretation.

demonstrated the advantages of CBCT in the differential diagnosis of such structures from pathologic conditions.[21,29,71,137]

Cone-beam computerized tomography should not be seen as a replacement for conventional dental radiography, but rather as a diagnostic adjunct. The advantage of conventional dental radiography is that it can visualize most of the structures in one image. CBCT can show great detail in many planes of vision but can also leave out important details if the "slice" is not in the area of existing pathosis (Fig. 1-31). There is a promising future for the use of CBCT for endodontic diagnosis and treatment. It has already proven invaluable in the detection of dental and nondental pathoses (Fig. 1-32). For a further review of CBCT and radiography, see Chapter 2.

Magnetic Resonance Imaging (MRI)

MRI has also been suggested for dental diagnosis. It may offer simultaneous three-dimensional hard- and soft-tissue imaging of teeth without ionizing radiation.[58] The use of MRI in endodontics is still limited.

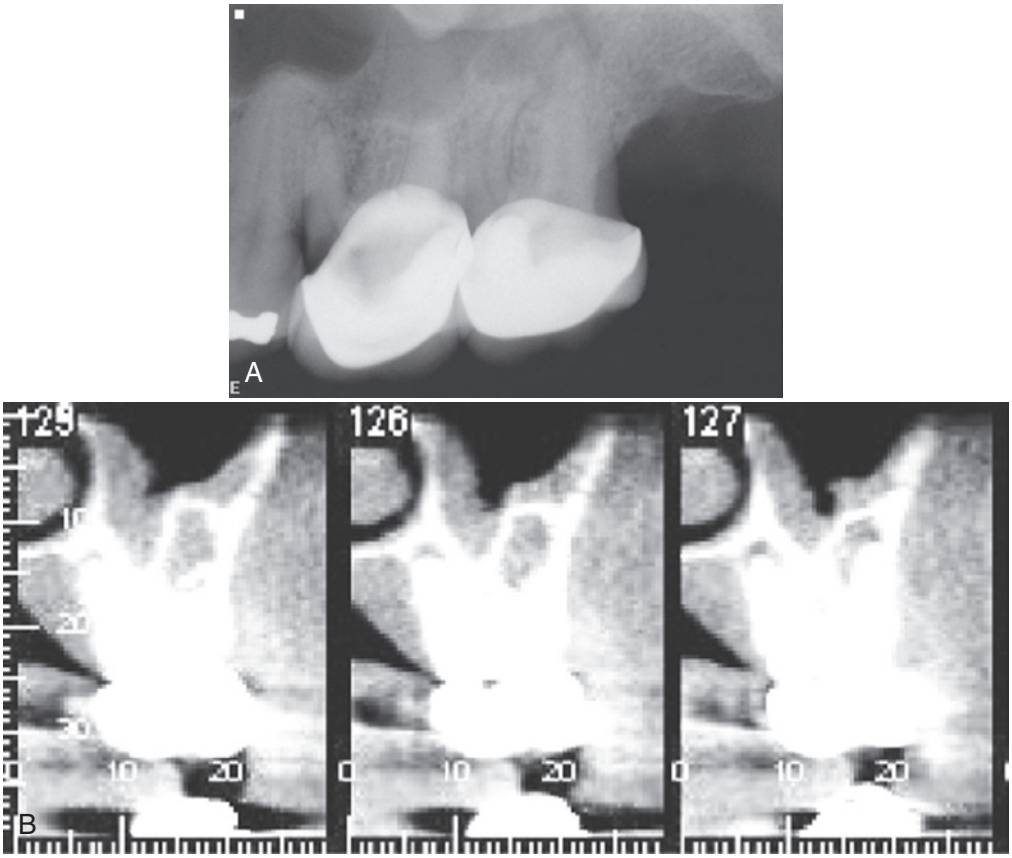

FIG. 1-31 **A,** This standard two-dimensional radiographic image reveals recurrent caries under the mesial margin of the maxillary first molar. However, the patient localized pain to mastication on the maxillary second molar. **B,** Cone-beam volumetric tomography revealed an apical radiolucency associated with the maxillary second molar. The bone loss was obscured on the two-dimensional radiograph by the maxillary sinus, zygoma, and cortical bone.

Cracks and Fractures

The wide variety of types of cracks and fractures in teeth and their associated signs and symptoms often make their diagnosis difficult. The extensiveness of the crack or fracture line may directly alter the prognosis assessment for a given tooth and should be examined before treatment decision making. Certain types of cracks may be as innocent as a superficial enamel craze line, or they may be as prominent as a fractured cusp. The crack may progress into the root system to involve the pulp, or it may split the entire tooth into two separate segments. The crack may be oblique, extending cervically, such that once the coronal segment is removed the tooth may or may not be restorable. Any of these situations may present with mild, moderate, or severe symptoms or possibly no symptoms at all.

Crack Types

There have been many suggestions in the literature of was to classify cracks in teeth. By defining the type of crack present, an assessment of the prognosis may be determined and treatment alternatives can be planned (see Chapter 21). Unfortunately, it is often extremely difficult to determine how extensive a crack is until the tooth is extracted.

Cracks in teeth can be divided into three basic categories:

- Craze lines
- Fractures (also referred to as *cracks*)
- Split tooth/roots

Craze lines are merely cracks in the enamel that do not extend into the dentin and either occur naturally or develop after trauma. They are more prevalent in adult teeth and usually occur more in the posterior teeth. If light is transilluminated through the crown of such a tooth, these craze lines may show up as fine lines in the enamel with light being able to transmit through them, indicating that the crack is only superficial. The use of optical coherence tomography (OCT) has also been suggested for detection of enamel cracks.[59] Craze lines typically will not manifest with symptoms. No treatment is necessary for craze lines unless they create a cosmetic issue.

Fractures extend deeper into the dentin than superficial craze lines and primarily extend mesially to distally, involving the marginal ridges. Dyes and transillumination are helpful for visualizing potential root fractures.

Symptoms from a fractured tooth range from none to severe pain. A fracture in the tooth does not necessarily dictate that the tooth has split into two pieces; however, left alone or especially with provocations such as occlusal prematurities, the fracture may progress into a split root. A fractured tooth may be treated by a simple restoration, endodontics (nonsurgical or surgical), or even extraction, depending on the extent and orientation of the fracture, the degree of symptoms, and whether the symptoms can be eliminated. This makes the clinical management of fractured teeth difficult and sometimes unpredictable.

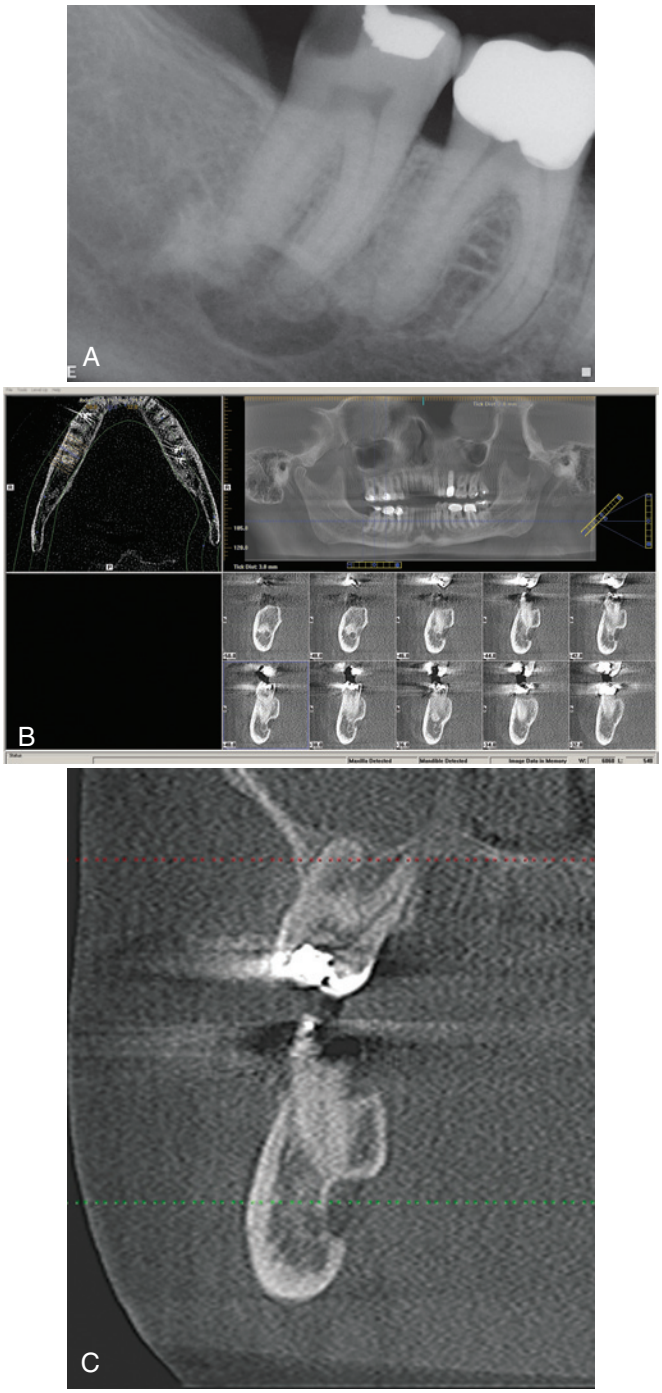

FIG. 1-32 A, Periapical radiograph showing a large apical radiolucency associated with the mandibular second molar. Apical pathosis should be ruled out. B, Cone-beam volumetric tomography revealed salivary indentation of the mandible in the area apical and lingual to the mandibular second molar, consistent with a Stafne defect. C, Enlargement of coronal section in the area of the mandibular second molar and the Stafne defect located on the lingual aspect of the mandible.

A definitive combination of factors, signs, and symptoms that, when collectively observed, allows the clinician to conclude the existence of a specific disease state is termed a *syndrome*. However, given the multitude of signs and symptoms that fractured roots can present with, it is often difficult to achieve an objective definitive diagnosis. For this reason, the terminology of *cracked tooth syndrome*[22,108] should be avoided.[6] The subjective and objective factors seen in cases of fractured teeth will generally be diverse; therefore, a tentative diagnosis of a fractured tooth will most likely be more of a prediction. Once this prediction is made, the patient must be properly informed as to any potential decrease in prognosis of the pending dental treatment. Because treatment options for repairing fractured teeth have only a limited degree of success, early detection and prevention, and proper informed consent, are crucial.[9,10,72,119,120,124,132]

Split tooth/roots occur when a fracture extends from one surface of the tooth to another surface of the tooth, with the tooth separating into two segments. If the split is more oblique, it is possible that once the smaller separated segment is removed, the tooth might still be restorable—for example, a fractured cusp. However, if the split extends below the osseous level, the tooth may not be restorable and endodontic treatment may not result in a favorable prognosis.

Proper prognosis assessment is imperative before any dental treatment but is often difficult in cases of cracked teeth. Because of the questionable long-term success from treating cases of suspected or known fractures, the clinician should be cautious in making the decision to continue with treatment and should avoid endodontic treatment in cases of a definitive diagnosis of split roots.

Vertical Root Fractures

One of the more common reasons for recurrent endodontic pathosis is the *vertical root fracture,* a severe crack in the tooth that extends longitudinally down the long axis of the root (Figs. 1-33 and 1-34). Often it extends through the pulp and to the periodontium. It tends to be more centrally located within the tooth, as opposed to being more oblique, and typically traverses through the marginal ridges. These fractures may be present before endodontic treatment, secondary to endodontic treatment, or may develop after endodontic treatment has been completed. Because diagnosing these vertical root fractures may be difficult, they often go unrecognized. Therefore, diagnosing the existence and extent of a vertical root fracture is imperative before any restorative or endodontic treatment is done, as it can dramatically affect the overall success of treatment.

A patient who consents to endodontic treatment must be informed if the tooth has a questionable prognosis. The clinician must be able to interpret the subjective and objective findings that suggest a vertical root fracture or split tooth, be able to make a prediction as to the eventual potential of healing, and convey this information to the patient. A more detailed discussion on vertical root fractures is described in Chapter 21.

Perforations

Root perforations are clinical complications that may lead to treatment failure. When root perforation occurs, communications between the root canal system and either periradicular tissues or the oral cavity may reduce the prognosis of treatment. Root perforations may result from extensive carious lesions, resorption, or operator error occurring during root canal instrumentation or post preparation.

The treatment prognosis of root perforations depends on the size, location, time of diagnosis and treatment, degree of periodontal damage, as well as the sealing ability and biocompatibility of the repair material.[45] It has been recognized that

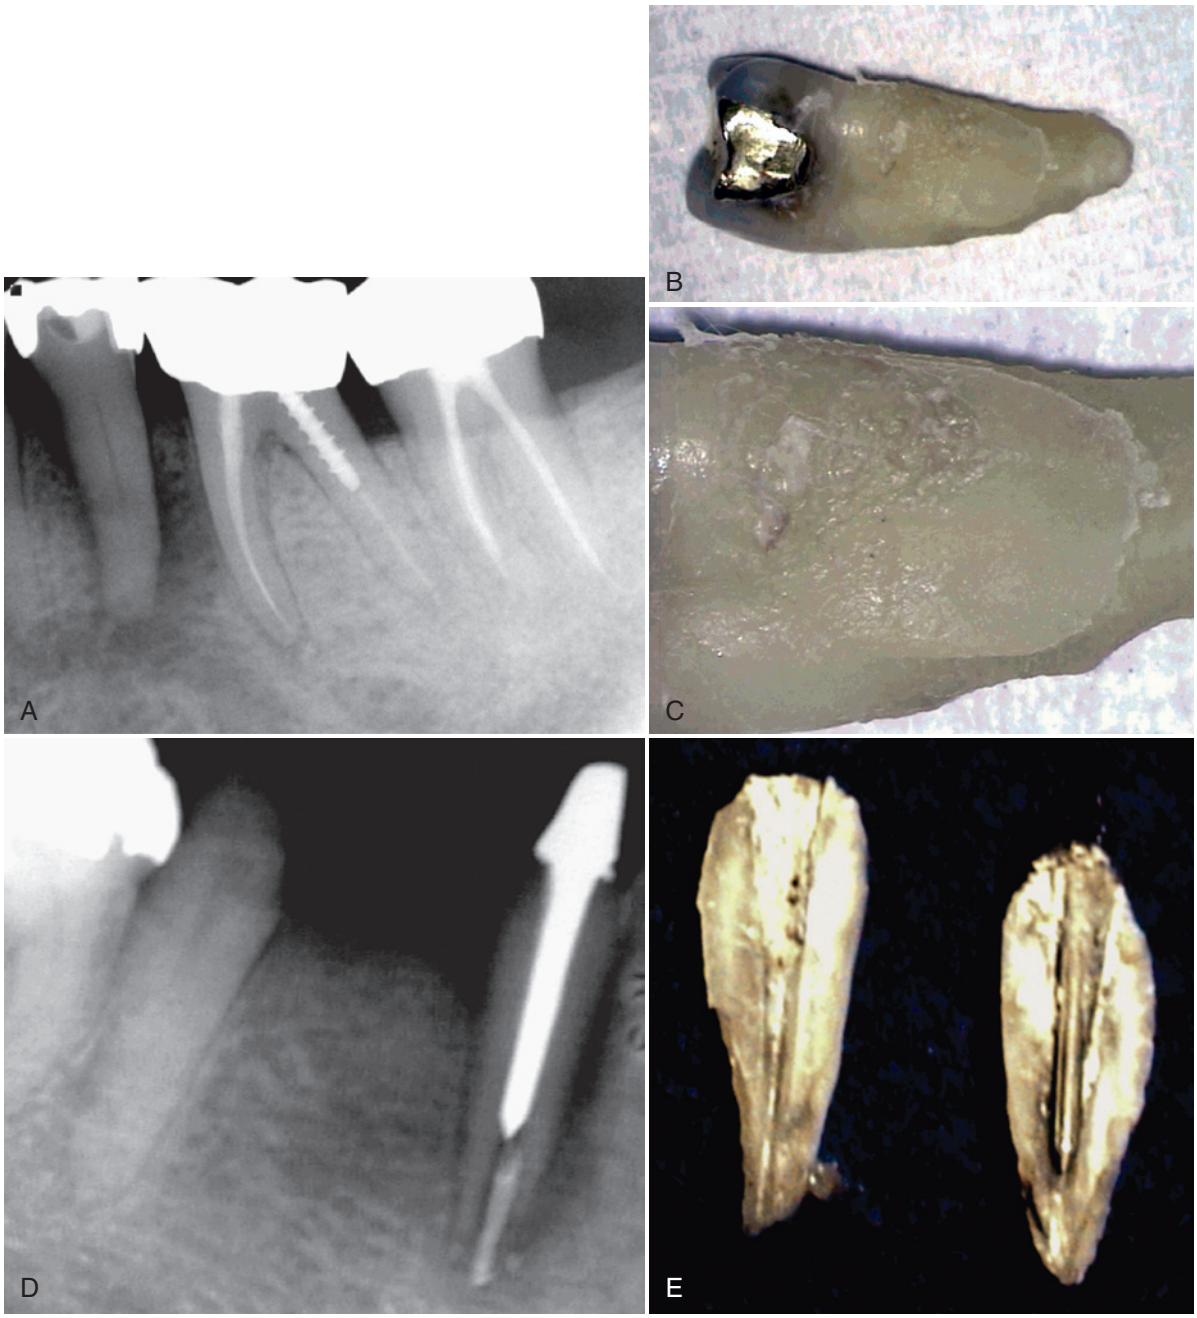

FIG. 1-33 Poorly fitting intracoronal restorations can place stresses within the tooth that can cause a vertical root fracture. **A,** This radiograph of a mandibular second premolar (with a gold inlay) reveals extensive periapical and periradicular bone loss, especially on the distal aspect. **B,** The tooth pulp tested nonvital, and there was an associated 12-mm-deep, narrow, isolated periodontal pocket on the buccal aspect of the tooth. After the tooth was extracted, the distal aspect was examined. **C,** On magnification (×16) the distal aspect of the root revealed an oblique vertical root fracture. Similarly, the placement of an ill-fitting post may exert intraradicular stresses on a root that can cause a fracture to occur vertically. **D,** This radiograph depicts a symmetrical space between the obturation and the canal wall, suggesting a vertical root fracture. **E,** After the tooth is extracted, the root fracture can be easily observed.

treatment success depends mainly on immediate sealing of the perforation and appropriate infection control. Among the materials that are commonly used to seal root perforations are mineral trioxide aggregate (MTA), Super EBA, intermediate restorative material (IRM), glass ionomer cements, and composites. The topic of perforations is further discussed in Chapter 19.

CLINICAL CLASSIFICATION OF PULPAL AND PERIAPICAL DISEASES

Many attempts have been made over the years to develop classifications of pulpal and periapical disease. However, studies have shown that making a correlation between clinical signs and symptoms and the histopathology of a given clinical

FIG. 1-34 Physical trauma from sports-related injuries or seizure-induced trauma, if directed accordingly, may cause a vertical root fracture in a tooth. This fracture occurred in a 7-year-old child secondary to trauma from a grand mal seizure.

condition is challenging.[122,123] Therefore, *clinical* classifications have been developed in order to formulate treatment plan options. In the most general terms, the objective and subjective findings are used to classify the suspected pathosis, with the assigned designations merely representing the presence of healthy or diseased tissue.

The terminology and classifications that follow are based on those suggested by the American Association of Endodontists in 2012.[6]

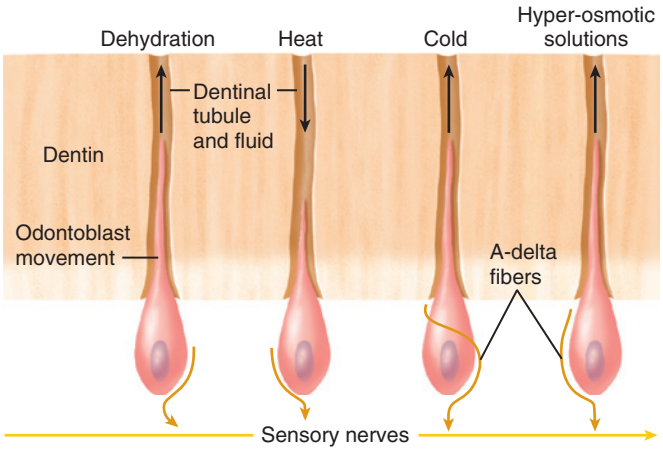
Pulpal Disease

Normal Pulp

This is a clinical diagnostic category in which the pulp is symptom-free and normally responsive to pulp testing.[6] Teeth with normal pulp do not usually exhibit any spontaneous symptoms. The symptoms produced from pulp tests are mild, do not cause the patient distress, and result in a transient sensation that resolves in seconds. Radiographically, there may be varying degrees of pulpal calcification but no evidence of resorption, caries, or mechanical pulp exposure. No endodontic treatment is indicated for these teeth.

Pulpitis

This is a clinical and histologic term denoting inflammation of the dental pulp, clinically described as reversible or irreversible and histologically described as acute, chronic, or hyperplastic.[6]



Dentin tubule fluid movement

FIG. 1-35 Dentinal tubules are filled with fluid that, when stimulated, will cause sensation. Temperature changes, air, and osmotic changes can provoke the odontoblastic process to induce the stimulation of underlying A-delta fibers.

Reversible Pulpitis

This is a clinical diagnosis based on subjective and objective findings indicating that the inflammation should resolve and the pulp return to normal.[6] When the pulp within the tooth is irritated so that the stimulation is uncomfortable to the patient but reverses quickly after irritation, it is classified as *reversible pulpitis*. Causative factors include caries, exposed dentin, recent dental treatment, and defective restorations. Conservative removal of the irritant will resolve the symptoms. Confusion can occur when there is exposed dentin, without evidence of pulp pathosis, which can sometimes respond with sharp, quickly reversible pain when subjected to thermal, evaporative, tactile, mechanical, osmotic, or chemical stimuli. This is known as *dentin* (or *dentinal*) *sensitivity* (or *hypersensitivity*). Exposed dentin in the cervical area of the tooth accounts for most of the cases diagnosed as dentin sensitivity.[103]

As described in Chapter 12, fluid movement within dentinal tubules can stimulate the odontoblasts and associated fast-conducting A-delta nerve fibers in the pulp, which in turn produce sharp, quickly reversible dental pain (Fig. 1-35). The more open these tubules are (e.g., from a newly exposed preparation, dentin decalcification, periodontal scaling, tooth-bleaching materials, or coronal tooth fractures), the more the tubule fluid will move and, subsequently, the more the tooth will display dentin sensitivity when stimulated. When making a diagnosis, it is important to discriminate this dentin sensitivity sensation from that of reversible pulpitis, which would be secondary to caries, trauma, or new or defective restorations. Detailed questioning about recent dental treatment and a thorough clinical and radiographic examination will help to separate dentin sensitivity from other pulpal pathosis, as the treatment modalities for each are completely different.[18]

Irreversible Pulpitis

As the disease state of the pulp progresses, the inflammatory condition of the pulp can change to *irreversible pulpitis*. At this stage, treatment to remove the diseased pulp will be necessary. This condition can be divided into the subcategories of *symptomatic* and *asymptomatic* irreversible pulpitis.

Symptomatic Irreversible Pulpitis

This is a clinical diagnosis based on subjective and objective findings indicating that the vital inflamed pulp is incapable of healing.[6] Teeth that are classified as having *symptomatic irreversible pulpitis* exhibit intermittent or spontaneous pain. Rapid exposure to dramatic temperature changes (especially to cold stimuli) will elicit heightened and prolonged episodes of pain even after the thermal stimulus has been removed. The pain in these cases may be sharp or dull, localized, diffuse, or referred. Typically, there are minimal or no changes in the radiographic appearance of the periradicular bone. With advanced irreversible pulpitis, a thickening of the periodontal ligament may become apparent on the radiograph, and there may be some evidence of pulpal irritation by virtue of extensive pulp chamber or root canal space calcification. Deep restorations, caries, pulp exposure, or any other direct or indirect insult to the pulp, recently or historically, may be present. It may be seen radiographically or clinically or may be suggested from a complete dental history. Patients who present with symptomatic anterior teeth for which there are no obvious etiologic factors should be also questioned regarding past general anesthesia or endotracheal intubation procedures.[3,127,138] In addition, patients should be questioned about a history of orthodontic treatment. Typically, when symptomatic irreversible pulpitis remains untreated, the pulp will eventually become necrotic.[109,139]

Asymptomatic Irreversible Pulpitis

This is a clinical diagnosis based on subjective and objective findings indicating that the vital inflamed pulp is incapable of healing.[6] The patient, however, does not complain of any symptoms. On occasion, deep caries will not produce any symptoms, even though clinically or radiographically the caries may extend well into the pulp. Left untreated, the tooth may become symptomatic or the pulp will become necrotic. In cases of *asymptomatic irreversible pulpitis,* endodontic treatment should be performed as soon as possible so that symptomatic irreversible pulpitis or necrosis does not develop and cause the patient severe pain and distress.

Pulp Necrosis

This is a clinical diagnostic category indicating death of the dental pulp. The pulp is usually nonresponsive to pulp testing.[6] When pulpal *necrosis* (or *nonvital pulp*) occurs, the pulpal blood supply is nonexistent and the pulpal nerves are nonfunctional. It is the only clinical classification that directly attempts to describe the histologic status of the pulp (or lack thereof). This condition is subsequent to symptomatic or asymptomatic irreversible pulpitis. After the pulp becomes completely necrotic, the tooth will typically become asymptomatic until such time when there is an extension of the disease process into the periradicular tissues. With pulp necrosis, the tooth will usually not respond to electric pulp tests or to cold stimulation. However, if heat is applied for an extended period of time, the tooth may respond to this stimulus. This response could possibly be related to remnants of fluid or gases in the pulp canal space expanding and extending into the periapical tissues.

Pulpal necrosis may be partial or complete and it may not involve all of the canals in a multirooted tooth. For this reason, the tooth may present with confusing symptoms. Pulp testing over one root may give no response, whereas over another root it may give a positive response. The tooth may also exhibit symptoms of symptomatic irreversible pulpitis. Pulp necrosis, in the absence of restorations, caries, or luxation injuries, is likely caused by a longitudinal fracture extending from the occlusal surface and into the pulp.[19]

After the pulp becomes necrotic, bacterial growth can be sustained within the canal. When this infection (or its bacterial byproducts) extends into the periodontal ligament space, the tooth may become symptomatic to percussion or exhibit spontaneous pain. Radiographic changes may occur, ranging from a thickening of the periodontal ligament space to the appearance of a periapical radiolucent lesion. The tooth may become hypersensitive to heat, even to the warmth of the oral cavity, and is often relieved by applications of cold. As previously discussed, this may be helpful in attempting to localize a necrotic tooth (i.e., by the application of cold one tooth at a time) when the pain is referred or not well localized.

Previously Treated

This is a clinical diagnostic category indicating that the tooth has been endodontically treated and the canals are obturated with various filling materials other than intracanal medicaments.[6] In this situation, the tooth may or may not present with signs or symptoms but will require additional nonsurgical or surgical endodontic procedures to retain the tooth. In most such situations, there will no longer be any vital or necrotic pulp tissue present to respond to pulp testing procedures.

Previously Initiated Therapy

This is a clinical diagnostic category indicating that the tooth has been previously treated by partial endodontic therapy (e.g., pulpotomy, pulpectomy).[6] In most instances, the partial endodontic therapy was performed as an emergency procedure for symptomatic or asymptomatic irreversible pulpitis cases. In other situations, these procedures may have been performed as part of vital pulp therapy procedures, traumatic tooth injuries, apexification, or apexogenesis therapy. At the time these cases present for root canal therapy it would not be possible to make an accurate pulpal diagnosis because all, or part, of the pulp tissue has already been removed.

Apical (Periapical) Disease

Normal Apical Tissues

This classification is the standard against which all of the other apical disease processes are compared. In this category the patient is asymptomatic and the tooth responds normally to percussion and palpation testing. The radiograph reveals an intact lamina dura and periodontal ligament space around all the root apices.

Periodontitis

This classification refers to an inflammation of the periodontium.[6] When located in the periapical tissues it is referred to as apical periodontitis. Apical periodontitis can be subclassified to symptomatic apical periodontitis and asymptomatic apical periodontitis.

Symptomatic Apical Periodontitis

This condition is defined as an inflammation, usually of the apical periodontium, producing clinical symptoms including a painful response to biting or percussion or palpation. It might or might not be associated with an apical radiolucent area.[6]

This tooth may or may not respond to pulp vitality tests, and the radiograph or image of the tooth will typically exhibit at least a widened periodontal ligament space and may or may not show an apical radiolucency associated with one or all of the roots.

Asymptomatic Apical Periodontitis

This condition is defined as inflammation and destruction of apical periodontium that is of pulpal origin, appears as an apical radiolucent area, and does not produce clinical symptoms.[6] This tooth does not usually respond to pulp vitality tests, and the radiograph or image of the tooth will exhibit an apical radiolucency. The tooth is generally not sensitive to biting pressure but may "feel different" to the patient on percussion. Manifestation of persistent apical periodontitis may vary among patients.[89]

Acute Apical Abscess

This condition is defined as an inflammatory reaction to pulpal infection and necrosis characterized by *rapid onset*, spontaneous pain, tenderness of the tooth to pressure, pus formation, and swelling of associated tissues.[6] A tooth with an *acute apical abscess* will be acutely painful to biting pressure, percussion, and palpation. This tooth will not respond to any pulp vitality tests and will exhibit varying degrees of mobility. The radiograph or image can exhibit anything from a widened periodontal ligament space to an apical radiolucency. Swelling will be present intraorally and the facial tissues adjacent to the tooth will almost always present with some degree of swelling. The patient will frequently be febrile, and the cervical and submandibular lymph nodes may exhibit tenderness to palpation.

Chronic Apical Abscess

This condition is defined as an inflammatory reaction to pulpal infection and necrosis characterized by *gradual onset*, little or no discomfort, and the intermittent discharge of pus through an associated sinus tract.[6] In general, a tooth with a *chronic apical abscess* will not present with clinical symptoms. The tooth will not respond to pulp vitality tests, and the radiograph or image will exhibit an apical radiolucency. Usually the tooth is not sensitive to biting pressure but can "feel different" to the patient on percussion. This entity is distinguished from asymptomatic apical periodontitis because it will exhibit intermittent drainage through an associated sinus tract.

REFERRED PAIN

The perception of pain in one part of the body that is distant from the actual source of the pain is known as *referred pain*. Whereas pain of nonodontogenic origin can refer pain to the teeth, teeth may also refer pain to other teeth as well as to other anatomic areas of the head and neck (see Chapters 4 and 17). This may create a diagnostic challenge, in that the patient may insist that the pain is from a certain tooth or even from an ear when, in fact, it is originating from a distant tooth with pulpal pathosis. Using electronic pulp testers, investigators found that patients could localize *which* tooth was being stimulated only 37.2% of the time and could narrow the location to three teeth only 79.5% of the time, illustrating that patients may have a difficult time discriminating the exact location of pulpal pain.[44]

Referred pain from a tooth is usually provoked by an intense stimulation of pulpal C fibers, the slow conducting nerves that when stimulated cause an intense, slow, dull pain. Anterior teeth seldom refer pain to other teeth or to opposite arches, whereas posterior teeth may refer pain to the opposite arch or to the periauricular area but seldom to the anterior teeth.[14] Mandibular posterior teeth tend to transmit referred pain to the periauricular area more often than maxillary posterior teeth. One study showed that when second molars were stimulated with an electric pulp tester, patients could discriminate accurately which arch the sensation was coming from only 85% of the time, compared with an accuracy level of 95% with first molars and 100% with anterior teeth.[136] The investigators also pointed out that when patients first feel the sensation of pain, they are more likely to accurately discriminate the origin of the pain. With higher levels of discomfort, patients have less ability to accurately determine the source of the pain. Therefore, in cases of diffuse or referred pain, the history of where the patient first felt the pain may be significant.

Because referred pain can complicate a dental diagnosis, the clinician must be sure to make an accurate diagnosis to protect the patient from unnecessary dental or medical treatment. If after all the testing procedures are complete and it is determined that the pain is not of odontogenic origin, then the patient should be referred to an orofacial pain clinic for further testing. For further information on pain of nonodontogenic origin, see Chapter 17.

SUMMARY

Endodontics is a multifaceted specialty, with much emphasis on how cases are clinically treated. Clinicians have increased their ability to more accurately perform endodontic procedures by way of increased visualization using the operating microscope, precise apical foramen detection using electronic apex locators, enhanced imaging techniques using digital radiography, and more. Practices have incorporated more refined canal cleaning and shaping techniques by using ultrasonics and rotary-driven nickel titanium files facilitated with computer-assisted electronic handpieces. Many other advancements have also been introduced with the objective of achieving an optimal result during endodontic treatment. However, these advancements are useless if an incorrect diagnosis is made. Before the clinician ever considers performing any endodontic treatment, the following questions must be answered:

- Is the existing problem of dental origin?
- Are the pulpal tissues within the tooth pathologically involved?
- Why is the pulpal pathosis present?
- What is the prognosis?
- What is the appropriate form of treatment?

Testing, questioning, and reasoning are combined to achieve an accurate diagnosis and to ultimately form an appropriate treatment plan. The art and science of making this diagnosis are the first steps that must be taken before initiating any endodontic treatment.

CHAPTER OUTLINE

Radiographic Interpretation
Imaging Modalities
Image Characteristics and Processing
Digital Imaging and Communications in Medicine (DICOM)
Diagnostic Tasks in Endodontics
Working Length Determination
Diagnosis and Healing
Three-Dimensional Imaging
Principles of Cone Beam Computed Tomography
Voxels and Voxel Sizes
Field of View
Imaging Tasks Improved or Simplified by Cone Beam Volumetric Computed Tomography
Differential Diagnosis
Diagnosis of Endodontic Treatment Failures
Evaluation of Anatomy and Complex Morphology
Intraoperative or Postoperative Assessment of Endodontic Treatment Complications
Materials Extending Beyond the Root Canal
Fractured Instruments
Calcified Canals
Perforations
Dentoalveolar Trauma
Internal and External Root Resorption
Presurgical Visualization
Outcomes Assessment
Implant Site Assessments
Image Perception and Viewing Environment
Future of CBCT
Conclusions

RADIOGRAPHIC INTERPRETATION

Interpretation of information captured by radiographic imaging modalities is central to the diagnostic process. It is very important to capture a diagnostically useful image using appropriate exposure parameters and view it with interactive manipulation of brightness and contrast or window/level (for cone beam computed tomography [CBCT] studies) in an optimal environment to adequately evaluate anatomy and diagnose pathoses. Accurate interpretation of root and canal morphology, determination of radiographic canal length, diagnosis of radicular and periradicular disease (Fig. 2-1), and postsurgical and long-term evaluation of the outcome of endodontic treatment are some of the routine diagnostic imaging tasks in endodontics.[181] Systematic and methodical interpretation processes must be followed for all images. Recognition of anatomy, anatomic variants, and pathologic conditions or deviations from normal is important. Various imaging modalities exist in radiology. Some use ionizing radiation, whereas others use ultrasonic waves (ultrasonography, or US) or powerful external magnetic fields (magnetic resonance imaging, or MRI). Interventional and noninterventional imaging modalities are also available. Imaging modalities using ionizing radiation are most frequently used in endodontic diagnoses. The different image capture modalities include conventional intraoral film and the more modern digital receptors.

Imaging Modalities

Digital radiography using electronic sensors or photostimulable phosphor (PSP) plates is widely used in endodontics. The advantages of using digital sensors over film are many. Significant advantages include noteworthy dose reduction (especially in comparison with D-speed film used with round collimation); almost instantaneous generation of high-resolution digital images with resolution approaching or equaling that of film for specific diagnostic tasks; the ability to postprocess images for enhanced diagnostic outcomes; elimination of variables associated with wet processing of conventional film; ease of transmission and of archiving and retrieving images from databases or picture archiving and communication systems (PACS); facilitation of use of an all-electronic patient record[123,188]; reduced exposure of personnel to hazardous chemicals; and reduced environmental impact.

Digital imaging modalities in endodontics use different image capture technologies, which include a charge-coupled device (CCD), a complementary metal oxide semiconductor (CMOS), or a PSP (also sometimes referred to as an indirect acquisition modality). Film images also can be digitized using a flatbed scanner or CCD/CMOS-based cameras mounted on a camera stand, with images captured using a frame grabber from a mounted, lighted platform.

CCD-based solid-state sensors were used extensively in endodontics initially. However, the earlier generation sensors had

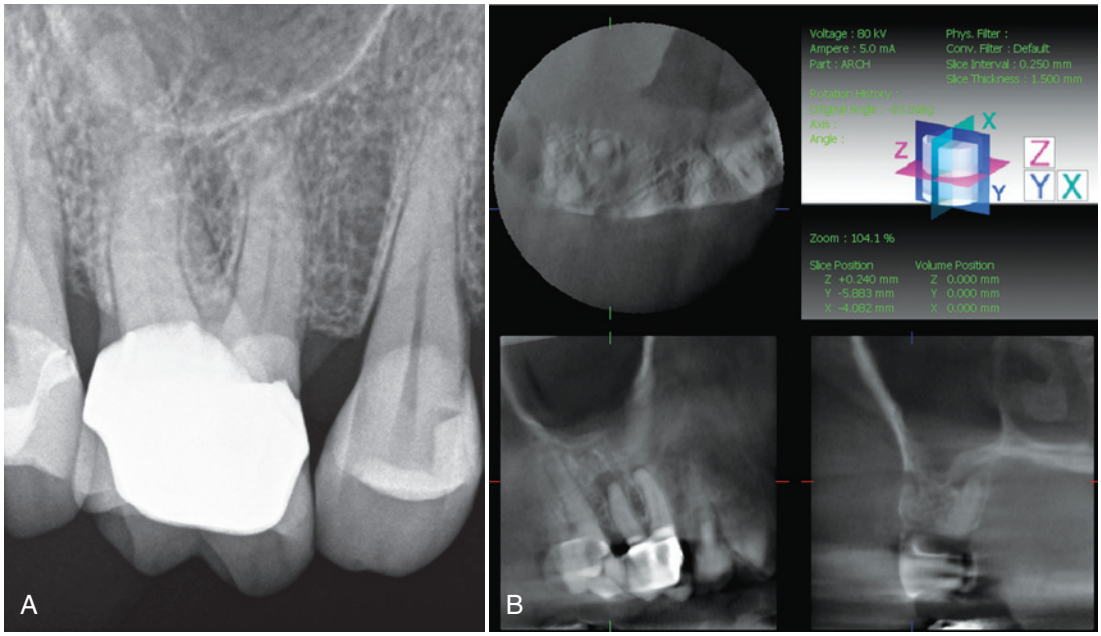

FIG. 2-1 A, A well-angulated periapical radiograph of the maxillary right first molar taken during a diagnostic appointment for endodontic evaluation of the maxillary right quadrant. At first glance, there is little radiographic evidence of significant or periradicular change. B, Contemporaneous CBCT image of same tooth gives an entirely different perspective; periapical changes are visible on all three roots in all three anatomic planes of section. (*B taken* with J. Morita Veraviewepocs 3D [J. Morita, Osaka, Japan]).

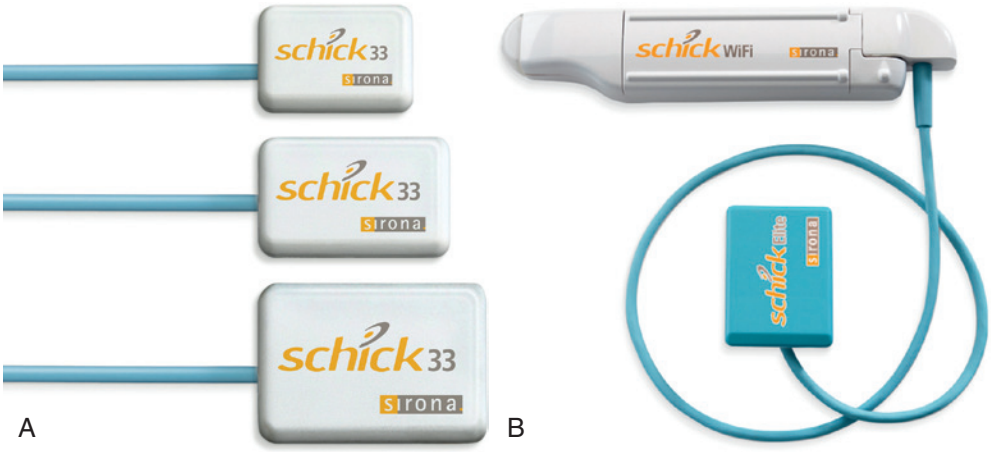

FIG. 2-2 A and B, High-resolution complementary metal oxide semiconductor (CMOS) sensors are available from many manufacturers. Note that Figure B shows wireless CMOS sensors transmit images to the chairside workstation by 2.4 GHz radio frequency. (Courtesy SIRONA DENTAL SYSTEMS, Long Island City, NY.)

a smaller active area and limited x-ray absorption and conversion efficiency, in addition to being bulky. Sensors use an array of radiation-sensitive elements that generate electric charges proportionate to the amount of incident radiation. To reduce the amount of radiation needed to capture an image, a light-sensitive array was developed that uses a scintillation layer laid on top of the CCD chip or added with a fiberoptic coupling. The generated charge is read out in a "bucket brigade" fashion and transferred to an analog-to-digital converter in the frame grabber assembly of the workstation. The digital information is processed, and an image is formed. CMOS-based sensors, on the other hand, have an active transistor at each element location. The area available for signal generation is relatively less, and there is a fixed pattern noise. These sensors are less expensive to manufacture and have been shown to be equally useful for specific diagnostic tasks.[4] Unlike the CCD, the CMOS chip requires very little electrical energy; therefore, no external power supply is needed to support USB utilization, and wireless applications are feasible. Wireless sensors are available (Fig. 2-2). However, radiofrequency interference may be a problem with these sensors. The current WiFi sensor is less bulky and has a wire attached to it that enables transmission via 802.11 b/g standard. It uses a lithium-ion polymer battery that can last for approximately 100 exposures.

Yet another type of sensor uses PSPs for image capture. PSP technology is also referred to as *computed radiography* (CR).[94,169]

Unlike the CCD and CMOS sensors, PSP sensors are wireless. The phosphor is activated by a process called *doping*, which enables charges to be generated and stored when exposed to radiation. A latent image is stored in the sensor, and a PSP reader with a laser beam of specific wavelength is used to read out the image. Previously captured images can be erased by exposing the PSP sensor to white light. PSP plates can be damaged easily by scratching, but they are not as expensive as CCD or CMOS sensors. Incomplete erasure of the image can lead to ghost images when the plate is reused, and delayed processing can result in a decrease in image clarity.[2] PSP-based sensors are used in high-volume scenarios. Spatial resolution is lower with this type of sensor, but it has a wider dynamic range. These sensors can tolerate a wider range of exposures to produce a diagnostically useful image.

Radiation dose continues to be a concern with all imaging studies. The lowest possible dose must be delivered for each study. Most dental offices would not be in compliance with the latest recommendations of the National Council for Radiation Protection (NCRP) on reducing the radiation dose from intraoral radiographs (Box 2-1). Two terms have been specifically defined in the NCRP's report. The terms *shall* and *shall not* indicate that adherence to the recommendation would be in compliance with the standards of radiation safety. The terms *should* and *should not* indicate prudent practice and acknowledge that exceptions may be made in certain circumstances. In addition, the report establishes nine new recommendations for image processing of conventional film.

A strong argument can be made for clinicians to switch to a direct digital radiography (DDR) system to avoid all the drastic changes necessary to ensure compliance with the new recommendations. Even though restriction of an intraoral dental x-ray beam is mandated by federal law to a circle no greater than 7 cm, rectangular collimation has been proven to significantly reduce the radiation dose to the patient.

The American Dental Association (ADA) Council on Scientific Affairs has made the following statement:

> Tissue area exposed to the primary x-ray beam should not exceed the minimum coverage consistent with meeting diagnostic requirements and clinical feasibility. For periapical and bitewing radiography, rectangular collimation should be used whenever possible because a round field beam used with a rectangular image receptor produces … unnecessary radiation exposure to the patient.[1]

BOX 2-1

Recommendations of the National Council on Radiation Protection

1. Dentists must examine their patients before ordering or prescribing x-ray images (this is not a new guideline).
2. The use of leaded aprons on patients shall not be required if all other recommendations in this report are rigorously followed (read full Report #145).
3. Thyroid shielding shall be used for children and should be provided for adults when it will not interfere with the examination (e.g., panoramic imaging).
4. Rectangular collimation of the beam, which has been recommended for years, shall be routinely used for periapical radiographs. Each dimension of the beam, measured in the plane of the image receptor, should not exceed the dimension of the image receptor by more than 2% of the source-to-image receptor distance. Similar collimation should be used, when feasible, for bitewing radiographs.
5. Image receptors of speeds slower than ANSI speed Group E films shall not be used for intraoral radiography. Faster receptors should be evaluated and adopted if found acceptable. For extraoral radiography, high-speed (400 or greater) rare earth screen-film systems or digital-imaging systems of equivalent or greater speed shall be used.
6. Dental radiographic films shall be developed according to the film manufacturer's instructions using the time-temperature method. In practical application, this means that sight development (reading wet x-ray films at the time of the procedure) shall not be used.
7. Radiographic techniques for digital imaging shall be adjusted for the minimum patient dose required to produce a signal-to-noise ratio sufficient to provide image quality to meet the purpose of the examination.
8. Clinicians designing new offices or remodeling existing locations will need shield protection to be provided by a qualified expert.

Modified from the National Council on Radiation Protection and Measurements: Radiation protection in dentistry, Report #145, Bethesda, Md, 2003. Available at: www.ncrppublications.org/Reports/145.

Image Characteristics and Processing

Spatial resolution achieved with current generation digital sensors is equally good or better than that of conventional intraoral radiographic film. Intraoral film has a resolution of 16 line pairs per millimeter (lp/mm) as measured using a resolution tool, and it increases to 20 to 24 lp/mm with magnification. *Spatial resolution* is defined as the ability to display two objects that are close to each other as two separate entities. *Contrast resolution* is defined as the ability to differentiate between areas on the image based on density. Most diagnostic tasks in endodontics require a high-contrast resolution.[121] However, image quality is not just a function of spatial resolution. The choice of appropriate exposure parameters, sensor properties, the image processing used, and viewing conditions and modalities directly affect diagnostic accuracy.

Postprocessing of images may be carried out to alter image characteristics. Radiographs need not be reexposed if image quality is not adequate. Diagnostic information can be teased out of the image if appropriate image processing is used. However, the original image must be acquired with optimal exposure parameters to accomplish meaningful image processing.[178] Suboptimally exposed images cannot be processed to yield diagnostic information, which may lead to a reduction in the diagnostic accuracy of the image. Image enhancement must be task specific. Signal-to-noise ratio (SNR) must be optimized to extract necessary information from the image. The bit-depth of images also has a direct relationship to image quality. It indicates the number of shades of gray that the sensor can capture for display. For example, an 8-bit image can depict 256 shades of gray. Most sensors are 12 or 14 bits in depth, capturing 4,096 or 65,536 shades of gray, respectively. If the sensor captures several thousand shades of gray, the image can be manipulated through enhancement techniques to display those shades of gray that best depict the anatomy of interest. The human visual system is limited in the number of shades of gray that can be read at any point in time. Therefore, image

enhancement is a must for all images, so as to delineate signals of interest through manipulation of the grayscale. Most endodontic tasks require a high contrast and thus a shorter grayscale.

Digital radiographs can be saved in different file formats. Several file formats are available: DICOM (*D*igital *I*maging and *C*ommunications in *M*edicine); tiff (*t*agged *i*mage *f*ile *f*ormat); jpeg (*j*oint *p*hotographic *e*xperts *g*roup); gif (*g*raphics *i*nterchange *f*ormat); BMP (Windows' bitmap image file); PNG (*p*ortable *n*etwork *g*raphics); and so on. There also are several proprietary formats. "Lossy" and "lossless" compression schemes can be used for saving images, although lossless compression is preferred.[58]

Digital Imaging and Communications in Medicine (DICOM)

DICOM is a set of international standards established in 1985 by the American College of Radiology (ACR) and the National Electrical Manufacturers Association (NEMA)[46,175] to address the issue of vendor-independent data formats and data transfers for digital medical images.[77] The ADA has promoted the interoperability of dental images through the efforts of its Working Group 12.1.26. DICOM serves as a standard for the transferal of radiologic images and other medical information between computers, allowing digital communication between systems from various manufacturers and across different platforms (e.g., Apple iOS or Microsoft Windows).[78] The DICOM standard provides for several hundred attribute fields in the record header, which contains information about the image (e.g., pixel density, dimensions, and number of bits per pixel), in addition to relevant patient data and medical information. Although earlier versions did not specify the exact order and definition of the header fields, each vendor is required to publish a DICOM conformance statement, which gives the location of pertinent data. The big hurdle is to support medical and dental consultations between two or more locations with different imaging software. With DICOM in place, dental clinicians can change vendors and maintain database interoperability. Most software vendors are striving to achieve full DICOM compliance, and some have achieved at least partial compliance. However, proprietary DICOM images are still produced in different systems, with the capability to export in universal DICOM format as needed. Diagnostic images are best saved as DICOM files to preserve image fidelity or as tiff files with no compression. Diagnosis suffers when images undergo lossy compression.[50,103,180]

Based on the DICOM model, the ADA Standards Committee on Dental Informatics has identified four basic goals for electronic standards in dentistry: (1) interoperability, (2) electronic health record design, (3) clinical workstation architecture, and (4) electronic dissemination of dental information.[7] The dental profession must continue to promote DICOM compatibility so that proprietary software and file types do not hinder communication and risk making data obsolete.

DIAGNOSTIC TASKS IN ENDODONTICS

Working Length Determination

Digital imaging systems perform as well as intraoral film or better for working length determination.[121] No significant difference was noted between measurements made on digital images.[99] Older studies compared the early generation digital sensors with limited bit-depth to D-speed films, and the films showed better performance. It is important to analyze the type of sensor used, software, processing, video card and monitor, and viewing conditions to determine whether the sensor is good for a specific diagnostic task. Calibration improves the diagnostic accuracy.[108] Likewise, the use of optimal processing parameters improves image quality to the extent of making a significant difference in the diagnostic outcome. For instance, density plot analysis was shown to help with endodontic file measurements.[146] The major advantage of direct digital radiography (CCD, CMOS) is that the dose is significantly less compared with that required for film. The use of DDR, therefore, is justified when its performance is comparable to that of film with no statistically significant differences.[101]

The three types of measurement generally available with digital imaging software are (1) linear measurement, the distance between two points in millimeters (Fig. 2-3); (2) angle measurement, the angle between two lines; and (3) area measurement, the area of the image or a segment of the image. Because magnification and distortion errors play a significant role in the accuracy of two-dimensional (2D) radiographic measurement, both film and digital systems are subject to parallax error. However, a study that compared endodontic file length images of human teeth taken with a custom jig suggested that "measurement error was significantly less for the digital images than the film-based images."[49] This was true even though, as the authors pointed out, the measurement differences may not have been clinically significant. Sophisticated calibration algorithms are under development, and accurate measurement of parallel images should be more feasible in the future.[30]

Diagnosis and Healing

Image enhancement of direct and indirect digital radiographs based on the diagnostic task at hand has been shown to increase diagnostic accuracy compared to film-based images, which cannot be enhanced.[2,190] Posttreatment endodontic evaluation of healing of apical radiolucent areas is a challenge. Early changes indicating healing and bone fill are difficult to detect on conventional or digital radiographs. However, bone fill can be detected using more sensitive techniques, such as digital subtraction radiography, in which two images, separated in time but acquired with the exact same projection geometry and technique factors, can be subtracted from one another to tease out subtle changes in the periodontium and surrounding bone. Subtraction techniques are difficult to carry out in routine clinical practice because they are technique sensitive and can yield incorrect information if not performed accurately. Several studies have shown the usefulness of subtraction radiography using digital sensors.[117,129,194]

Three-Dimensional Imaging

Computed tomography (CT) was introduced by Sir Godfrey Hounsfield in the 1970s. *Tomography* refers to "slice imaging," in which thin slices of the anatomy of interest are captured and synthesized manually or using an algorithm. CT makes use of automated reconstruction. Medical-grade CT used a translate-rotate image acquisition scheme as the technology developed, but the modality always resulted in higher radiation dose delivery because of redundancy of data capture, in addition to longer scan times with the potential for motion artifact.

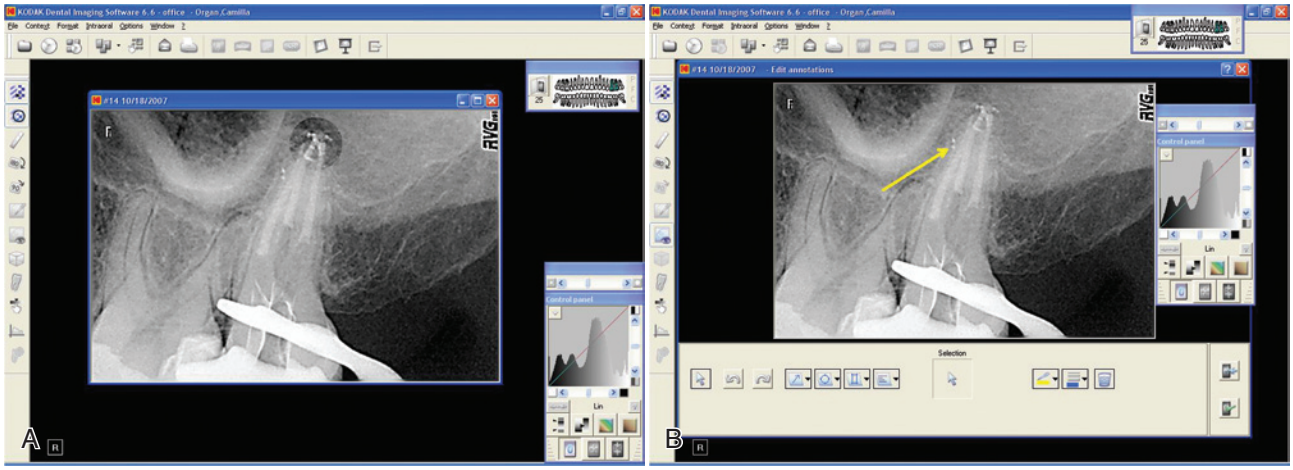

FIG. 2-3 A, Certain regions of interest (ROI) can be highlighted with a preset contrast tool that can be moved around the image. B, Preprogramed filters that enhance sharpness and contrast can be selected to optimize the image acquired. (Courtesy Carestream Dental LLC, Atlanta, GA.)

Multiple detectors and x-ray sources were used in later generations of CT units to reduce scanning times. The increased radiation dose, artifacts from metallic restorations, cost of scanning, long acquisition times, and lack of adequate dental-specific software have been drawbacks limiting the use of the technology in dentistry until recently. The advent of cone beam volumetric computed tomography (CBVCT) introduced a faster, low-dose, low-cost, high-contrast imaging modality that could capture information in three dimensions using a limited field of view.

CBVCT, or cone beam CT (CBCT), is a relatively new diagnostic imaging modality that has been recently added to the endodontic imaging armamentarium. This modality uses a cone beam instead of a fan-shaped beam in multidetector computed tomography (MDCT), acquiring images of the entire volume as it rotates around the anatomy of interest. Compared with MDCT images, CBCT offers relatively high-resolution, isotropic images, allowing effective evaluation of root canal morphology and other subtle changes within the root canal system. Even though the resolution is not as high as that of conventional radiographs (18 microns), the availability of three-dimensional (3D) information, the relatively higher resolution, and a significantly lower dose compared to MDCT make CBCT the imaging modality of choice in challenging situations demanding localization and characterization of root canals.

The adoption of advanced imaging modalities such as CBCT for select diagnostic tasks is becoming popular with clinicians performing endodontic procedures. Two-dimensional gray-scale images, whether conventional film based or digital, cannot accurately depict the full 3D representation of the teeth and supporting structures. In fact, traditional images are poor representations of even the pulpal anatomy. They grossly underestimate canal structure and often cannot accurately visualize periapical changes, especially where there is thick cortical bone, as in the presence of anatomic obstructions (Fig. 2-4, *A*). CBCT, however, allows the clinician to view the tooth and pulpal structures in thin slices in all three anatomic planes: axial, sagittal, and coronal. This capability alone allows visualization of periapical pathoses and root morphology previously impossible to assess (Fig. 2-4, *B* and *C*). Several tools available in CBCT, such as the ability to change the vertical or horizontal angulation of the image in real time, in addition to thin-slice, grayscale data of varying thicknesses, will never be available for conventional or even digital radiography. Furthermore, the use of CBCT data to view the region of interest in three anatomic planes of section at very low x-ray doses has never been as easy or accessible as it is today.

Microcomputed tomography (micro-CT) has also been evaluated in endodontic imaging.[87,144,145] Comparison of the effects of biomechanical preparation on the canal volume of reconstructed root canals in extracted teeth using micro-CT data was shown to assist with characterization of morphologic changes associated with these techniques.[145] Peters et al.[144] used micro-CT to evaluate the relative performance of nickel-titanium (Ni-Ti) instruments after the shaping of root canals of varying preoperative canal geometry (for examples, see Chapter 6). A study to examine the potential and accuracy of micro-CT for imaging of filled root canals showed it to be a highly accurate and nondestructive method for the evaluation of root canal fillings and its constituents. The qualitative and quantitative correlations between histologic and micro-CT examination of root canal fillings were high.[87] However, it is important to note that micro-CT remains a research tool and cannot be used for human imaging in vivo.

This chapter discusses the principles, applications, imaging attributes, image artifacts, and potential liability of adopting CBCT technology for endodontic procedures. Given this information, the student of endodontics will begin to realize the significant advantages, limitations, and diagnostic and treatment planning capabilities of this radiographic imaging modality.

PRINCIPLES OF CONE BEAM COMPUTED TOMOGRAPHY

Three important parameters of cone beam imaging are described in the following sections:

- Voxel size
- Field of view (FOV)
- Slice thickness/measurement accuracy

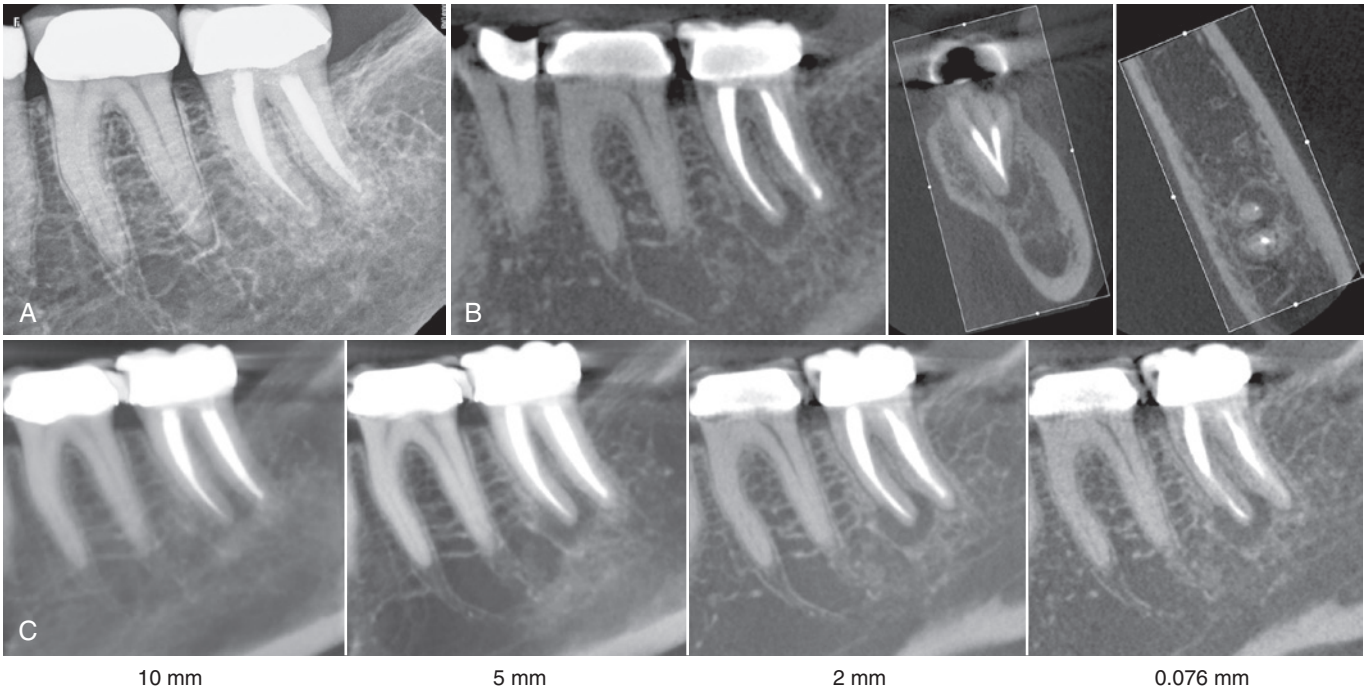

FIG. 2-4 This case demonstrates the difficulty in assessing lesions in the mandibular posterior region when there is a dense cortex. This well-angulated periapical radiograph **(A)** does not clearly show any radiolucencies associated with the mandibular left second molar, for which the patient has presented for evaluation and possible retreatment. The CBCT corrected sagittal, coronal, and axial reconstructed multiplanar views (**B**, *left to right,* sagittal, coronal, and axial views) show previous endodontic treatment, with a 6-mm diameter radiolucency with a well-defined, mildly corticated border, centered over a point on the buccal aspect of the root, 2 mm coronal to the apex; these are features consistent with an apical rarefying osteitis. The ray sum images of the sagittal view, where the image is "thinned" by decreasing the number of adjacent voxels using postprocessing software, simulates a curvilinear projection, showing diminishing superimposition (**C**, *left to right,* image layer of 10 mm, 5 mm, 2 mm, and 0.076 mm). (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, Ga].)

Voxels and Voxel Sizes

Voxels are cuboidal elements that constitute a 3D volume, unlike pixels, which are 2D. Data are acquired and represented in three dimensions using voxels. Unlike with medical computed tomography (MDCT), cone beam units acquire x-ray information using low kV and low mA exposure parameters in a single pass from 180 to 360 degrees of rotation around the anatomy of interest. Medical scanners use higher voltages of 120 kV or more and current of about 400 mA. Several units used in maxillofacial imaging use significantly lower exposure parameters (Figs. 2-5 to 2-7). The x-ray dose for all cone beam units is significantly lower than the dose received from a MDCT unit. Image attributes are also different in that volumes are reconstructed from isotropic voxels; that is, the images are constructed from volumetric detector elements that are cubical in nature and have the same dimensions of length, width, and depth. These voxel sizes can be as small as 0.076 to 0.6 mm.[118] By comparison, MDCT slice data are 0.5 mm to 1 cm thick. Fig. 2-8 illustrates the difference between a pixel and a voxel, the difference between an anisotropic pixel of MDCT and an isotropic pixel (voxel) of CBCT, and how the pixel data are acquired from both modalities.

The patient is positioned on a gantry in an MDCT unit, and images are acquired multiple slices at a time, which

FIG. 2-5 i-CAT unit. (Courtesy Imaging Sciences International, Hatfield, Pa.)

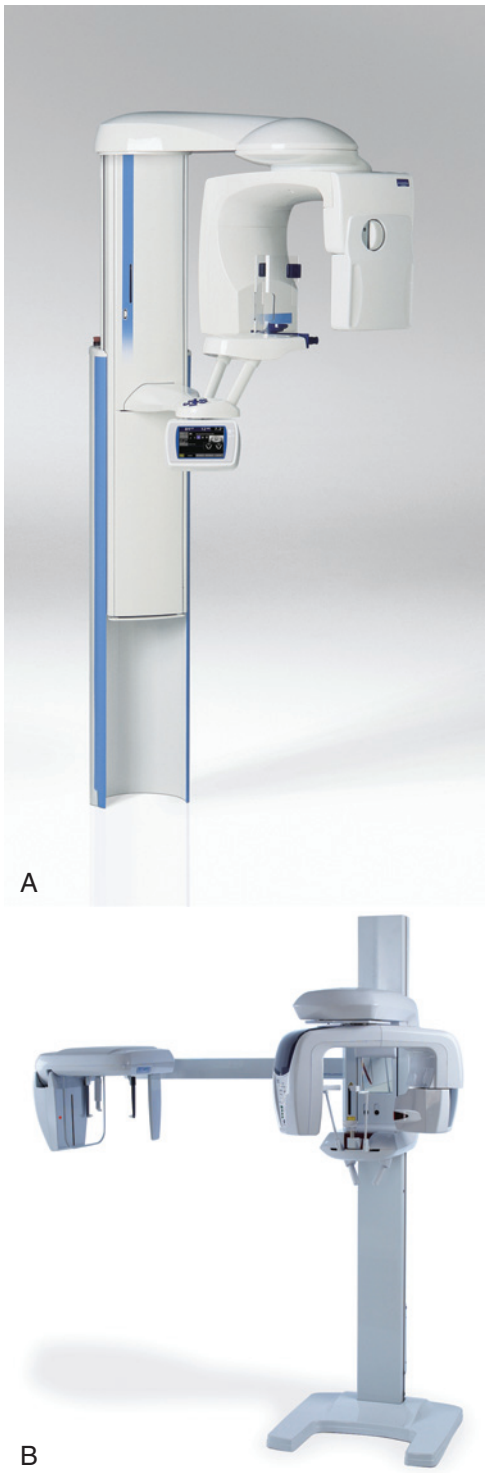

FIG. 2-6 **A**, Planmeca ProMax 3D. **B**, J. Morita Veraviewepocs 3D. (**A** courtesy Planmeca Oy, Helsinki, Finland; **B** courtesy J. Morita Corp, Osaka, Japan.)

prolongs the acquisition time. The number of slices acquired is a direct function of the sensor array configuration. Spiral CT uses continuous translator motion of the gantry as images are acquired, thus shortening the acquisition time. This results in significantly higher absorbed x-ray doses for the patient. A typical CBCT examination would expose the patient to only about 20 to 500 μSv in a single study, whereas a typical medical examination of the head would approach 2100 μSv[2] because the image data are gathered one section at a time. Therefore, soft tissue imaging is better with MDCT because the signal intensity is higher. However, this is not a requirement for dental diagnostic tasks because hard tissue visualization is more important. Consequently, CBCT data have a much higher resolution than MDCT data for hard tissue visualization because of the smaller voxel sizes that medical-grade scanners are incapable of achieving at a significantly lower dose. Increased noise is observed as a result of volumetric acquisition, but the SNR is maintained at a desirable level that facilitates adequate diagnosis based on hard tissue signals.

Field of View

The field of view (FOV) (Figs. 2-9 and 2-10) ranges from as small as a portion of a dental arch to an area as large as the entire head. The selection of the FOV depends on several factors. Among the most important are the following:

- Diagnostic task
- Type of patient
- Spatial resolution requirements

Diagnostic Task

The diagnostic task is the single most important determinant of the FOV in any imaging study. Based on the outcome of the clinical assessment, history, and evaluation of previous and other available imaging studies, a segment of the jaw or a larger area may need to be imaged using an appropriate FOV. If systemic conditions or generalized disorders are suspected, a larger FOV is sometimes required. For most endodontic purposes, a limited FOV can be used, if no signs or symptoms of systemic conditions are reported or noted. Under no circumstances should a screening study be done using a large FOV in the absence of signs and symptoms justifying the procedure. Several multifunctional cone beam units are available that allow the clinician to acquire several image types. Image quality has a direct impact on the diagnostic outcome; therefore, the choice of an FOV should be made carefully. Figure 2-11 illustrates the advantages of using multiple image types for an endodontic case.

Additional benefits of CBCT imaging software include allowing the clinician to format the volume to generate an image that looks like a panoramic radiograph. Conventional panoramic machines, although not commonly used by endodontists, use the focal trough, or zone of sharpness, to position patients so as to minimize distortion along multiple axes. All inherent problems associated with panoramic imaging, including distortion, magnification, blurring, ghost shadows, and other artifacts, can be expected on the resulting image if patient positioning is not accurate. With CBCT, such artifacts are not generated, resulting in a distortion-free panoramic reconstruction (Fig. 2-12). However, it must be noted that CBCTs should not be generated in patients requiring a panoramic radiograph alone, because of dose concerns.

Newer hybrid units, such as the CS 9300 3D Extraoral Imaging System (Carestream Dental, Atlanta, Georgia), have a wide range of FOV choices for a variety of diagnostic tasks, in addition to a conventional panoramic imaging option

FIG. 2-7 A, CS 9000 3D and CS 8100 Extraoral imaging systems. B, Morita Accu-i-tomo 170. (A Courtesy Carestream Dental LLC, Atlanta, GA; B Courtesy J Morita, Irvine, CA.)

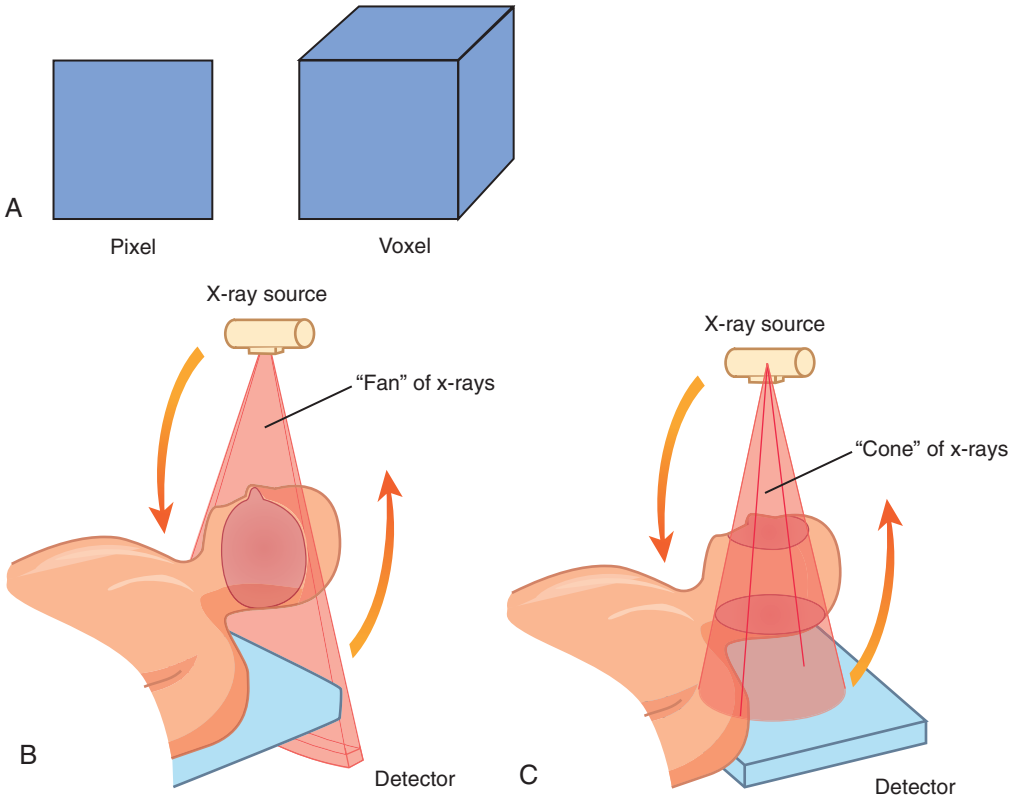

FIG. 2-8 *Left,* Drawing represents a *pixel* (picture element), the image capture and display element of any traditional digital image displayed on the computer. Shades of gray or color are displayed in these pixels to represent a 2D image. *Right,* Drawing represents a *voxel* (volume element). Voxels in CBCT are isometric and have the same dimension or length on all sides. They are very small (from 0.076 to 0.60 microns) and are the capture elements for cone beam imaging devices. Principles of conventional fan beam and cone beam computed tomography are presented in (B) and (C), respectively. (B and C from Babbush CA: *Dental implants: the art and science,* ed 2, St Louis, 2011, Elsevier/Saunders.)

(Fig. 2-13). The CS 9000 unit offers the lowest voxel size of 76 microns, whereas the CS 9300 can resolve down to 90 microns, with a range extending to 500 microns for larger FOV studies. Likewise, the Morita 3D Accuitomo 80 (J. Morita USA, Irvine, California) generates isotropic voxels of 80 microns. Although not necessary for use in every case, this technology, when appropriate, improves visualization and ultimately leads to better care in select situations. A record of exposure and doses must be maintained for each patient.

Type of Patient

Patient size and thus the amount of regional anatomy captured in the study also help determine the FOV. The smallest possible FOV must be chosen for the task at hand. Just because a

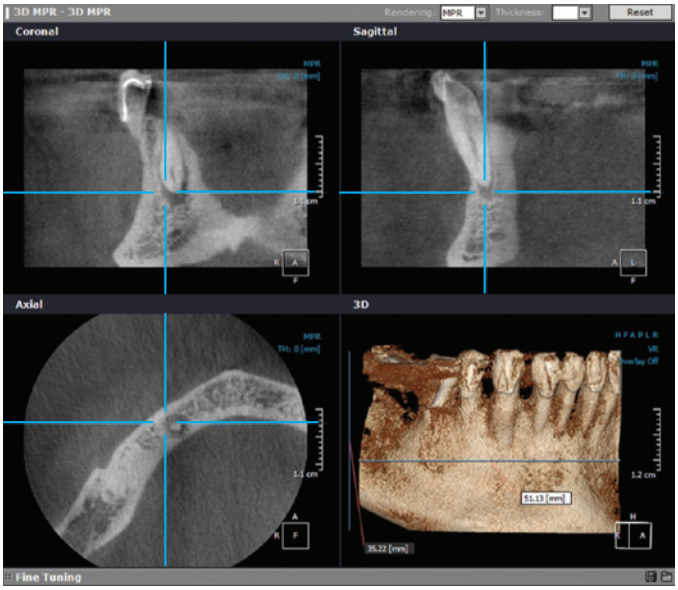

FIG. 2-9 Multiplanar and 3D color reconstructed views of the mandibular quadrant taken on a CBCT machine with a volume size of 37 × 50 mm. (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, Ga].)

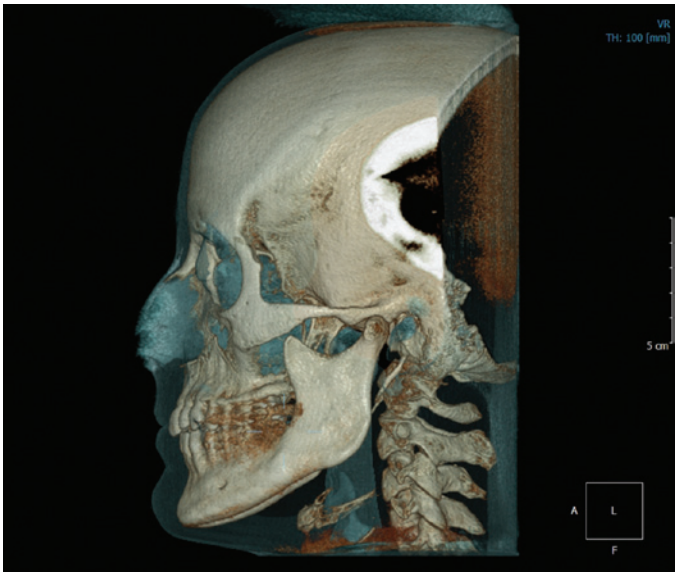

FIG. 2-10 Image of entire head (17 × 23 cm) from a large FoV machine. (Image acquired with i-CAT unit [Imaging Sciences International, Hatfield, Pa].)

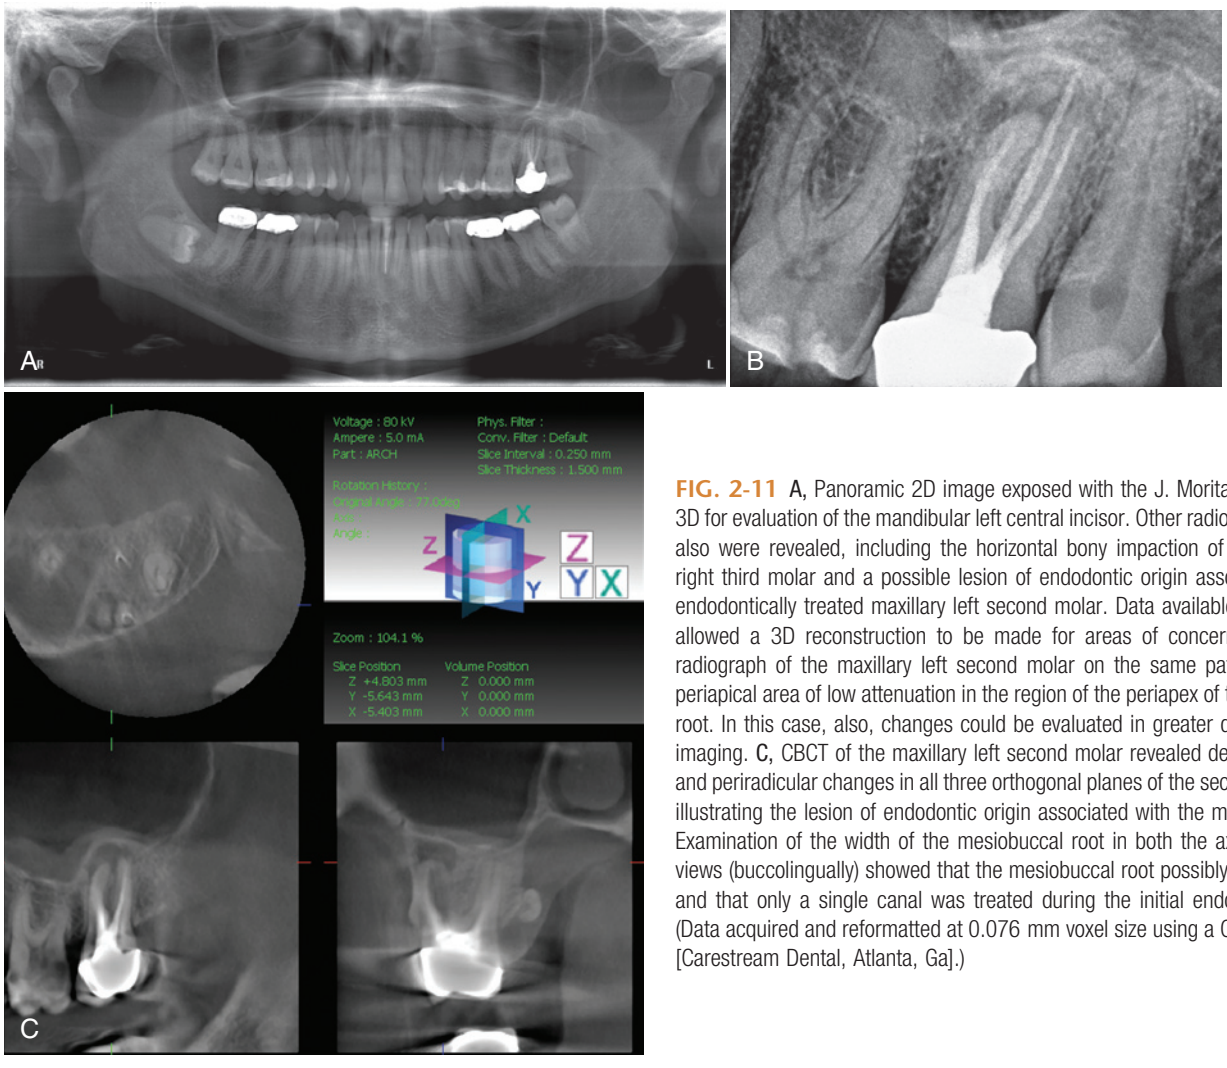

FIG. 2-11 A, Panoramic 2D image exposed with the J. Morita Veraviewepocs 3D for evaluation of the mandibular left central incisor. Other radiographic findings also were revealed, including the horizontal bony impaction of the mandibular right third molar and a possible lesion of endodontic origin associated with the endodontically treated maxillary left second molar. Data available from the scan allowed a 3D reconstruction to be made for areas of concern. B, Periapical radiograph of the maxillary left second molar on the same patient revealed a periapical area of low attenuation in the region of the periapex of the mesiobuccal root. In this case, also, changes could be evaluated in greater detail with CBCT imaging. C, CBCT of the maxillary left second molar revealed detailed periapical and periradicular changes in all three orthogonal planes of the section, specifically illustrating the lesion of endodontic origin associated with the mesiobuccal root. Examination of the width of the mesiobuccal root in both the axial and coronal views (buccolingually) showed that the mesiobuccal root possibly had two canals and that only a single canal was treated during the initial endodontic therapy. (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, Ga].)

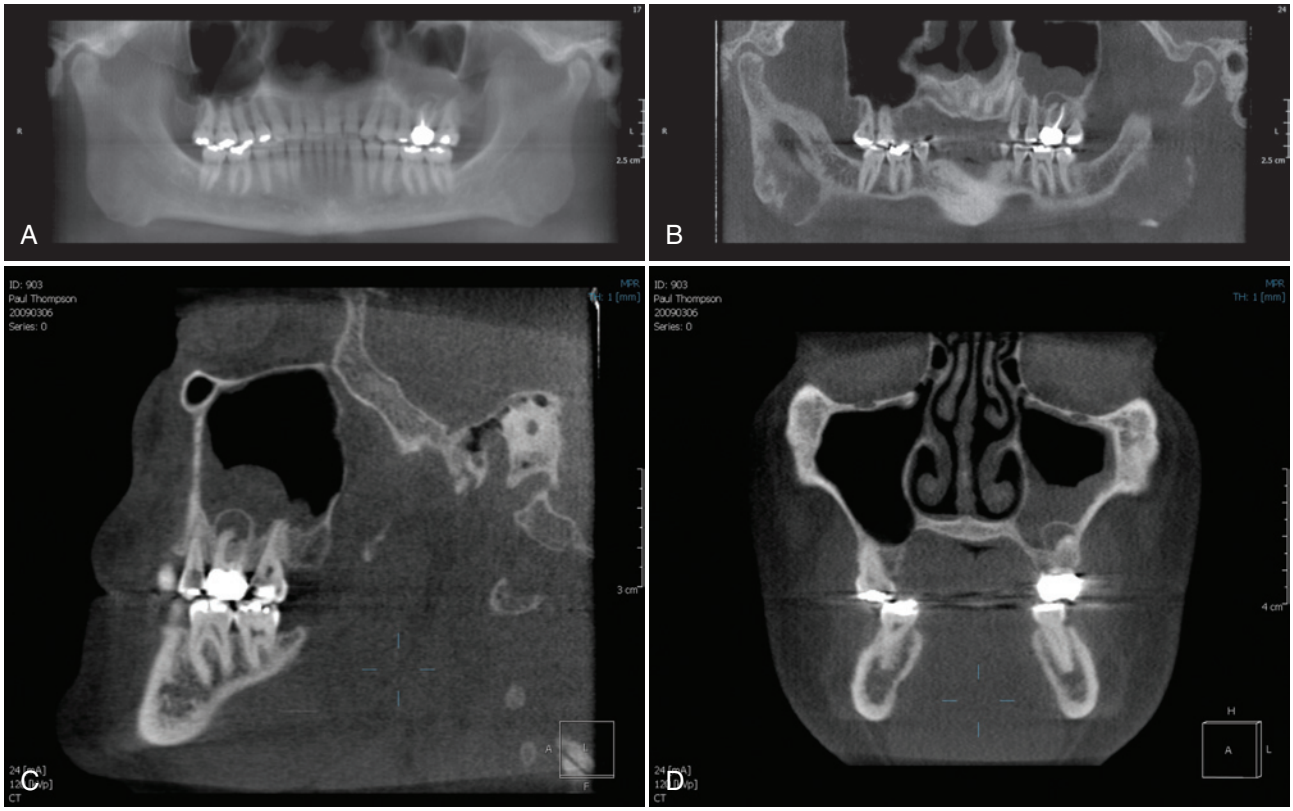

FIG. 2-12 A, This reconstructed panoramic image from CBCT data approximates the view one would see with a conventional panoramic radiograph. It is somewhat difficult to see the lesion on the maxillary left first molar. B, This thin-slice pseudopanoramic image shows the lesion more precisely because the thin slice (0.10 mm) removes most of the anatomic superimposition. These slices of the maxillary left first molar show the lesion in sagittal (C) and coronal (D) views, confirming the features seen in the pseudopanoramic view.

FIG. 2-13 CS 9300 3D Extraoral Imaging System. (Courtesy Carestream Dental LLC, Atlanta, GA.)

clinician owns a cone beam machine does *not* mean that every patient should be exposed to a cone beam study.[119] If previous studies are available, they need to be evaluated first in a recall patient. Use of imaging in children must be minimized. Cone beam machines with smaller FOVs can somewhat limit the radiation dose to critical organs and tissues of the head and neck in these cases.

Spatial Resolution Requirements

All endodontic imaging procedures require high spatial resolution. Assessment of canal structure, canal length, and lesions of endodontic origin (LEOs)[160] showing apical change, in addition to an understanding of possible revision cases, are important tasks requiring minute detail. If CBCT is used, the data acquisition should be performed at the smallest voxel size: the smaller the voxel size, the higher the spatial resolution. Many of the larger stand-alone cone beam machines, such as the i-CAT (Imaging Sciences International, Irvine, California), default to a 0.4 mm voxel size. This voxel size is inadequate for high spatial detail. However, these units often have a voxel size selection option that allows smaller voxel sizes to be used during the image acquisition. The absolute maximum voxel size for endodontic imaging should be 0.2 mm.[35] Units typically use voxel sizes of 0.076 to 0.16 mm for their native image capture (Fig. 2-14).

FIG. 2-14 A, Axial slice from data obtained with a 0.4 mm voxel size. Compare the trabecular pattern and outline of the mental foramina to the same location in an axial slice from data obtained with a 0.16 mm voxel size (B).

IMAGING TASKS IMPROVED OR SIMPLIFIED BY CONE BEAM VOLUMETRIC COMPUTED TOMOGRAPHY

The Executive Opinion of the American Academy of Oral and Maxillofacial Radiology and, later, the position paper on the use of CBCT in endodontics jointly developed by the American Association of Endodontists (AAE) and the American Academy of Oral and Maxillofacial Radiology (AAOMR), list indications for potential use in selected cases, including evaluation of the anatomy and complex morphology, differential diagnosis of complex pathoses with certain qualifiers, intraoperative or postoperative assessment of endodontic treatment, dentoalveolar trauma, resorption, presurgical case planning, and dental implant case planning.[34] Use of CBCT must be determined on a case-by-case basis only. These indications do not in any way mandate the use of CBCT for every case that falls into one of the preceding categories. For endodontic treatment and assessments, there are at least five primary imaging tasks in which CBCT scans have a distinct advantage over traditional 2D radiographs. These tasks include evaluation of the following factors:

1. Differential diagnosis
   a. Lesions of endodontic origin
   b. Lesions of nonendodontic origin
   c. Diagnosis of endodontic treatment failures
   d. Vertical root fractures
2. Evaluation of anatomy and complex morphology
   a. Anomalies
   b. Root canal system morphology
3. Intraoperative or postoperative assessment of endodontic treatment complications
   a. Overextended root canal obturation material
   b. Separated endodontic instruments
   c. Calcified canal identification
   d. Localization of perforation
4. Dentoalveolar trauma
5. Internal and external root resorption
6. Presurgical case planning
7. Dental implant case planning

Differential Diagnosis

Lesions of Endodontic Origin

Clinical endodontic diagnosis relies on subjective and objective information collected during patient examinations. Diagnosis of the pulpal status of the teeth can sometimes be challenging if adequate radiographic information is unavailable. It is fundamental to understand that lesions of endodontic origin arise secondary to pulpal breakdown products and form adjacent to canal portals of exit.[155,161] These radiolucent lesions, formed as a result of loss of bone mineralization, can and do form three dimensionally anywhere along the root surface anatomy.[154] A 30% to 40% mineral content loss is needed for these lesions to be visualized on conventional radiographs.[116] Furthermore, the thickness of the cortical plate covering the lesion may significantly affect the radiographic appearance of the lesion on a conventional image.[192] In a comparative investigation of the use of CBCT and periapical (PA) radiography in the evaluation of the periodontal ligament (PDL), Pope et al.[148a] showed that necrotic teeth examined with CBCT had widened PDLs, but healthy, vital teeth showed significant variation. They called for further investigation to determine whether health and disease can be appropriately judged by the use of CBCT in epidemiologic investigations.

Digital subtraction radiography (DSR) has been observed to increase diagnostic capability; observers identified incipient periapical lesions in more than 70% of the cases.[116] Before the advent of CBCT, clinicians were unable to routinely visualize the presence, specific location, and extensiveness of periapical bone loss using conventional radiography.[107] This was especially true in areas with superimposition of anatomic structures. Visual obstruction from anatomic features, such as buccal bone and the malar process over the apices of maxillary roots, simply "disappears" when the examiner can scroll through the slices of the bone from facial to palatal in 0.1 mm sections while also changing axial orientations. CBCT showed significantly higher rates of detection of

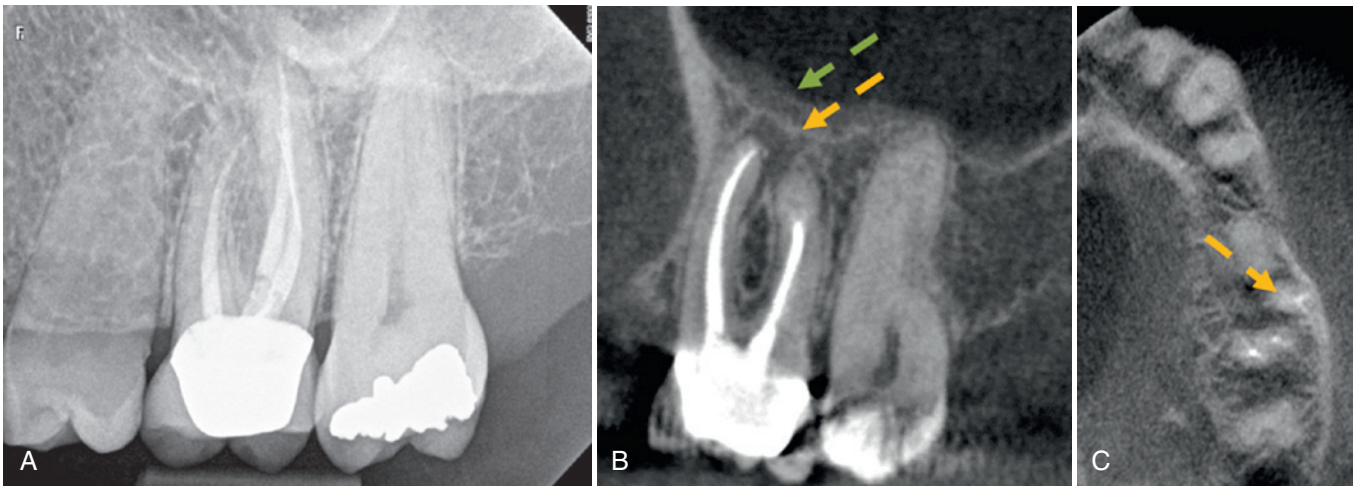

FIG. 2-15 A 62-year-old female was referred for evaluation and possible treatment for chronic continuous dentoalveoar pain (CCDAP) in the maxillary left region. The patient could alleviate this condition by placing a moist cotton roll in the adjacent vestibule to prevent the buccal mucosa from contacting the alveolus supporting the maxillary teeth in this area. This condition began after a history of local anesthetic administration, persisted for 1 year, and led to three successive new crowns and endodontic treatment on the "offending tooth," in an effort to remedy the condition without improvement. The response to endodontic tests, TMJ, and myofascial evaluations were normal. Application of topical xylocaine resulted in cessation of pain for 15 minutes. A PA radiograph **(A)** showed a root-treated, maxillary left first molar with no apparent radiographic lesion. A limited FOV CBCT of the maxillary left posterior was exposed. The corrected sagittal view **(B)** showed an approximately 4 mm, well-defined oval, mildly corticated area of low attenuation (radiolucent) centered over the apex of the mesiobuccal root and extending to the junction of the middle and apical third of the mesiobuccal root (yellow arrow). There was a mild mucositis (green arrow). There was a previously untreated mesioaccessory canal **(C)** and a mild mucositis. A diagnosis of neuropathic pain and a chronic apical periodontitis was made. Daily application of topical ketamine, gabapentin, and clonidine was prescribed. Endodontic revision of the maxillary left first molar was performed 3 months after the patient was stabilized with the topical medications. (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D [Carestream Dental, LLC, Atlanta, GA].)

periapical lesions in maxillary molars and premolars compared to PA radiography.[109]

Lesions of Nonendodontic Origin

Differential diagnosis of periapical pathology is crucial to endodontic treatment planning. Substantial evidence in the literature points to a significant chance that lesions of the tooth-supporting structures are nonendodontic in origin, such as periapical cemento-osseous dysplasia; central giant cell granulomas; simple bone cysts; odontogenic cysts, tumors, or malignancies; and neuropathic pain (Fig. 2-15).*

Neuropathic orofacial pain or atypical odontalgia (AO), also known as *chronic continuous dentoalveolar pain* (CCDAP)[131a] and *persistent idiopathic facial pain* (PDAP),[80a] is related to a tooth, teeth, or pain at an extraction site where no clinical or radiographic pathosis is evident. Two systematic reviews of AO showed the incidence of persistent pain of more than 6 months' duration after nonsurgical and surgical endodontic treatment, excluding local inflammatory causes, was 3.4%.[130a] The pathophysiology of this pain is uncertain, but it is hypothesized to involve deafferentation of peripheral sensory neurons in predisposed patients. The diagnosis of AO is challenging and depends on the patient history and clinical examination findings, in addition to the absence of radiographic findings. In some cases the symptoms from AP and AO are closely related. Pigg et al.[146a] conducted a study of 20 patients with AO. All of the patients had at least one tooth in the region of discomfort that had undergone invasive treatment; 21 of 30 teeth had undergone endodontic treatment. These researchers found that 60% had no periapical lesions, and among those who did, CBCT showed 17% more periapical lesions than conventional radiography. This study demonstrated that CBCT may be a useful supplement to 2D radiography (see Fig. 2-15).

The 3D radiographic appearance of a periapical lesion provides additional information about the lesion's relationship to the tooth and other anatomic structures (e.g., the vascular bundle) and about the aggressiveness of the lesion. This information, along with pulp sensitivity testing, is useful for adequate treatment planning and management of these conditions.

Diagnosis of Endodontic Treatment Failures

Failure of previous endodontic therapy can be attributed to various factors, such as procedural errors, missed canals, or persistent periapical pathosis. Knowledge of the cause of failure is pertinent to the treatment of these cases because it allows the cause to be adequately rectified. With the advent of CBCT, in select cases of retreatment in which the cause of failure is otherwise undetectable, adequate information may be collected to apply to the treatment plan (Fig. 2-16). The technology is most useful in detecting uninstrumented and unfilled

*References 28, 54, 56, 81, 130, 143, 151, and 152.

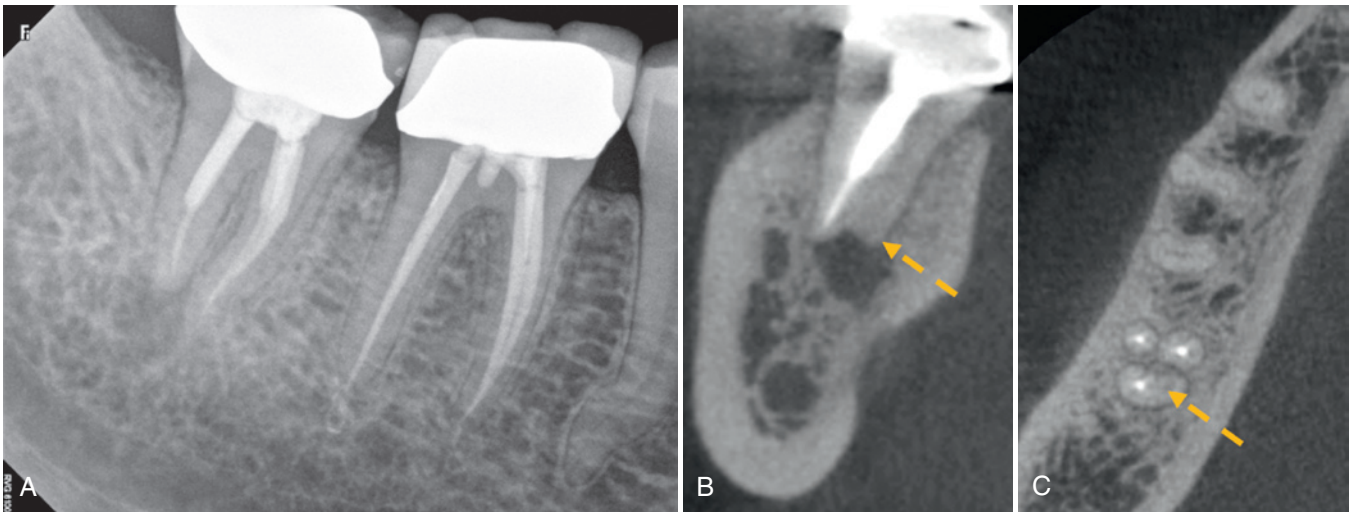

FIG. 2-16 This 38-year-old female patient presented for evaluation and treatment of a symptomatic mandibular right second molar, which had been endodontically treated more than 10 years previously. This tooth was sensitive to percussion and biting forces; periodontal findings were normal. Microscopic examination of the exposed dentin was negative for a vertical fracture. The PA radiograph **(A)** showed the previous endodontic treatment; a post present in the distal canal; and an approximately 5 mm diameter, unilocular, diffuse area of low density centered at the periapex of the distal root. Contemporaneous CBCT sagittal **(B)** and axial **(C)** images revealed a previously untreated distobuccal canal. (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, Ga].)

canals, extension of the root canal filling, and the presence and extent of periradicular bone loss. The sensitivity of CBCT and PA radiographs for diagnosing strip perforations in root-filled teeth has been shown to be low.[51] Radiopaque filling materials in the root canals of endodontically treated teeth can produce streak artifacts, which can mimic fracture lines or perforations.[166,198]

Vertical Root Fractures

Vertical root fractures (VRFs) that run along the long axis of a tooth are often difficult to diagnose clinically. The prevalence of VRF in endodontically treated teeth has been reported to range from 8.8% to 13.4%.[61,174,196] These fractures typically run in the buccolingual direction and are confined to the roots, making it difficult to visualize the fracture. Visualizing the fracture on a conventional radiograph is possible when the x-ray beam is parallel to the plane of the fracture.[153] Challenges in diagnosis with regard to the extent and exact location of the fracture often lead to unwarranted extraction of teeth. Since the introduction of CBCT to dentistry, various reports of the application of the technology to detect vertical root fractures have been published. The reported sensitivity for detection of VRFs has ranged from 18.8% to 100%[115]; by comparison, conventional radiographs have a reported sensitivity of approximately 37%[48,75] (Fig. 2-17). CBCT has been used to visualize VRFs in controlled clinical studies in which clinical diagnosis was difficult.[48] Vertical root fractures were successfully detected at a spatial resolution ranging from 76 to 140 microns. However, only a limited number of units provide such high resolution. A comparison of various CBCT units for the detection of VRFs demonstrated that the units with flat panel detectors (FPDs) were superior to the image intensifier tube/charge-coupled device (IIT/CCD)–based detectors; the smaller FOV and the ability to view axial slices also improved detection of VRFs.[76] Continued improvement of sensor technology, including the use of FPDs, has resulted in enhanced resolution. Voxel dimensions are smaller in these units. Detection of vertical root fractures with thickness ranging from 0.2 to 0.4 mm was found to be more accurate with CBCT than with digital radiography.[133,138] The presence of root canal filling in the teeth lowers the specificity of CBCT in detecting vertical root fractures[75,76,95]; this has been attributed to the radiopaque material causing streak artifacts that mimic fracture lines.[198]

Evaluation of Anatomy and Complex Morphology

The precise location and visualization of dental anomalies, root morphology, and canal anatomy are vastly improved with CBCT data. Root curvature, additional roots, and anomalies within the canals themselves (e.g., obstructions, narrowing, bifurcation) are made more apparent when all three anatomic planes of section are available for review, especially with the capability of narrowing the slice thickness to as little as 0.076 mm. Visual obstruction from anatomic features such as buccal bone and the malar process over the apices of maxillary roots simply will "disappear" when you can scroll through the slices of the bone from facial to palatal in 0.076 mm sections while also changing axial orientations (Fig. 2-18).

Dental Anomalies

The use of CBCT technology has been reported in the diagnosis and treatment planning of various dental anomalies (e.g., dens invaginatus) that often have complex morphologic presentations.[131] The prevalence of dens invaginatus was as high as 6.8% in the adolescent Swedish population studied.[14] The complex nature of the anomaly presents a diagnostic challenge

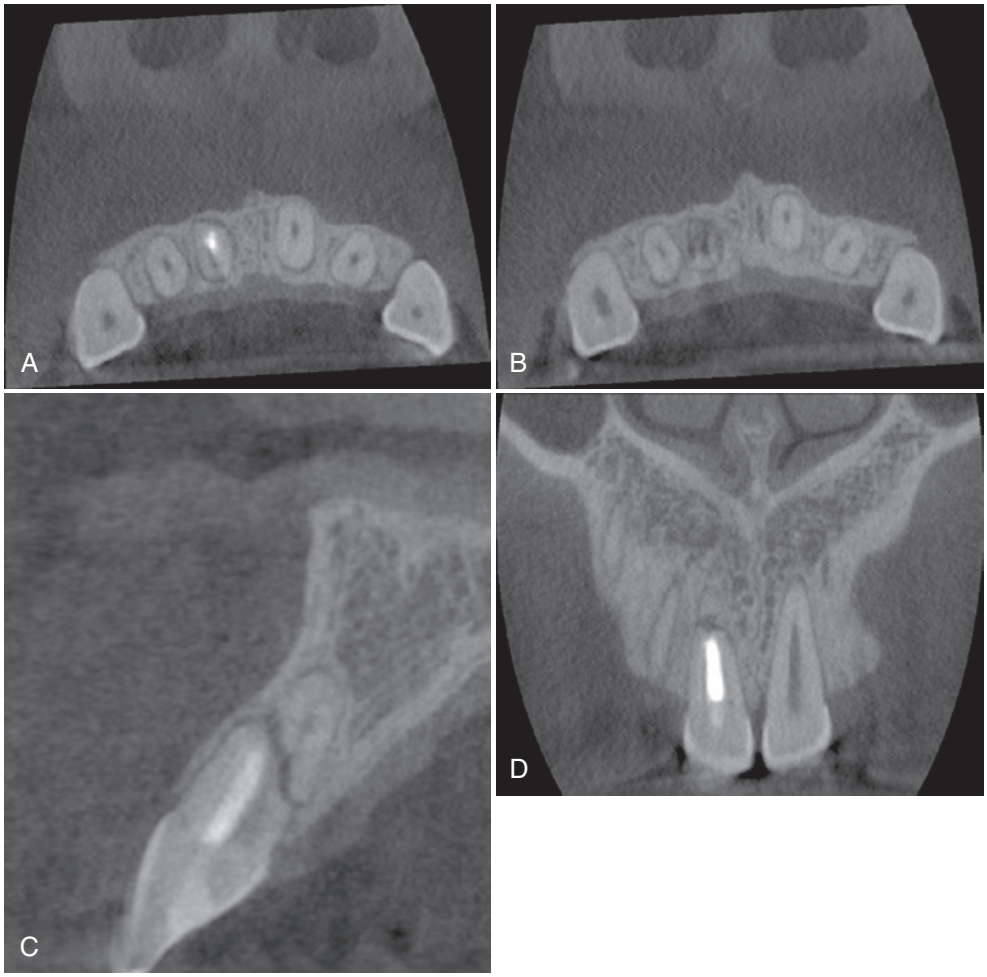

FIG. 2-17 Root fracture in an endodontically obturated maxillary right central incisor. **A**, Axial view with artifacts from a highly attenuating (opaque) obturant. **B**, View without artifacts from obturant. **C**, Oblique parasagittal view. **D**, Paracoronal view. (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, Ga].)

when conventional radiographs are used.[137] In case reports in which CBCT was used for diagnosis and treatment planning, treatment options included conservative endodontic treatment of the invagination, surgical treatment of the periapical pathology, and complete revascularization of the dens after removal of the invagination (Fig. 2-19).[124,185]

Root Canal System Morphology

As the adage goes, nature seldom makes a straight line and never makes two of the same. This statement is dramatically illustrated in the evaluation of root canal system morphology. With ever-present unusual and atypical root shapes and numbers, there is sometimes a need to look further than what a clinician can see or imagine with 2D radiography (Fig. 2-20). Variations in root canal morphology have been studied using various in vitro techniques.[57,147,182,183] The results of these studies point to the fact that there is significant variation in the root canal morphology among various ethnic population groups.[3,72,73,128,187] CBCT has been reported to be comparable to canal staining and clearing techniques for identification of the root canal morphology,[125] and CBCT studies report variation in the root canal morphology among various ethnic groups.[126,173,197,199]

INTRAOPERATIVE OR POSTOPERATIVE ASSESSMENT OF ENDODONTIC TREATMENT COMPLICATIONS

Materials Extending Beyond the Root Canal

CBCT scans provide the opportunity to map endodontic treatment complications through the examination of 3D representations of the teeth and supporting structures in different planes. Few high-level studies related to the effects of endodontic treatment complications have been published in the endodontic literature.[176] However, it is generally recognized that overfilling of the root canal, causing damage to vital structures such as the inferior alveolar neurovascular bundle (IAN) (Fig. 2-21) or the maxillary sinus, can cause significant morbidity.[24,25,60,64]

Endodontic therapy undertaken in close proximity to the IAN should receive special attention because direct trauma, mechanical compression, chemical neurotoxicity, and an increase in temperature greater than 10° C may cause irreversible damage.[51,68,71,179] Scolozzi et al.[162] reported that sensory disturbances can include pain, anesthesia, paresthesia,

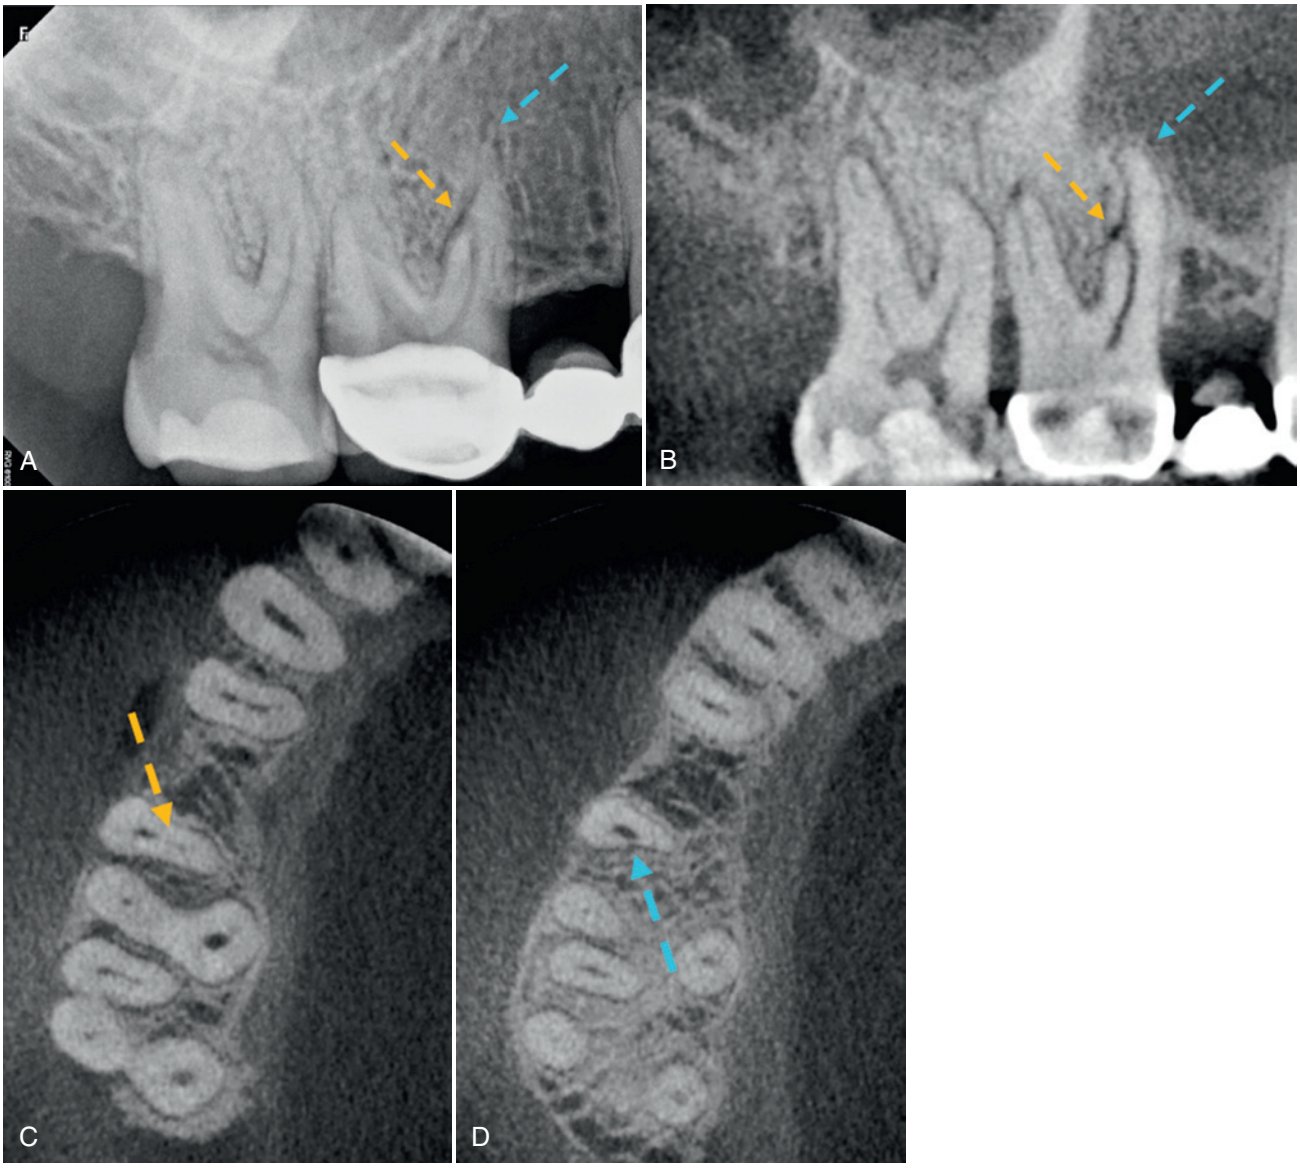

FIG. 2-18 This patient was referred for evaluation and possible treatment after emergency pulp extirpation performed by others. The location of the physiologic terminus and radiographic apex did not appear to coincide even remotely in the PA radiograph **(A)**, so a CBCT-aided assessment was required. A CBCT scan was able to clearly show the exact location of the canal terminus and radiographic apex **(B)**, the presence of a mesioaccessory canal with an isthmus **(C)**, and the oval canal **(D)**, facilitating treatment of this case. (Courtesy Dr. Anastasia Mischenko, Chevy Chase, Md. Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, Ga].)

hypoesthesia, and dysesthesia.[162] The IAN is located in the cribriform bone-lined mandibular canal and courses obliquely through the ramus of the mandible and horizontally through the mandible body to the mental foramen and the incisive foramen.[8] There are many anatomic variations of the IAN, including the anterior loop and bifid mandibular canals.[35] Kovisto et al.[97] used CBCT measurements from 139 patients to show that the apices of the mandibular second molar were closest to the IAN. In females, the mesial root of the second molar was closer than in males, and the distances in all roots measured increased with the age of the patient. There was a high correlation between the measurements from left to right side in the same patient; an average distance of 1.51 to 3.43 mm in adults.[97] Procedures involving the mandibular second molar were most likely to cause nerve damage.[106] Further research is required to clarify the risks and benefits of CBCT when endodontic treatment is contemplated on teeth with a proximal relationship between the IAN and root apices. Porgrel[148] treated 61 patients with involvement of the IAN after root canal therapy during a 7-year period. Eight patients were asymptomatic; 42 patients were seen for mild symptoms or were examined more than 3 months postoperatively, with only 10% experiencing improvement. Five patients underwent surgical treatment before 48 hours elapsed and recovered completely.

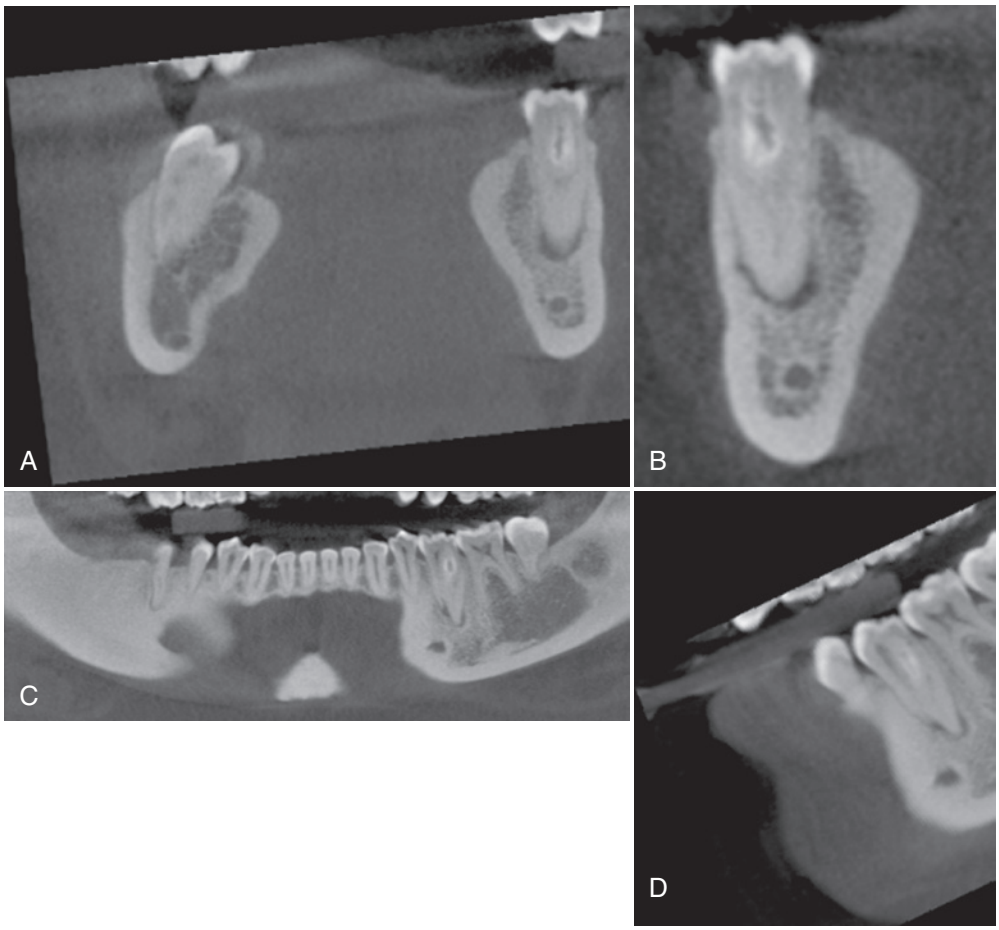

FIG. 2-19 **A,** Dens in dente of the mandibular left second bicuspid; coronal slice. **B,** Coronal view. **C,** Panoramic reconstruction from CBCT. **D,** Sagittal view. (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, Ga].)

Six patients underwent surgery between 10 days and 3 months, with four experiencing partial recovery; the remaining two had no improvement.[148]

New imaging technologies, such as high-resolution magnetic resonance imaging (MRI-HR) and magnetic resonance neurography (MRN), promise to improve isolation of the IAN from the neighboring artery and vein contained within the inferior alveolar bony canal. MRN studies have documented the ability to demonstrate nerve continuity and localize extraneural nerve compression before surgical nerve exploration. Postoperative periapical radiographs should be exposed on the day of endodontic treatment completion or a suspected iatrogenic event, and any suspected compromise of the IAN or other vital structures should be evaluated immediately. In all cases in which trauma to the IAN is suspected from periapical or panoramic radiography or by the report of symptoms consistent with nerve injury, exposure of a CBCT image volume should be considered. It is generally accepted that immediate surgical debridement should be attempted to maximize recovery.[51,149] With the introduction of MRI algorithms for dental diagnostic purposes, it is expected that this imaging modality will be increasingly used in diagnostic and treatment planning. MRI has the capability to demonstrate vascularity to the tooth of interest, in addition to the presence of inflammatory exudates in the apical regions, without exposing the patient to ionizing radiation. Receiver coils are being developed to enhance the image quality of maxillofacial and dental magnetic resonance studies.

The accidental introduction of root canal instruments, irrigating solutions, obturation material, and root tips into the maxillary sinus has been reported. Serious consequences associated with the intrusion of foreign bodies into the maxillary sinus include pain, paresthesia, and aspergillosis, a rare but well-documented complication of endodontic treatment.[16a] Guivarc'h et al.[71a] reported that the overextension of heavy metal–containing root canal sealers, such as zinc oxide eugenol cement, may promote fungal infection in immunocompromised patients, leading to bone destruction and damage to adjacent structures. This case report described the use of computed tomography to assess the patient before surgery and at 6 months.[71a] The use of CBCT as an aid in the localization and retrieval of an extreme overextension of thermoplasticized injectable gutta-percha into the sinus and contiguous soft tissues has been described by Brooks and Kleinman.[26]

Fractured Instruments

Instrument fracture can occur at any stage of endodontic treatment, and in any canal location. The incidence of this complication, reported in clinical studies on a per canal or per tooth basis, ranges from 0.39% to 5.0%.[44,135] Molars are

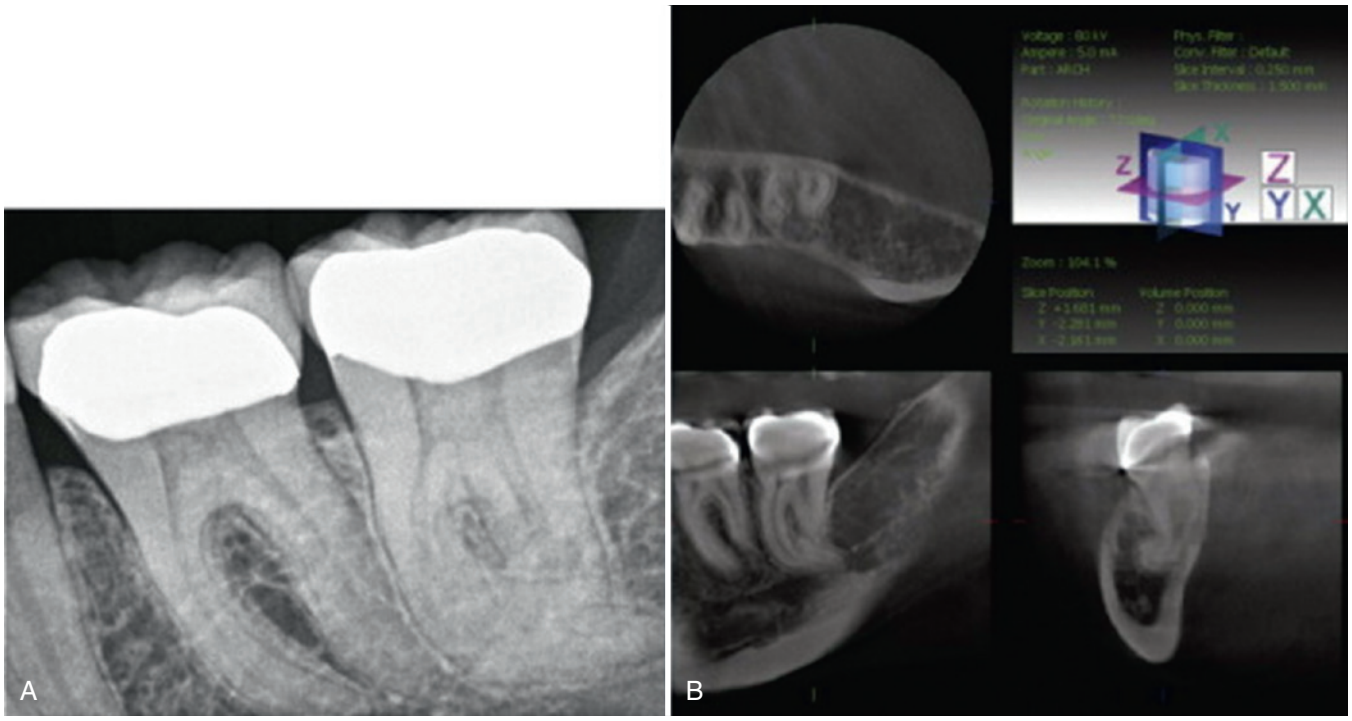

FIG. 2-20 A, Mandibular left second molar referred for endodontic evaluation and possible treatment. This 2D radiograph reveals significant pulp stones and canal calcification developing not only in the coronal aspect of the root canal system, but also extending down the visible distal canal. The apical third of the canal system appears unusual and dilacerated. Cone beam volumetric tomography (CBVT) would be beneficial in visualizing the root canal anatomy, so as to create the ideal endodontic access. B, Single slice of the CBVT image for tooth #18. Information about the direction of the root canal anatomy is provided in all three planes of the section: axial, coronal, and sagittal. Interestingly, the axial slice shows that the mesial lingual root actually traverses buccally as it approaches its terminal extent. This is valuable information for the clinician before the entire root canal system is cleaned and shaped; it also establishes a higher degree of treatment predictability.

predominantly affected by instrument fracture, with the highest incidence found in the apical third of mandibular molars.[4,40,103,127]

A systematic review and meta-analysis showed that when endodontic treatment was performed at a high technical standard, instrument fracture did not significantly reduce the prognosis. More specifically, when no initial radiographic periapical lesion was present initially, 92.4% of cases remained healthy; when a periapical lesion was present initially, 80.7% of periapical lesions showed radiographic healing. However, the presence or absence of periradicular lesions on preoperative and postoperative examinations was based on planar radiographic assessments, which calls these findings into question.[134] Other studies showed that the chances of endodontic failure increased if the canal system could not be thoroughly disinfected, if a periradicular periodontitis was present, or if technical standards were compromised.[39,91,168,170] Use of CBCT to triangulate the retained instrument and assess the canal shape, especially in cases in which the operating microscope does not allow direct visualization, can be helpful in formulating a removal strategy. If the fractured instrument is lodged in the lingual aspect of a ribbon-shaped canal, for example, an instrument may be inserted toward the buccal to bypass and remove the imbedded instrument without forcing the fragment further apically. Without the use of CBCT, intracanal instruments can be reliably removed or bypassed in 85.3% of cases if straight-line access is possible; however, reliable removal or bypass is possible in only 47.7% of cases if the instrument is not visible (Fig. 2-22).[127] When a separated instrument is lodged in the apical third of a root canal, the chances of retrieval are the lowest, but the apical terminus may be adequately sealed by treatment of an anastomosing canal, if present.[63] The possibility of instrument removal based on CBCT triangulation has not been published to date.

Calcified Canals

According to the Pew Research Center, 10,000 U.S. individuals will reach the age of 65 every day until 2030, and the nation's 65-year-old and over cohort will grow to 81 million in 2050, up from 37 million in 2005 (also see Chapter 26).[82] This aging population will present increasing challenges for dental clinicians because calcification of the root canal system increases as part of the natural aging process,[69] possibly leading to more untreated canals that may serve as a niche for microorganisms.[19,88] Pulp chambers in the crown of the tooth decrease in size, forming more rapidly on the roof and floor of posterior teeth.[184] Typically, root canals calcify at the coronal aspect first, with decreasing calcification as the canal travels apically. Magnification and illumination are essential tools for the identification and treatment of calcified canals, but CBCT can assist in the perioperative treatment of such conditions.[16] Preoperative assessment of calcified teeth using CBCT can suggest the best tactic for locating calcified canals in the chamber floor and

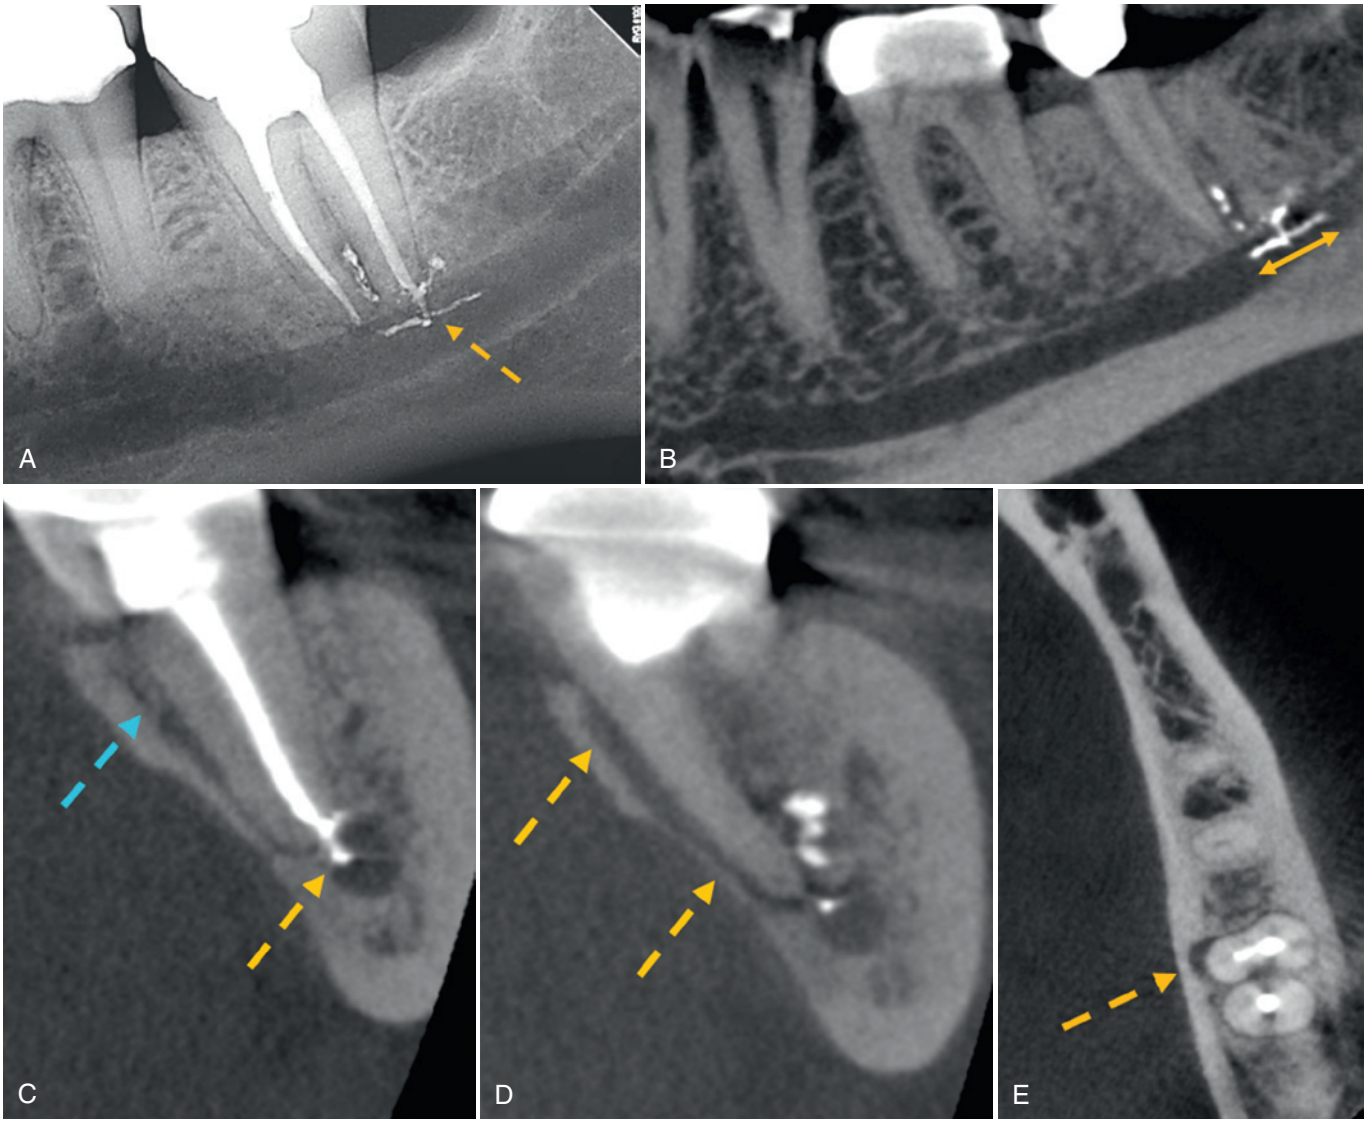

FIG. 2-21 This 64-year-old male patient presented with sensitivity when biting on the mandibular left second molar. The history included endodontic revision more than 6 months earlier and subsequent transient paresthesia and dysesthesia along the distribution of the inferior alveolar nerve, which persisted for 1 week after the retreatment. The results of periodontal probing and microscopic examination of the exposed root surface at the sulcus were normal. The PA radiograph showed the approximate location of the excess radiopaque material, a feature consistent with extruded sealer (**A**, *yellow arrow*). The length of approximately 3.4 mm and the true location of the offending material in the mandibular canal were assessed in the corrected sagittal view (**B**, *yellow arrow*) and corrected cross-sectional view (**C**, *yellow arrow*). The corrected cross-sectional view also showed a lesion of low attenuation extending from the apex to an area near the crest of the alveolus with erosion of the lingual cortical plate (**C**, *blue arrow;* **D**, *yellow arrows*). The same lesion was shown in the corrected axial view (**E**, *yellow arrow*). Examination of the extracted tooth revealed a vertical fracture at the lingual aspect of the distal root. (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, Ga].)

roots using software-based measurement tools. The insertion of radiopaque markers, such as instruments or obturation material, can facilitate reliable canal localization using available multiplanar reformations. The increased sensitivity and specificity provided by CBCT can also assist in the determination of the periapical status of calcified root canals that may not require measures that can lead to procedural errors, such as off-course access, instrument fracture, or root perforation.[83] The difficulty in locating calcified canals can be further compounded by morphologic anomalies associated with gender and ethnic origin.[163] CBCT can be an important adjunct to magnification and illumination in these cases.

Perforations

A *perforation* is defined as a "mechanical or pathologic communication between the root canal system and external tooth surface"[6]; it is usually associated with an iatrogenic event,[159] accounting for about 10% of all nonhealed cases.[85] Root perforations can be caused by a post preparation, the search for a calcified canal, a strip perforation, or an attempt to retrieve a

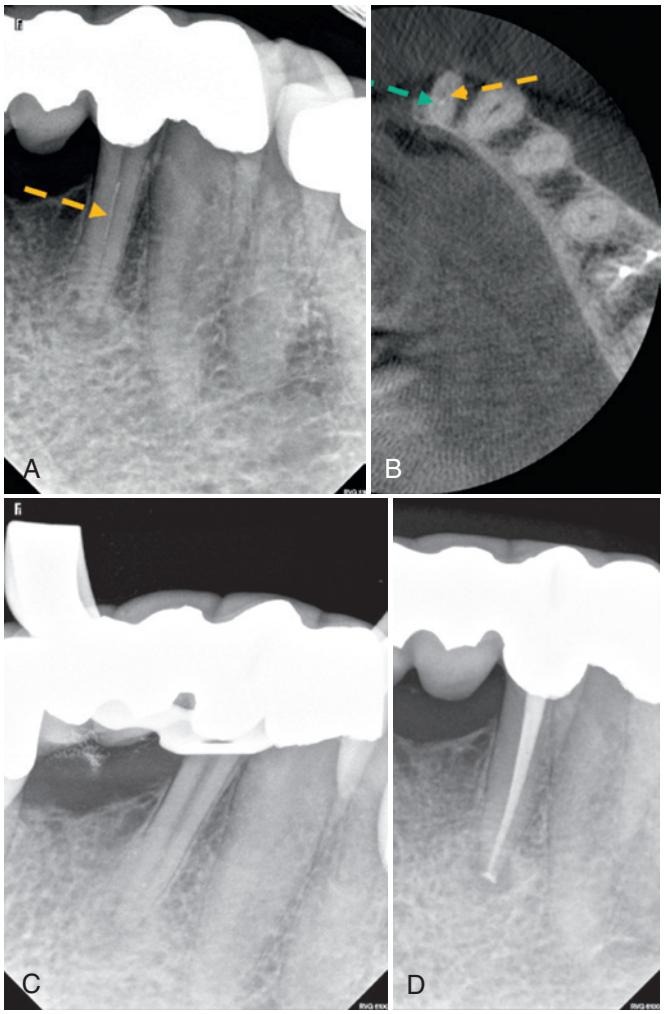

FIG. 2-22 Unexpected torsional and flexural failure of endodontic instruments can occur during instrumentation. This PA radiograph **(A)** shows a separated stainless steel hand file located at the midroot of the mandibular left lateral incisor in a patient referred for revision therapy. To aid development of a retreatment strategy, CBCT was used to localize the instrument (**B**, *yellow arrow*) in the lingual canal. The patient's buccal canal was identified (**B**, *green arrow*), and subsequent instrumentation allowed removal of the offending instrument segment **(C)**, leading to successful completion of treatment (**D**). (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, Ga].)

fractured instrument. They are often difficult to localize with conventional imaging because no information about the buccolingual dimension can be obtained.[195] Shemesh et al.[166] compared the sensitivity and specificity of CBCT scans with two-angulation periapical imaging using phosphor plates to assess the likelihood of detecting root or strip perforations after root canal treatment with laterally compacted gutta-percha and sealer. They found that the two methods showed similar specificity, but the CBCT image volumes showed higher sensitivity. Single-angulated periapical radiographs (PAs) showed 40% of the perforations, and two-angled PAs showed 63%, suggesting that if PAs alone are used, two-angled images were superior. There was no significant difference in the detection of root perforations between PA and CBCT radiography. The researchers noted that the results may have been affected by the small size of the perforations and that the method of obturation did not favor extravasation of obturation material.[166] CBCT images suffer from beam hardening artifact resulting from root canal obturation and restorative materials (e.g., gutta-percha, posts, and perforation repair materials), which creates challenges to the interpretation of root integrity. An approach advocated by Bueno et al.[29] suggested that a map-reading strategy of viewing sequential axial slices reduces the beam hardening effect. Newer root canal obturation materials with lower radiopacity profiles and improved CBCT software algorithms are expected to reduce artifact formation in the future.

Dentoalveolar Trauma

Systematic epidemiologic data suggest that facial trauma is a common occurrence, resulting in injuries to the dentition in 57.8% of household and play accidents, 50.5% of sports accidents, 38.6% of work-related accidents, 35.8% of acts of violence, and 34.2% of traffic accidents, with 31% unspecified.[62] The prevalence of traumatic dental injuries varies according to the population studied, but these injuries occur most commonly in children 7 to 10 years of age (also see Chapter 20).[13] Dental traumatic injuries affect one fourth of all schoolchildren and almost one third of adults, and most injuries occur before the age of 19.[65] Maxillary central incisors sustain approximately 80% of all dental traumatic injuries, followed by maxillary lateral incisors and mandibular incisors.[9] The most common type of traumatic dental injuries in the primary dentition are luxation injuries, whereas crown fractures are the predominant dental injury to the permanent dentition.[98] Determination of the extent of injury to the dentinopulpal complex requires a methodical approach that evaluates the teeth, periodontium, and associated structures (Fig. 2-23) and may result in significant long-term complications.[5,42]

Injuries to the orofacial complex can cause dental trauma that results in the following injuries to the primary and permanent dentition: (1) infraction; (2) crown fracture, uncomplicated and complicated; (3) crown/root fracture; (4) root fracture; (5) concussion; (6) subluxation; (7) lateral luxation; (8) intrusion; (9) extrusion; and (10) avulsion.[12] The International Association of Dental Traumatology's guidelines for the management of traumatic dental injures suggest that CBCT may be beneficial when used to assess and monitor healing in patients after dental traumatic injuries, especially in cases of lateral luxation and root fracture.[45] (These guidelines can be reviewed at *www.dentaltraumaguide.org*.) Intra-alveolar root fractures generally affect the permanent dentition of males and are relatively uncommon, accounting for 0.5% to 7% of dental impact injuries.[12,41,67,132] Root-fractured teeth are a challenging condition to diagnose, and the limitations of planar radiography have been well documented in the dental literature.[38,45,96,136] A systematic retrospective study showed that maxillary central (68%) and lateral (27%) incisors were primarily affected, with only limited occurrence in mandibular incisors (5%). This retrospective study concluded that CBCT allowed improved treatment planning compared with PA imaging alone.[191] At least seven systematic laboratory studies and one systematic in vivo animal study reported significantly improved accuracy for the detection of root fractures when CBCT was compared with periapical radiography.* In a systematic clinical study,

*References 75, 76, 84, 114, 133, and 189.

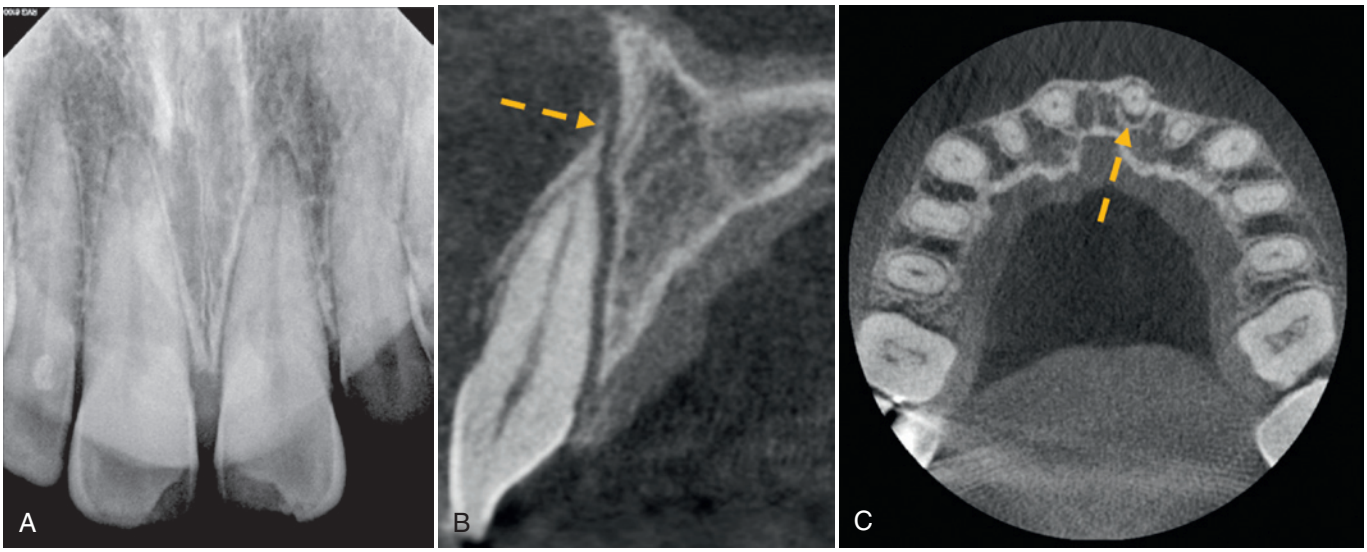

FIG. 2-23 After a traumatic injury to the maxillary right and left central incisors, crown fractures were noted. The PA radiograph showed an extrusive luxation injury in the maxillary left central incisor (**A**). The alveolar fracture (**B**, *yellow arrow*) and true extent of the displacement (**C**, *yellow arrow*) became evident with CBCT. (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, Ga].)

Bornstein et al.[23] examined 38 patients with 44 permanent teeth that sustained intra-alveolar fractures. In the study sample reported, 68.2% of teeth had oblique fractures that extended to the cervical third of the root, contradicting the findings of previous studies conducted with periapical imaging alone. CBCT imaging offered improved visualization of the location and angulation of root fractures compared to periapical and occlusal intraoral radiographs.[23]

Several of these studies suggest that lower resolution scans using voxel sizes in excess of 0.3 mm may not improve radiographic assessments.[76,189] A study by Wang et al.[186] showed that the sensitivity and specificity of PA radiography for root fractures were 26.3% and 100%, respectively; the findings for CBCT were 89.5% and 97.5%, respectively. CBCT images of root-filled teeth showed lower sensitivity and unchanged specificity, whereas 2D images showed the same sensitivity and specificity.[186] CBCT allows for the management of traumatic injuries in which a root fracture or alveolar fracture is suspected by providing undistorted multiplanar views of the dentition and supporting bone without the superimposition of anatomic structures.[37,107,157] CBCT image volumes provide superior sensitivity in detecting intra-alveolar root fractures compared with multiple PA radiographs; this allows for the detection of dental and alveolar displacements, including damage to other perioral structures, such as the maxillary sinus and nasal floor.[89] The presence of root canal fillings and posts affected the specificity of the findings as a result of artifact generation.[76,114] Outcome measurements of a region of interest can be compared over time with greater geometric accuracy using CBCT.[74]

The healing of root fractures is influenced by many factors, most prominently the stage of root development, with immature roots showing better healing than mature roots.[59] Other factors that influence healing are the extent of dislocation and repositioning, type of splinting, use of antibiotics, and location of the fracture on the root. The long-term survival of teeth with intra-alveolar root fractures was evaluated in a systematic study by Andreasen et al.[11] This study showed that the type of healing (e.g., hard tissue fusion, PDL interposition with and without bone) and the location of the fracture on the root had the most influence on tooth loss. CBCT should be considered when placement of individual PA radiographs will adversely affect patient management; PA radiographs will produce a higher radiation dose for assessment of the region of interest; or intra-alveolar fracture of the root or supporting structures is suspected and sufficient information cannot be obtained with conventional radiography.[89]

The decision to use CBCT imaging for assessment of traumatic injuries should be based on the diagnostic yield expected and in accordance with the "as low as reasonably achievable" (ALARA) principle. CBCT scan volumes that use the most appropriate detector size and shape, beam projection geometry, and beam collimation should be selected to produce high-resolution images and reduce x-radiation exposure whenever possible.[158] In all cases, it should be recognized that children and young adults are more susceptible to the effects of radiation than adults, and CBCT studies should answer specific clinical questions that cannot be answered by lower dose PA and panoramic imaging technologies.[79] New technologies that allow for comparison of matched CBCT images in a serial fashion at a reduced dose have been tested. This technology promises a dose reduction of 10 to 40 times by using the initial scan as prior knowledge and adaptive prior image constrained compressed sensing (APICCS) algorithms to greatly reduce the number of projections and x-ray tube current levels required (Fig. 2-24).[100]

Internal and External Root Resorption

Most clinicians are aware, and ideally communicate to their patients, that the long-term prognosis for teeth with extensive root resorption may be unpredictable. Endodontic treatment can often resolve these defects, and early diagnosis and treatment typically mean an improved prognosis. CBCT imaging of these resorptive lesions provides the clinician with enhanced

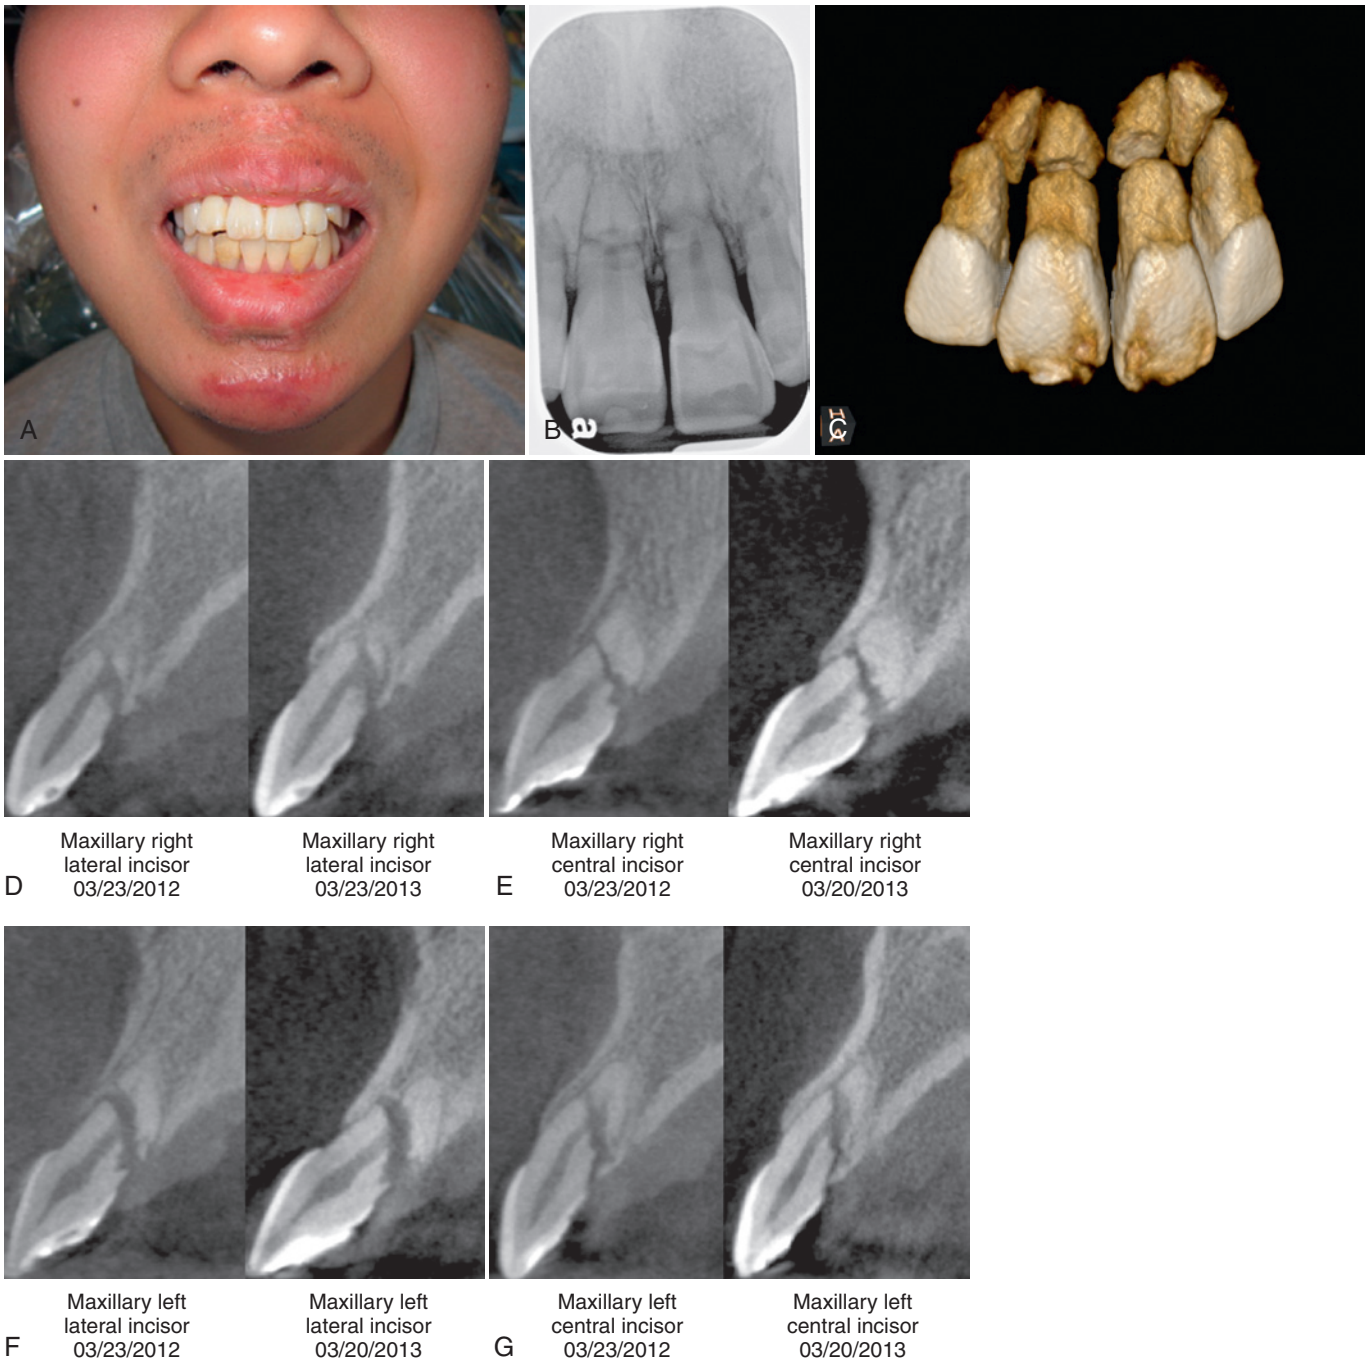

FIG. 2-24 Horizontal root fractures resulting from trauma (A) were evident in this 22-year-old male patient, who was referred with a contemporaneous film–based PA radiograph (B) for evaluation and possible treatment 9 months after trauma to his maxillary lateral and central incisors. Since the trauma, the teeth had been stabilized with a ribbon-type splint on the palatal surface; they were of normal color and responded to all pulp tests within normal limits. There was slight mobility in all of the traumatized teeth. The true nature of the root fractures (C, 3D reconstructed view) was evident in the corrected sagittal views of the maxillary right lateral (D) and central (E) incisors, and in the maxillary left central (F) and lateral (G) incisors. Temporal examination revealed no changes at the initial presentation, 12-month, and 30-month reevaluations (left to right in each group). Task-specific exposure parameters allowed each successive CBCT image volume to be exposed with lower kVp and mA, resulting in a 20% radiation dose reduction. (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, Ga].)

information so that more appropriate treatment planning options are available.

As described in Chapter 16, root resorption (RR) results in the loss of dentin, cementum, or bone by the action of clastic cells.[15] In the primary dentition, RR is caused by normal physiologic processes, except when resorption is premature; in the permanent dentition, it is caused by inflammatory processes.[36,52,141] The successful management of RR in the adult dentition depends on clinical and radiographic examination leading to early detection and accurate diagnosis.[142] Unfortunately, teeth affected by RR have a poor prognosis if the causative lesion is not treated.[140] Although parallax intraoral imaging techniques can be helpful in localizing RR,[86] only CBCT assessments can provide the true size and position of all resorptive defects in the region of interest.[36,140] Intraoral imaging produced false-negative results in 51.9% of cases studied and false-positive results in 15.3%.[122] The interpretation of RR should rely on the least invasive test that can reliably detect the occurrence of the condition.[140] The use of CBCT in the evaluation of RR eliminates structure superimposition and compression of 3D features. Patel et al.[140] compared the sensitivity and specificity of PA imaging with CBCT scans using the receiver operating characteristic (ROC) curve, a standard measure of diagnostic performance. PA imaging showed satisfactory (Az 0.78) accuracy, whereas CBCT showed perfect results (Az 1.00).[140]

Although the literature describes many classification systems, this section divides inflammatory root resorption into two groups, according to location: internal root resorption (IRR) and external root resorption (ERR).[177] IRR is a relatively rare occurrence that is usually detected on routine diagnostic PA or panoramic radiographs.[102,139] It is characterized by structural changes in the tooth that appear as oval or round radiolucent enlargements of the pulp canal, usually with smooth, well-defined margins.[32] IRR is usually asymptomatic, associated with pulpal necrosis coronal to the resorptive lesion and vital or partially vital pulps where active.[140] These lesions can easily be confused with extracanal invasive cervical resorption because the radiographic appearance of the two lesions can be identical. CBCT is helpful for diagnosing the location and exact size of IRR. In a study by Estrela et al.,[52] 48 PA radiographs and CBCT scans were exposed on 40 individuals.[52] IRR was detected in 68.8% of PA radiographs, whereas CBCT scans showed 100% of the lesions. Conventional radiographs were able to detect only lesions between 1 and 4 mm in 52.1% of the images, whereas CBCT was able to show 95.8% of the lesions. This finding was in agreement with other studies that demonstrated the value of tomographic analysis.[36,105] In a study by Kim et al.,[92] the extent and location of the IRR was accurately reproduced with the fabrication of a rapid prototyping tooth model. Although relatively few systematic studies on artificially induced IRR have been reported because of the difficulty in creating such defects, Kamburoglu and Kursun[90] concluded that high-resolution CBCT imaging performed better than low-resolution CBCT imaging in detecting simulated small internal resorptive lesions.

ERR is typically idiopathic, but severe luxation and avulsion injuries can result in lesions that may progress rapidly, and early treatment is recommended.[47] The recommended timing of radiographic examinations using CBCT has not been established with a strong evidence grade. Many ERR cases involve young patients, in whom the radiation dose is critical, and multiple scans would be difficult to justify. ERR can be classified as surface resorption, external inflammatory resorption, external replacement resorption, external cervical resorption, and transient apical breakdown (Fig. 2-25).[141] These lesions are always associated with bony resorption, making comparability of laboratory studies problematic because the lesions lack the changes in the periodontal membrane and associated bony changes that would improve visualization. Differentiation between IRR and ERR is challenging, even with multiple changes in x-ray angulation. The early stages of ERR were difficult to view with conventional radiography, and lesions less than 0.6 mm in diameter and 0.3 mm in depth could not be detected. Medium-sized lesions were visible in 6 of 13 cases, with improved visualization for proximal lesions without regard to the root third being examined.[10]

ERR is difficult to detect if the lesion is confined to the buccal, palatal, or lingual surfaces of the root.[20,66] Liedke et al.[105] conducted systematic diagnostic performance tests and showed similar sensitivity and specificity among the different

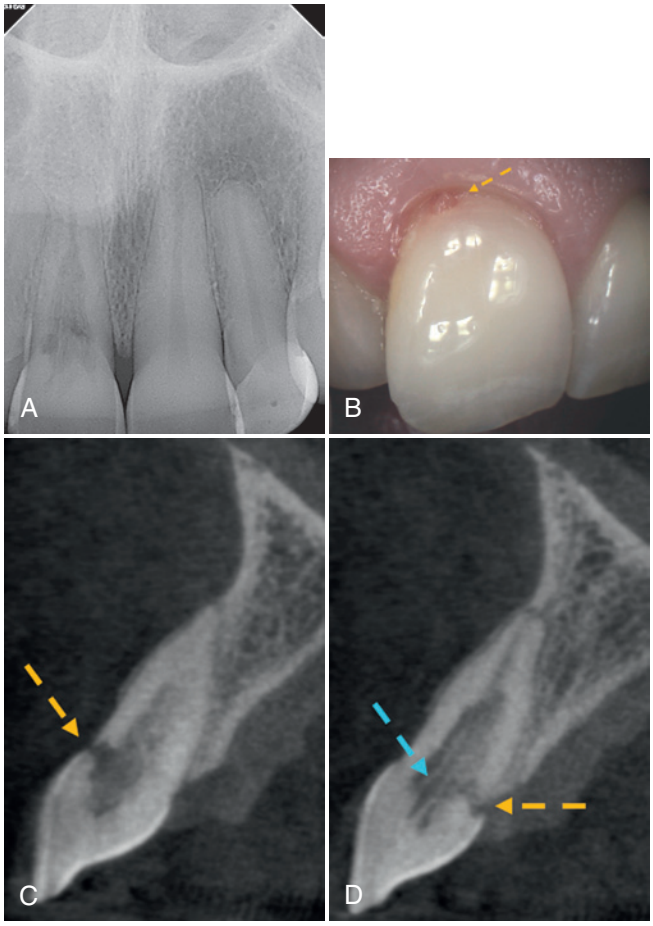

FIG. 2-25 Invasive cervical resorption, a form of external resorption, was evaluated in this patient after a PA radiographic image **(A)** and visual examination **(B)** showed pathognomonic signs of this lesion. A CBCT image was exposed to determine the true extent of resorption and also restorability. The lesion showed a perforative defect at the CEJ on the facial (**C**, *yellow arrow*) and palatal (**D**, *yellow arrow*) aspects. An intact layer of predentin (**D**, *blue arrow*) is a hallmark of this condition. (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, Ga].)

voxel sizes studied (0.4, 0.3, and 0.2 mm); however, the likelihood ratio showed better probability of correct identification of ERR with either 0.3 or 0.2 mm scans. These researchers suggested the use of a 0.3 mm voxel size protocol, rather than a 0.2 mm one, to reduce scanning time and the resulting dose.[105] Although voxel size is an important consideration, the SNR of different detectors, the radiation dose, viewing conditions, and the processing algorithms also affect detection probability.

Even though many in vitro studies have been performed on the ability of CBCT to detect RR, additional evaluations that use in vivo methodology will add to the cumulative knowledge.

PRESURGICAL VISUALIZATION

Surgical endodontic treatment is often performed in cases of endodontic nonhealing when nonsurgical retreatment is not possible. In the past, conventional and digital 2D PA radiographs were the only means of assessing the apical region. Unfortunately, the information available from these images may not adequately prepare the clinician to resolve the pathosis surgically. For example, the clinician may be unable to observe whether the lesion has perforated the buccal or palatal cortical plates, as in the example that follows, or even observe which root or roots are involved. Presurgical confusion is resolved with cone beam imaging. Multiplanar views allow the clinician to see the defect and suspected causes from the axial, sagittal, and coronal aspects; 3D grayscale or color imaging helps the clinician visualize the entire defect before the incision is made. This is an immense improvement over conventional imaging (Fig. 2-26).

The relationship of the teeth and the associated pathology to important anatomic landmarks must be taken into consideration in the treatment planning for endodontic surgical procedures. These anatomic landmarks include, but are not limited to, the maxillary sinus, the mandibular canal, the mental foramen, the incisive canal, and the buccal and lingual/palatine cortical plate. The close proximity of the maxillary posterior teeth to the sinus has been linked to maxillary sinusitis of odontogenic origin; changes in the maxillary sinus have ranged from thickening of the schneiderian membrane to actual accumulation of fluid in the sinuses.[110,111,113] The relationship of the roots of the posterior teeth to the sinus during presurgical treatment planning and the changes within the sinus can be best appreciated with the use of CBCT images.[22,111,165]

The relationship of the roots of the mandibular posterior teeth and associated periapical pathology to the mandibular canal, the presence of an anterior loop, and the distance of the mandibular canal from the buccal and lingual cortical plates are pertinent pieces of information when surgical procedures in mandibular posterior teeth are planned.[21] The 3D nature of

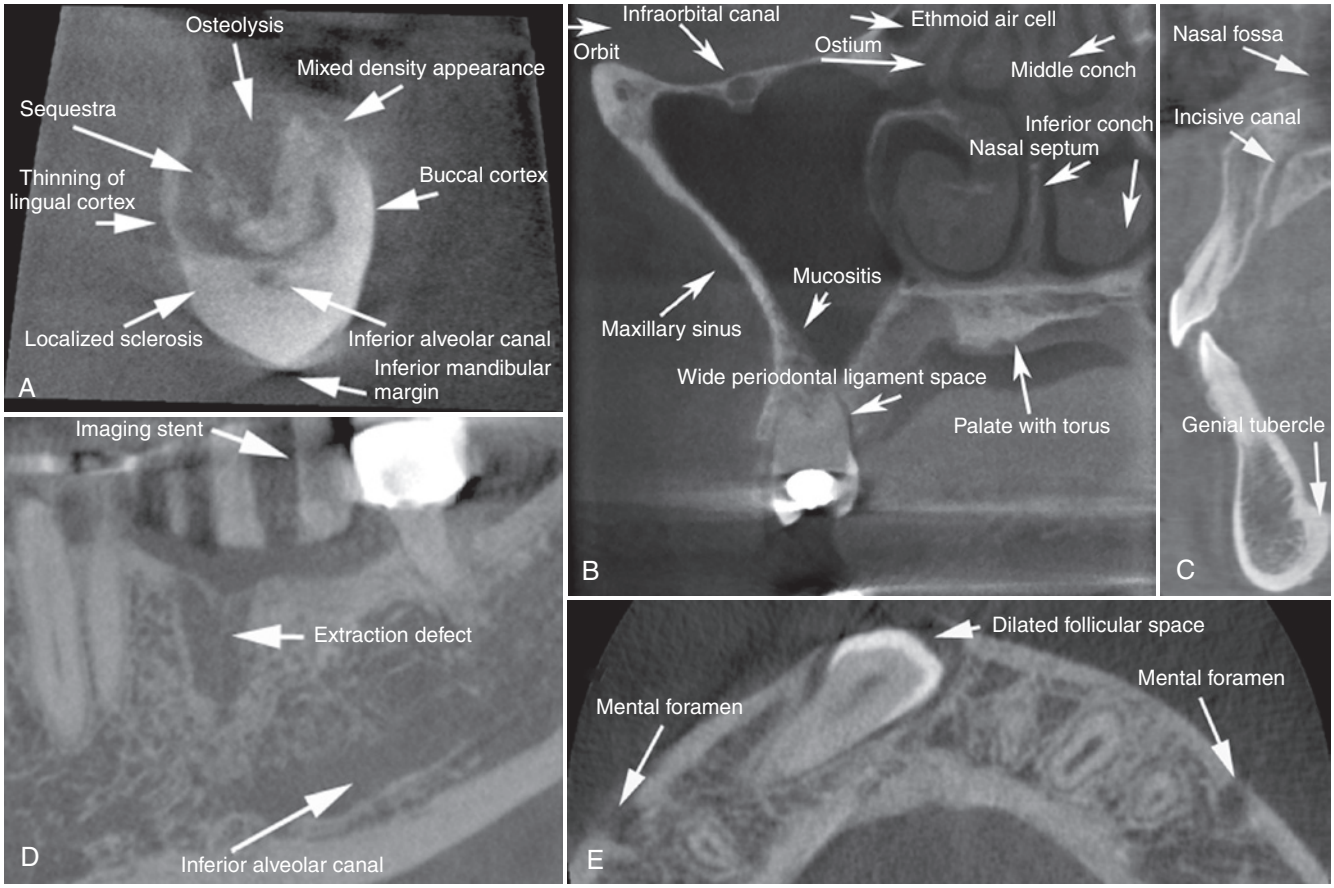

FIG. 2-26 **A** to **W**, Anatomic landmarks on CBCT images acquired using CS 9000, CS 9300, and i-CAT units. (Carestream Dental, Atlanta, Ga [CS 9000 and CS 9300 units]; and Imaging Sciences International, Hatfield, Pa [i-CAT unit].)

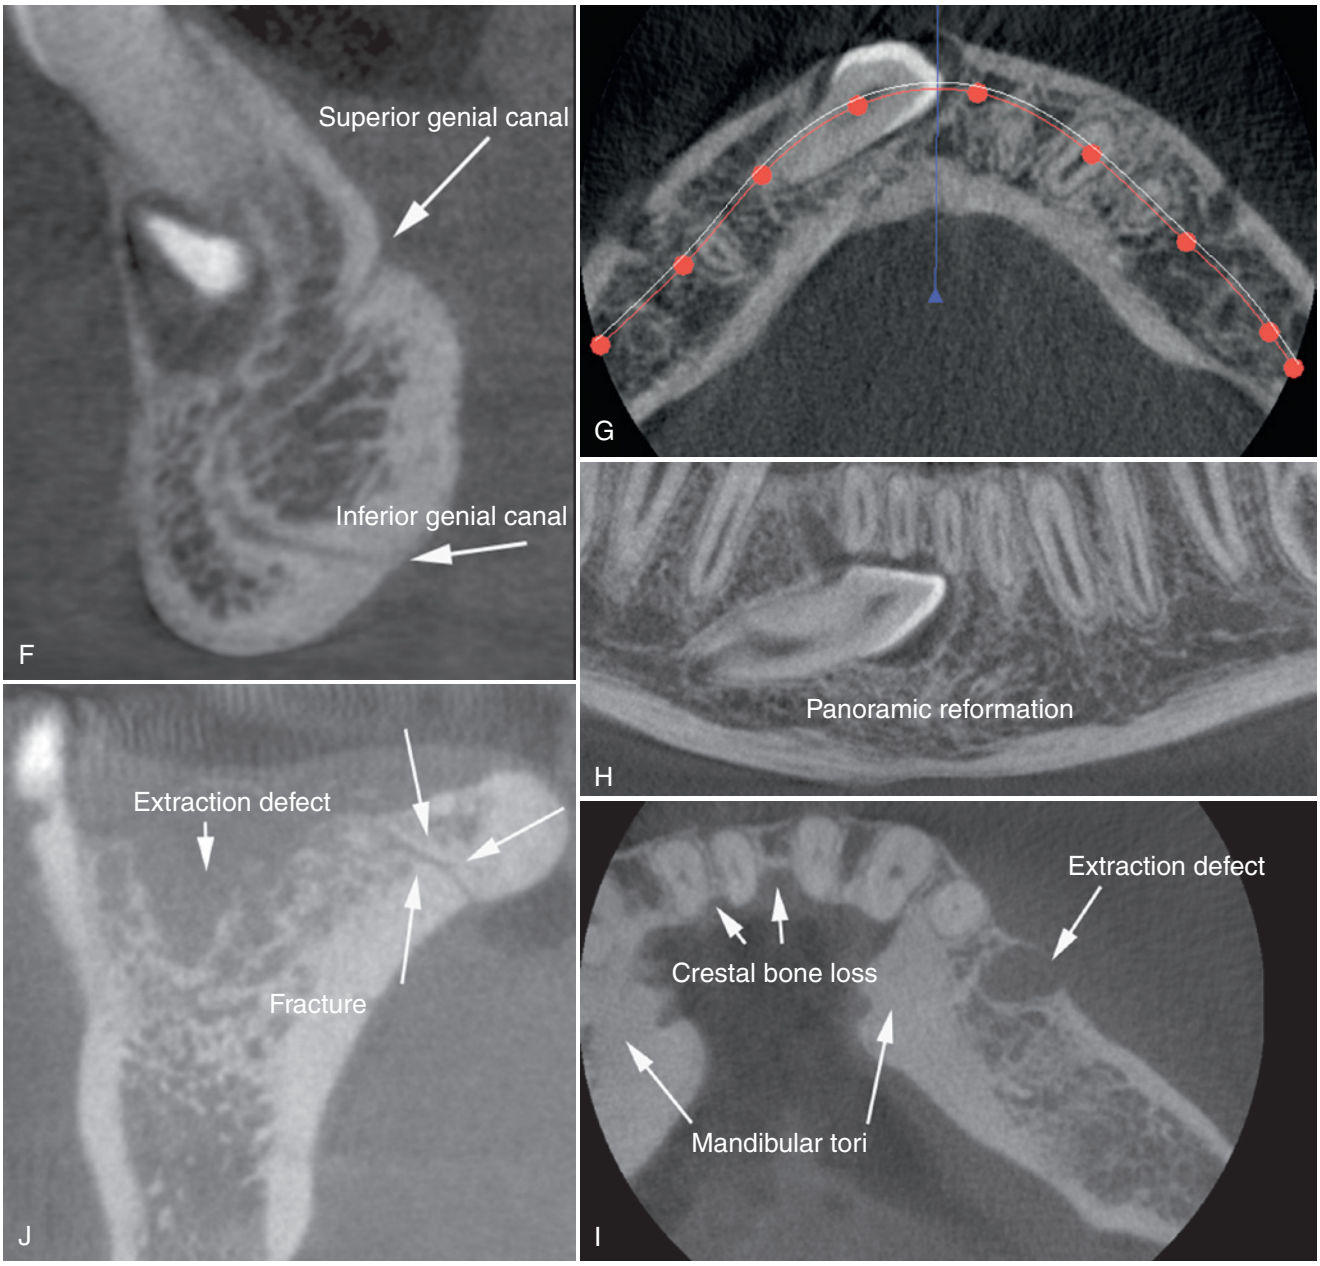

FIG. 2-26, cont'd

this relationship can best be assessed using CBCT.[93] A potential difference in the location of the mandibular canal with respect to age and gender has been reported.[97,167]

Outcomes Assessment

Endodontic treatment outcome predictors using PA radiographs and CBCT imaging have been shown to vary and also are influenced by patient inclusion and exclusion criteria.[104] Historically, PA radiographs and physical examinations were used to determine the success of endodontic treatment, and the absence of posttreatment periradicular radiolucencies and symptoms was considered the criterion for success. However, these planar imaging–based studies have resulted in an overestimation of successful outcomes, compared to CBCT assessments,[192a] because apical periodontitis confined within the cancellous bone or lesions covered by a thick cortex may be undetectable with conventional radiographic assessments.[18] Additional discrepancies between PA radiography and CBCT have resulted from geometric distortion, limiting comparisons of time-based evaluations, even with careful attention to paralleling technique factors.[112] A clinical study comparing the sensitivity, specificity, predictive values, and accuracy of PA and panoramic radiography and CBCT imaging in 888 consecutive patients showed that the prevalence of apical periodontitis in root-treated teeth was 17.6%, 35.3% and 63.3%, respectively. Conventional radiography showed increased accuracy when the evaluation of larger lesions was assessed.[53]

Outcome predictors identified with PA radiographs and CBCT scans may be different depending on the research performed. Liang et al.[104] retrospectively evaluated 115 endodontically treated teeth with vital pulps 2 years after treatment.

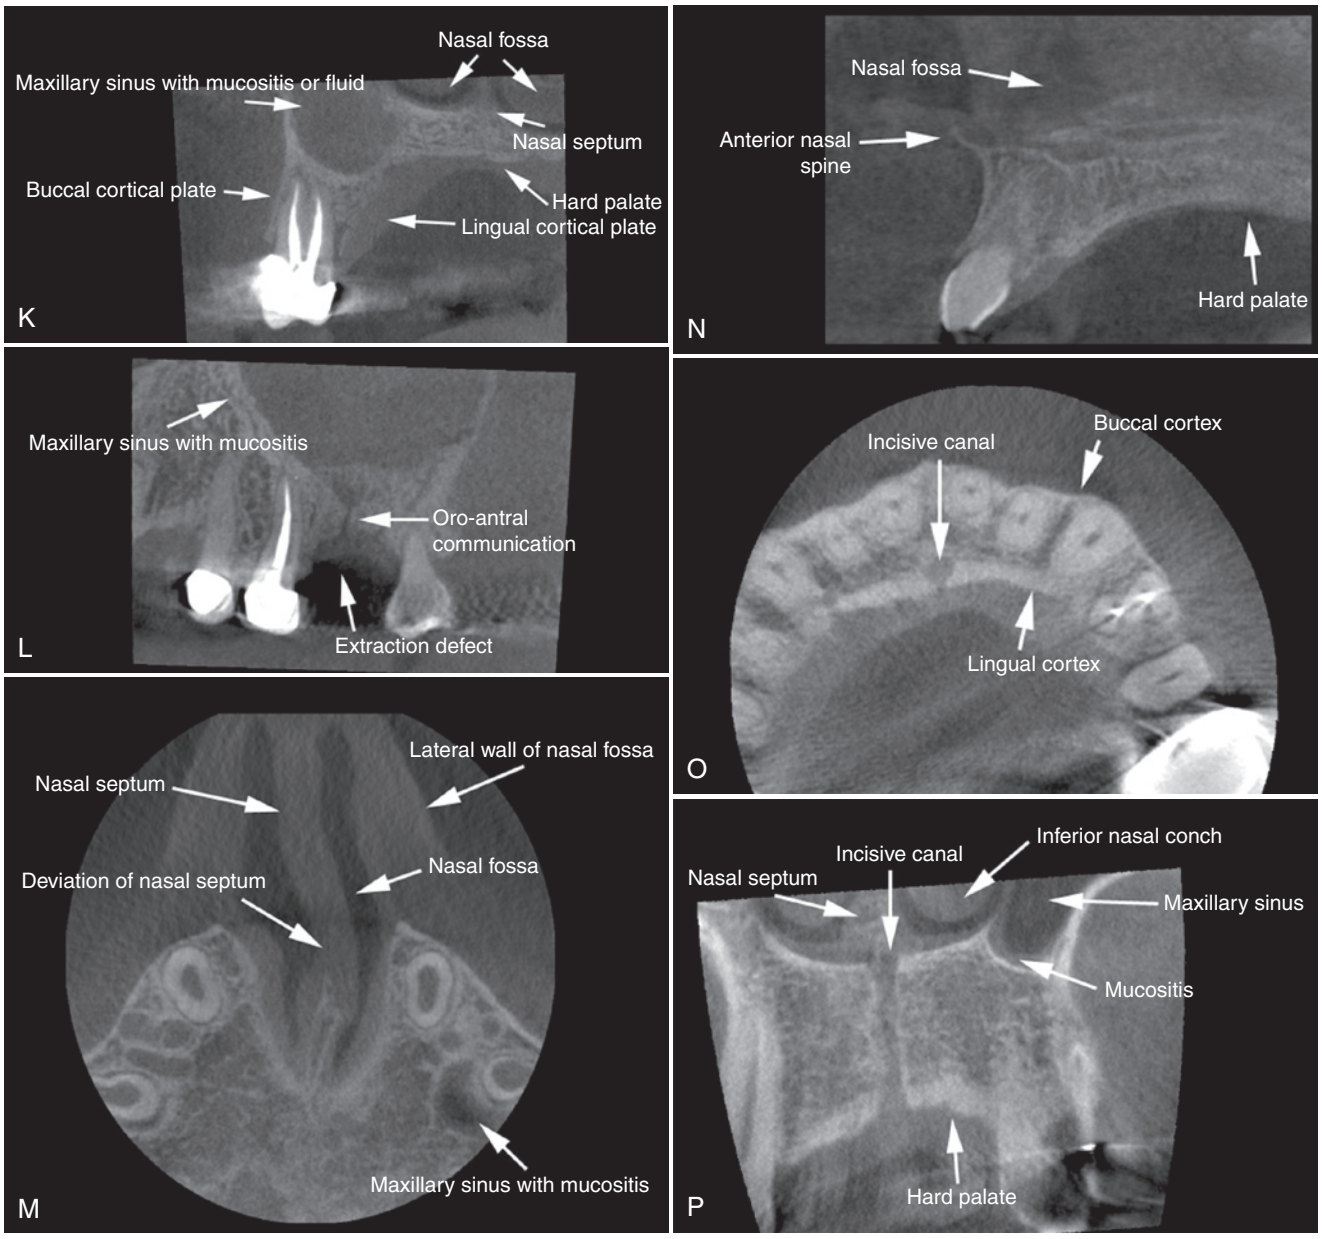

FIG. 2-26, cont'd

Continued

The authors noted that the recall rate of 36% was comparable to that in other studies, but the result may have been affected because patients with symptomatic or already extracted teeth may not have responded. This lost-to-follow-up cohort significantly reduced the level of evidence.[59a] PA radiography identified periapical lesions in only 12.6% of teeth compared to CBCT images, which identified 25.9% of teeth with periapical lesions. In multivariate logistic regression analysis, the extent of root fillings and density were outcome predictors when using PA imaging, whereas density of root fillings and quality of the coronal restoration were outcome predictors when using CBCT scans. The use of cross-sectional tomography in endodontic treatment is not yet supported by high-level studies that show improved outcomes for patients.

The predictive value and diagnostic accuracy of radiologic assessments are critical to the practice of dentistry, and the diagnostic value of radiographs depends on the radiograph's ability to show the histology of apical periodontitis (AP). De Paula-Silva et al.[43] evaluated the periapex of 83 root-treated and untreated dogs' teeth using PA radiography, CBCT scans, and histopathologic analysis. PA radiography detected AP in 71% of roots; CBCT scans detected AP in 84%; and histologic analysis detected AP in 93%. These findings, corroborated by other studies,[27,70,150] emphasized the low negative predictive value (NPV) of PA radiography at 0.25, showing that when the periapical tissues had a normal appearance, 75% actually had AP. CBCT scans resulted in an NPV almost two times higher than that for PA radiography; however, CBCT scans were not able to detect some AP that was confined to the apical foramen or had little volumetric bone loss. The positive predictive value was the same for PA radiography and CBCT scans compared with histologic examination, but true positive and true

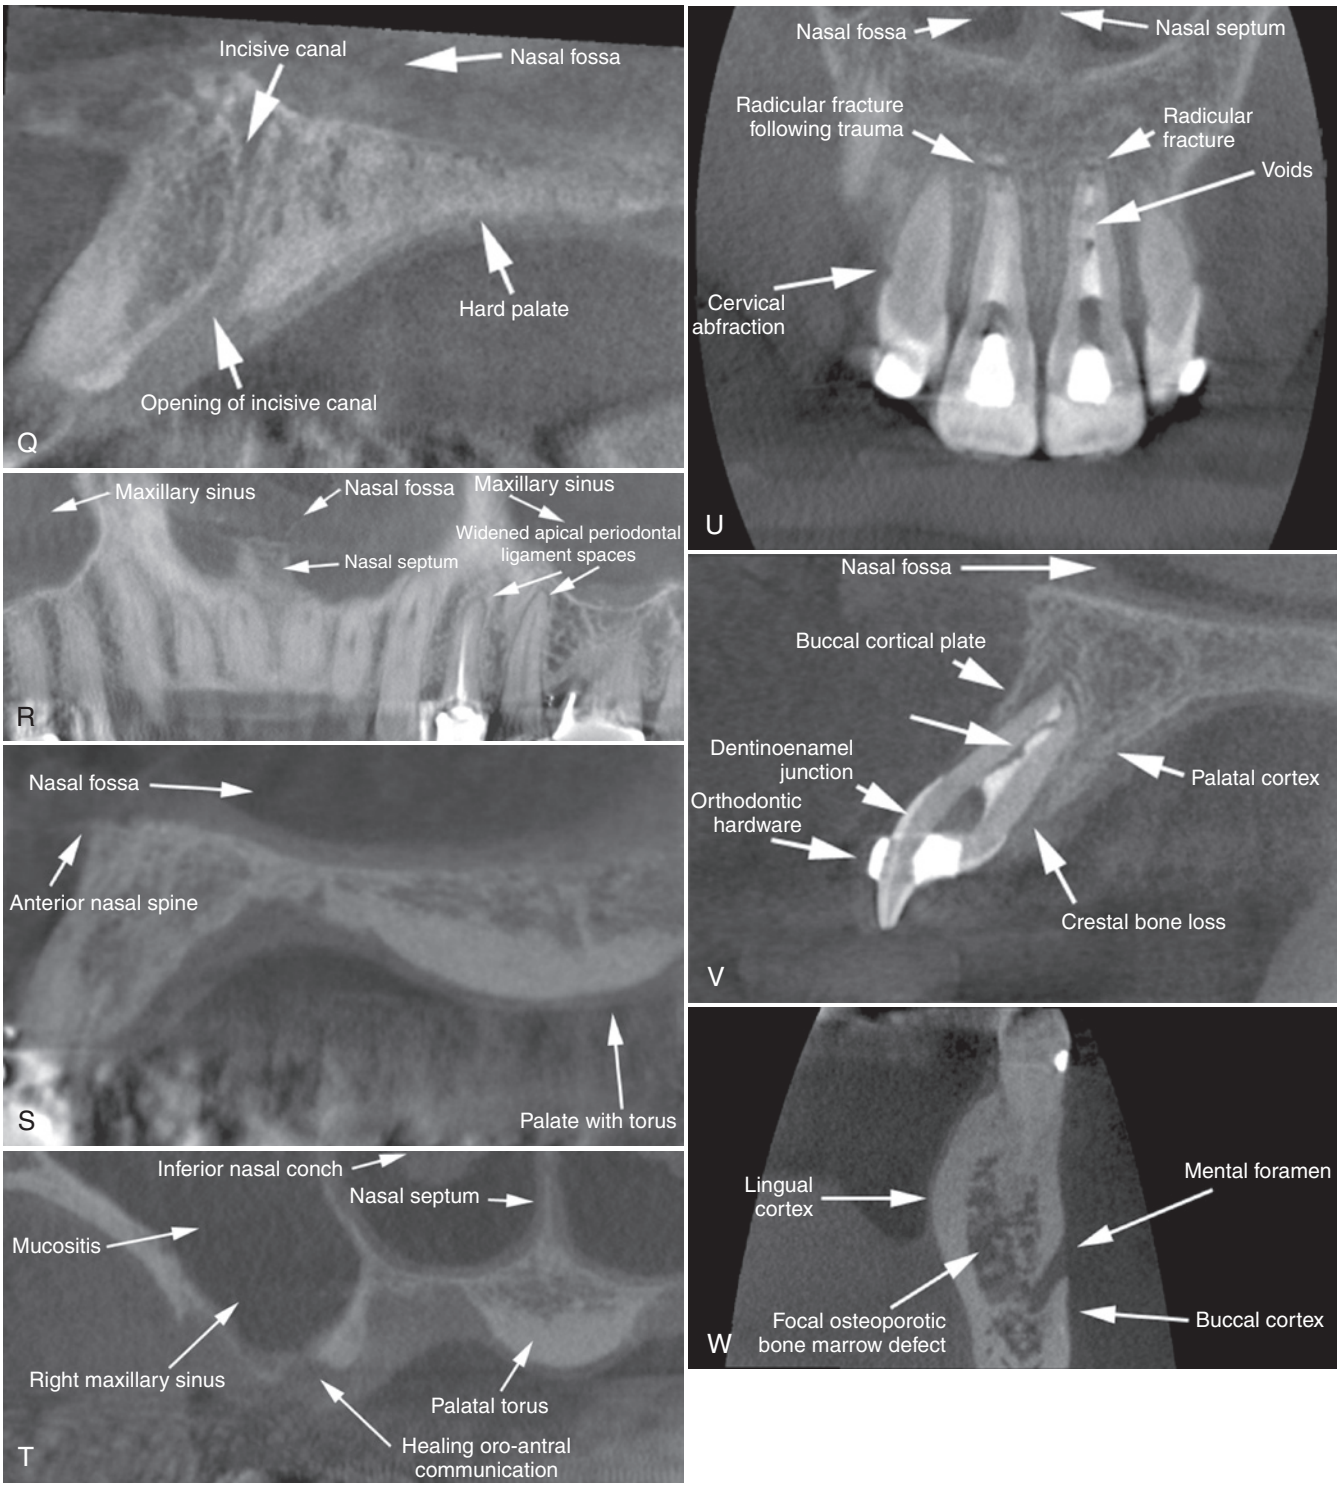

FIG. 2-26, cont'd

negative diagnosis of AP using CBCT scans occurred in 92% of cases.

Determination of healing or nonhealing in individual cases should depend on the clinical and radiographic findings, adjusted for risk factors for the patient, radiation dose, and cost (Fig. 2-27). For patients who are medically complex and subject to possible increased detriment from apical periodontitis (i.e., patients with altered immune systems, such as those undergoing chemotherapy or anti-HIV protocols or who have risk factors associated with prosthetic joints and/or infective endocarditis), these factors should be considered in the decision on whether to use CBCT. The American Academy of Periodontology has published a position paper stating that periodontal disease might contribute to adverse systemic health conditions.[156] The scientific basis for the relationship of AP and adverse systemic health conditions has not been

FIG. 2-27 This series of radiographs shows a maxillary left central incisor several months after a bicycle accident. The patient complained of significant discomfort and mobility with slight swelling in the periapical region. The preoperative PA radiograph (**A**, *left*) and contemporaneous CBCT image (**A**, *right,* corrected sagittal view) showed an approximately 6 mm, well-defined periapical radiolucency with a noncorticated diffuse border, centered over the apex, consistent with a periradicular periodontitis. No root or alveolar fractures were observed. A postoperative PA radiograph (**B**) showed satisfactory canal obturation. At a 3-month checkup visit, the patient complained of continued sensitivity to touch and mobility. There was excessive contact with the opposing incisor, which was adjusted. Because the 3-month checkup PA radiograph (**C**, *left*) showed no change in the periradicular radiolucency, a CBCT image (**C**, *right,* corrected sagittal view) was required to assess healing. The periradicular radiolucency was smaller, consistent with progress in healing. A subsequent 5-month CBCT image (**D**, corrected sagittal view) showed continued healing. Consistent with the as low as reasonably achievable (ALARA) principle, no PA radiograph was exposed. (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, Ga].)

established[33]; however, new associations between AP and systemic health should be predicated on research that uses CBCT in the detection of endodontic disease.[193]

IMPLANT SITE ASSESSMENTS

Successful endosseous implant site assessment requires the development of a prosthetically driven approach,[130b] with special emphasis on the evaluation of bone volume, the osseous topography, and the location of anatomic structures in relation to positioning of the implant. The AAOMR has published advisory recommendations suggesting all radiographic studies should interface with the dental and medical histories, clinical examinations, and treatment planning. Panoramic radiography, which may be supplemented by PA radiography, should be used for initial imaging assessments. Cross-sectional imaging, including CBCT, should not be used as an initial imaging examination. The AAOMR affirms the need for cross-sectional imaging in the preoperative diagnostic phase, recommending CBCT because it provides the highest diagnostic yield at an acceptable radiation dose risk. CBCT should be used at the smallest FOV necessary, with optimized technique factors, to minimize radiation dose in accordance with the ALARA principle.[177a]

CBCT allows for precise planning and delivery of implants that can reproduce the anatomy with submillimetric accuracy, leading to improved outcomes.[171] The use of CBCT to assess linear measurements, proximity to vital anatomic structures, mapping of the alveolar ridge topography, and fabrication of surgical guides is supported by the dental literature. The use of CBCT to gauge bone density, provide intraoperative surgical navigation, and assess implant integration is generally considered an area that requires further research.[17]

Virtual implant planning using CBCT data allows clinicians to visualize the result before the commencement of treatment, facilitating the virtual investigation of multiple treatment scenarios until the best plan is attained. The evaluation of bone dimensions, bone quality, the long axis of the alveolar bone, internal anatomy, and jaw boundaries; the detection of pathologic features; and the transfer of radiographic information are the main imaging goals. Pathoses of the jaws, such as retained root tips, inflammatory lesions, cysts, and tumors, in addition to extraoral structures, such as the sinuses and temporomandibular joints (TMJs), must also be assessed.[80] CBCT imaging should be considered to evaluate implant sites in the region of teeth with a high likelihood of periradicular pathosis.[200]

IMAGE PERCEPTION AND VIEWING ENVIRONMENT

Medical image perception is an important area of knowledge, and ongoing research relies on an understanding of perceptual issues, such as psychological factors, dwell time, visual search physiology, search tactics, appreciation for the reading environment, and fatigue factors, to increase search satisfaction. Understanding these issues may improve the ability to interpret and report on dental radiographic findings.[155a]

The increasing use of digital radiography in the dental environment has led to a sea change in workflow and the necessity for new ways to view and document radiographic images. Simple to accomplish, but important to improve, are the viewing conditions for softcopy interpretation, including moderately reduced ambient lighting, ranging from 25 to 40 lux.[110a]

FUTURE OF CBCT

The first decade of the twenty-first century saw the development of a wide range of CBCT applications, especially in dentistry. Lower radiation dose, higher spatial resolution, smaller FOV, and relatively lower cost may contribute to CBCT becoming the standard of care in 3D dentomaxillofacial imaging in selected cases. CBCT systems are increasingly being used in medical applications, such as operating rooms, emergency departments, intensive care units, and private otolaryngology offices. Operating room–based C-arm systems have been in use for a number of years, with applications in interventional angiography, cancer surgery, vascular surgery, orthopedic surgery, neurosurgery, and radiotherapy.[55] Applications in otolaryngology and mammography are common, and imaging of extremities in weight-bearing scenarios is under development. Many of these applications rely on systems that use task-specific protocols that benefit from CBCT's 2D flat panel detectors, which allow for a single rotation of the source to generate a study of the region of interest, as opposed to complex MDCTs that use redundant imaging via multiple slice acquisitions to generate a 3D volume.[164]

The introduction of new, high-performance, flat-panel detectors and software algorithms centering on improving the noise-power spectrum and noise-equivalent quanta will continue to increase the utility of CBCT systems in the future. Areas of research include (1) image perception and image quality assessment, to better understand how physicians and dentists analyze radiographic images and thereby improve diagnostic decision making[172]; (2) iterative reconstruction that uses sophisticated algorithms to reduce artifacts; (3) known-component reconstructions that use a model-based 3D image reconstruction and iterative software to reduce image artifacts in the presence of metallic devices such as screws and implants; (4) image registration to align tissues for image-guided surgery and outcomes assessment,[120] (5) image-guided procedures that provide up-to-the-minute surgical navigation; and (6) segmentation to allow discrimination between normal and diseased tissues and permit volumetric measurements (Fig. 2-28).

CONCLUSIONS

Digital radiography has several advantages and has become an indispensable diagnostic tool for many dentists in daily practice. Once the digital image appears on the monitor, the dental x-ray software allows image enhancement, which should be used with caution and based on the diagnostic task. Inappropriate use of enhancement has been shown to adversely affect diagnosis.[121] If digital radiographs are exported using various software packages created for graphic design and image manipulation, digital information can be altered, added, or removed. The DICOM standard has been accepted as the universal standard for image transmission and archiving, so that each image can be transmitted and stored without the use of proprietary software that would seriously limit its distribution. DICOM ensures that all images are readable in any viewing software without loss of fidelity or diagnostic information. Image enhancement features of digital radiography allow

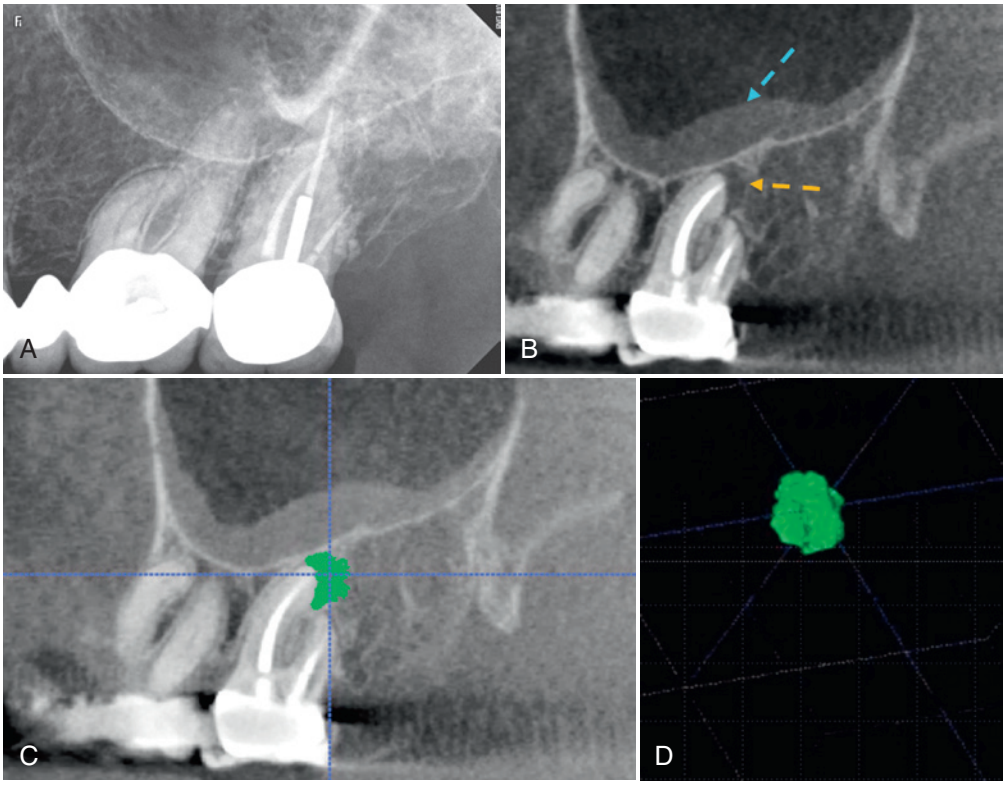

FIG. 2-28 The problem of superimposition of unrelated structures onto the features of interest is reduced when tomographic slices are used instead of images in which an entire volume of data is compressed into a planar image. This PA radiographic image **(A)** of the maxillary left second molar shows no radiographic indicators of pathosis. A contemporaneously exposed CBCT image (**B**, corrected sagittal view) shows a 4.3 × 1.9 mm, well-defined unilocular, noncorticated area of low attenuation centered over the apex of the mesiobuccal root, consistent with a periradicular periodontitis *(yellow arrow).* There is a moderate mucositis in the region of the maxillary sinus adjacent to this tooth *(blue arrow).* Experimental semiautomated segmentation of this image using active contour methods (ITK-SNAP) allowed for measurement of the true volume of the lesion **(C)** and for future temporal comparisons based on volumetric measurements **(D).** This lesion measured 85,112 voxels and 38.1044 cubic mm. (Data acquired and reformatted at 0.076 mm voxel size using a CS 9000 3D unit [Carestream Dental, Atlanta, Ga]; volumetric segmentation and measurement using ITK-SNAP [Radiology Department, School of Medicine, University of Pennsylvania].)

mishandling of images, leading to potential abuse. Published studies illustrate the potential for fraudulent use of digital radiography.[31]

There is a dearth of studies related to the diagnostic performance of the different sensor types currently available on the market. Slight to moderate differences in spatial resolution capabilities exist. With rapid advancement in sensor technology and frequent software upgrades, selection of one system over another for a specific diagnostic task may appear challenging. A review of the most commonly used solid-state sensors notes that most systems perform comparably with intraoral film and also allow for postprocessing of images, which is not possible with film-based images. Other factors that assume significance in this context are the availability of technical and customer support, frequency of both hardware and software upgrades, dimensions of the sensor and its active area, number of sensors needed in a practice (and thus cost issues), the detector quantum efficiency (DQE), and conformance to the DICOM standard for seamless integration with other systems. CCD/CMOS sensors appear to offer the best contrast and spatial resolution, in addition to facilitating instantaneous image capture, and therefore are recommended for endodontic applications. Careful and appropriate image processing further helps tease out the signal of interest. In an enterprise-wide setting or in larger private practices that have multiple specialty areas, PSP-based sensors may be more cost effective for large volume imaging (e.g., full mouth series of radiographs). However, at least one or two CCD/CMOS-based systems should be available for faster image acquisition, such as for endodontic purposes and intraoperative procedures.

It is recommended that the literature be constantly reviewed for updates on digital radiography and advanced imaging modalities for specific endodontic applications because hardware and software upgrades continue to make rapid progress. Previous studies have shown that most digital images performed comparably to conventional intraoral film for a variety of diagnostic tasks. Most of these studies were done with earlier generation sensors. The advances in sensor technology have resulted in greatly enhanced image quality, and this trend is expected to continue. Also of interest in the future will be the use of task-based, appropriate image processing parameters

that result in a reduced radiation dose and significant enhancement of the diagnostic information. Automation of this process will result in faster and more consistent image processing based on the diagnostic task. Such procedures are routinely carried out in medical radiology.

Three-dimensional imaging will continue to be used extensively as sensor characteristics improve and more user-friendly software is introduced. As bit-depth and spatial resolution of images increase, CBCT will continue to be explored for more applications in endodontics. Image interpretation also is important. Occult pathology and incidental findings in adjacent regions can be easily missed or go unrecognized by those who have not received specific training in the interpretation of regional anatomy. Image processing can greatly alter signal characteristics, thus rendering the task fairly challenging. Besides, if other pathoses are discovered, additional imaging may be necessary, including MRI, nuclear medicine studies, or even MDCT for evaluation of soft tissues, with and without the use of contrast.

The advent of 3D imaging has provided the endodontist with tools that were not available until now, facilitating interactive image manipulation and enhancement and thus significantly increasing the amount of information that can be gleaned from a volume. Lack of distortion, magnification, artifacts associated with conventional radiography, and the relative low radiation dose compared to medical-grade CT will result in more clinicians adopting such technology to enable accurate diagnoses and treatment planning, in addition to long-term follow-up and the evaluation of healing. Judicious use of CBCT and all other imaging modalities using ionizing radiation is advocated. The AAE/AAOMR position paper provides recommendations for the use of CBCT in endodontics.[34] That position paper is presented at the end of this chapter.

When the clinician works with different vendor products, it is important to have a quality assurance program in place. This is not being done currently. Additionally, accreditation of stand-alone imaging laboratories is now a requirement for reimbursement of medical and dental diagnostic procedures from government agencies and some major third-party insurance providers. Several states are considering enforcing this requirement to prevent abuse of CBCT.

Likewise, definitive referral criteria are lacking. Indications, contraindications, and choice of alternate imaging modalities need to be considered before CBCT is used. There is a learning curve to this technology, and appropriate positioning, choice of exposure parameters (and thus the effective dose), reconstruction schemes, choice of postprocessing algorithms based on diagnostic task, voxel sizes, and cost must be considered. The literature contains few studies to help us formulate definitive guidelines for the use of CBCT in dentistry.

It is equally important to record the doses associated with each study. Accreditation criteria have been developed by the Intersocietal Accreditation Commission for cone beam CT in dentistry that are useful for ensuring the safe use of these units. The lowest possible dose must be imparted to the patient as part of a radiologic examination to minimize stochastic effects that have no known threshold for expression. No dose can be considered a "safe dose." The benefits of any radiographic study must outweigh the risks. All studies must be interpreted fully because signals from adjacent areas may appear in the volume of interest, including small FOV studies. Retakes can be avoided by adhering to protocol selection based on the task at hand. The ALARA principle must be followed, regardless of the dose values reported by the vendor, to optimize the dose for the specific examination. Use of thyroid collars and lead aprons is recommended in the NCRP guidelines, as long as they do not interfere with image acquisition.

Joint Position Statement of the American Association of Endodontists and the American Academy of Oral and Maxillofacial Radiology on the Use of Cone Beam Computed Tomography in Endodontics: 2015 Update

This statement was prepared by the Special Committee to Revise the Joint AAE/AAOMR Position Statement on Use of CBCT in Endodontics, and approved by the AAE Board of Directors and AAOMR Executive Council in May 2015.

INTRODUCTION

This updated joint position statement of the American Association of Endodontists (AAE) and the American Academy of Oral and Maxillofacial Radiology (AAOMR) is intended to provide scientifically-based guidance to clinicians regarding the use of cone beam computed tomography (CBCT) in endodontic treatment and reflects new developments since the 2010 statement.[1] The guidance in this statement is not intended to substitute for a clinician's independent judgment in light of the conditions and needs of a specific patient.

Endodontic disease adversely affects quality of life and can produce significant morbidity in afflicted patients. Radiography is essential for the successful diagnosis of odontogenic and non-odontogenic pathoses, treatment of the root canal systems of a compromised tooth, biomechanical instrumentation, evaluation of final canal obturation, and assessment of healing.

Until recently, radiographic assessments in endodontic treatment were limited to intraoral and panoramic radiography. These radiographic technologies provide two-dimensional representations of three-dimensional anatomic structures. If any element of the geometric configuration is compromised, the image may demonstrate errors.[2] In more complex cases, radiographic projections with different beam angulations can allow parallax localization. However, complex anatomy and surrounding structures can render interpretation of planar images difficult.

The advent of CBCT has made it possible to visualize the dentition, the maxillofacial skeleton, and the relationship of anatomic structures in three dimensions.[3] CBCT, as with any technology, has known limitations, including a possible higher radiation dose to the patient. Other limitations include potential for artifact generation, high levels of scatter and noise, and variations in dose distribution within a volume of interest.[4]

CBCT should be used only when the patient's history and a clinical examination demonstrate that the benefits to the patient outweigh the potential risks. CBCT should not be used routinely for endodontic diagnosis or for screening purposes in the absence of clinical signs and symptoms. Clinicians should use CBCT only when the need for imaging cannot be met by lower dose two-dimensional (2D) radiography.

VOLUME SIZE(S)/FIELD OF VIEW

There are numerous CBCT equipment manufacturers, and several models are available. In general, CBCT is categorized into large, medium and limited-volume units based on the size of their "field of view" (FOV). The size of the FOV describes the scan volume of CBCT machines. That volume determines the extent of anatomy included. It is dependent on the detector size and shape, beam projection geometry, and the ability to collimate the beam. To the extent practical, FOV should only slightly exceed the dimensions of the anatomy of interest.

Generally, the smaller the FOV, the lower the dose associated with the study. Beam collimation limits the radiation exposure to the region of interest and helps ensure that an optimal FOV can be selected based on disease presentation. Smaller scan volumes generally produce higher resolution images. Because endodontics relies on detecting small alterations such as disruptions in the periodontal ligament space, optimal resolution should be sought.[5]

The principal limitations of large FOV CBCT imaging are the size of the field irradiated and the reduced resolution compared to intraoral radiographs and limited volume CBCT units with inherent small voxel sizes.[5] The smaller the voxel size, the higher is the spatial resolution. Moreover, the overall scatter generated is reduced due to the limited size of the FOV. Optimization of the exposure protocols keeps doses to a

minimum without compromising image quality. If a low-dose protocol can be used for a diagnostic task that requires lower resolution, it should be employed, absent strong indications to the contrary.

In endodontics, the area of interest is limited and determined prior to imaging. For most endodontic applications, limited FOV CBCT is preferred to medium or large FOV CBCT because there is less radiation dose to the patient, higher spatial resolution, and shorter volumes to be interpreted.

DOSE CONSIDERATIONS

Selection of the most appropriate imaging protocol for the diagnostic task must be consistent with the ALARA principles that every effort should be made to reduce the effective radiation dose to the patient "as low as reasonably achievable." Because radiation dose for a CBCT study is higher than that for an intraoral radiograph, clinicians must consider overall radiation dose over time. For example, will acquiring a CBCT study now eliminate the need for additional imaging procedures in the future? It is recommended to use the smallest possible FOV, the smallest voxel size, the lowest mA setting (depending on the patient's size), and the shortest exposure time in conjunction with a pulsed exposure-mode of acquisition.

If extension of pathoses beyond the area surrounding the tooth apices or a multifocal lesion with possible systemic etiology is suspected, and/or a non-endodontic cause for devitalization of the tooth is established clinically, appropriate larger field of view protocols may be employed on a case-by-case basis.

There is a special concern with overexposure of children (up to and including 18 year-olds) to radiation, especially with the increased use of CT scans in medicine. The AAE and the AAOMR support the Image Gently Campaign led by the Alliance for Radiation Safety in Pediatric Imaging. The goal of the campaign is, "to change practice; to raise awareness of the opportunities to lower radiation dose in the imaging of children." Information on use of CT is available at http://www.imagegently.org/Procedures/ComputedTomography.aspx

INTERPRETATION

If a clinician has a question regarding image interpretation, it should be referred to an oral and maxillofacial radiologist.[6]

RECOMMENDATIONS

The following recommendations are for limited FOV CBCT scans.

Diagnosis

Endodontic diagnosis is dependent upon thorough evaluation of the patient's chief complaint, history, and clinical and radiographic examination. Preoperative radiographs are an essential part of the diagnostic phase of endodontic therapy. Accurate diagnostic imaging supports the clinical diagnosis.

Recommendation 1: Intraoral radiographs should be considered the imaging modality of choice in the evaluation of the endodontic patient.

Recommendation 2: Limited FOV CBCT should be considered the imaging modality of choice for diagnosis in patients who present with contradictory or non-specific clinical signs and symptoms associated with untreated or previously endodontically-treated teeth.

Rationale:

- In some cases, the clinical and planar radiographic examinations are inconclusive. Inability to confidently determine the etiology of endodontic pathosis may be attributed to limitations in both clinical vitality testing and intraoral radiographs to detect odontogenic pathoses. CBCT imaging has the ability to detect periapical pathosis before it is apparent on 2D radiographs.[7]
- Preoperative factors such as the presence and true size of a periapical lesion play an important role in endodontic treatment outcome. Success, when measured by radiographic criteria, is higher when teeth are endodontically treated before radiographic signs of periapical disease are detected.[8]
- Previous findings have been validated in clinical studies in which primary endodontic disease detected with intraoral radiographs and CBCT was 20% and 48%, respectively. Several clinical studies had similar findings, although with slightly different percentages.[9,10] Ex vivo experiments in which simulated periapical lesions were created yielded similar results.[11,12] Results of in vivo animal studies, using histologic assessments as the gold standard also showed similar results observed in human clinical and ex-vivo studies.[13]
- Persistent intraoral pain following root canal therapy often presents a diagnostic challenge. An example is persistent dentoalveolar pain also known as atypical odontalgia.[14] The diagnostic yield of conventional intraoral radiographs and CBCT scans was evaluated in the differentiation between patients presenting with suspected atypical odontalgia vs. symptomatic apical periodontitis, without radiographic evidence of periapical bone destruction.[15] CBCT imaging detected 17% more teeth with periapical bone loss than conventional radiography.

Initial Treatment

Preoperative:

Recommendation 3: Limited FOV CBCT should be considered the imaging modality of choice for initial treatment of teeth with the potential for extra canals and suspected complex morphology, such as mandibular anterior teeth, and maxillary and mandibular premolars and molars, and dental anomalies.

Intraoperative:

Recommendation 4: If a preoperative CBCT has not been taken, limited FOV CBCT should be considered as the imaging modality of choice for intra-appointment identification and localization of calcified canals.

Postoperative:

Recommendation 5: Intraoral radiographs should be considered the imaging modality of choice for immediate postoperative imaging.

Rationale:

- Anatomical variations exist among different types of teeth. The success of non-surgical root canal therapy depends on

identification of canals, cleaning, shaping and obturation of root canal systems as well as quality of the final restoration.

- 2D imaging does not consistently reveal the actual number of roots and canals. In studies, data acquired by CBCT showed a very strong correlation between sectioning and histologic examination.[16,17]
- In a 2013 study, CBCT showed higher mean values of specificity and sensitivity when compared to intraoral radiographic assessments in the detection of the MB2 canal.[18]

Non-Surgical Retreatment

Recommendation 6: Limited FOV CBCT should be considered the imaging modality of choice if clinical examination and 2D intraoral radiography are inconclusive in the detection of vertical root fracture (VRF).

Rationale:

- In non-surgical retreatment, the presence of a vertical root fracture significantly decreases prognosis. In the majority of cases, the indication of a vertical root fracture is more often due to the specific pattern of bone loss and periodontal ligament space enlargement than direct visualization of the fracture. CBCT may be recommended for the diagnosis of vertical root fracture in unrestored teeth when clinical signs and symptoms exist.
- Higher sensitivity and specificity were observed in a clinical study where the definitive diagnosis of vertical root fracture was confirmed at the time of surgery to validate CBCT findings, with sensitivity being 88% and specificity 75%.[19] Several case series studies have concluded that CBCT is a useful tool for the diagnosis of vertical root fractures. In vivo and laboratory studies[20,21] evaluating CBCT in the detection of vertical root fractures agreed that sensitivity, specificity, and accuracy of CBCT were generally higher and reproducible. The detection of fractures was significantly higher for all CBCT systems when compared to intraoral radiographs. However, these results should be interpreted with caution because detection of vertical root fracture is dependent on the size of the fracture, presence of artifacts caused by obturation materials and posts, and the spatial resolution of the CBCT.

Recommendation 7: Limited FOV CBCT should be the imaging modality of choice when evaluating the non-healing of previous endodontic treatment to help determine the need for further treatment, such as non-surgical, surgical or extraction.

Recommendation 8: Limited FOV CBCT should be the imaging modality of choice for non-surgical re-treatment to assess endodontic treatment complications, such as overextended root canal obturation material, separated endodontic instruments, and localization of perforations.

Rationale:

- It is important to evaluate the factors that impact the outcome of root canal treatment. The outcome predictors identified with periapical radiographs and CBCT were evaluated by Liang et al.[22] The results showed that periapical radiographs detected periapical lesions in 18 roots (12%) as compared to 37 on CBCT scans (25%). 80% of apparently short root fillings based on intraoral radiographs images appeared flush on CBCT. Treatment outcome, length and density of root fillings and outcome predictors determined by CBCT showed different values when compared with intraoral radiographs.
- Accurate treatment planning is an essential part of endodontic retreatment. Incorrect, delayed or inadequate endodontic diagnosis and treatment planning places the patient at risk and may result in unnecessary treatment. Treatment planning decisions using CBCT versus intraoral radiographs were compared to the gold standard diagnosis.[23] An accurate diagnosis was reached in 36%-40% of the cases with intraoral radiographs compared to 76%-83% with CBCT. A high level of misdiagnosis was noted in invasive cervical resorption and vertical root fracture. In this study, the examiners altered their treatment plan after reviewing the CBCT in 56%-62.2% of the cases, thus indicating the significant influence of CBCT.

Surgical Retreatment

Recommendation 9: Limited FOV CBCT should be considered as the imaging modality of choice for pre-surgical treatment planning to localize root apex/apices and to evaluate the proximity to adjacent anatomical structures.

Rationale:

The use of CBCT has been recommended for treatment planning of endodontic surgery.[24,25] CBCT visualization of the true extent of periapical lesions and their proximity to important vital structures and anatomical landmarks is superior to that of periapical radiographs.

Special Conditions

a. Implant Placement:

Recommendation 10: Limited FOV CBCT should be considered as the imaging modality of choice for surgical placement of implants.[26]

b. Traumatic Injuries:

Recommendation 11: Limited FOV CBCT should be considered the imaging modality of choice for diagnosis and management of limited dento-alveolar trauma, root fractures, luxation, and /or displacement of teeth and localized alveolar fractures, in the absence of other maxillofacial or soft tissue injury that may require other advanced imaging modalities.[27]

c. Resorptive Defects:

Recommendation 12: Limited FOV CBCT is the imaging modality of choice in the localization and differentiation of external and internal resorptive defects and the determination of appropriate treatment and prognosis.[28,29]

CHAPTER 3

Case Selection and Treatment Planning

PAUL A. ROSENBERG | MATTHEW MALEK

CHAPTER OUTLINE

Common Medical Findings That May Influence Endodontic Treatment Planning
- *Cardiovascular Disease*
- *Diabetes*
- *Pregnancy*
- *Malignancy*
- *Medication-Related Osteonecrosis of the Jaws (MRONJ)*
- *Human Immunodeficiency Virus (HIV) and Acquired Immunodeficiency Syndrome (AIDS)*
- *End-Stage Renal Disease and Dialysis*
- *Prosthetic Implants*
- *Behavioral and Psychiatric Disorders*
- *Psychosocial Evaluation*

Development of the Endodontic Treatment Plan

Endodontic Prognosis
- *Single-Visit versus Multiple-Visit Treatment*

Interdisciplinary Treatment Planning
- *Periodontal Considerations*
- *Surgical Considerations*
- *Restorative and Prosthodontic Considerations*
- *Endodontic Therapy or Dental Implant*

Other Factors That May Influence Endodontic Case Selection
- *Anxiety*
- *Scheduling Considerations*

The process of case selection and treatment planning begins after a clinician has diagnosed an endodontic problem. The clinician must determine whether the patient's oral health needs are best met by providing endodontic treatment and maintaining the tooth or by advising extraction. The use of rotary instruments, ultrasonics, and microscopy as well as new materials has made it possible to predictably retain teeth that previously would have been extracted. In addition, even teeth that have failed initial endodontic treatment can often be successfully retreated using nonsurgical or surgical procedures.

Increased knowledge concerning the importance of anxiety control, premedication with a nonsteroidal anti-inflammatory drug (NSAID) or acetaminophen, profound local anesthesia, appropriate occlusal adjustment, and biology-based clinical procedures enables clinicians to complete endodontic procedures without intraoperative or posttreatment pain.

Questions concerning tooth retention and possible referral can be answered only after a complete patient evaluation. The evaluation must include assessment of medical, psychosocial, and dental factors as well as consideration of the relative complexity of the endodontic procedure. Although most medical conditions do not contraindicate endodontic treatment, some can influence the course of treatment and require specific modifications. A number of valuable texts are available that review the subject of dental care for the medically compromised patient.[14,48,110] The American Academy of Oral Medicine (Edmonds, WA) has an excellent website (www.aaom.com) that can be used to elicit information about medically compromised patients.

Perhaps the most important advice for a clinician who plans to treat a medically compromised patient is to be prepared to communicate with the patient's physician. The proposed treatment can be reviewed, and medical recommendations should be documented. Fig. 3-1 depicts a sample medical consultation letter that can be modified as necessary.

The American Society of Anesthesiologists (ASA; Park Ridge, IL) Physical Status Classification system is commonly used to express medical risk (Box 3-1). The ASA classification system remains the most widely used assessment method for preanesthetic patients despite some inherent limitations to its use as a peritreatment risk predictor. This classification system is a generally accepted and useful guide for pretreatment assessment of relative risk but does not advise appropriate treatment modifications. The clinician should go beyond the classification system and gather more information from the patient and physician, including the patient's compliance with suggested medication, frequency of physician visits, and most recent visit.

Typical questions include the following: *Do you take medication as prescribed by your physician?* Or, *when was the last time you were examined by your physician?* Other systems have been proposed that would better reflect the increasing number of

Michael White, MD
1 Walker Street
Brown City, OK

Dear Dr. White,

Your patient, Ms. Mary Smith, presented for consultation on August 10, 2009, concerning tooth #19. The tooth is asymptomatic at this time, but a small (4 mm x 3 mm), well-circumscribed periradicular radiolucency associated with the palatal root was noted on radiographic examination. The tooth was tested for vitality using thermal and electrical modalities and found to be nonvital, indicating an odontogenic cause for the lesion. The tooth will require endodontic treatment in order to be maintained. The prognosis for nonsurgical endodontic treatment in this case is good. I anticipate that her dental medication plan would include lidocaine with epinephrine for anesthesia and ibuprofen for postoperative pain control.

In a review of the patient's medical history she noted that she is being treated for a malignancy of the thyroid gland and is undergoing radiation therapy. She was unable to provide more specific information about her treatment.

I would appreciate information regarding her ability to undergo endodontic treatment at this time. Please call me if there is further information that you would require concerning the dental treatment to be provided. Thank you.

Yours truly,

Peter Jones, DDS

FIG. 3-1 Sample medical consultation letter.

BOX 3-1

American Society of Anesthesiologists Physical Status Classification System

P1: Normal, healthy patient; no dental management alterations required
P2: Patient with mild systemic disease that does not interfere with daily activity or who has a significant health risk factor (e.g., smoking, alcohol abuse, gross obesity)
P3: Patient with moderate to severe systemic disease that is not incapacitating but may alter daily activity
P4: Patient with severe systemic disease that is incapacitating and a constant threat to life

From: www.asahq.org/clinical/physicalstatus.htm.

medically complex patients treated by clinicians as Americans live longer.[35] Regardless of the classification system used, these generalized guidelines need to be individualized for the patient under care.

An alternative means of considering risk assessment is to review the following issues:

- History of allergies
- History of drug interactions, adverse effects
- Presence of prosthetic valves, joints, stents, pacemakers, and so on
- Antibiotics required (prophylactic or therapeutic)
- Hemostasis (normal expected, modification to treatment)
- Patient position in chair
- Infiltration or block anesthesia with or without vasoconstrictor
- Significant equipment concerns (radiographs, ultrasonics, electrosurgery)
- Emergencies (potential for occurrence, preparedness)
- Anxiety (past experiences and management strategy)

A review of these areas provides the clinician with essential background data before initiating treatment.

COMMON MEDICAL FINDINGS THAT MAY INFLUENCE ENDODONTIC TREATMENT PLANNING

Cardiovascular Disease

Patients with some forms of cardiovascular disease are vulnerable to physical or emotional stress that may be encountered during dental treatment, including endodontics. Patients may be confused or ill informed concerning the specifics of their particular cardiovascular problem. In these situations, consultation with the patient's physician is mandatory before the initiation of endodontic treatment. "For patients with symptoms of unstable angina or those who have had an MI [myocardial infarction] within the past 30 days (major risk category), elective care should be postponed."[48] One study found "no significant increase in the risk of experiencing a second vascular event after dental visits, including those that involved invasive procedures, in periods up to 180 days after a first recorded ischemic stroke, transient ischemic attack (TIA) or acute MI."[94]

The use of vasoconstrictors in local anesthetics poses potential problems for patients with ischemic heart disease. In these patients, local anesthetics without vasoconstrictors may be used as needed. If a vasoconstrictor is necessary, patients with intermediate clinical risk factors (i.e., a past history of MI without ischemic symptoms) and those taking nonselective beta-blockers can safely be given up to 0.036 mg epinephrine (two cartridges containing 1:100,000 epinephrine) at one appointment. For patients at higher risk (i.e., those who have

had an MI within the past 7 to 30 days and unstable angina), the use of vasoconstrictors should be discussed with the physician.[48]

Vasoconstrictors may interact with some antihypertensive medications and should be used only after consultation with the at-risk patient's physician. Local anesthetic agents with minimal or no vasoconstrictors are usually adequate for nonsurgical endodontic procedures[48] (see also Chapter 4). A systematic review of the cardiovascular effects of epinephrine concluded that the increased risk for adverse events among uncontrolled hypertensive patients was low, and the reported adverse events associated with epinephrine use in local anesthetics was minimal.[4] Another review highlighted the advantages of including a vasoconstrictor in the local anesthesia and stated that "pain control was significantly impaired in those patients receiving the local anesthetic without the vasoconstrictor as compared to those patients receiving the local anesthetic with vasoconstrictor."[13]

A patient who has specific heart conditions may be susceptible to an infection of the heart valves, induced by a bacteremia. This infection is called *infective* or *bacterial endocarditis* and is potentially fatal. In 2008, the American College of Cardiology and American Heart Association (AHA) Task Force on Practice Guidelines published an update on their previous guidelines, which focused on infectious endocarditis. This guideline stated that "prophylaxis against infective endocarditis is reasonable for the following patients at highest risk for adverse outcomes from infective endocarditis who undergo dental procedures that involve manipulation of either gingival tissue or the periapical region of teeth or perforation of the oral mucosa: patients with prosthetic cardiac valves or prosthetic material used for cardiac valve repair . . . , patients with previous infective endocarditis . . . [and] patients with congenital heart disease."[71]

The specific recommendations are summarized in a reference guide by the American Association of Endodontists (AAE; Chicago, IL), found online at www.aae.org/uploadedfiles/publications_and_research/guidelines_and_position_statements/antibioticprophylaxsisquickrefguide.pdf). Because the AHA periodically revises its recommended antibiotic prophylactic regimen for dental procedures, it is essential that the clinician stay current concerning this important issue. There is a low compliance rate among at-risk patients regarding their use of the suggested antibiotic coverage before dental procedures. Therefore, the clinician must question patients concerning their compliance with the prescribed prophylactic antibiotic coverage before endodontic therapy. If a patient has not taken the antibiotic as recommended, it may be administered up to 2 hours after the procedure.[71]

Patients with artificial heart valves are considered susceptible to bacterial endocarditis. Consulting the patient's physician in such cases regarding antibiotic premedication is essential. Some physicians elect to administer parenteral antibiotics in addition to or in place of the oral regimen.

A dentist may be the first to detect elevated blood pressure if he or she routinely evaluates blood pressure before treatment. Furthermore, patients receiving treatment for hypertension may not be controlled adequately because of poor compliance or inappropriate drug therapy. Abnormal blood pressure readings may be the basis for physician referral.

Some patients may be disposed to serious life-threatening complications due to stress. Acute heart failure during a stressful dental procedure in a patient with significant valvular disease and heart failure or the development of infectious endocarditis represent two such life-threatening disorders.[91] Careful evaluation of patients' medical histories including the cardiac status of patients, the use of appropriate prophylactic antibiotics, and stress reduction strategies will minimize the risk of serious cardiac sequelae.

There is a widespread belief among dentists and physicians that oral anticoagulation therapy in which patients receive drugs such as warfarin (Coumadin) must be discontinued before dental treatment to prevent serious hemorrhagic complications, especially during and after surgical procedures. Aspirin is a drug commonly used as an anticoagulant on a daily basis without the supervision of a physician. Clinical studies do not support the routine withdrawal of anticoagulant therapy before dental treatment for patients who are taking such medications.[10,39,48]

When patients report they are receiving an anticoagulant medication, they can benefit from the clinician using the following guidelines:

- Identify the reason why the patient is receiving anticoagulant therapy.
- Assess the potential risk versus benefit of altering the drug regimen.
- Know the laboratory tests used to assess anticoagulation levels (i.e., the international normalized ratio [INR] value should be 3.5 or less for patients who are taking warfarin to safely undergo dental or surgical endodontic procedures).[48] Be familiar with methods used to obtain hemostasis both intraoperatively and postoperatively.
- Be familiar with the potential complications associated with prolonged or uncontrolled bleeding.
- Consult the patient's physician to discuss the proposed dental treatment and to determine the need to alter the anticoagulant regimen.

Another cardiac complication may occur in patients with Hodgkin disease or breast cancer, who often receive irradiation to the chest as an element of treatment. Although the therapy often cures the malignancy, it has been implicated in causing late-onset heart disease that may influence the development of a treatment plan and subsequent treatment. Dentists must identify patients who have received irradiation to the chest and consult with patients' physicians to determine whether that therapy has damaged the heart valves or coronary arteries. Patients with radiation-induced valvular disease may require prophylactic antibiotics when undergoing specific dental procedures that are known to cause a bacteremia and a heightened risk of developing endocarditis. Patients with radiation-induced coronary artery disease should be administered only limited amounts of local anesthetic agents containing a vasoconstrictor. They may require the administration of sedative agents and cardiac medications to preclude ischemic episodes. Consultation with the patient's physician is an appropriate response when a patient presents with a history that includes prior radiation to the chest.[29]

Diabetes

The Centers for Disease Control and Prevention (CDC, Atlanta, GA) in 2011 reported that 25.8 million people, or 8.3% of the U.S. population, have diabetes. There were also about 1.9 million people aged 20 years or older newly diagnosed with diabetes in 2010. (See Centers for Disease Control and

Prevention *Diabetes Fact Sheet*, available at http://cdc.gov/diabetes/pubs/estimates11.htm#2, 2011.) Diabetes is the seventh leading cause of death in the United States,[61] and, according to the *Diabetes Fact Sheet*, the risk for death among people with diabetes is about twice that of people of similar age but without diabetes. It is likely that patients with diabetes who require endodontic treatment will be increasingly common.

Diabetes mellitus appears to have multiple causes and several mechanisms of pathophysiology.[48] It can be thought of as a combination of diseases that share the key clinical feature of glucose intolerance. Patients with diabetes, even those who are well controlled, require special consideration during endodontic treatment. The patient with well-controlled diabetes, who is free of serious complications such as renal disease, hypertension, or coronary atherosclerotic disease, is a candidate for endodontic treatment. However, special considerations exist in the presence of acute infections. The non–insulin-controlled patient may require insulin, or the insulin dose of some insulin-dependent patients may have to be increased.[79] When surgery is required, consultation with the patient's physician is advisable in order to consider adjustment of the patient's insulin dosage, antibiotic prophylaxis, and dietary needs during the posttreatment period.

The clinician should ask patients with diabetes who self-monitor their glucose levels to bring a glucometer to each visit. If pretreatment glucose levels are below normal fasting range (80 to 120 mg/dl), it may be appropriate to take in a carbohydrate source.[100] A source of glucose (e.g., glucose tablets, orange juice, or soda) should be available if signs of insulin shock (hypoglycemic reaction caused by overcontrol of glucose levels) occur.[48] Signs and symptoms of hypoglycemia include confusion, tremors, agitation, diaphoresis, and tachycardia.[100] The clinician can avoid a hypoglycemic emergency by taking a complete, accurate history of the time and amount of the patient's insulin and meals. When questions arise concerning the appropriate course to follow, the patient's physician should be contacted or treatment deferred.

Appointments should be scheduled with consideration given to the patient's normal meal and insulin schedule.[79] Usually, a patient with diabetes who is well managed medically and is under good glycemic control without serious complications such as renal disease, hypertension, or coronary atherosclerotic heart disease can receive any indicated dental treatment.[57] However, patients with diabetes who have serious medical complications may need a modified dental treatment plan. For instance, although prophylactic antibiotics generally are not required, it "may be prescribed a patient with brittle (very difficult to control) diabetes for whom an invasive procedure is planned but whose oral health is poor and the fasting plasma glucose exceeds 200 mg/dL."[48] Local anesthesia would not be an issue in the presence of well-controlled diabetes, "but for patients with concurrent hypertension or history of recent myocardial infarction, or with a cardiac arrhythmia, the dose of epinephrine should be limited to no more than two cartridges containing 1 : 100,000 epinephrine."[48]

Inadequate diabetic control may predispose such patients to several oral infections, including dental pulp infection.[45] One study determined that although apical periodontitis may be significantly more prevalent in untreated teeth in patients with type 2 diabetes, the disease does not seem to influence the response to root canal treatment.[52] However, other studies suggest that diabetes is associated with a decrease in the success of endodontic treatment in cases with pretreatment periradicular lesions.[12,28] In a prospective study on the impact of systemic diseases on the risk of tooth extraction, it has been also shown that an increased risk of tooth extraction after nonsurgical root canal treatment was significantly associated with diabetes mellitus, hypertension, and coronary heart disease.[103] Patients with diabetes and other systemic diseases may be best served by referral to an endodontist for treatment planning.

Pregnancy

Although pregnancy is not a contraindication to endodontics, it does modify treatment planning. Protection of the fetus is a primary concern when administration of ionizing radiation or drugs is considered. Of all the safety aids associated with dental radiography, such as high-speed film, digital imaging, filtration, and collimation, the most important is the protective lead apron with thyroid collar.[5,107] Although drug administration during pregnancy is a controversial subject, Box 3-2 presents commonly used dental drugs usually compatible with both pregnancy and breast-feeding. Based on U.S. Food and Drug Administration pregnancy risk factor definitions,[35] local anesthetics administered with epinephrine generally are considered safe for use during pregnancy and are assigned to the pregnancy risk classification categories B and C. (See www.fda.gov/Drugs/DevelopmentApprovalProcess/DevelopmentResources/Labeling/ucm093310.htm.) Few anxiolytics are considered safe to use during pregnancy. However, a single, short-term exposure to nitrous oxide–oxygen (N_2O-O_2) for less than 35 minutes is not thought to be associated with any human fetal anomalies, including low birth weight.[48] If a need exists for antibiotic therapy, penicillins, cephalosporins, and macrolides are considered first-line agents.

The analgesic of choice during pregnancy had been acetaminophen (category B).[78] However, a link between acetaminophen and childhood asthma has been suggested. Research has found that "the use of acetaminophen in middle to late but not early pregnancy may be related to respiratory symptoms in the first year of life."[74] This finding, although not completely validated, should be discussed with pregnant patients when an analgesic is being considered. Aspirin and nonsteroidal anti-inflammatory drugs also convey risks for constriction of the ductus arteriosus, as well as for postpartum hemorrhage and delayed labor.[78]

A major concern is that a drug may cross the placenta and be toxic or teratogenic to the fetus. In addition, any drug that is a respiratory depressant can cause maternal hypoxia, resulting in fetal hypoxia, injury, or death. Ideally, no drug should be administered during pregnancy, especially during the first trimester. If a specific situation makes adherence to this rule

BOX 3-2

Partial List of Drugs Usually Compatible with Both Pregnancy and Breast-Feeding

- Local anesthetics including lidocaine, etidocaine, and prilocaine
- Many antibiotics including penicillins, clindamycin, and azithromycin
- Acetaminophen
- Acyclovir
- Prednisone
- Antifungals including fluconazole and nystatin

difficult, then the clinician should review the appropriate current literature and discuss the case with the physician and patient.[11,55,60]

Further considerations exist during the postpartum period if the mother breast-feeds her infant. A clinician should consult the responsible physician before using any medications for the nursing mother. Alternative considerations include using minimal dosages of drugs, having the mother bank her milk before treatment, having her feed the child before treatment, or suggesting the use of a formula for the infant until the drug regimen is completed. Limited data are available on drug dosages and the effects on breast milk.[48]

In terms of treatment planning, elective dental care is best avoided during the first trimester because of the potential vulnerability of the fetus. The second trimester is the safest period in which to provide routine dental care. Complex surgical procedures are best postponed until after delivery.

Malignancy

Some malignancies may metastasize to the jaws and mimic endodontic pathosis, whereas others can be primary lesions (Fig. 3-2). The most common malignancies metastasize to the jaws are breast, lung, thyroid, and prostate.[53] A panoramic radiograph and a cone-beam computer tomography image are useful in providing an overall view of all dental structures. When a clinician begins an endodontic procedure on a tooth with a well-defined apical radiolucency, it might be assumed to result from a nonvital pulp. Pulp testing is essential to confirm a lack of pulp vitality in such cases. A vital response in such cases indicates a nonodontogenic lesion.

Careful examination of pretreatment radiographs from different angulations is important because lesions of endodontic origin would not be expected to be shifted away from the radiographic apex in the various images. Alternative methods, such a cone-beam computed tomography (CBC), may provide important diagnostic information (see Chapter 2).

A useful website for the differential diagnosis of radiographic lesions (Oral Radiographic Differential Diagnosis [ORAD] II) is available online at www.orad.org/index.html. A definitive diagnosis of periradicular lesions can be made only after biopsy. When a discrepancy exists between the initial diagnosis and clinical findings, consultation with an endodontist is advisable.

Patients undergoing chemotherapy or radiation to the head and neck may have impaired healing responses.[48] Treatment should be initiated only after the patient's physician has been

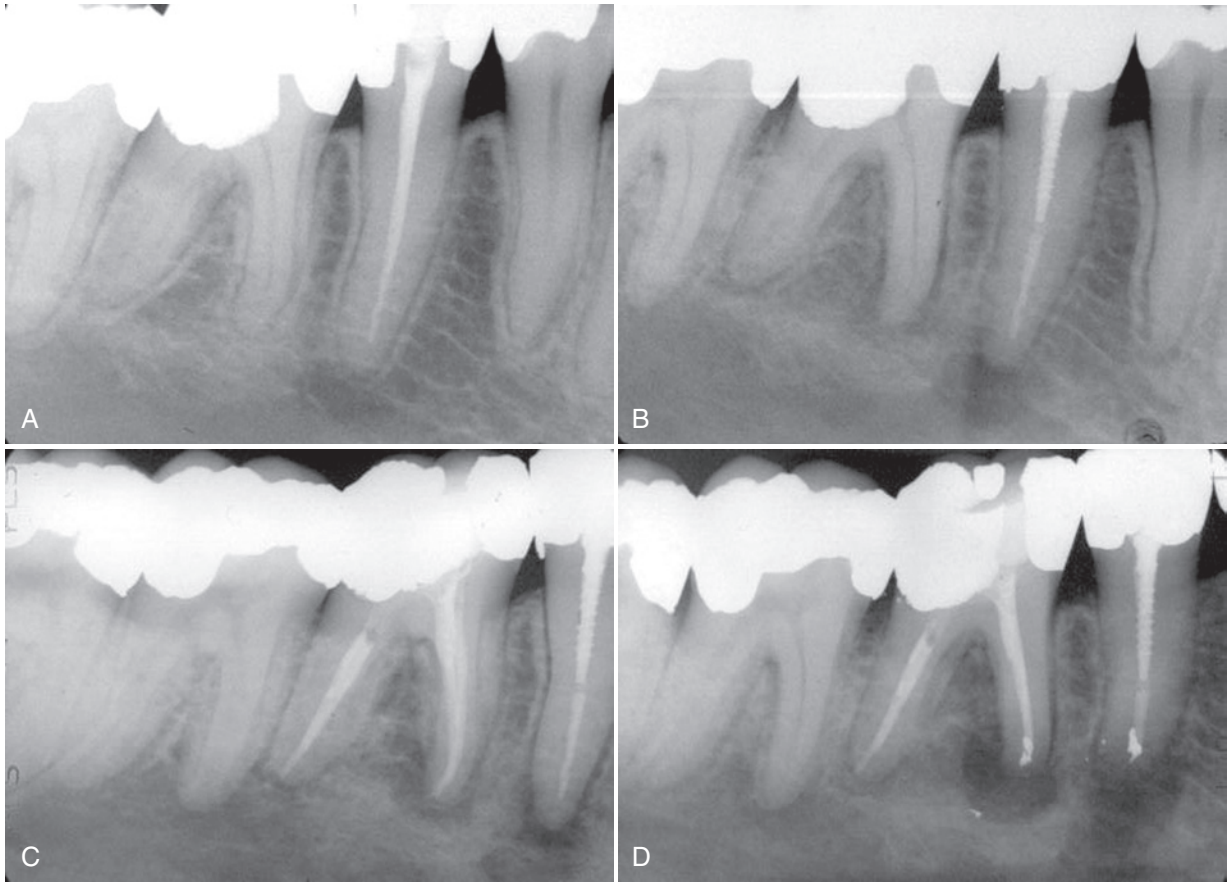

FIG. 3-2 **A**, Periapical view of tooth #29 after endodontic treatment by a general dental clinician. The diagnosis was irreversible pulpitis. **B**, Patient was referred to an endodontist 4 months later to evaluate radiolucencies of teeth #29 and #30. Symptoms indicated irreversible pulpitis of tooth #30, with concurrent lower right lip and chin paresthesia. Past medical history revealed breast cancer in remission. **C**, Nonsurgical endodontics was performed on tooth #30. Immediate referral was made to an oncologist/oral surgeon for biopsy to rule out nonodontogenic origin of symptoms. **D**, Surgical posttreatment radiograph of teeth #29 and #30. The biopsy report confirmed metastatic breast cancer. (Courtesy Dr. R. Sadowsky, Dr. L. Adamo, and Dr. J. Burkes.)

consulted. A dialogue among the dentist, physician, and patient is required prior to determining whether a tooth or teeth should be extracted or endodontically treated prior to radiation.

The effect of the external beam of radiation therapy on normal bone is to decrease the number of osteocytes, osteoblasts, and endothelial cells, thus decreasing blood flow. Pulps may become necrotic from this impaired condition.[48] Toxic reactions during and after radiation and chemotherapy are directly proportional to the amount of radiation or dosage of cytotoxic drug to which the tissues are exposed. Delayed toxicities can occur several months to years after radiation therapy.

Oral infections and any potential problems should be addressed before initiating radiation. It is advised that symptomatic nonvital teeth be endodontically treated at least 1 week before initiating radiation or chemotherapy, whereas treatment of asymptomatic nonvital teeth may be delayed.[48] The outcome of endodontic treatment should be evaluated within the framework of the toxic results of radiation and drug therapy. The white blood cell (WBC) count and platelet status of a patient undergoing chemotherapy should also be reviewed before endodontic treatment. In general, routine dental procedures can be performed if the granulocyte count is greater than 2000/mm^3 and the platelet count is greater than 50,000/mm^3. If urgent care is needed and the platelet count is below 50,000/mm^3, consultation with the patient's physician is required.[48]

Medication-Related Osteonecrosis of the Jaws (MRONJ)

Bisphosphonates offer great benefits to patients at risk of bone metastases and in the prevention and treatment of osteoporosis, although this and other drugs (e.g., denosumab) are associated with a rare occurrence of osteonecrosis.

To distinguish medication-related osteonecrosis of the jaws (MRONJ) from other delayed healing conditions, the following working definition of MRONJ has been adopted by the American Association of Oral and Maxillofacial Surgeons (AAOMS): Patients may be considered to have MRONJ if all of the following three characteristics are present (see American Association of Oral and Maxillofacial Surgeons: Position paper on Bisphosphonate-Related Osteonecrosis of the Jaw—2014 update, available at www.aaoms.org/docs/position_papers/mronj_position_paper.pdf?pdf=MRONJ-Position-Paper):

1. Current or previous treatment with an antiresorptive drug such as a bisphosphonate or an antiangiogenic drug (e.g., sunitinib [Sutent], sorafenib [Nexavar], bevacizumab (Avastin), or sirolimus (Rapamune)
2. Exposed, necrotic bone in the maxillofacial region that has persisted for more than 8 weeks
3. No history of radiation therapy to the jaws

A patient's risk of developing osteonecrosis of the jaw while receiving oral bisphosphonates appears to be low, but there are factors known to increase the risk for MRONJ (Box 3-3). According to the American Association of Endodontists (available at www.aae.org/uploadedFiles/Publications_and_Research/Guidelines_and_Position_Statements/bisphosonatesstatement.pdf, 2012), such risks include a history of taking bisphosphonates, especially intravenous (IV) formulations, previous history of cancer, and a history of a traumatic dental procedure. In addition to the usual risk factors, patients receiving high-dose IV bisphosphonates for more than 2 years are at most risk for developing osteonecrosis of the jaw.

BOX 3-3

Risk Factors for Development of Bisphosphonate-Associated Osteonecrosis

- History of taking bisphosphonates for more than 2 to 3 years, especially with intravenous therapy
- History of cancer, osteoporosis, or Paget disease
- History of traumatic dental procedure
- Patient more than 65 years of age
- History of periodontitis
- History of chronic corticosteroid use
- History of smoking
- History of diabetes

It has been reported that patients with multiple myeloma and metastatic carcinoma to the skeleton who are receiving intravenous, nitrogen-containing bisphosphonates are at greatest risk for osteonecrosis of the jaws. These patients represent 94% of published cases. The mandible is more commonly affected than the maxilla (2:1 ratio), and 60% of cases are preceded by a dental surgical procedure.[108] Treatment outcomes of MRONJ are unpredictable, and prevention strategies are extremely important.

Management of high-risk patients might include nonsurgical endodontic treatment of teeth that otherwise would be extracted. The combination of orthodontic extrusion and bloodless extraction—exfoliation of the extruded roots after their movement—has also been suggested with the aim of minimizing trauma and enhancing the health of the surrounding tissues in patients at risk of developing MRONJ or when a patient refuses to undergo conventional tooth extraction.[95]

For patients at higher risk of MRONJ, surgical procedures such as extractions, endodontic surgery, or placement of dental implants should be avoided. (See www.aae.org/uploadedFiles/Publications_and_Research/Guidelines_and_Position_Statements/bisphosonatesstatement.pdf, 2012.) Sound oral hygiene and regular dental care may be the best approach to lowering the risk of MRONJ. Patients taking bisphosphonates and undergoing endodontic therapy should sign an informed consent form, inclusive of the risks, benefits, and alternative treatment plans. The following recommendations have been suggested to reduce the risk of MRONJ associated with endodontic treatment[58]:

- Apply a 1-minute mouth rinse with chlorhexidine prior to the start of the treatment with the aim of lowering the bacterial load of the oral cavity.
- Avoid the use of anesthetic agents with vasoconstrictors in order to prevent impairment of tissue vascularization.
- Work under aseptic conditions, including removing of all caries and placement of rubber dam prior to intracanal procedures.
- Avoid damage to the gingival tissues during the placement of rubber dam.
- Avoid maintaining patency of the apical foramen to prevent bacteremia.
- Use techniques that reduce the risk of overfilling and overextension.

Aggressive use of systemic antibiotics is indicated in the presence of an infection in a patient taking bisphosphonates.[48] Discontinuing bisphosphonate therapy may not eliminate any

risk of developing MRONJ.[51,54,56] Some clinicians have proposed use of the CTX (C-terminal telopeptide of type I collagen α_1 chain) test (Quest Diagnostics, Madison, NJ) for assessing the risk of developing bone osteonecrosis (BON). For patients who have developed MRONJ, close coordination with an oral maxillofacial surgeon or oncologist is highly recommended.

An astute awareness of the potential risk of MRONJ in patients receiving bisphosphonate therapy is critical. Increased attentiveness to the prevention, recognition, and management of MRONJ will allow the clinician to make the best treatment decisions. Our knowledge of MRONJ is developing rapidly and it is essential that the clinician monitor the literature for changes in treatment protocols.[51,54,56]

Human Immunodeficiency Virus (HIV) and Acquired Immunodeficiency Syndrome (AIDS)

From 1987 through 1994, HIV disease mortality increased and reached a plateau in 1995. Subsequently, the mortality rate for this disease decreased an average of 33% per year from 1995 through 1998, and 5.5% per year from 1999 through 2009.[61] This dramatic improvement seems to be due to the use of a combination of highly active antiretroviral therapy (HAART) and improved preventive strategies.[48]

It is important, when treating patients with AIDS, that the clinician understand the patient's level of immunosuppression, drug therapies, and the potential for opportunistic infections. Although the effect of HIV infection on long-term prognosis of endodontic therapy is unknown, it has been demonstrated that clinicians may not have to alter their short-term expectations for periapical healing in patients infected with HIV.[77] The clinical team must also minimize the possibility of transmission of HIV from an infected patient, and this is accomplished by adherence to universal precautions. (See Universal Precautions for Prevention of Transmission of HIV and Other Bloodborne Infections, available at www.cdc.gov/niosh/topics/bbp/universal.html.)

Although saliva is not the main route for transmission of HIV, the virus has been found in saliva and its transmission through saliva has been reported.[33] Infected blood can transmit HIV, and during some procedures it may become mixed with saliva. Latex gloves and eye protection are essential for the clinician and staff. HIV can be transmitted by needlestick or via an instrument wound, but the frequency of such transmission is low, especially with small-gauge needles. Nevertheless, "Patients at high risk for AIDS and those in whom AIDS or HIV has been diagnosed should be treated in a manner identical to that for any other patient—that is, with standard precautions."[48]

A vital aspect of treatment planning for the patient with HIV/AIDS is to determine the current $CD4^+$ lymphocyte count and level of immunosuppression. In general, patients having a $CD4^+$ cell count exceeding 350 cells/mm^3 may receive all indicated dental treatments. Patients with a $CD4^+$ cell count of less than 200 cells/mm^3 or severe neutropenia (neutrophil count lower than 500/μL) will have increased susceptibility to opportunistic infections and may be effectively medicated with prophylactic drugs. White blood cell and differential counts, as well as a platelet count, should be ordered before any surgical procedure is undertaken. Patients with severe thrombocytopenia may require special measures (platelet replacement) before surgical procedures. Care in prescribing medications must also be exercised with any medications after which the patient may experience adverse drug effects, including allergic reactions, toxic drug reactions, hepatotoxicity, immunosuppression, anemia, serious drug interactions, and other potential problems. The practitioner should also be aware of oral manifestations of the disease as far as it concerns diagnosis and treatment planning. For instance, candidiasis of the oral mucosa, Kaposi sarcoma, hairy leukoplakia of the lateral borders of the tongue, herpes simplex virus (HSV), herpes zoster, recurrent aphthous ulcerations, linear gingival erythema, necrotizing ulcerative periodontitis, necrotizing stomatitis, oral warts, facial palsy, trigeminal neuropathy, salivary gland enlargement, xerostomia, and melanotic pigmentation are all reported to be associated with HIV infection. It is essential that consultation with the patient's physician occurs before performing surgical procedures or initiating complex treatment plans.[48,86]

End-Stage Renal Disease and Dialysis

Consultation with the patient's physician is important before dental care is initiated for patients being treated for end-stage renal disease. Depending on the patient's status and the presence of other diseases common to renal failure (e.g., diabetes mellitus, hypertension, and systemic lupus erythematosus), dental treatment may be best provided in a hospital setting. The goal of dental care for patients being treated for end-stage renal disease is to slow the progression of dental disease and preserve the patient's quality of life.[48,76]

The most recent American Heart Association guidelines do not include a recommendation for prophylactic antibiotics before invasive dental procedures for patients receiving dialysis with intravascular access devices, unless an abscess is being incised and drained.[3,48] Because controversy exists about the need for prophylactic antibiotics, consultation with the physician is important for patients receiving hemodialysis and those who have known cardiac risk factors. When prophylaxis is used, the standard regimen of the American Heart Association is recommended.[3]

Some drugs frequently used during endodontic treatment are affected by dialysis. Drugs metabolized by the kidneys and nephrotoxic drugs should be avoided. Both aspirin and acetaminophen are removed by dialysis and require a dosage adjustment in patients with renal failure. Amoxicillin and penicillin also require dosage adjustment as well as a supplemental dosage subsequent to hemodialysis.[76] It is advisable to consult the patient's physician concerning specific drug requirements during endodontic treatment. Endodontic treatment is best scheduled on the day after dialysis. On the day of dialysis, patients are generally fatigued and could have a bleeding tendency.[48]

Chronic renal failure is a disorder that may stimulate secondary hyperparathyroidism that can cause a variety of bone lesions. In some instances, these lesions appear in the periapical region of teeth and can lead to a misdiagnosis of a lesion of endodontic origin.[50]

Prosthetic Implants

Patients with prosthetic implants are frequently treated in dental practices. The question concerning the need for antibiotic prophylaxis to prevent infection of the prosthesis has been debated for many years. A statement was issued jointly in 2003 by the American Dental Association (ADA; Chicago, IL) and

the American Academy of Orthopaedic Surgeons (AAOS; Rosemont, IL) in an attempt to clarify the issue.[1] The statement concluded that scientific evidence does not support the need for antibiotic prophylaxis for dental procedures to prevent prosthetic joint infections. It went on to state that antibiotic prophylaxis is not indicated for dental patients with pins, plates, and screws, nor is it routinely indicated for most patients with total joint replacements. However, the statement indicated that some "high-risk patients" who are at increased risk for infection and undergoing dental procedures likely to cause significant bleeding should receive antibiotic prophylactic treatment. Such patients would include those who are immunocompromised or immunosuppressed, who have insulin-dependent (type 1) diabetes, who are in the first 2 years following joint replacement, or who have previous joint infections, malnourishment, or hemophilia.[1] The advisory statement concludes that the final decision on whether to provide antibiotic prophylaxis is the responsibility of the clinician, who must consider potential benefits and risks.[1] It should be noted that although endodontics has been shown to be a possible cause of bacteremia,[19,90] the risk is minimal in comparison with extractions, periodontal surgery, scaling, and prophylaxis.[72] In February 2009, the AAOS published a statement entitled "Antibiotic Prophylaxis for Bacteremia in Patients with Joint Replacements." In this updated publication it was stated: "Given the potential adverse outcomes and cost of treating an infected joint replacement, the AAOS recommends that clinicians consider antibiotic prophylaxis for all total joint replacement patients prior to any invasive procedure that may cause bacteremia." (See American Academy of Orthopaedic Surgeons: AAOS releases new statement on antibiotics after arthroplasty, www.aaos.org/news/aaosnow/may09/cover2.asp, 2012.)

However, the American Academy of Oral Medicine's (AAOM) position on this statement is that the "2009 information statement is more an opinion than an official guideline, AAOM believes that it should not replace the 2003 joint consensus statement prepared by the relevant organizations: the ADA, the AAOS and the Infectious Disease Society of America (IDSA)."[49] In 2012, an evidenced-based guideline was published that included recommendations of the AAOS-ADA clinical practice guideline for Prevention of Orthopaedic Implant Infection in Patients Undergoing Dental Procedures. This guideline stated that there is limited evidence for discontinuing the practice of routinely prescribing prophylactic antibiotics for patients with hip and knee prosthetic joint implants undergoing dental procedures. (See American Academy of Orthopaedic Surgeons: Prevention of orthopaedic implant infection in patients undergoing dental procedures, available at www.aaos.org/research/guidelines/PUDP/PUDP_guideline.pdf, 2012.)

Consultation with the patient's physician on a case-by-case basis is advisable to assess the need for prophylaxis.

Behavioral and Psychiatric Disorders

Stress reduction is an important factor in the treatment of patients with behavioral and psychiatric disorders. Sensitivity to the patient's needs must be part of the dental team's approach. Significant drug interactions and side effects are associated with tricyclic antidepressants, monoamine oxidase inhibitors, and antianxiety medications.[48] Consultation with physicians in such cases is essential before using sedatives, hypnotics, antihistamines, or opioids.

Psychosocial Evaluation

The initial visit, during which medical and dental histories are gathered, provides an opportunity to consider the patient's psychosocial status. Although some patients may want to maintain a tooth with a questionable prognosis, others may lack the ability to comprehend the potential risks and benefits. It would be a mistake to lead patients beyond what they can appreciate, and patients should not be allowed to dictate treatment that has a poor prognosis.

The clinician should also assess the patient's level of anxiety as an important part of preparation for the procedure to follow. It is reasonable to assume that most patients are anxious to some degree, especially when they are about to undergo endodontic treatment. A conversation describing the procedure and what the patient can expect is an important part of an anxiety-reduction protocol. It is well documented that a high level of anxiety is a predictor of poor anesthesia and posttreatment pain.[15,62] More than 200 studies indicate that behavioral intervention for the highly anxious patient before treatment decreases anxiety before and after surgery, reduces posttreatment pain, and accelerates recovery.[15]

DEVELOPMENT OF THE ENDODONTIC TREATMENT PLAN

The strategic value of a tooth in question should be considered before presenting alternative treatment plans to the patient. Although some decisions may be straightforward, considering alternative treatment options can be challenging as the clinician weighs multiple factors that will play a role in determining the ultimate success or failure of the case. Referral of the patient to a specialist should be considered when the complexity of a procedure is beyond the ability of a clinician. Factors that affect endodontic prognosis, including periodontal and restorative considerations, must be considered. The alternative of a dental implant is another choice when the endodontic prognosis is poor.

ENDODONTIC PROGNOSIS

Prognostic studies have identified a number of preoperative factors affecting the outcome of primary endodontic treatment. In a systematic review, it was determined that the absence of periapical radiolucency improves the outcome of root canal treatment significantly. The same study also showed that tooth vitality does not have an impact on the endodontic prognosis, as long as the periapex is healthy.[70] Studies have shown that the size of the radiolucency may also affect the outcome of endodontic treatment.[31,70] Another study found that the existence of sinus tract, narrow but deep periodontal probing depth, pain, and discharging sinus have a significant effect on the outcome of nonsurgical root canal treatment.[67] Preoperative pain is not only one of the most important predictors for postoperative pain,[64] it also has an impact on tooth survival after endodontic treatment.[68]

These findings suggest that all preexisting signs and symptoms that could affect the prognosis of treatment, along with the prognostic factors associated with other disciplines—which will be discussed in the next segment—should be taken into consideration when developing a treatment plan. It is of utmost importance that the prognosis and risks and benefits of the

treatment be relayed to the patient before the initiation of the treatment as well.

There is a general belief that the prognoses for retreatment cases are less than those for primary treatment, but this is not universally supported. In a systematic review it was suggested that the outcome of retreatment cases should be similar to treatment cases as long as access to the apical infection can be reestablished.[65] However, there is some evidence indicating that the incidence of postoperative pain and flare-up is higher in retreatment cases in comparison to treatments.[36] The presence of preoperative periapical lesion, apical extent of root filling, and quality of coronal restoration has been proved to significantly affect the outcome of retreatment cases.[65]

Retreatment cases offer a particular set of challenges to the clinician (Figs. 3-3 and 3-4), and this topic is covered extensively in Chapter 8. Important questions to be considered before retreatment include the following:

- Why did the treatment fail?
- Can the point of bacterial entry to the canal space be identified?
- Are prior radiographs available for review?
- Is there an obvious procedural problem that can be corrected?
- Is the canal system readily accessible for reentry?
- Are there additional factors (other than endodontic) that may have contributed to the failure?
- Is the tooth critical to the treatment plan?
- Does the patient understand the prognosis for the tooth and want to attempt retreatment?

A retreatment plan should be developed after the clinician has determined the cause of failure and weighed other factors that may affect the prognosis (e.g., root fracture, defective restoration) (Figs. 3-5 to 3-8). Retreatment cases may require surgical endodontics in combination with nonsurgical retreatment. Referral to a specialist is often helpful when planning treatment for complex cases. If retreatment (with or without surgery) on a tooth with a new restoration is being considered, it must be weighed against the possibility of an implant. Many variables must be considered before a reasonable conclusion can be reached.

Single-Visit versus Multiple-Visit Treatment

Some vital cases are suitable for single-visit treatment. The number of roots, time available, and the clinician's skills are factors to be considered. Severity of the patient's symptoms is

FIG. 3-3 Incision and drainage should be performed on this fluctuant swelling *(arrow)* in conjunction with canal instrumentation.

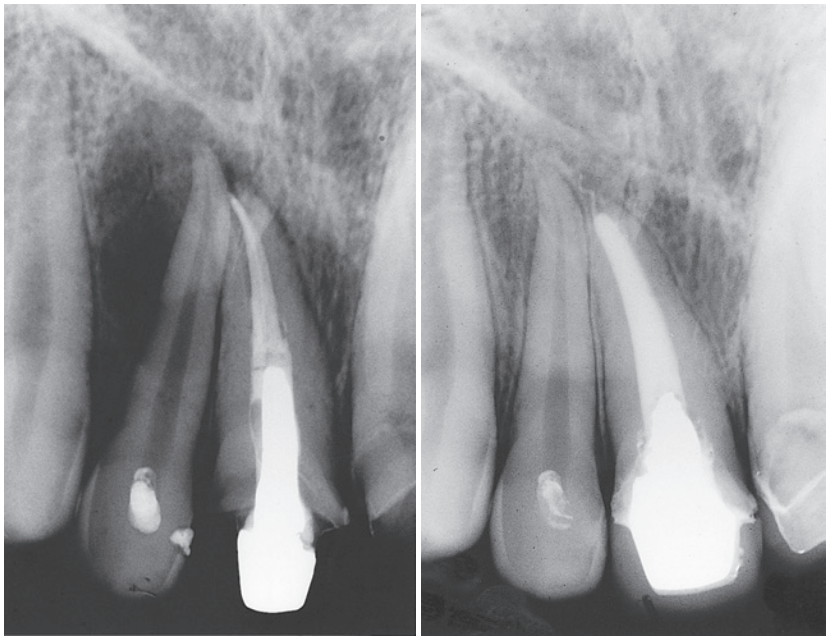

FIG. 3-4 Two years after endodontic therapy of tooth #8, the patient returned with pain and swelling. A clinician mistakenly began endodontic access on tooth #7, without confirming the apparent radiographic diagnosis by sensibility testing. Tooth #7 was vital, and tooth #8 was successfully retreated after removal of the post. (Courtesy Dr. Leon Schertzer.)

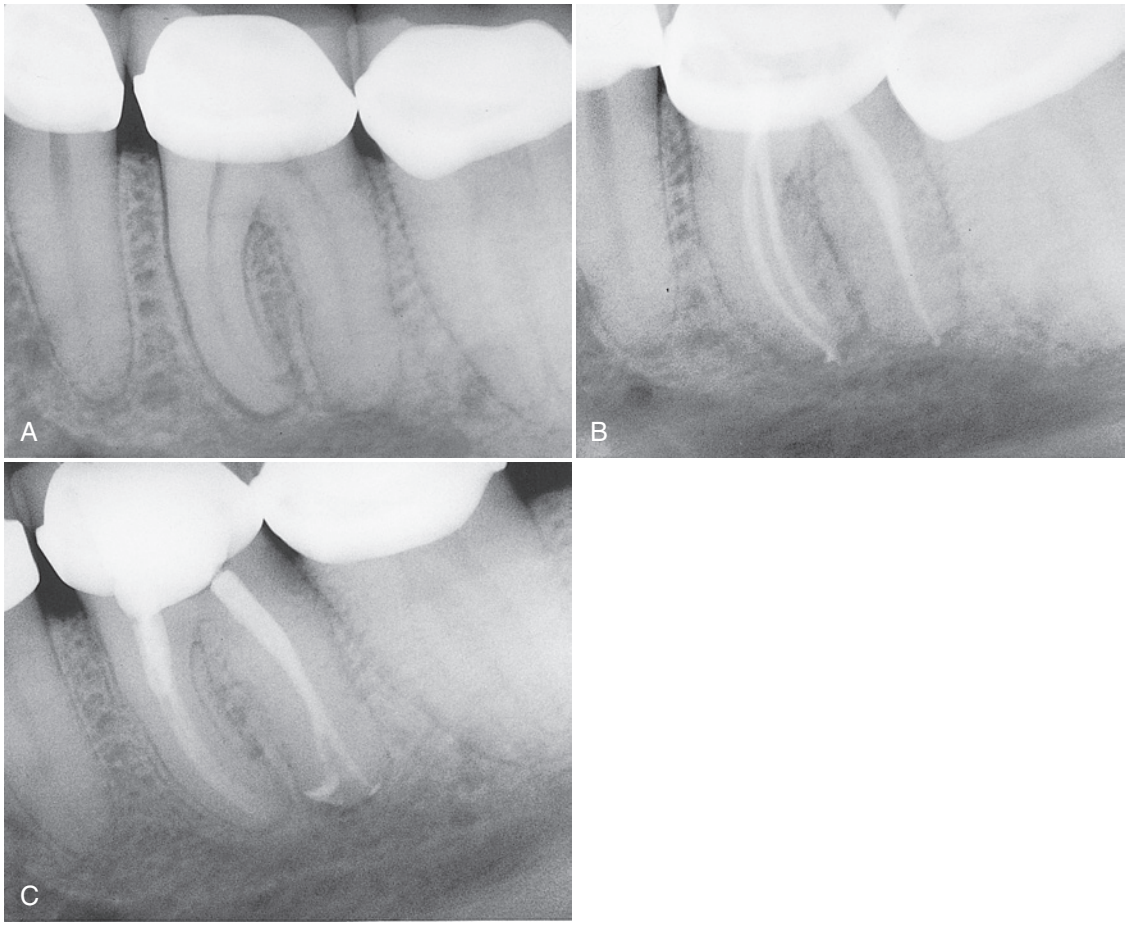

FIG. 3-5 Many years after endodontic treatment of tooth #19, the patient returned with a chief complaint of pain and an inability to chew with the tooth. Despite the radiographic appearance of excellent endodontic treatment, the tooth was retreated and the patient's pain disappeared. Note the unusual distal root anatomy, which was not apparent during the initial procedure. **A,** Initial radiograph. **B,** Completion of initial endodontic therapy. **C,** Retreatment.

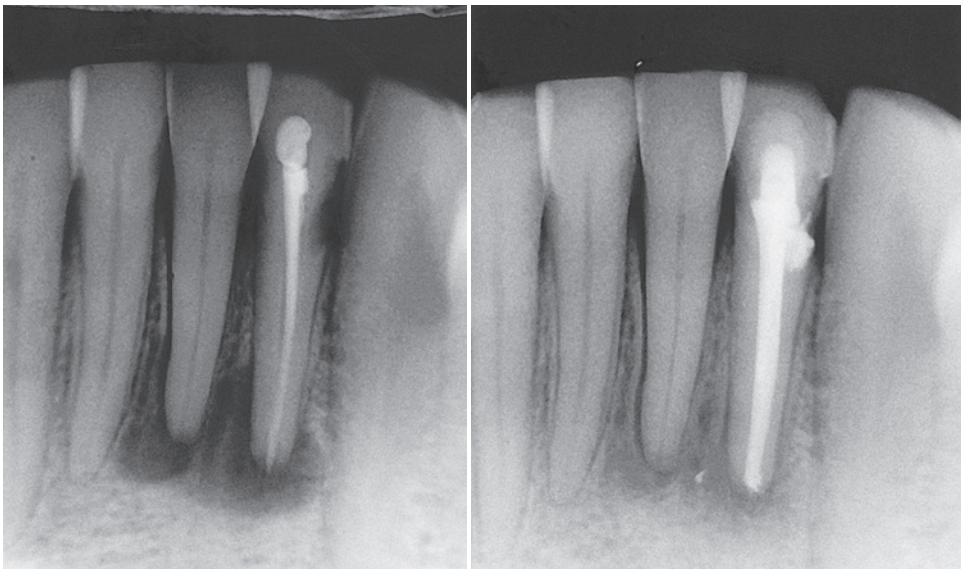

FIG. 3-6 Initial radiograph was misleading and implicated tooth #23 and tooth #24. Pulp testing indicated a vital pulp in tooth #24, and it was not treated. Retreatment of #23 resulted in healing of the periradicular lesion. (Courtesy Dr. Leon Schertzer.)

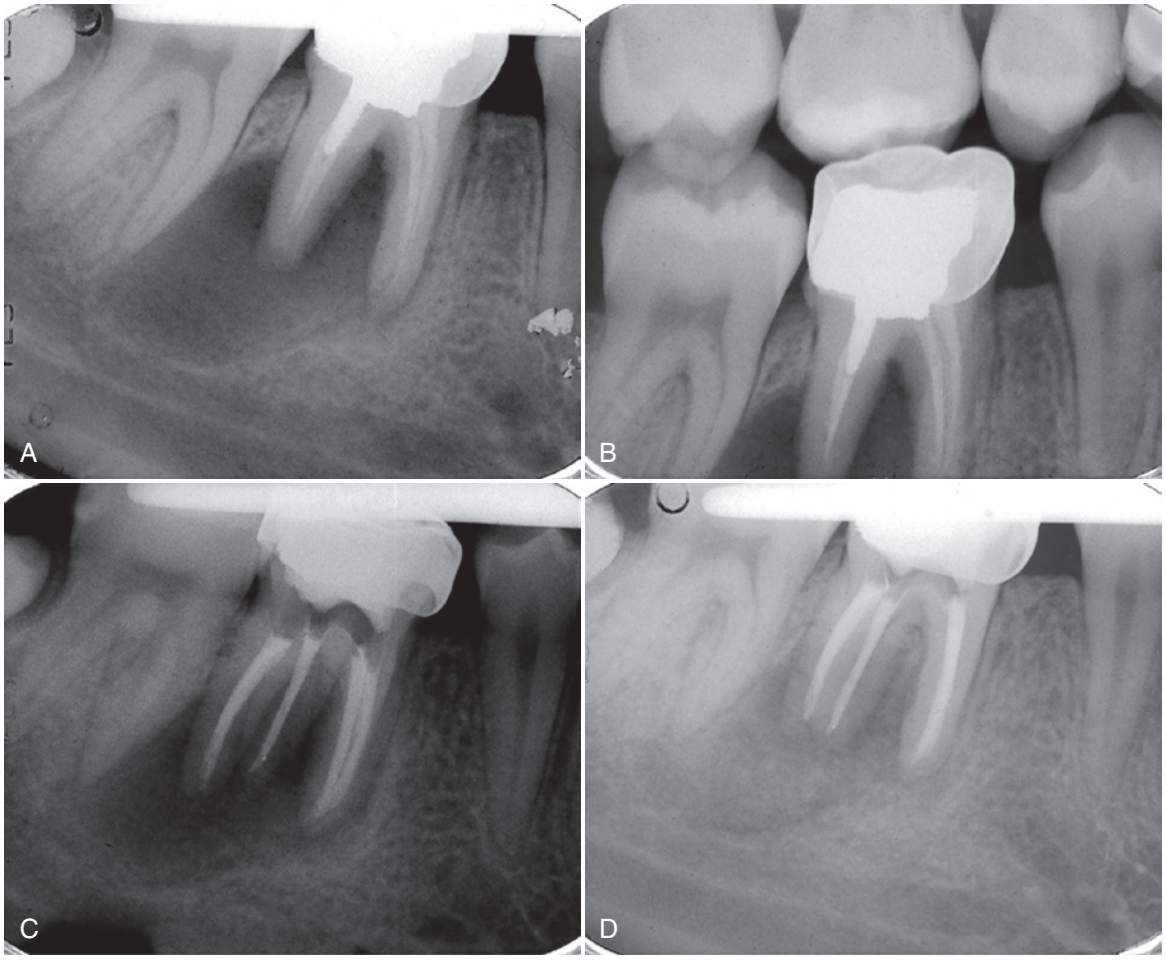

FIG. 3-7 Nonsurgical retreatment of tooth #30. An additional root was located and treated. **A**, Note inadequate endodontic treatment and large periapical lesion. **B**, Bitewing radiograph. **C**, Retreatment after post removal. **D**, Eighteen-month recall radiograph indicates periapical healing.

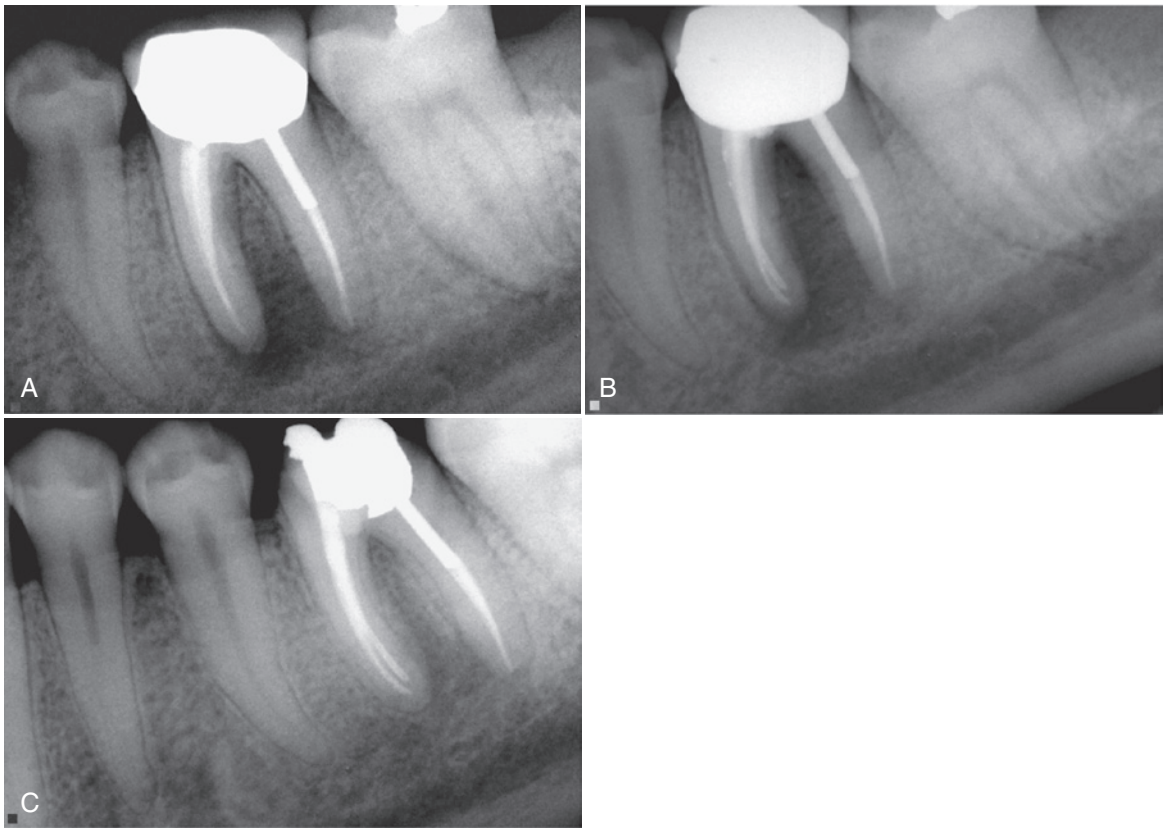

FIG. 3-8 Despite several exacerbations during endodontic retreatment, this case responded rapidly after the completion of therapy. Radiographic evaluation indicates a good periapical response after only 4 months.

another important consideration. For example, a patient in severe pain, with or without swelling, should not experience a long visit including access, instrumentation, and obturation. Treatment in such cases should be directed at alleviating pain, with filling of the canal postponed until a later visit. The clinician's judgment of what the patient can comfortably tolerate (regarding duration of the visit) is made on a case-by-case basis.

There are advantages in having a patient return for a second visit, after initially presenting with an endodontic emergency due to pain or swelling with or without a stoma. The second visit allows the clinician to determine the effect of the treatment on inflamed and infected tissues. Deferring the filling of the canal(s) leads to a shorter initial visit for the emergency patient.

Although some studies have reported less posttreatment pain in single-visit cases,[26,80,96] a systematic review found that the incidence of postobturation discomfort was similar in the single- and multiple-visit approaches.[27] In another systematic review it was concluded that there was a lack of compelling evidence indicating a significantly different prevalence of posttreatment pain/flare-up with either single- or multiple-visit root canal treatment.[85] Differences in research methodology explain the conflict in these findings.

Regarding the healing rate of single- and multiple-visit cases, a systematic review found that there was no detectable difference in the effectiveness of root canal treatment in terms of radiologic success between single and multiple visits.[27] A more recent systematic review also found that the healing rate of single- and multiple-visit root canal treatment is similar for infected teeth.[96]

Teeth with nonvital pulps and apical periodontitis pose a microbiologic problem. It is important to avoid pushing bacterial debris into the periapical tissues. Agreement is lacking concerning the appropriateness of single-visit endodontics for treating these patients. Some have postulated that the intervisit use of an antimicrobial dressing is essential to thoroughly disinfect the root canal system.[92,93,99] In contrast, other researchers have found no statistically significant difference in success when using the single-visit or multiple-visit approach to the nonvital tooth with apical periodontitis.[27,31,59,73,75,106] A systematic review found that, single-visit root canal treatment appeared to be slightly more effective than multiple-visit treatment (6.3% higher healing rate). However, the difference between these two treatment regimens was not statistically significant.[84] This is a complicated issue because the inability to detect differences between groups might also be due to variations in research methodology, including sample size, duration of follow-up, and treatment methods.

It is possible that total elimination of bacteria may not be absolutely necessary for healing. Perhaps maximal reduction of bacteria, effective root canal filling, and a timely satisfactory coronal restoration can result in a high level of clinical success. However, regardless of the number of appointments, effective bacteriologic disinfection of the root canal system is critical.[46]

Treatment planning for an endodontic case should be based on biologic considerations. Patients who present with acute symptoms present a different set of biologic issues than those with an asymptomatic tooth. Swelling associated with an abscess, cellulitis, or presence of a stoma represent signs of pathologic processes. The biologic significance of these conditions should be considered before determining specific goals for each visit.

Developing specific goals at each visit helps to organize the treatment. For example, for an uncomplicated molar or premolar, some clinicians will set a specific goal for the first visit that includes access and thorough instrumentation while deferring the obturation to a second visit. Uncomplicated single-rooted, vital teeth may be planned for a single-visit approach. It is important that ample time be allowed so that the procedure can be adequately completed without undue stress.

These recommendations have a biologic basis. Biologically, it is not reasonable to partially instrument root canal systems, thereby leaving residual inflamed pulpal remnants or necrotic debris in the canal, because such remnants may cause pain and be susceptible to infection. The clinician would be well advised to begin canal instrumentation only if time permits the extirpation of all pulp tissue and debridement of the root canal system.

Although in most cases the clinical procedures required to complete endodontic treatment can be accomplished in a single visit, that does not mean it is the better course of treatment. What can be done and what should be done represent two very different approaches to endodontic treatment planning. The patient's systemic health, level of anxiety, and symptoms, as well as the complexity of the root canal system, are factors that must be considered.

A study concerning the outcome of initial treatment noted the complexity of treating apical periodontitis.[31] The author commented:

Treatment of this disease cannot be improved merely by changing treatment techniques. Because apical periodontitis results from interactions between microorganisms, their environment and the host immune system, only use of effective modifiers of any of these three factors might significantly improve the outcome of treatment.

INTERDISCIPLINARY TREATMENT PLANNING

Periodontal Considerations

Extensive periodontal lesions may complicate endodontic prognosis. Lesions with endodontic and periodontal components may necessitate consultation with an endodontist or periodontist in order to gather more information about the tooth's prognosis.

A 4-year retrospective study found that attachment loss and periodontal status affected endodontic prognosis of endodontically treated molars.[87] It is crucial that the dental practitioner be aware of the periodontal factors that may influence the prognosis of endodontic treatment, such as root perforations, bone loss, and clinical attachment loss.

When establishing the prognosis of a tooth with an endodontic/periodontal lesion, there are essential factors to be considered. Determination of pulp vitality and the extent of the periodontal defect are central to establishing the prognosis and developing a treatment plan for a tooth with an endodontic/periodontal lesion (see also Chapter 25).

In primary endodontic disease, the pulp is nonvital (Figs. 3-9 and 3-10), whereas in primary periodontal disease, the pulp retains vitality. True combined endodontic-periodontal disease occurs less frequently. The combined lesion is found

http://dentalebooks.com

FIG. 3-9 A, Inflamed, edematous interproximal tissue *(arrow)* caused by acute endodontic pathosis. B, Soft tissue healing *(arrow)* 3 days after initiation of endodontic treatment. C, Periradicular pathosis. D, Completed endodontic therapy. E, Periradicular healing at 1-year recall.

when the endodontic disease process advances coronally and joins with a periodontal pocket progressing apically. There is significant attachment loss with this type of lesion, and the prognosis is guarded.[81] The radiographic appearance of combined endodontic-periodontal lesions may be similar to that of a vertically fractured tooth. Therapy for true combined lesions requires both endodontic and periodontal therapy. Sequencing of treatment is based on addressing the initial chief complaint.

The prognosis and treatment of each type of endodontic-periodontal disease vary. Primary endodontic disease should be treated solely by endodontic therapy, and the prognosis is usually good. Primary periodontal disease should be treated only by periodontal therapy, and the prognosis varies depending on the seventy of the disease and patient's response to treatment.[81]

Pathogenesis of the lesion can be better understood after sensibility testing, periodontal probing, radiographic assessment, and evaluation of dental history. When extensive prostheses are planned, the potential risk of including a tooth with a questionable prognosis must be considered. It is not prudent to incorporate a chronic problem into a new complex prosthesis (Fig. 3-11).

Surgical Considerations

Surgical evaluation is particularly valuable in the diagnosis of lesions that may be nonodontogenic. Biopsy is the definitive means of diagnosing osseous pathosis, which may mimic a lesion of endodontic origin. When retreatment is being considered, the clinician must determine whether nonsurgical, surgical, or combined treatment is appropriate. This decision is influenced by the presence of complex restorations, posts, and the radiographic assessment of prior endodontic therapy.

Endodontic surgery is most often performed in an attempt to improve the apical seal and correct failure of nonsurgical therapy. Bacteria are the essential cause of failure. It is important that the clinician determine the bacterial path of ingress. For example, a deficient restoration or recurrent decay will result in microleakage into the root canal space. Unless that issue is addressed, apical surgery may not be predictable (Fig. 3-12).

When a deficient restoration is identified, it must be replaced to prevent continued bacterial penetration. Endodontic surgery (see Chapter 9) may also be performed as a primary procedure when there are complications such as calcific metamorphosis. In those cases, by using surgery as primary therapy, an apical seal can be established while preserving the crown of the tooth.

http://dentalebooks.com

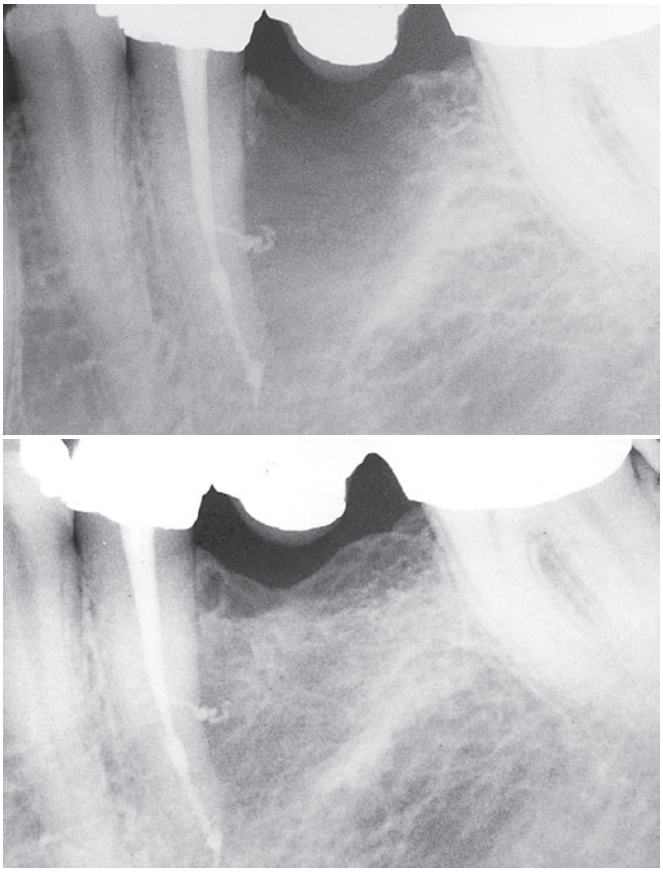

FIG. 3-10 A large, bony defect associated with tooth #20 healed after endodontic therapy. The tooth was nonvital, and no significant periodontal probing depth indicated pulpal disease.

The treatment plan for these cases is determined after reviewing multiple radiographs and considering the possibility of completing nonsurgical therapy without destroying an otherwise functional crown or natural tooth. Endodontic surgery without prior nonsurgical therapy should be a treatment of last resort and only when nonsurgical treatment is not possible.

Reviewing the best available evidence for alternative treatments is an important aspect of treatment planning for a tooth with failed endodontics. Evidence concerning healing potential after endodontic surgery is an important consideration in the management of posttreatment disease.[30] Numerous studies

FIG. 3-11 Tooth #30 has a poor prognosis. Periodontal probing reached the apex of the distal root. Extraction is indicated and should be done as soon as possible to prevent further damage to the mesial bone associated with tooth #31. Implant site preservation is another consideration in treatment planning for this case.

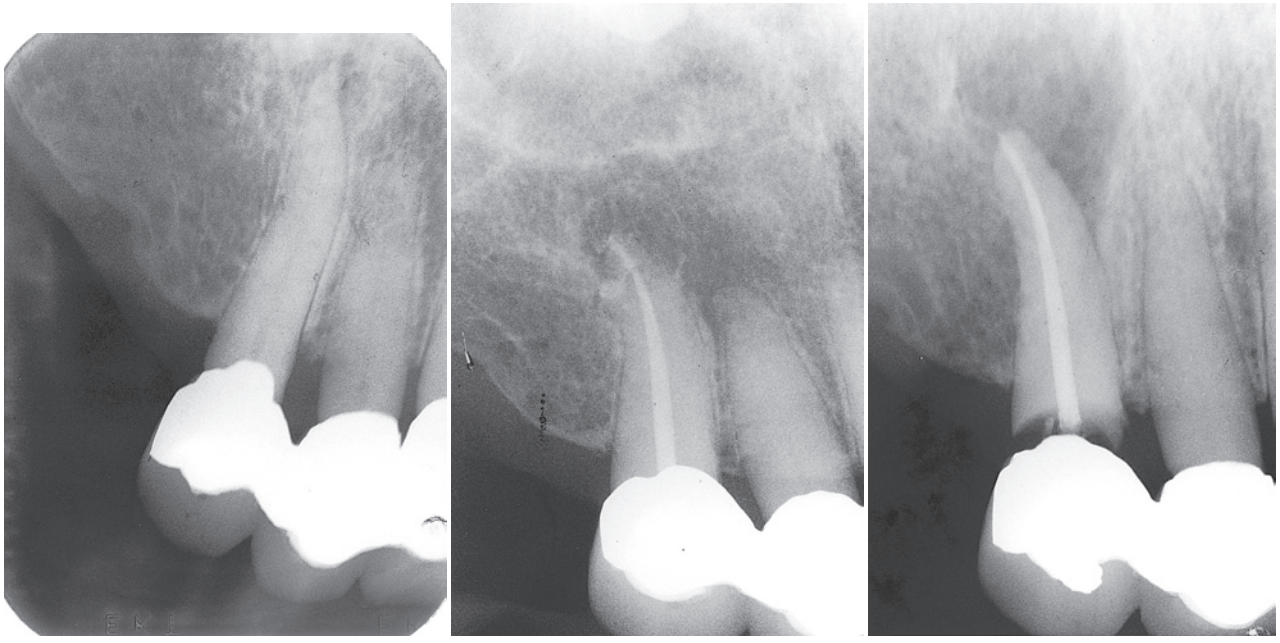

FIG. 3-12 Four years after endodontic therapy, the patient complained of pain and swelling associated with tooth #6. The initial impression was that apical surgery was indicated. However, further radiographs revealed the true cause of the endodontic failure. The initial endodontic access through the crown or caries damaged the coronal seal and recurrent decay followed.

http://dentalebooks.com

have examined the outcome of apical surgery and the results vary considerably.[101,104,112] This variability may reflect actual outcome differences or reflect variations in case selection techniques, recall periods, and methodology.

One prospective study indicated that there is an increased odds ratio for disease persistence for teeth with larger pretreatment lesions and pretreatment root canal filling of adequate length.[104] Another study found that patients presenting with pain at the initial examination before surgery had a significantly lower rate of healing at the 1-year follow-up compared with patients who did not have pain at the initial examination.[101]

It should also be noted that the periodontal condition of the tooth, including the interproximal bone levels and the amount of marginal bone loss, has been shown to significantly affect the long-term prognosis of periapical surgery.[102,105] Moreover, it has been shown that isolated endodontic lesions have much higher success rates at the 1- to 5-year follow-up (95.2%) in comparison with endodontic-periodontal combined lesions (77.5%).[40]

Dramatic changes in surgical technique and materials have occurred: The advent of microscopy, endoscopy, and ultrasonics, as well as improved retrograde filling materials, represents important modifications of surgical technique. An outcome study comparing traditional root-end surgery (TRS) and endodontic microsurgery (EMS) found that the probability of success for EMS was 1.58 times greater than the probability of success for TRS.[89] Another study comparing the EMS techniques with and without the use of higher magnification found that the difference of probability of success between the groups was statistically significant for molars, but no significant difference was found for the premolar or anterior teeth.[88] Cone-beam computed tomography has proved to be of value in some surgical cases. It produces three-dimensional images of a tooth, pathosis, and adjacent anatomic structures. It is beneficial for localizing the mandibular canal,[42] mental foramen, maxillary sinus, and nasal cavity.[16]

Restorative and Prosthodontic Considerations

A satisfactory restoration may be jeopardized by a number of factors. Subosseous root caries (perhaps requiring crown lengthening), poor crown-to-root ratio, and extensive periodontal defects or misalignment of teeth may have serious effects on the final restoration. These problems must be recognized before endodontic treatment is initiated. For complex cases, a restorative treatment plan should be in place before initiating endodontic treatment (see Chapter 22). Some teeth may be endodontically treatable but nonrestorable, or they may represent a potential restorative complication because of a large prosthesis. Reduced coronal tooth structure under a full-coverage restoration makes endodontic access more difficult because of reduced visibility and lack of radiographic information about the anatomy of the chamber. It is not unusual for restorations to be compromised during endodontic access (see Fig. 3-12). Whenever possible, restorations should be removed before endodontic treatment.

Full coverage restorations are usually suggested after endodontic treatment. In a systematic review on tooth survival following nonsurgical root canal treatment, four factors were found to be of significance in tooth survival[66]:

- A crown restoration after root canal treatment
- Tooth having both mesial and distal proximal contacts
- Tooth not functioning as an abutment for removable or fixed prosthesis
- Tooth type or specifically nonmolar teeth

Another systematic review found that the odds for healing of apical periodontitis increase with both adequate root canal treatment and adequate restorative treatment. However, poorer clinical outcomes may be expected with adequate root filling/inadequate coronal restoration and inadequate root filling/adequate coronal restoration, with no significant difference in the odds of healing between these two combinations.[34] These findings suggest that the quality of the coronal restoration is as important as the quality of the root canal treatment. Therefore, to increase the success of the treatment, it is strongly suggested that the clinician discuss the restorative plan of the tooth with both the patient and—if it is a referred patient—with the referring dentists before initiation of treatment.

Endodontic Therapy or Dental Implant

The successful evolution of dental implants as a predictable replacement for missing teeth has had a positive impact on patient care. A clinician now has an additional possibility to consider when developing a treatment plan for a patient with a missing tooth or teeth. More challenging is the decision concerning whether or not to provide endodontic therapy for a tooth with a questionable prognosis or extract and use a single-tooth implant as a replacement. Numerous studies have evaluated both nonsurgical endodontic therapy[18,69,70,82,97,98] and endosseous dental implants.[2,17,37,47]

It is not possible to compare outcome studies because of variations in research methodologies, follow-up periods, and criteria associated with determining success or failure. A review of outcome studies points to the need for randomized controlled trials with standardized or similar methodologies that could provide a higher level of evidence to use in answering important clinical prognostic questions.

A synthesis of available evidence indicates that both primary root canal treatment and single-tooth implants are highly predictable procedures when treatment is appropriately planned and implemented. A study assessed clinical and radiographic success of initial endodontic therapy of 510 teeth over a 4- to 6-year period. It was found that 86% of teeth healed and 95% remained asymptomatic and functional.[18] Another study considered the outcomes of endodontic treatment on 1,462,936 teeth. More than 97% of teeth were retained after 8 years.[82] In a similar study it was found that overall, 89% of the 4744 teeth were retained in the oral cavity 5 years after the endodontic retreatment.[83] A study concerning the outcome of endodontic therapy on 1312 patients in general practice with a mean follow-up time of 3.9 years found a combined failure rate of 19.1%, concluding that "failure rates for endodontic therapy are higher than previously reported in general practices, according to results of studies based on dental insurance claims data."[7]

The American Dental Association's Council on Scientific Affairs has reported high survival rates for endosseous implants. An evaluation of 10 studies with more than 1400 implants demonstrated survival rates ranging from 94.4% to 99% with a mean survival rate of 96.7%.[2] With such high survival rates reported for endodontics and single-tooth implants, a clinician must consider a multiplicity of factors within the context of the

http://dentalebooks.com

best available evidence. Most current studies indicate no significant difference in the long-term prognosis between restored endodontically treated teeth and single-tooth implants.[37]

In a retrospective cross-sectional comparison of initial nonsurgical endodontic treatment and single-tooth implants, it was suggested that restored endodontically treated teeth and single-tooth implant restorations have similar survival rates, although the implant group showed a longer average and median time to obtain function and a higher incidence of posttreatment complications requiring subsequent treatment intervention.[20] A review summarized the best available evidence concerning factors influencing treatment planning involving preservation of a tooth with endodontic therapy or replacement by a single-tooth implant. Factors considered included prosthetic restorability of the natural tooth, quality of bone, aesthetic concerns, cost-to-benefit ratio, systemic factors, potential for adverse effects, and patient preferences.[37] The authors concluded that "endodontic treatment of teeth represents a feasible, practical and economical way to preserve function in a vast array of cases and that dental implants serve as a good alternative in selected indications in which prognosis is poor."[37]

Aside from treatment outcome, there are other factors involved in any treatment that the practitioner has to consider when making a treatment planning decision. In a study evaluating the quality of life of endodontically treated versus implant treated patients, the results showed a high rate of satisfaction with both treatment modalities.[32] One study found that comparing to endodontic molar retreatment and fixed partial dentures, implant-supported restoration, despite its high survival rate, has been shown to be the least cost-effective treatment option.[41] Another study found that "endodontically treated natural teeth may provide more effective occlusal contact during masticatory function compared with implant-supported restorations, leading to more efficient mastication."[109]

Another important factor is the patient's health status. Implants require a surgical procedure that may not be possible due to the patient's medical status. One area of concern is diabetes mellitus. However, it has been shown that dental implant osseointegration can be accomplished in these subjects as long as they have good glycemic control.[38]

It seems clear that patients are best served by retaining their natural dentition as long as the prognosis for long-term retention is positive. It is not reasonable to extract a tooth if endodontics with a good prognosis can be completed. It is also not reasonable for a patient to invest in root canal therapy, a post, and a crown if the prognosis is highly questionable and an implant with a good prognosis can be placed. An important advantage of providing endodontic therapy is to allow rapid return of the patient's compromised dentition to full function and aesthetics. This rapid return is in marked contrast to the use of provisional restorations associated with dental implants while waiting for osseous integration. The challenge is to weigh all pretreatment variables and reach a reasonable conclusion concerning the prognosis for tooth retention or implant placement.

Interestingly, some endodontic advanced education programs are now including implant training in their curricula. This training will enable the endodontist to provide more value to the patient and referring the dental clinician as treatment plans are determined. Such dually trained endodontists will be well positioned to provide endodontic therapy or place an implant as best serves the patient.

OTHER FACTORS THAT MAY INFLUENCE ENDODONTIC CASE SELECTION

A variety of factors may complicate proposed endodontic therapy. Calcifications, dilacerations, or resorptive defects may compromise endodontic treatment of a tooth with potentially strategic value (Fig. 3-13). The inability to isolate a tooth is also a problem and may result in bacterial contamination of the root canal system. Extra roots and canals pose a particular

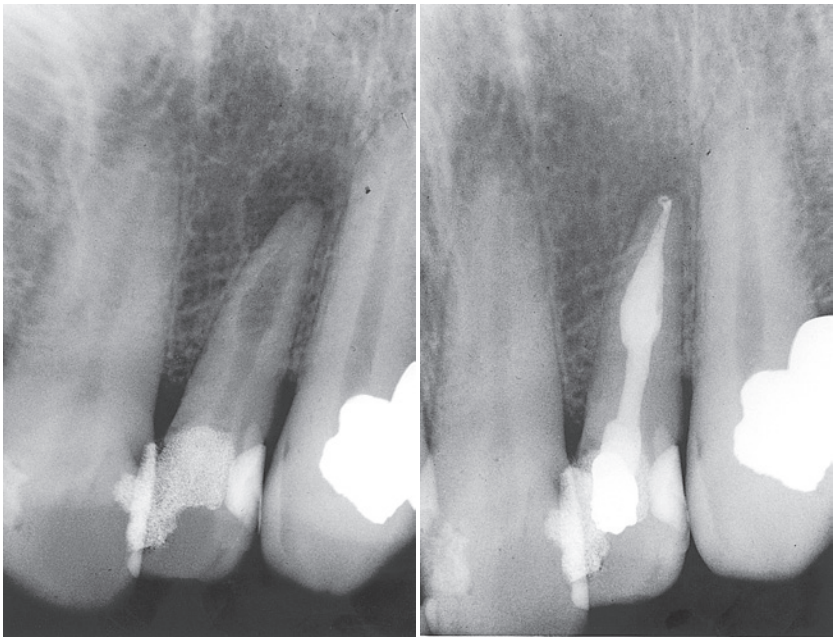

FIG. 3-13 Resorptive defects can be successfully treated. Early intervention, before there is perforation of the root, increases the chance of success. (Courtesy Dr. Leon Schertzer.)

http://dentalebooks.com

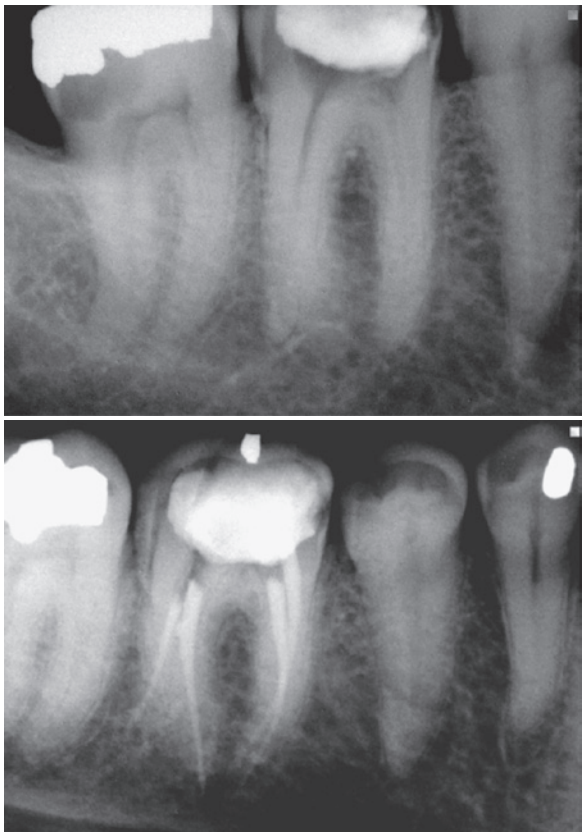

FIG. 3-14 The presence of curved roots and multiple canals is a complicating factor.

anatomic challenge that radiographs do not always reveal (Fig. 3-14). A bitewing radiograph is useful in providing an accurate image of the pulp chambers of posterior teeth. The clinician should recognize these potential problems and be able to manage and factor them into the decision concerning the tooth's prognosis, including the possibility that the patient should be referred to a specialist.

Another consideration is the stage of maturity of the tooth. Primary and immature permanent teeth may have a pulpal pathosis caused by caries or trauma; preserving these young teeth is essential. Premature loss of an anterior tooth can lead to malocclusion, predispose the patient to tongue habits, impair aesthetics, and damage the patient's self-esteem. (See Chapters 20 and 24 for further information.)

Some clinicians use a simple formula for determining which endodontic cases they treat and which they refer to a specialist. The number of roots may be the determining factor in a decision concerning referral, or the key factor may be the chronic or acute status of the case. Others consider the complexity of the ultimate prosthesis as a factor in considering an endodontic referral. The most important variables in determining whether to refer a patient to a specialist are the skills of the clinician and the complexity of the case.

The American Association of Endodontists (AAE) developed guidelines for assessing endodontic case difficulty (available at www.aae.org/uploadedFiles/Publications_and_Research/Guidelines_and_Position_Statements/2006CaseDifficultyAssessmentFormB_Edited2010.pdf) (see Fig. 2-1). The AAE Endodontic Case Difficulty Assessment Form enables a clinician to assign a level of difficulty to a particular case. The form describes cases with minimal, moderate, and high degrees of difficulty. This form lists criteria that can be used to identify cases that should be referred to a specialist. The use of surgical operating microscopes, endoscopes, and ultrasonics enables the specialist to predictably treat teeth that would not previously have been treatable.

Anxiety

Anxiety presents a problem at many levels of dental care (see also Chapter 28). Avoidance of dental treatment due to anxiety appears to be associated with significant deterioration of oral and dental health.[111] Even at the diagnostic stage, severe anxiety may confuse the process.[23] Several studies support the hypothesis that pain or fear of pain is a primary source of anxiety as well as an obstacle to seeking dental care.[44,111] Also, highly anxious patients appear to be more sensitive to pain.[24,43] High levels of anxiety have been found to negatively affect clinical procedures including local anesthesia.[62] In 2009, Binkley tested the hypothesis that having natural red hair color, which is caused by variants of the melanocortin-1 receptor (*MC1R*) gene, could predict a patient's experiencing dental care–related anxiety and dental care avoidance.[8] She found that participants with *MC1R* gene variants reported significantly more dental care–related anxiety and fear of dental pain than did participants with no *MC1R* gene variants. A more recent study confirmed the relationship between the red hair phenotype and anxiety. However, this study found no association between the red hair phenotype and the success of local anesthesia.[21]

It has been demonstrated that dental anxiety and expectation of pain had a profound effect on a patient's ability to understand information provided.[25] A person's cognitive ability to process information is significantly affected by stress.[25] A study found that 40% of patients who had minor oral surgery did not remember receiving both written and verbal instructions, contributing to 67% noncompliance with antibiotic prescriptions.[9] Patients' anxiety can compromise their understanding of complex treatment plans. Decisions made by a patient concerning options involving tooth retention or loss may be markedly affected by anxiety.

Unfortunately, the impact that a high level of anxiety can have on patient's cognition, local anesthesia, and intraoperative and postoperative experiences is not always recognized. A landmark medical study found that pretreatment discussion of surgical treatments and associated discomfort reduced by 50% the need for posttreatment morphine and reduced the time to discharge.[22] Existing research has focused primarily on the effect of pretreatment information on reducing anxiety and stress during surgery.[25]

More than 200 studies indicate that preemptive behavioral intervention decreases anxiety before and after surgery, reduces posttreatment pain intensity and intake of analgesics, and accelerates recovery.[15] A calm setting, reassurance by the clinician and explanation of the treatment plan, as well as a discussion about pain prevention strategies are all important steps even before treatment starts.[63] A written description as well as a verbal description of the proposed treatment are helpful. It may also be of value to have a family member or friend accompany the patient for a discussion of the treatment plan.

http://dentalebooks.com

Scheduling Considerations

If a vital case is to be treated by a multivisit approach, it is suggested that the clinician allow 5 to 7 days between canal instrumentation and obturation to allow periradicular tissues to recover. When a vital case is to be treated in a single visit, adequate time must be scheduled so that the clinician can comfortably complete the procedure. Because profound inferior alveolar nerve block anesthesia can require approximately 15 to 20 minutes, it is wise to include that time when scheduling a patient's appointment (see also Chapter 4).

Appointments to fill nonvital cases should be scheduled approximately 1 week after instrumentation to maximize the antimicrobial effect of the intracanal dressing when calcium hydroxide is used.[6,92,93] Acute (pain or swelling) nonvital cases should be seen every 24 to 48 hours to monitor the patient's progress and bring the acute symptoms under control. Further cleaning and shaping are important components of the treatment as the clinician seeks to eliminate persistent microbes in the canal system. Long delays between visits contribute to the development of resistant microbial strains and should be avoided.

CHAPTER 4

Pain Control

AL READER | JOHN NUSSTEIN | ASMA KHAN

CHAPTER OUTLINE

I. LOCAL ANESTHESIA FOR RESTORATIVE DENTISTRY AND ENDODONTICS

Mechanisms of Action for Anesthetics

Clinically Available Local Anesthetics

Selection of a Local Anesthetic: Possible Adverse Effects, Medical History, and Preoperative Anxiety

Possible Adverse Effects

Effects of Systemic Diseases or Conditions on Local Anesthetics

Clinical Anesthesia and Routes of Anesthetic Administration

Important Clinical Factors in Local Anesthesia

Traditional Methods of Confirming Anesthesia

Determining Pulpal Anesthesia in Asymptomatic Vital Teeth

Determining Pulpal Anesthesia in Symptomatic Vital Teeth

Patient Who Has Had Previous Difficulty with Anesthesia

Failure to Achieve Anesthesia in Patients with Pain

Use of Topical Anesthetics

Reversing the Action of Local Anesthetics

Inferior Alveolar Nerve Block for Restorative Dentistry

2% Lidocaine and 1:100,000 Epinephrine

Anesthetic Success

Anesthetic Failure

Noncontinuous Anesthesia

Slow Onset

Duration

Alternative Anesthetic Solutions for the Inferior Alveolar Nerve Block

Plain Solutions: 3% Mepivacaine (Carbocaine, Polocaine, Scandonest) and 4% Prilocaine (Citanest Plain)

4% Prilocaine with 1:200,000 Epinephrine (Citanest Forte) and 2% Mepivacaine with 1:20,000 Levonordefrin (Carbocaine with Neo-Cobefrin)

Articaine with 1:100,000 Epinephrine (Septocaine, Articadent, Zorcaine)

Long-Acting Anesthetics

Buffered Lidocaine

Use of Mannitol

Alternative Injection Sites

Gow-Gates and Vazirani-Akinosi Techniques

Incisive Nerve Block/Infiltration at the Mental Foramen

Lidocaine Infiltrations

Articaine Infiltrations

Attempts to Increase Success of the Inferior Alveolar Nerve Block

Increasing the Volume of Anesthetic

Increasing the Epinephrine Concentration

Addition of Hyaluronidase

Carbonated Anesthetic Solutions

Diphenhydramine as a Local Anesthetic Agent

Addition of Meperidine to Lidocaine

Factors in Failure of the Inferior Alveolar Nerve Block

Accessory Innervation: Mylohyoid Nerve

Accuracy of Injection

Needle Deflection

Needle Bevel and Success

Speed of Injection and Success

Cross-Innervation

Red Hair

A Theory on Why Failure Occurs with the Inferior Alveolar Nerve Block in Restorative Dentistry

Enhancement of Mandibular Anesthesia for Restorative Dentistry

Supplemental Articaine Infiltrations

Supplemental Intraosseous Anesthesia

Supplemental Intraligamentary Anesthesia

Maxillary Anesthesia for Restorative Dentistry

2% Lidocaine with 1:100,000 Epinephrine

Anesthetic Success

Onset of Pulpal Anesthesia

Duration of Pulpal Anesthesia

Time Course of Pulpal Anesthesia for the Maxillary First Molar

Significance of Lip Numbness

Alternative Anesthetic Solutions for Infiltrations

Plain Solutions; 3% Mepivacaine (Carbocaine, Polocaine, Scandonest) and 4% Prilocaine (Citanest Plain)

4% Prilocaine with 1:200,000 Epinephrine (Citanest Forte), 2% Mepivacaine with 1:20,000 Levonordefrin (Carbocaine with Neo-Cobefrin), and 4% Articaine with 1:100,000 Epinephrine (Septocaine, Articadent, Zorcaine)

0.5% Bupivacaine with Epinephrine (Marcaine)

Extending the Duration of Pulpal Anesthesia for Maxillary Teeth

Increasing the Solution Volume

Increasing the Epinephrine Concentration

Repeating the Infiltration

Alternative Maxillary Injection Techniques for Restorative Dentistry
Posterior Superior Alveolar (PSA) Nerve Block
Infraorbital Nerve Block
Second Division Nerve Block
Palatal–Anterior Superior Alveolar (P-ASA) Nerve Block
Anterior Middle Superior Alveolar (AMSA) Nerve Block
Supplemental Anesthesia for Restorative Dentistry in the Mandible and Maxilla
Indications
Infiltrations
Intraosseous Anesthesia
Intraligamentary Anesthesia
Local Anesthesia for Endodontics
Success of the Inferior Alveolar Nerve Block in Patients Presenting with Symptomatic Irreversible Pulpitis
Success of Maxillary Molar Infiltration in Patients Presenting with Irreversible Pulpitis
Asymptomatic Irreversible Pulpitis versus Symptomatic Irreversible Pulpitis
Supplemental Techniques
Management of Anesthesia in Endodontic Cases
Symptomatic Irreversible Pulpitis
Anesthetizing Mandibular Posterior Teeth
Anesthetizing Mandibular Anterior Teeth
Anesthetizing Maxillary Posterior Teeth
Anesthetizing Maxillary Anterior Teeth
Anesthetizing Symptomatic Teeth with Total Pulpal Necrosis and Periapical Abscess
Anesthetizing Asymptomatic Teeth with Total Pulp Necrosis and Periapical Radiolucencies
Interim Treatment for Irreversible Pulpitis Using Pulpotomy
Pain Reduction in Irreversible Pulpitis When Endodontic Treatment Is Impossible
Oral Conscious Sedation with Triazolam (Halcion) and Alprazolam (Xanax)
Conscious Sedation with Nitrous Oxide
Preemptive Nonsteroidal Antiinflammatory Drugs (NSAIDs)
Patient Satisfaction with Painful Dental Procedures
Anesthesia for Surgical Procedures
Incision for Drainage
Periapical Surgery
Summary and Future Directions for Effective Anesthesia
II. ANALGESICS AND THERAPEUTIC RECOMMENDATIONS
Non-Narcotic Analgesics
Limitations and Drug Interactions
Acetaminophen
Opioid Analgesics
Corticosteroids
Intracanal Administration
Systemic Administration
Antibiotics
Pain Management Strategies
Pretreatment
Long-Acting Local Anesthetics
Flexible Plan
Future Directions
Summary

I. LOCAL ANESTHESIA FOR RESTORATIVE DENTISTRY AND ENDODONTICS

Effective local anesthesia is the bedrock of pain control in endodontics and restorative dentistry. Regardless of the clinician's skills, both treatment and patient management are difficult or impossible to deliver without effective pain control. This chapter reviews the pharmacology of local anesthetics and the relative advantages and limitations of various anesthetics and routes of administration. Other chapters in this book provide complementary information on the use of local anesthetics in diagnosis (see Chapter 1) and the treatment of emergency patients (see Chapter 18). The authors assume that the reader is familiar with various anesthetic injection techniques; several excellent texts are available for review regarding this point.[195,262,353]

MECHANISMS OF ACTION FOR ANESTHETICS

Most dental pharmacology courses teach that local anesthetics block sodium channels by partitioning into two types, the uncharged basic form of the molecule (RN), which crosses cell membranes, and the charged acid form of the molecule (RNH^+), which binds to the inner pore of the sodium channel. As a first approximation, this model is reasonably accurate. However, molecular research has demonstrated the existence of at least nine subtypes of voltage-gated sodium channels (VGSCs) that differ in their expression pattern, biophysical properties, and roles in mediating peripheral pain (Table 4-1). These channels have a clear clinical relevance.[39,170,241] Indeed, several groups of patients have been described with genetic mutations to a VGSC, with significant reported effects on pain sensitivity.

The broad class of VGSCs can be divided into channels that are blocked by a toxin (tetrodotoxin [TTX]) and those that are resistant to the toxin (TTX-R). Most TTX-R channels are found primarily on nociceptors (e.g., Na_v 1.8 and Na_v 1.9).[433] These channels also are relatively resistant to local anesthetics and are sensitized by prostaglandins.[148] As is explained later in the chapter, the presence of TTX-R sodium channels may explain why local anesthetics are less effective when administered to patients with odontalgia. Many of the adverse effects of local anesthetics are attributed to their ability to block other VGSCs expressed in the central nervous system (CNS) or heart (see Table 4-1).

http://dentalebooks.com

VGSCs consist of an alpha and a beta subunit. The alpha subunit serves as a voltage sensor, leading to channel activation and sodium ion passage when the channel detects an electrical field. The biologic basis for an electrical pulp tester, therefore, is the generation of a small electrical field across the dental pulp that can activate VGSCs.[170] Interestingly, sensitization of TTX-R channels by prostaglandins lowers the activation threshold and increases the number of sodium ions that flow through the channel.[148] Put another way, an inflammation-induced elevation in prostaglandin levels sensitizes TTX-R channels, leading to greater activation with weaker stimuli. This may explain the increased responsiveness to electrical pulp testing seen in patients with irreversible pulpitis.

TABLE 4-1
Voltage-Gated Sodium Channels and Pain

Channel Subtype	Tissue Expression	Tetrodotoxin Sensitive	Peripheral Role in Pain

Na_v 1.9	Sensory neurons	No	Yes

Local anesthetics have other mechanisms that may contribute to their pharmacology for treating odontogenic pain. For example, local anesthetics modulate certain G protein–coupled receptors (GPCRs). The GPCRs are a major class of cell membrane receptors, and many classes of dental drugs (e.g., opioids, catecholamines) and endogenous mediators produce their effects by activating specific GPCRs and their related second messenger pathways. Studies suggest that local anesthetics inhibit the G-alpha-q ($G_{\alpha q}$) class of GPCRs, which includes receptors activated by inflammatory mediators such as bradykinin.[183] Local anesthetics may therefore block the actions of a major hyperalgesic agent.

Other studies have indicated that local anesthetics potentiate the actions of the G-alpha-i ($G_{\alpha i}$) class of GPCRs.[32] This could have a major effect in potentiating the actions of vasoconstrictors, including the newly recognized analgesic role that vasoconstrictors play in inhibiting pulpal nociceptors.[43,169] Prolonged alteration of GPCR function might explain why analgesia obtained with long-acting local anesthetics persists well beyond the period of anesthesia.[78,104,300] More research is needed on this exciting aspect of local anesthetic pharmacology.

CLINICALLY AVAILABLE LOCAL ANESTHETICS

The most common forms of injectable local anesthetics are in the amide class. In 2003, the American Dental Association specified a uniform color code for dental cartridges to prevent confusion among brands (Table 4-2). Local anesthetics can be divided roughly into three types: short duration (30 minutes of pulpal anesthesia), intermediate duration (60 minutes of pulpal anesthesia), and long duration (over 90 minutes of pulpal anesthesia). However, clinical anesthesia does not always follow these guidelines, depending on whether the local anesthetic is used as a block or for infiltration. For example, bupivacaine is classified as a long-acting agent, and when it is used in an inferior alveolar nerve (IAN) block, this is true.[112] However, when it is used for infiltration for anterior teeth, it

TABLE 4-2
Local Anesthetics Available in the United States*

Anesthetic	Vasoconstrictor	Dental Cartridge Color Codes†	Maximum Allowable Dose	Typical Maximum Dose
2% Lidocaine	1:100,000 epinephrine	Red	13	8
2% Lidocaine	1:50,000 epinephrine	Green	13	8
2% Lidocaine	Plain (no vasoconstrictor)	Light blue	8	8
2% Mepivacaine	1:20,000 levonordefrin	Brown	11	8
3% Mepivacaine	Plain (no vasoconstrictor)	Tan	7	5½
4% Prilocaine	1:200,000 epinephrine	Yellow	5½	5½
4% Prilocaine	Plain (no vasoconstrictor)	Black	5½	5½
0.5% Bupivacaine	1:200,00 epinephrine	Blue	10	10
4% Articaine	1:100,000 epinephrine	Gold	7	7
4% Articaine	1:200,000 epinephrine	Silver	7	7

*This table provides the maximum dosage in two formats. The maximum allowable dose generally is approached only with complex oral and maxillofacial surgical procedures. The typical maximum dose is the usual outer envelope of drug dosage for most endodontic, surgical, and restorative dental procedures. Both columns show the number of cartridges that would be required for an adult weighing 67.5 kg (150 pounds).
†Uniform dental cartridge color codes were mandated by the American Dental Association in June, 2003.

has a shorter duration of anesthetic action than 2% lidocaine with 1:100,000 epinephrine[81,156] (this is discussed in more detail later in the chapter).

SELECTION OF A LOCAL ANESTHETIC: POSSIBLE ADVERSE EFFECTS, MEDICAL HISTORY, AND PREOPERATIVE ANXIETY

Possible Adverse Effects

Possible adverse reactions to local anesthetics can be divided into six major categories: cardiovascular reactions, systemic effects, methemoglobinemia, peripheral nerve paresthesia, allergic reactions to the anesthetic and/or latex, and reactions to anesthetics containing a sulfite antioxidant. These reactions range from fairly common (e.g., tachycardia after intraosseous injection of 2% lidocaine with 1:100,000 epinephrine) to extremely rare (e.g., allergic reactions to lidocaine).

Cardiovascular Reactions

Although classic research studies have reported that large dosages or intravenous (IV) injections of local anesthetics were required to produce cardiovascular effects,[192,419] it now is well recognized that even comparatively small amounts of epinephrine can induce measurable tachycardia after nerve block or intraosseous injection.[113,150,358] Several authors have reported increases in heart rate with infiltration injections and nerve blocks using 2% lidocaine with 1:100,000 epinephrine[2,172,236,375,418]; others have reported that no significant changes in heart rate occurred or that the changes were clinically insignificant.[282,413,422] When specific information was given on dosing and heart rate increases, several studies found mean heart rate increases.[2,172,235,418] Two studies found increases on average of about 4 beats/min with approximately 20 μg of epinephrine[172,235]; three studies recorded increases of 10 to 15 beats/min with 45 to 80 μg of epinephrine[2,235,375]; and one study found increases of approximately 21 beats/min using 144 μg.[418] Increasing the amount of epinephrine in an infiltration or block injection, therefore, increases the likelihood of an elevated heart rate.

Tachycardia after injection is primarily a pharmacologic effect. The cardiovascular effects are the result of alpha-adrenoceptor stimulation by systemic distribution of the vasoconstrictor throughout the vascular compartment. The patient may also report heart palpitations associated with anxiety or fear and may experience transient tachycardia and changes in blood pressure. Large doses or inadvertent IV injection may lead to lidocaine toxicity and CNS depression.[115,308] To reduce this risk, the clinician should always aspirate before making the injection, inject slowly, and use dosages within accepted guidelines. The maximal dosages for local anesthetics are listed in Table 4-2.

Systemic Effects

Acute toxicity from an overdose of a local anesthetic often is the result of inadvertent IV administration or of a cumulative large dose (e.g., repeated injections). As shown in Table 4-1, VGSCs are found in the CNS and the myocardium, the two major sites of anesthetic-induced toxicity. Although systemic effects from a local anesthetic are rare, they can include an initial excitatory phase (e.g., muscle twitching, tremors, grand mal convulsions) and a subsequent depressive phase (e.g., sedation, hypotension, and respiratory arrest).[86,115] It should be noted that symptomatic management (possibly including cardiopulmonary resuscitation [CPR], airway support, and supplemental oxygen) is the primary response to this adverse event.[229,233] An acute hypotensive crisis with respiratory failure also has been interpreted as the result of hypersensitivity to local anesthetics[62]; these patients should be evaluated with allergy testing. To reduce the risk of systemic effects from anesthetics, the clinician must always aspirate before giving the injection and must use dosages within accepted guidelines (see Table 4-2). Finder and Moore[115] proposed a "rule of 25" as a simple means of remembering maximal local anesthetic dosages: with currently formulated local anesthetic cartridges, it generally is safe to use one cartridge of local anesthetic for every 25 pounds of patient weight (e.g., six cartridges for a patient weighing 150 pounds [67.5 kg]).

Methemoglobinemia

Metabolism of certain local anesthetics (e.g., prilocaine, benzocaine, articaine, and to a lesser extent lidocaine) can produce a metabolite that causes methemoglobinemia; this effect often occurs several hours after injection of the local anesthetic.[265,439] Typical signs and symptoms include cyanosis, dyspnea, emesis, and headache. In a study on benzocaine-induced methemoglobinemia, 67% of reported adverse effects of benzocaine were associated with methemoglobinemia; of these events, 93% occurred with spray formulations of benzocaine, and only one case involved the gel formulation.[301] To reduce the risk of methemoglobinemia, clinicians should take care to refrain from giving excessive dosages of local anesthetics.

Peripheral Nerve Paresthesia

Postinjection paresthesia is a rare adverse effect of local anesthetics.[161,265,453] The incidence of paresthesia (which involved the lip and/or tongue) associated with articaine and prilocaine was higher than that found with either lidocaine or mepivacaine.[132,140,161] Another study evaluated patients referred with a diagnosis of damage to the inferior alveolar and/or lingual nerve that could only have resulted from an IAN block.[345] In 35% of these cases, the paresthesia was caused by a lidocaine formulation, and in 30%, it was caused by an articaine formulation. The conclusion was that there was not a disproportionate nerve involvement from articaine, although this interpretation does not account for large differences in clinical usage of the two local anesthetics. However, with any paresthesia, documentation of the patient's reported area of altered sensation, the type of altered sensation (e.g., anesthesia, paresthesia, dysesthesia), and regular follow-up are important.[463]

Allergic Reactions to Local Anesthetics and Latex

The amide local anesthetics appear to have little immunogenicity and therefore have an extremely low rate of allergic reactions.[382] One study included more than 140 patients specifically referred for allergy testing because of adverse effects after injection of a local anesthetic; none of these patients had hypersensitivity reactions to intradermal local anesthetics,[368] but case reports of hypersensitivity reactions after administration of local anesthetics have been published.[41,62,302,382] Some concern has been raised that the rubber latex stopper in dental anesthetic cartridges might be a source of allergen to patients allergic to latex. In a review of this literature (1966 to 2001), Shojaei and Haas[385] concluded that some evidence for exposure

http://dentalebooks.com

to the latex allergen exists, although no causal study has been published.

Local anesthetic formulations that contain vasoconstrictors also contain sulfite to prevent oxidation of this agent. Sulfite-induced reactions came to prominence with the report of six deaths after exposure to salad bars or homemade wine.[20] Common reported signs and symptoms include allergic-like reactions, such as urticaria, bronchospasm, and anaphylaxis. Risk factors include an active history of asthma (perhaps 5% of asthmatics are at risk) and atopic allergy. The use of local anesthetics without vasoconstrictors is a possible alternative with these patients. No sulfite reaction in dental practice has ever been documented, possibly because the amount of sulfite in local anesthetic cartridges is relatively small.

EFFECTS OF SYSTEMIC DISEASES OR CONDITIONS ON LOCAL ANESTHETICS

It has been stated that vasoconstrictors should be avoided in patients with high blood pressure (higher than 200 mmHg systolic or 115 mmHg diastolic), cardiac dysrhythmias, unstable angina, less than 6 months since myocardial infarction or cerebrovascular accident, or severe cardiovascular disease.[262] However, these conditions are contraindications to routine dental treatment. Patients taking antidepressants, nonselective beta-blocking agents, medicine for Parkinson disease, and cocaine have a potential for problems.[262,353] In patients taking these medications, plain mepivacaine (3% Carbocaine) can be used for the inferior alveolar nerve block.

Alcoholics have been found to be more sensitive to painful stimulation.[406] Alcoholics with a history of depression/unhappiness may also have reduced pulpal anesthesia.[116] In contrast, alcoholics in recovery may not be at increased risk for inadequate pain control with local anesthesia.[116]

Any of the commonly available local anesthetics are safe for use in pregnant or lactating women.[162] The most important aspect of care with pregnant patients is to eliminate the source of pain by performing the indicated endodontic treatment; this reduces the need for systemic medications.[162]

Local anesthetics may interact with a patient's medications, so a thorough review of the medical history is an absolute requirement. Potential drug-drug interactions occur primarily with the vasoconstrictors in local anesthetic formulations (Table 4-3). Judicious use of local anesthetic solutions without vasoconstrictors (e.g., 3% mepivacaine) is a reasonable alternative for adult patients.

Studies have found that women try to avoid pain more than men, accept it less, and fear it more.[99,114,249,303] One study found that women find postsurgical pain more intense than males, but men are more disturbed than women by low levels of pain that lasts several days.[303] Another study found gender differences in analgesia for postoperative endodontic pain.[374] Anxiety

TABLE 4-3
Possible Drug Interactions with Vasoconstrictors

Drugs	Possible Adverse Effects	Recommendations
Tricyclic Antidepressants		
Amitriptyline, doxepin	Increased cardiovascular responses	Reduce or eliminate vasoconstrictors
Nonselective Beta-Blockers		
Nadolol, propranolol	Hypertension, bradycardia	Reduce or eliminate vasoconstrictors
Recreational Drugs		
Cocaine	Hypertension, myocardial infarction, dysrhythmias	Instruct patient to abstain from drug use for 48 hours before procedure; do not use vasoconstrictors
COMT Inhibitors		
Entacapone, tolcapone	Increased cardiovascular responses	Reduce or eliminate vasoconstrictors
Antiadrenergic Drugs		
Guanadrel, guanethidine	Increased cardiovascular responses	Reduce or eliminate vasoconstrictors
Nonselective Alpha-Adrenergic Blockers		
Chlorpromazine, clozapine, haloperidol	Increased cardiovascular responses	Reduce or eliminate vasoconstrictors
Digitalis		
Digoxin	Dysrhythmias (especially with large dosage of vasoconstrictor)	Reduce or eliminate vasoconstrictor
Hormone		
Levothyroxine	Dysrhythmias (especially with large dosage of vasoconstrictor)	*Euthyroid:* No precaution *Hyperthyroid:* Reduce or eliminate vasoconstrictors
Monoamine Oxidase Inhibitors		
Furazolidone, linezolid, selegiline, tranylcypromine	No interaction	None

may also modulate differences in pain responses between males and females. In addition, pain threshold response varies greatly at different stages of the menstrual cycle.[42] Other studies have shown that women report greater pain relief from kappa opioid agonists (e.g., pentazocine) after endodontic treatment.[420] We should be aware that women might react differently to pain than men.[114]

CLINICAL ANESTHESIA AND ROUTES OF ANESTHETIC ADMINISTRATION

Recognition is growing that evidence-based therapeutics offers an excellent source of information that should become an aspect of treatment in conjunction with the practitioner's clinical skills and the patient's particular needs. In many areas of dentistry, this is a limited concept because few randomized, placebo-controlled, double-blind clinical trials have been conducted. However, this is not the case with dental pharmacology. The astute clinician can make informed decisions on various local anesthetics and routes of injection based on a large collection of well-designed clinical trials. The following discussion focuses on the clinical aspects of local anesthesia, with special emphasis on restorative dentistry and endodontics.

IMPORTANT CLINICAL FACTORS IN LOCAL ANESTHESIA

Traditional Methods of Confirming Anesthesia

Traditional methods of confirming anesthesia usually involve questioning the patient ("Is your lip numb?"), soft tissue testing (e.g., lack of mucosal responsiveness to a sharp explorer), or simply beginning treatment. However, these approaches may not be effective for determining pulpal anesthesia.[60,179,277,424]

Determining Pulpal Anesthesia in Asymptomatic Vital Teeth

Anesthesia in asymptomatic vital teeth can be measured more objectively by applying a cold refrigerant (Fig. 4-1) or by using an electrical pulp tester (EPT), as described in Chapter 1 (Fig. 4-2). Application of cold or the electrical pulp tester can be used to test the tooth under treatment for pulpal anesthesia before a clinical procedure is started.[56,100,201,257]

Determining Pulpal Anesthesia in Symptomatic Vital Teeth

In symptomatic (painful) vital teeth and after administration of a local anesthetic, testing with a cold refrigerant or an electrical pulp tester can be used to evaluate pulpal anesthesia before an endodontic procedure is started.[68,100,323,355] If the patient responds to the stimulus, pulpal anesthesia has not been obtained, and supplemental anesthetic should be administered. However, in patients presenting for an emergency appointment with a painful vital tooth (e.g., symptomatic irreversible pulpitis), the lack of a response to pulp testing may not guarantee pulpal anesthesia.[100,323,355] Therefore, if a patient experiences pain when the endodontic procedure is started, supplemental anesthetic is indicated, regardless of the responsiveness to pulpal testing. If the chamber is necrotic and the canals are vital, no objective test can predict the level of clinical anesthesia.

FIG. 4-1 A cold refrigerant may be used to test for pulpal anesthesia before the start of a clinical procedure. (Coltène/Whaledent Inc., Cuyahoga Falls, OH.)

FIG. 4-2 An electrical pulp tester also may be used to test for pulpal anesthesia before a clinical procedure is started. (Courtesy SybronEndo, Corporation Orange, CA.)

Patient Who Has Had Previous Difficulty with Anesthesia

Anesthesia is more likely to be unsuccessful in patients who report a history of previous difficulty with anesthesia.[214] These patients generally make comments such as, "Novocaine doesn't work on me" or "It takes a lot of shots to get my teeth numb." A good clinical practice is to ask the patient if dentists previously have had difficulty obtaining anesthesia. If the answer is yes, supplemental injections should be considered.

http://dentalebooks.com

Failure to Achieve Anesthesia in Patients with Pain

Obtaining anesthesia is often difficult in patients with endodontic pain of pulpal origin. A number of explanations have been proposed for this.[170] One is that conventional anesthetic techniques do not always provide profound pulpal anesthesia, and patients with preexisting hyperalgesia may be unable to tolerate any noxious input. Another explanation relates to the theory that inflamed tissue has a lower pH, which reduces the amount of the base form of anesthetic that penetrates the nerve membrane. Consequently, less of the ionized form is available in the nerve to achieve anesthesia. However, this explanation does not account for the mandibular molar with pulpitis that is not readily blocked by an inferior alveolar injection administered at some distance from the area of inflammation. Correlating localized inflammatory changes with failure of the IAN block is difficult.

Another explanation for failure is that nerves arising from inflamed tissue have altered resting potentials and decreased excitability thresholds.[51,427] Two studies demonstrated that local anesthetics were unable to prevent impulse transmission because of these lowered excitability thresholds.[292,427] Another factor might be the TTX-R sodium channels, which are resistant to the action of local anesthetics,[373] are increased in inflamed dental pulp,[399,431,433] and are sensitized by prostaglandins.[148] A related factor is the increased expression of sodium channels.[399,431,433]

Finally, patients in pain are often apprehensive, which lowers the pain threshold. Therefore, practitioners should consider supplemental techniques (e.g., intraosseous injections[320,323,332,355] or periodontal ligament injections[68]) if an IAN block fails to provide pulpal anesthesia for patients with irreversible pulpitis.

Use of Topical Anesthetics

Fear of needle insertion is a major cause of apprehension in dental patients.[234,289,290] Although some studies have demonstrated the effectiveness of topical anesthetics,[146,175,186,312,372] others have shown no significant pain reduction.[146,222,270] Interestingly, one study showed that patients who thought they were receiving a topical anesthetic anticipated less pain regardless of whether they actually received the anesthetic.[270] The most important aspect of a topical anesthetic may not be its clinical effectiveness, but rather its psychological effect on the patient, who believes the practitioner is doing everything possible to prevent pain.

Reversing the Action of Local Anesthetics

Phentolamine mesylate (0.4 mg in a 1.7-ml cartridge [OraVerse, Novalar Pharmaceuticals, San Diego, California]) is a recently developed agent that shortens the duration of soft tissue anesthesia. The duration of soft tissue anesthesia is longer than pulpal anesthesia and is often associated with difficulty eating, drinking, and speaking.[176,245] The best use of OraVerse is after dental procedures when postoperative pain is not a concern. Asymptomatic endodontic patients may benefit from the use of a reversal agent when they have speaking engagements or important meetings or must perform in musical or theatrical events.[121] Therefore, OraVerse may be used to shorten the duration of soft tissue anesthesia if the patient presents with an asymptomatic tooth and little postoperative pain is anticipated.[121]

INFERIOR ALVEOLAR NERVE BLOCK FOR RESTORATIVE DENTISTRY

2% Lidocaine and 1:100,000 Epinephrine

Because failure occurs most often with the IAN block,[214] factors that modify mandibular anesthesia must be carefully reviewed. The technique for administering an IAN block can be reviewed in available textbooks.[195,262] The following discussion reviews the expected outcomes after administration of a conventional IAN block to asymptomatic patients using 1.8 ml of 2% lidocaine with 1:100,000 epinephrine (Xylocaine, Lignospan, Octocaine). Although anesthesia requirements vary among dental procedures, the following discussion concentrates on *pulpal* anesthesia in asymptomatic patients and thus is directly relevant to endodontic therapy.

Anesthetic Success

One way to define anesthetic success for nerve blocks is the percentage of subjects who achieve two consecutive nonresponsive readings on electrical pulp testing within 15 minutes and continuously sustain this lack of responsiveness for 60 minutes. In other words, the objective is to achieve anesthesia within 15 minutes and to have it last 1 hour. This endpoint is as important for restorative dentistry as it is for endodontic treatment, so it is used as a benchmark for clinically significant information from research on local anesthetics. Using this criterion, the percentage of cases in which anesthesia was obtained after IAN block injections ranged from 10% (central incisor) to 65% (second molar).* It is important to note that all patients from these studies reported a positive lip sign (e.g., profound lip numbness); therefore, profound lip numbness *does not* predict pulpal anesthesia. However, lack of soft tissue anesthesia is a useful indicator that the block injection was not administered accurately for that patient. Missed blocks occur in about 5% of cases, and the clinician should readminister the nerve block before continuing with treatment.

Anesthetic Failure

Anesthetic failure can be defined as the percentage of subjects who never achieved two consecutive nonresponsive EPT readings at any time during a 60-minute period. Using this criterion, anesthetic failure rates ranged from 17% (second molar) to 58% (central incisor).†

Noncontinuous Anesthesia

Another measure of mandibular anesthesia is noncontinuous anesthesia, which may be related to the action of the anesthetic solution on the nerve membrane (blocking and unblocking the sodium channels). This occurs in about 12% to 20% of patients.‡

Slow Onset

After a conventional IAN block injection, the onset of pulpal anesthesia occurs within 10 to 15 minutes in most cases (Fig. 4-3).§ Slow onset can be defined as the percentage of

*References 60, 165, 179, 277, 322, 353, and 424.

http://dentalebooks.com

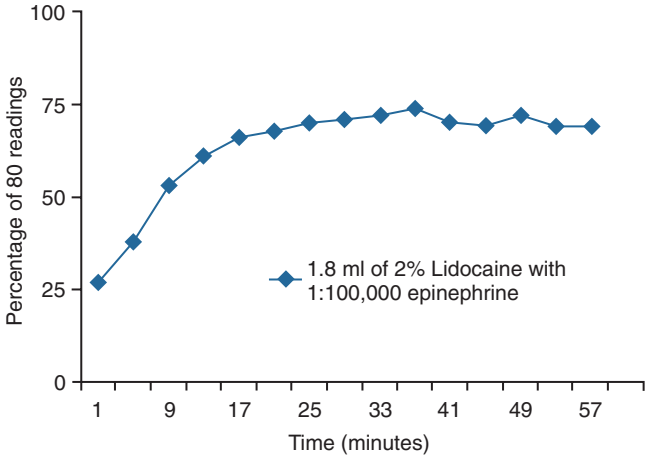

FIG. 4-3 Incidence of first mandibular molar anesthesia as determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes.

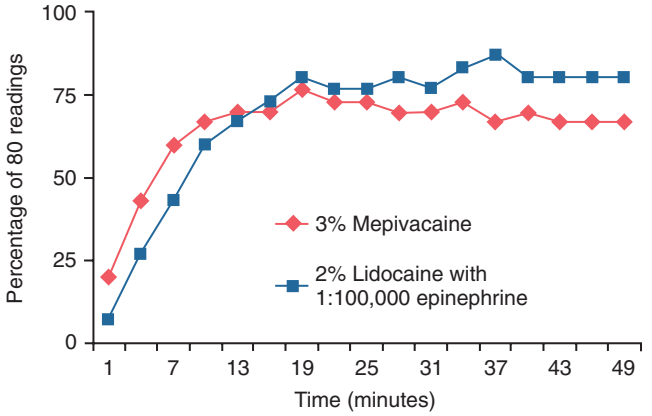

FIG. 4-4 Incidence of first mandibular molar anesthesia: comparison of 3% mepivacaine to 2% lidocaine with 1:100,000 epinephrine. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 50 minutes. No significant difference between the two solutions was noted.

subjects who achieved a nonresponsive EPT reading after 15 minutes. In mandibular teeth, slow onset occurs in 12% to 20% of patients.

Duration

The duration of action for pulpal anesthesia in the mandible is very good.* If patients are anesthetized initially, anesthesia usually persists for approximately 2½ hours.[112] Figure 4-3 depicts the time course for complete pulpal anesthesia for an asymptomatic first molar, as defined by the percentage of patients who did not respond to a stimulus (EPT) across time for 60 minutes. Most patients achieved pulpal anesthesia within 15 minutes and had a duration of anesthesia of at least 1 hour, but the success rate was not 100% for the population.

ALTERNATIVE ANESTHETIC SOLUTIONS FOR THE INFERIOR ALVEOLAR NERVE BLOCK

Plain Solutions: 3% Mepivacaine (Carbocaine, Polocaine, Scandonest) and 4% Prilocaine (Citanest Plain)

In a study of volunteers without dental pathosis, anesthesia from IAN injection of 3% mepivacaine plain and 4% prilocaine plain was as effective as that from 2% lidocaine with 1:100,000 (Fig. 4-4).[277] A clinical study of patients with irreversible pulpitis also found that 3% mepivacaine and 2% lidocaine with 1:100,000 epinephrine were equivalent for IAN blocks.[68] These findings support the selection of 3% mepivacaine as a local anesthetic when medical conditions or drug therapies suggest caution in the administration of solutions containing epinephrine.

4% Prilocaine with 1:200,000 Epinephrine (Citanest Forte) and 2% Mepivacaine with 1:20,000 Levonordefrin (Carbocaine with Neo-Cobefrin)

In a study of volunteers without dental pathosis, IAN injection of 4% prilocaine with 1:200,000 epinephrine or 2% mepivacaine with 1:20,000 levonordefrin worked as well as 2% lidocaine with 1:100,000 epinephrine in achieving pulpal anesthesia.[179]

Levonordefrin has 75% alpha activity and only 25% beta activity, making it seemingly more attractive than epinephrine (50% alpha activity and 50% beta activity).[262] However, levonordefrin is marketed as a 1:20,000 concentration in dental cartridges.[262] Clinically, the higher concentration of levonordefrin makes it equipotent to epinephrine in clinical and systemic effects,[158,179] so 1:20,000 levonordefrin offers no clinical advantage over 1:100,000 epinephrine.

Articaine with 1:100,000 Epinephrine (Septocaine, Articadent, Zorcaine)

Articaine has been reported to be a safe and effective local anesthetic.[378] It was approved for use in the United States in April, 2000, and is marketed as a 4% solution with either 1:100,000 or 1:200,000 epinephrine.[265,299] Articaine is classified as an amide. It has a thiophene ring (instead of a benzene ring, as do the other amide local anesthetics) and an extra ester linkage, which results in hydrolysis of articaine by plasma esterases.[271] A number of studies have evaluated articaine and concluded that it is safe when used in appropriate doses.* Lidocaine and articaine have the same maximal dose of 500 mg for adult patients (recommended dose, 6.6 to 7 mg/kg), but the maximum number of cartridges is different because of the differences in drug concentration (see Table 4-2).[262]

*References 60, 112, 165, 179, 277, 322, 353, 388, 424, and 425.

http://dentalebooks.com

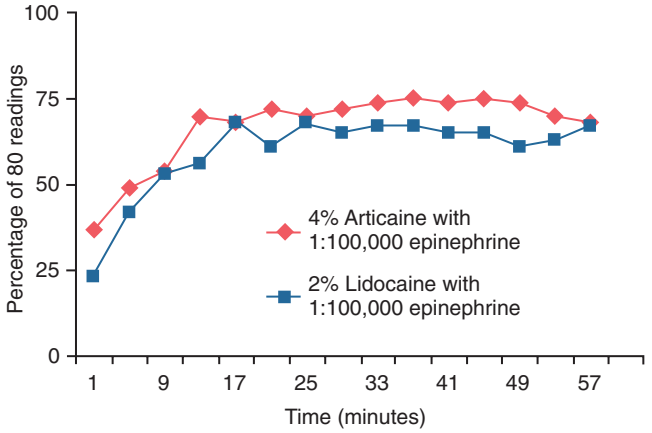

FIG. 4-5 **Incidence of first mandibular molar anesthesia: comparison of 4% articaine with 1:100,000 epinephrine to 2% lidocaine with 1:100,000 epinephrine.** Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. No significant difference between the two solutions was noted.

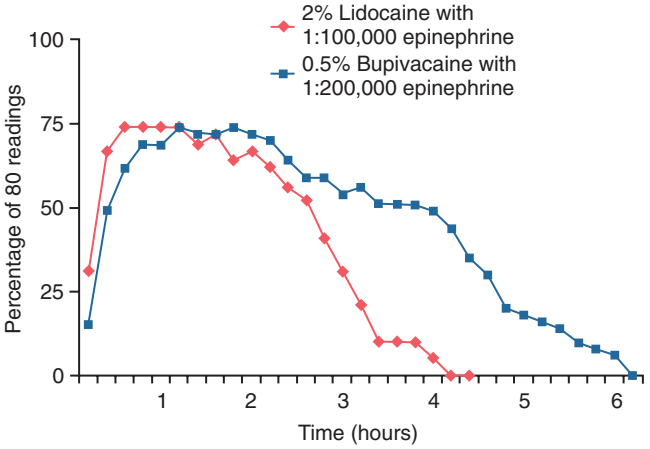

FIG. 4-6 **Incidence of first mandibular molar anesthesia: comparison of 0.5% bupivacaine with 1:200,000 epinephrine to 2% lidocaine with 1:100,000 epinephrine.** Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 6 hours. The bupivacaine solution showed a longer duration of anesthesia than the lidocaine solution.

Clinical Effectiveness of Articaine for Inferior Alveolar Nerve Blocks

The available literature indicates that articaine is equally effective for IAN blocks when statistically compared to other local anesthetics.* In comparing the anesthetic efficacy of 4% articaine with 1:100,000 epinephrine to 2% lidocaine with 1:100,000 epinephrine for IAN blocks, one study found that the two solutions were not significantly different (Fig. 4-5).[288] Two studies found no difference in efficacy between 4% articaine with 1:100,000 and 1:200,000 epinephrine.[299,412] In summary, repeated clinical trials have failed to demonstrate any statistical superiority of articaine over lidocaine for IAN blocks.

Articaine and Uncorroborated Insurance Carrier Warning

A letter was sent to thousands of U.S. dentists in 2006 by insurer Emery and Webb/Ace USA stating, "... we have noticed an increase in reversible and, in some cases, nonreversible paresthesias (with Septocaine) … We are writing you to alert you to these events in hopes that you will not fall victim to one of these incidents."[261] Knowledgeable dentists and educators communicated their concerns, and a Notice of Retraction was issued:

> Unfortunately, we at Emery & Webb discovered upon further review, and subsequent to the mailings, that both documents contained inaccuracies and an alarmist tone, which was not warranted … Emery and Webb has not noted an increase in malpractice claims or lawsuits in connection with articaine … It should be made clear that Emery and Webb has not conducted any scientific investigation, sampling, testing, or other investigation of the articaine anesthetic, and has no independent knowledge or data which would restrict the use of the product.[261]

Astute clinicians should be very careful of Web chat sites and colleagues' clinical endorsements, because they may not accurately reflect the correct information regarding articaine.

Long-Acting Anesthetics

Clinical trials with bupivacaine (Marcaine) and etidocaine (Duranest) have been conducted in patients undergoing oral surgery,[84,371] endodontic treatment,[104,300] and periodontic treatment.[78,254] Etidocaine was withdrawn from the market by Dentsply Pharmaceuticals (York, Pennsylvania). Bupivacaine was found to have a slower onset of pulpal anesthesia than lidocaine for IAN blocks.[112] Generally, bupivacaine provides prolonged analgesia and is indicated when postoperative pain is anticipated, but not all patients want lip numbness for an extended period.[371] Patients should be questioned about their preference. Although bupivacaine has a somewhat slower onset than lidocaine, its duration of pulpal anesthesia in the mandible is almost twice as long (approximately 4 hours; Fig. 4-6).[112]

Ropivacaine (Naropin), a relatively new long-acting local anesthetic, is a structural homolog of bupivacaine.[223] A number of studies have shown that ropivacaine has a lower potential for toxic CNS and cardiovascular effects than bupivacaine but produces equivalent pharmacologic effects.[223] Ropivacaine and levobupivacaine are being developed as potentially new local anesthetics based on their stereochemistry. Both are S-isomers and are thought to cause less toxicity than the racemic mixture of bupivacaine currently marketed.[392] A clinical trial has indicated that levobupivacaine showed significantly better postoperative pain control at 4 and 24 hours after infiltration injection than ropivacaine.[331] Because of their decreased potential for cardiac and CNS toxicity, ropivacaine and levobupivacaine may replace bupivacaine with epinephrine in clinical dental practice.

Buffered Lidocaine

Buffering lidocaine using sodium bicarbonate raises the pH of the anesthetic solution. In medicine there is evidence that buffering lidocaine results in less pain during the injection.[55,164]

*References 64, 95, 159, 160, 263, 264, 288, 421, and 450.

http://dentalebooks.com

In dentistry, some studies[15,16,44,210] found that buffered lidocaine produced less pain on injection and a faster onset of anesthesia. However, other dental studies[350,435] did not find less pain on injection or a faster onset with buffered lidocaine for IAN block. Using a commercial buffering system (Onpharma, Los Gatos, California) in asymptomatic subjects, one study[266] found a reduction in onset time and injection pain, whereas another study[180] found no difference in these measurements. In symptomatic patients with a diagnosis of pulpal necrosis and associated acute swelling, no significant decrease in pain of infiltrations or significant decrease in pain of an incision and drainage procedure was found when the buffered anesthetic formulation was used.[29] Most patients who had the incision and drainage procedure experienced moderate to severe pain.

Use of Mannitol

An Ohio State University research group studied the use of mannitol to increase the efficacy of nerve blocks. Mannitol, a hyperosmotic sugar solution, is thought to temporarily disrupt the protective covering (perineurium) of sensory nerves, allowing the local anesthetic to gain entry to the innermost part of the nerve.[22] These researchers found that the use of mannitol in combination with lidocaine increased anesthetic success in IAN blocks about 15% to 20% but did not provide complete pulpal anesthesia for restorative or endodontic treatment.[239,398,443] The drug combination may be introduced sometime in the future.

ALTERNATIVE INJECTION SITES

Gow-Gates and Vazirani-Akinosi Techniques

Some clinicians have reported that the Gow-Gates technique[154] has a higher success rate than the conventional IAN block injection,[259,262] but controlled experimental studies have failed to show superiority of the Gow-Gates technique.[11,149,294,411] Neither has the Vazirani-Akinosi technique[12,149,262] been found superior to the standard inferior alveolar injection.[149,271,394,411,460] In a small study of 21 patients, no difference was found between lidocaine (11 patients) and articaine (10 patients) formulations for the Gow-Gates injection in patients with irreversible pulpitis.[384] Another study found the Gow-Gates technique had a higher success rate (52%) than the Vazirani-Akinosi technique (41%) in patients with irreversible pulpitis.[4] Further research is indicated with both techniques in patients presenting with symptomatic irreversible pulpitis. The Vazirani-Akinosi technique is indicated for cases involving a limited mandibular opening (trismus).

Incisive Nerve Block/Infiltration at the Mental Foramen

The incisive nerve block is successful 80% to 83% of the time in anesthetizing the premolar teeth for about 20-30 minutes.[30,202,313,437] It is not effective for the central and lateral incisors.[313]

Lidocaine Infiltrations

Labial or lingual infiltration injections of a lidocaine solution alone are not effective for pulpal anesthesia in the mandible.[118,281,459]

Articaine Infiltrations

Articaine is significantly better than lidocaine for buccal infiltration of the mandibular first molar.[75,203,205,362] However, articaine alone does not predictably provide pulpal anesthesia of the first molar. There is no difference between 4% articaine with 1:100,000 and 1:200,000 epinephrine for buccal infiltration.[275]

In anterior teeth, buccal and lingual infiltrations of articaine provide initial pulpal anesthesia, but the anesthesia declines over 60 minutes.[190,326]

ATTEMPTS TO INCREASE SUCCESS OF THE INFERIOR ALVEOLAR NERVE BLOCK

Increasing the Volume of Anesthetic

One possible method for increasing anesthetic success could be to double the injection volume of local anesthetic solution. However, increasing the volume of 2% lidocaine with epinephrine to 3.6 ml (two cartridges) does not increase the incidence of pulpal anesthesia with the IAN block (Fig. 4-7).[322,455]

Increasing the Epinephrine Concentration

A second approach for increasing the success of the IAN block could be to increase the concentration of epinephrine. However, when this technique was evaluated in clinically normal teeth, no advantage was seen in using a higher concentration (1:50,000 versus 1:100,000) of epinephrine.[80,425]

Addition of Hyaluronidase

Hyaluronidase reduces the viscosity of the injected tissue, permitting a wider spread of injected fluids.[21] Early studies in dentistry found that an IAN block was more easily attained and was more complete when hyaluronidase was added to an anesthetic solution.[230,258] A recent study found that hyaluronidase may increase the duration of the effects of lidocaine.[377] However, a controlled clinical trial found that adding hyaluronidase to a lidocaine solution with epinephrine did not statistically increase the incidence of pulpal anesthesia in IAN blocks.[360] In addition, hyaluronidase increased the occurrence of adverse effects (i.e., increased pain and trismus).[360]

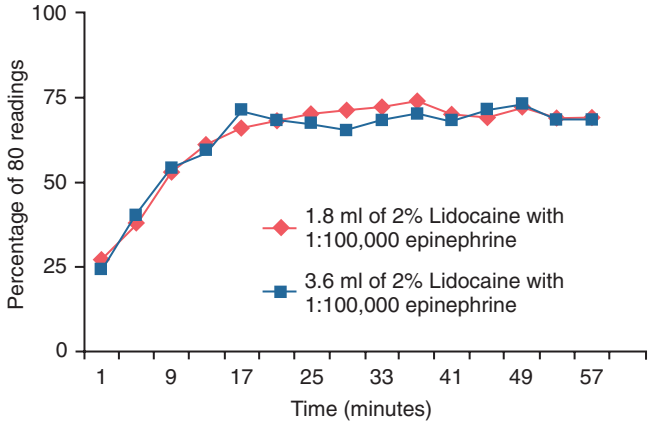

FIG. 4-7 Incidence of first mandibular molar anesthesia: comparison of 1.8 ml and 3.6 ml of 2% lidocaine with 1:100,000 epinephrine. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. No significant difference between the two volumes was noted.

http://dentalebooks.com

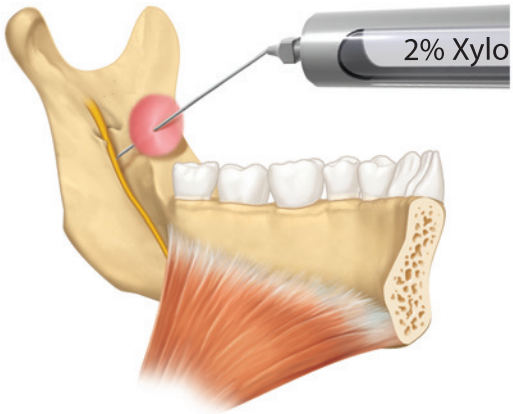

FIG. 4-8 Injection site for the mylohyoid nerve block.

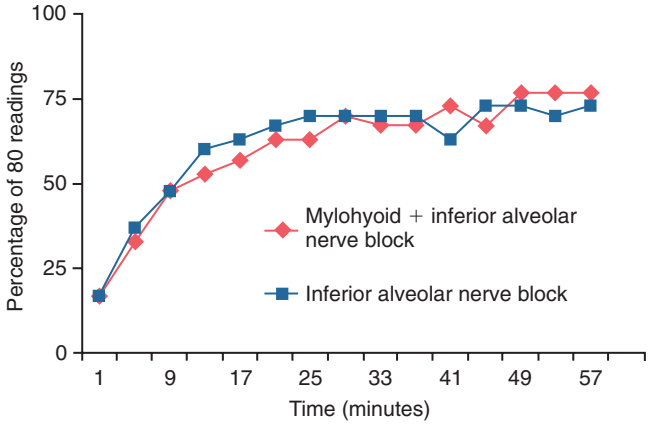

FIG. 4-9 Incidence of first mandibular molar anesthesia: comparison of the combination mylohyoid infiltration plus the inferior alveolar nerve block to the inferior alveolar nerve block alone. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. No significant difference between the two techniques was noted.

CARBONATED ANESTHETIC SOLUTIONS

Experimentally, carbonated anesthetic solutions are more effective because the anesthetic is trapped in the nerve.[60] In addition, carbon dioxide (CO_2) has a synergistic relationship with local anesthetics and a direct depressant action on nerves.[60] However, a controlled clinical study was unable to demonstrate a superior effect of lidocaine hydrocarbonate in IAN blocks.[60]

Diphenhydramine as a Local Anesthetic Agent

Diphenhydramine (Benadryl) has been advocated for patients who are allergic to commonly used local anesthetics. Two studies found that diphenhydramine was less effective than lidocaine for extractions.[286,432] Another study found that the combinations of lidocaine/diphenhydramine with epinephrine, and diphenhydramine with epinephrine, were significantly less effective for pulpal anesthesia than lidocaine with epinephrine for IAN blocks.[440] These researchers also found that the diphenhydramine solutions were more painful on injection and had a high incidence of moderate postoperative pain.

Addition of Meperidine to Lidocaine

Two studies found that the addition of meperidine (Demerol) to a lidocaine formulation did not increase the success of the IAN block.[37,151]

FACTORS IN FAILURE OF THE INFERIOR ALVEOLAR NERVE BLOCK

Accessory Innervation: Mylohyoid Nerve

The mylohyoid nerve is the accessory nerve most often cited as a cause of failure of mandibular anesthesia.[127,441] A controlled clinical trial compared the IAN block alone to a combination of the IAN block and a mylohyoid nerve block using 2% lidocaine with 1:100,000 epinephrine (Fig. 4-8), which was aided by the use of a peripheral nerve stimulator.[66] The investigators found that the mylohyoid injection did not significantly enhance pulpal anesthesia of the IAN block (Fig. 4-9), so the study does not support the hypothesis that the mylohyoid nerve is a major factor in failure of the IAN block.

Accuracy of Injection

It has been theorized that an inaccurate injection contributes to inadequate mandibular anesthesia, but a number of studies determined that the use of ultrasound, a peripheral nerve stimulator, or radiographs to guide needle placement for IAN blocks did not result in more successful pulpal anesthesia.[35,134,165,387] The authors of these studies speculated that the anesthetic solution migrated along the path of least resistance, which was determined by fascial planes and structures encountered in the pterygomandibular space. These studies highlight an important clinical point: Lack of pulpal anesthesia is not necessarily the result of an inaccurate injection.

Needle Deflection

Needle deflection has been proposed as a cause of failure with the IAN block.[70,83,182] Several in vitro studies have shown that beveled needles tend to deflect toward the nonbeveled side (i.e., away from the bevel).* To compensate for this, a bidirectional needle rotation technique using the computer-controlled local anesthetic delivery system (CCLAD) (Milestone Scientific, Livingston, New Jersey) has been proposed in which the CCLAD handpiece assembly and needle are rotated in a fashion similar to the rotation of an endodontic hand file.[182] The technique was found to reduce deflection during insertion of the needle. A controlled clinical trial compared the anesthetic success of the conventional IAN block using two needle insertion methods.[224] However, no significant difference in anesthetic success was seen when the needle bevel was oriented away from the mandibular ramus (so that the needle would deflect toward the mandibular foramen [50% success]) compared with the bidirectional CCLAD needle rotation technique (56% success).[224] Neither technique resulted in an acceptable rate of anesthetic success in patients with symptomatic irreversible pulpitis.

Needle Bevel and Success

In asymptomatic subjects, the orientation of the needle bevel away or toward the mandibular ramus for an IAN block did

*References 13, 70, 83, 182, 199, and 363.

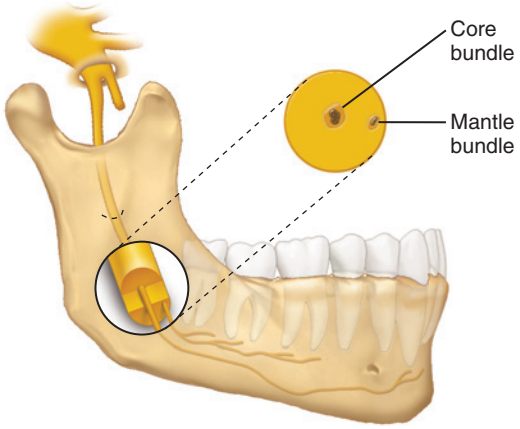

FIG. 4-10 Central core theory. The axons in the mantle bundle supply the molar teeth, and those in the core bundle supply the anterior teeth. The extraneural local anesthetic solution diffuses from the mantle to the core. (Modified and redrawn from De Jong RH: *Local anesthetics,* St Louis, 1994, Mosby.)

not affect anesthetic success or failure.[405] Therefore, the use of commercial needles with markers to indicate the needle bevel is not necessary.

Speed of Injection and Success

A slow inferior alveolar nerve block increases success over a fast injection[204] but not for patients diagnosed with irreversible pulpitis.[9]

Cross-Innervation

Cross-innervation from the contralateral inferior alveolar nerve has been implicated in failure to achieve anesthesia in anterior teeth after an IAN injection. Experimentally, cross-innervation occurs in incisors[367,458] but plays a very small role in failure of an IAN block.

Red Hair

In medicine, red-haired females have shown reduced subcutaneous efficacy of lidocaine and increased requirements for desflurane.[102] However, in dentistry, having red hair was unrelated to success rates of the inferior alveolar nerve block,[102] although it has been shown to be associated with higher levels of dental anxiety.[102]

A Theory on Why Failure Occurs with the Inferior Alveolar Nerve Block in Restorative Dentistry

The central core theory may be the best explanation of why failure occurs with the IAN block.[85,407] According to this theory, nerves on the outside of the nerve bundle supply molar teeth, and nerves on the inside of the nerve bundle supply anterior teeth (Fig. 4-10). Even if deposited at the correct site, the anesthetic solution may not diffuse into the nerve trunk and reach all nerves to produce an adequate block. Although this theory may explain the higher experimental failure rates with the IAN block in anterior teeth compared with posterior teeth,* it does not explain the increased failure rate observed in painful teeth.

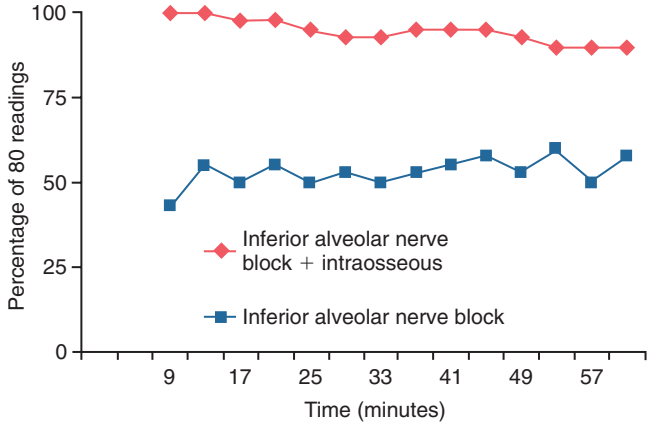

FIG. 4-11 Incidence of first mandibular molar anesthesia: comparison of the combination intraosseous injection of 2% lidocaine with 1:100,000 epinephrine plus the inferior alveolar nerve block to the inferior alveolar nerve block alone. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. The combination technique was significantly better at all postinjection times.

ENHANCEMENT OF MANDIBULAR ANESTHESIA FOR RESTORATIVE DENTISTRY

Supplemental Articaine Infiltrations

An important clinical finding is that an articaine infiltration of the first molar, premolars, and anterior teeth after an IAN block should provide pulpal anesthesia for approximately 1 hour.[163,206,326] The second molar may require a supplemental intraosseous (IO) or intraligamentary (IL) injection to achieve success.

Supplemental Intraosseous Anesthesia

Supplemental IO injections of lidocaine and mepivacaine with vasoconstrictors allow quick onset and increase the success of the inferior alveolar nerve block for approximately 60 minutes (Fig. 4-11).[103,158] The addition of a supplemental IO injection reduced the incidence of slow onset of pulpal anesthesia to zero compared with the IAN block alone (18% incidence).[103] Using 3% mepivacaine plain for IO injection results in pulpal anesthesia for approximately 30 minutes (Fig. 4-12).[137]

Supplemental Intraligamentary Anesthesia

Supplemental IL injections of 2% lidocaine with 1:100,000 epinephrine increase the success of the inferior alveolar nerve block, but the duration is approximately 23 minutes.[61]

MAXILLARY ANESTHESIA FOR RESTORATIVE DENTISTRY

Descriptions of conventional techniques for maxillary anesthesia are available for review in numerous articles and textbooks.[195,262]

2% Lidocaine with 1:100,000 Epinephrine

As a frame of reference, the most commonly used injection for anesthetization of maxillary teeth is infiltration with a cartridge of 2% lidocaine with 1:100,000 epinephrine.

http://dentalebooks.com

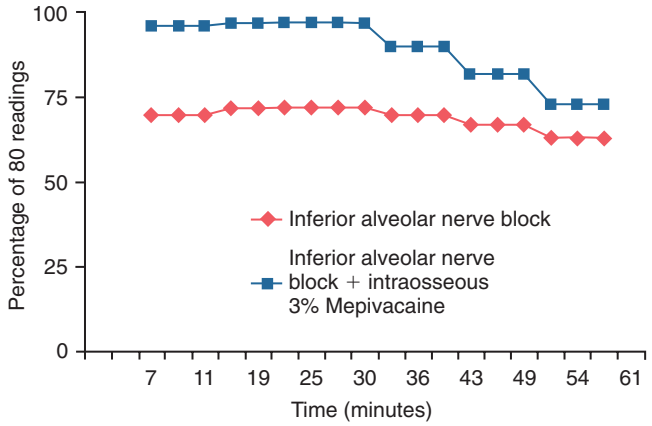

FIG. 4-12 **Incidence of first mandibular molar anesthesia: comparison of the combination intraosseous injection with 3% mepivacaine plus the inferior alveolar nerve block to the inferior alveolar nerve block alone.** Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. The combination technique proved significantly better for approximately 30 minutes.

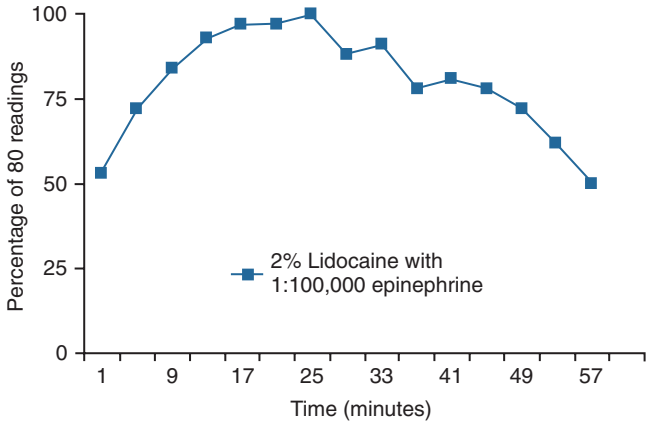

FIG. 4-13 Incidence of first maxillary molar anesthesia, as determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes.

Anesthetic Success

Infiltration results in a fairly high incidence of successful pulpal anesthesia (around 87% to 92%).* However, some patients may not be anesthetized because of individual variations in response to the drug administered, operator differences, and variations of anatomy and tooth position.

Onset of Pulpal Anesthesia

Pulpal anesthesia usually occurs in 3 to 5 minutes.†

Duration of Pulpal Anesthesia

The duration of pulpal anesthesia is a problem with maxillary infiltrations.‡ Pulpal anesthesia of the anterior teeth declines after about 30 minutes, with most losing anesthesia by 60 minutes.§ In premolars and first molars, pulpal anesthesia is good until about 40-45 minutes and then it starts to decline.‖ Additional local anesthetic should be administered depending on the duration of the procedure and the tooth group affected.

Time Course of Pulpal Anesthesia for the Maxillary First Molar

Figure 4-13 shows the time course for complete pulpal anesthesia for an asymptomatic first molar, as defined by the percentage of patients who do not respond at all to an EPT stimulus over time. Some patients had a slow onset of anesthesia until around 11 minutes. The overall success rate (no response at the device's highest setting) is 95% to 100%, with peak effects observed at around 30 minutes after injection.

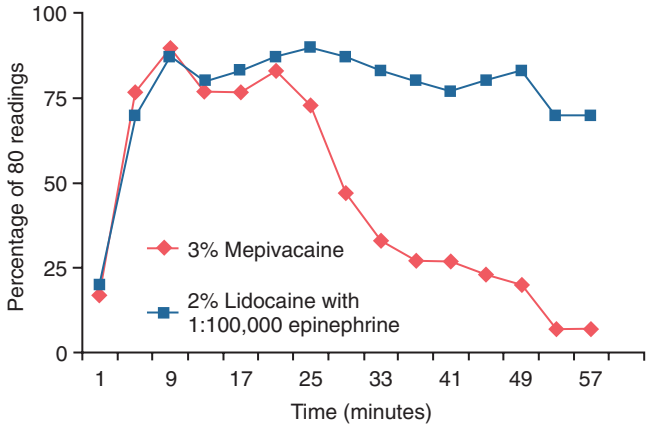

FIG. 4-14 **Incidence of first maxillary molar anesthesia: comparison of 3% mepivacaine to 2% lidocaine with 1:100,000 epinephrine.** Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. The 3% mepivacaine showed a shorter duration of anesthesia than the lidocaine solution.

Significance of Lip Numbness

Soft tissue anesthesia (lip or cheek numbness) is not necessarily related to the duration of pulpal anesthesia. Pulpal anesthesia does not last as long as soft tissue anesthesia.[156,272,287]

ALTERNATIVE ANESTHETIC SOLUTIONS FOR INFILTRATIONS

Plain Solutions: 3% Mepivacaine (Carbocaine, Polocaine, Scandonest) and 4% Prilocaine (Citanest Plain)

Anesthesia duration is shorter with these solutions.[211,272] Therefore, use these for procedures of short duration (10 to 15 minutes) (Fig. 4-14). These agents are generally not as safe as solutions with vasoconstrictors if *large* volumes are administered because they are rapidly absorbed systemically, resulting in excessive plasma concentrations and possible toxic reactions.[262]

http://dentalebooks.com

4% Prilocaine with 1:200,000 Epinephrine (Citanest Forte), 2% Mepivacaine with 1:20,000 Levonordefrin (Carbocaine with Neo-Cobefrin), and 4% Articaine with 1:100,000 Epinephrine (Septocaine, Articadent, Zorcaine)

These formulations are similar to 2% lidocaine with 1:100,000 epinephrine.[108,211,246]

0.5% Bupivacaine with Epinephrine (Marcaine)

Success rates (no response to EPT) with bupivacaine range from 80% to 95% in the maxillary lateral incisor, compared with 50% in the maxillary second premolars.[81,156,223,410] Although bupivacaine provides long-term anesthesia with the IAN block, it *does not* provide prolonged pulpal anesthesia with maxillary infiltration injection.[81,156,223] In the lateral incisor, bupivacaine has a shorter duration of pulpal anesthesia than lidocaine.[81,156] In the first molar, bupivacaine's duration of pulpal anesthesia is equivalent to that of lidocaine.[156] Neither agent provides pulpal anesthesia for an hour.[81,156]

EXTENDING THE DURATION OF PULPAL ANESTHESIA FOR MAXILLARY TEETH

Increasing the Solution Volume

A two-cartridge volume of 2% lidocaine with epinephrine extends the duration of pulpal anesthesia but not for 60 minutes.[287]

Increasing the Epinephrine Concentration

Increasing the epinephrine concentration to 1:50,000 epinephrine increases duration for the lateral incisor but not the first molar.[272] Duration was not 60 minutes in either teeth.[272]

Repeating the Infiltration

Adding another cartridge of 2% lidocaine with epinephrine at 30 minutes in anterior teeth and 45 minutes in posterior teeth significantly improves the duration of pulpal anesthesia and may be the best way to extend the duration of pulpal anesthesia (Fig. 4-15).[381]

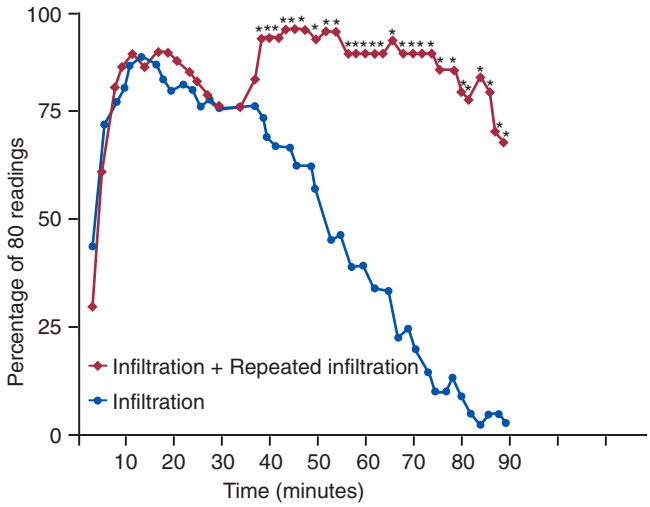

FIG. 4-15 Incidence of maxillary lateral incisor pulpal anesthesia using an initial infiltration and a repeated infiltration 30 minutes later (both infiltrations used 1.8 ml of 2% lidocaine with 1:100,000 epinephrine). Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings). The repeated infiltration injection significantly prolonged the duration of pulpal anesthesia.

ALTERNATIVE MAXILLARY INJECTION TECHNIQUES FOR RESTORATIVE DENTISTRY

Posterior Superior Alveolar (PSA) Nerve Block

The PSA nerve block anesthetizes the second molars and about 80% of first molars.[257,343] An additional mesial infiltration injection may be necessary to anesthetize the first molar. Generally, the PSA block injection is not advocated for routine restorative procedures. An infiltration of the molars is preferred.

Infraorbital Nerve Block

The infraorbital nerve block results in lip numbness but does not predictably anesthetize incisor pulps.[33,209] It usually anesthetizes the canines and premolars, but the duration is less than 1 hour.[33,209] Essentially, this injection technique is the same as an infiltration injection over the premolar teeth for pulpal anesthesia. Generally, the infraorbital injection is not advocated for routine restorative procedures. An infiltration of the individual maxillary teeth is preferred.

Second Division Nerve Block

The second division nerve block usually anesthetizes pulps of molars and some second premolars but does not predictably anesthetize first premolars, canines, or lateral and central incisors.[47,117] The high tuberosity technique is preferred to the greater palatine approach because it is easier and less painful.[47] Generally, the second division nerve block is not advocated for routine restorative procedures. An infiltration of the individual teeth is preferred.

Palatal–Anterior Superior Alveolar (P-ASA) Nerve Block

Traditionally, maxillary anterior teeth have been anesthetized with an infiltration injection near the apex of the target tooth. In the late 1990s, the P-ASA injection, a site-specific injection for maxillary anterior teeth, was introduced.[125,126] The P-ASA injection involves a palatal injection into the incisive canal; it derives its name from the injection's supposed ability to anesthetize both the right and left anterior superior alveolar nerves (Fig. 4-16). Unfortunately, the injection technique does not provide predictable pulpal anesthesia for the incisors and canines[50] and is often painful.[318]

Anterior Middle Superior Alveolar (AMSA) Nerve Block

The AMSA injection is another new technique for anesthetizing maxillary teeth.[123,124,126,130] The AMSA injection site is located palatally at a point that bisects the premolars and is approximately halfway between the midpalatine raphe and the crest of the free gingival margin (Fig. 4-17). The AMSA injection

http://dentalebooks.com

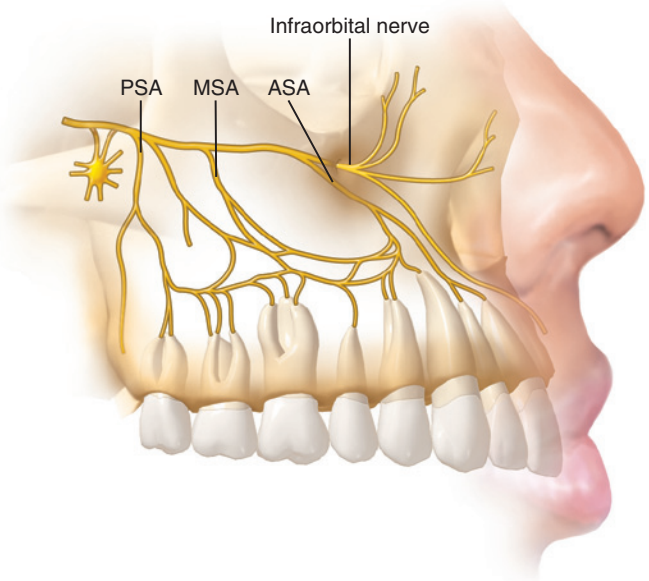

FIG. 4-16 Distribution of the maxillary division of the trigeminal nerve, showing the anterior superior alveolar (ASA) nerve, the middle superior alveolar (MSA) nerve, and the posterior superior alveolar (PSA) nerve.

FIG. 4-17 Palatal injection site for the anterior middle superior alveolar (AMSA) injection.

supposedly can anesthetize both the anterior and middle superior alveolar nerves[123,124,126] (see Fig. 4-16), resulting in unilateral anesthesia of the maxillary central and lateral incisors, canines, and first and second premolars. Unfortunately, the injection technique does not provide predictable pulpal anesthesia for these maxillary teeth[247] and is often painful.[321]

Pain, Inflammation, and Anxiety

Results differ from the normal when anesthesia is given to patients with any of these conditions.

SUPPLEMENTAL ANESTHESIA FOR RESTORATIVE DENTISTRY IN THE MANDIBLE AND MAXILLA

Indications

A supplemental injection is used if the standard injection is not effective. It is useful to repeat an initial injection only if the patient is not exhibiting the "classic" signs of soft tissue anesthesia (e.g., numbness of the lip). Generally, if the classic signs are present, reinjection is not very effective.[208] For example, after the inferior alveolar nerve block, the patient develops lip, chin, and tongue numbness and quadrant "deadness" of the teeth. A useful procedure is to pulp test the tooth with a cold refrigerant or an electrical pulp tester before the cavity preparation is begun.[56,100] If the patient feels pain to cold, a supplemental injection is indicated. To think that reinjection using the inferior alveolar nerve block approach will be successful is wishful thinking; failure the first time is usually followed by failure on the second attempt. Clinicians may think another injection is helpful because the patient sometimes achieves pulpal anesthesia after the second injection, but the patient may simply be experiencing slow onset of pulpal anesthesia from the first injection.

The clinician should go directly to a supplemental technique. Three such injections are *the infiltration injection; the IO injection; and the IL injection (formerly called the periodontal ligament [PDL] injection)*.

Infiltrations

Additional Infiltration of Lidocaine in the Maxilla

Because the duration of pulpal anesthesia for infiltration in the maxilla is not 60 minutes, adding an additional cartridge of 2% lidocaine with 1:100,000 epinephrine at 30 minutes in the anterior teeth and at about 45 minutes in premolar and molar teeth significantly improves the duration of pulpal anesthesia. This is an important clinical finding and may be the best way to extend the duration of pulpal anesthesia in maxillary teeth.[381]

Additional Infiltration of Articaine in the Mandible

Another important clinical finding is that an articaine infiltration of the first molar, premolars, and anterior teeth after an inferior alveolar nerve block should provide pulpal anesthesia for approximately 1 hour.[163,206,326] The second molar may require a supplemental IO or IL injection to achieve success.

Intraosseous Anesthesia

The IO injection is a supplemental technique that has been shown to be effective through substantial research and clinical usage. It is particularly useful in conjunction with a conventional injection when it is likely that supplemental anesthesia will be necessary (e.g., in mandibular second molar teeth).[103,137,158] The IO injection allows placement of a local anesthetic directly into the cancellous bone adjacent to the tooth. When a primary IO injection was compared with an infiltration injection, the IO technique showed a quicker onset and a shorter duration of anesthesia (Fig. 4-18).[324]

The Stabident IO system (Fairfax Dental Inc., Miami, Florida) is composed of a slow-speed, handpiece-driven perforator and a solid 27-gauge wire with a beveled end that drills a small hole through the cortical plate (Fig. 4-19). The anesthetic solution is delivered to cancellous bone through the 27-gauge, ultrashort injector needle placed into the hole made by the perforator (Fig. 4-20).

The X-Tip IO anesthetic delivery system (Dentpsly International, York, Pennsylvania) consists of an X-tip that separates into two parts, the drill and the guide sleeve (Fig. 4-21). The drill, a special hollow needle, leads the guide sleeve through the cortical plate; it then is separated from the guide sleeve and withdrawn. The remaining guide sleeve is designed to accept a 27-gauge needle for injection of the anesthetic

http://dentalebooks.com

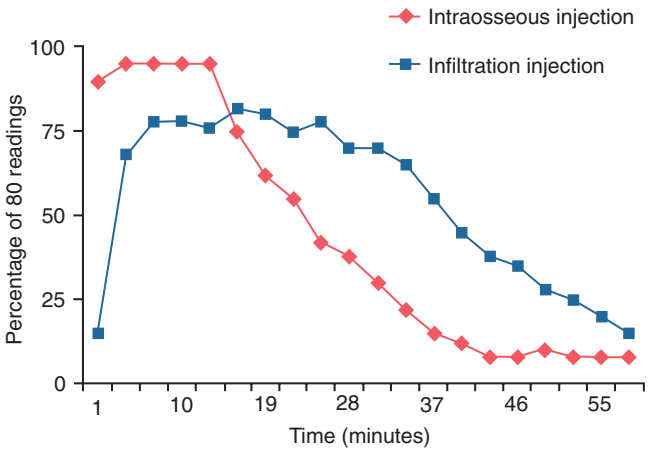

FIG. 4-18 **Incidence of anesthesia for intraosseous and infiltration injections.** Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. The intraosseous injection showed a quicker onset and a shorter duration of anesthesia.

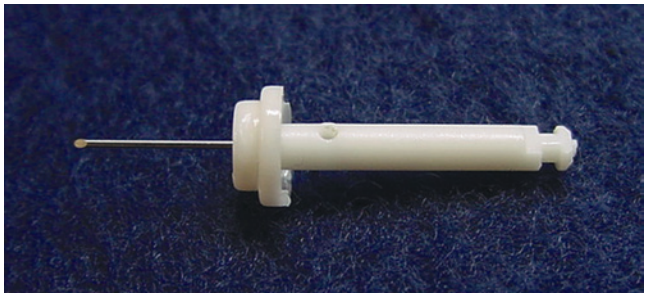

FIG. 4-19 The Stabident perforator, a solid, 27-gauge wire with a beveled end that is placed in a slow-speed handpiece.

FIG. 4-20 The anesthetic solution is delivered to the cancellous bone through the needle placed into the hole made by the perforator.

solution (Fig. 4-22). The guide sleeve is removed after the IO injection is complete.

The technique for IO injection of anesthetic using the Stabident or X-Tip system can be reviewed in the systems' instruction manuals or in published papers.[67,138,356-358]

Success

Supplemental IO injections of lidocaine and mepivacaine with vasoconstrictors allow quick onset and increase the success of

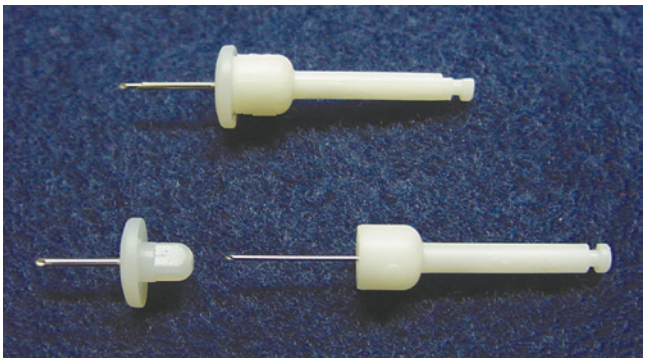

FIG. 4-21 The X-Tip anesthetic delivery system consists of an X-tip *(top)* that separates into two parts: the drill (a special hollow needle) and the guide sleeve component *(bottom)*.

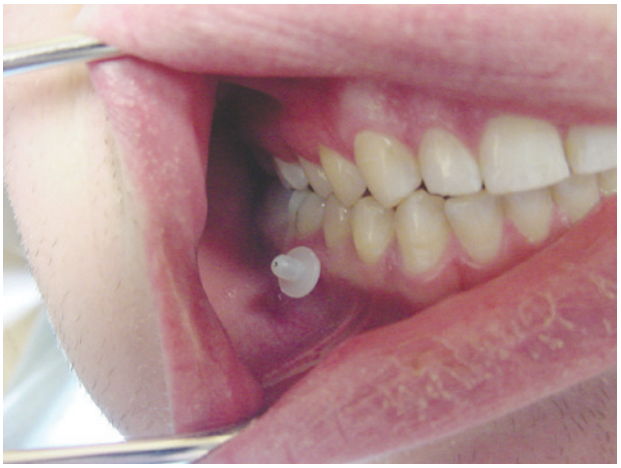

FIG. 4-22 Anesthetic solution is injected through the X-tip guide sleeve.

the inferior alveolar nerve block for approximately 60 minutes (see Fig. 4-11)[103,158] The addition of a supplemental IO injection reduced the incidence of slow onset of pulpal anesthesia to zero compared with the IAN block alone (18% incidence).[103] Using 3% mepivacaine plain results in pulpal anesthesia for approximately 30 minutes (see Fig. 4-12).[137]

Failure

If the anesthetic solution flows out of the perforation site (backflow), anesthetization will not occur.[139] Reperforation or use of another perforation site is a practical way to gain access to the cancellous bone in such cases. In fewer than 10% of cases, constricted cancellous spaces may limit the distribution of the anesthetic solution around the apices of the teeth.* In such cases, failure may result even if the anesthetic solution is delivered intraosseously.

Perforator Breakage

In about 1% of cases, the metal perforator separates from the plastic shank during use.[67,103,139,320,356-358] The metal wire is easily removed with a hemostat. This separation usually occurs during a difficult perforation (e.g., dense cortical bone); the wire probably is heated excessively, causing the plastic hub to melt. No perforator breakage (metal perforator breaking into parts) has been reported in numerous controlled clinical studies.[67,103,139,320,356-358] However, excessive torquing of the

*References 67, 103, 139, 158, 320, 323, 355-358, and 402.

http://dentalebooks.com

perforator laterally by an inexperienced operator may result in breakage.

Optimal Location for Injection Site

Injection at a site distal to the tooth to be anesthetized produces the best anesthesia.* Maxillary and mandibular second molars are an exception to this rule. A mesial site should be selected for these teeth because of the increased thickness of the cortical plate in the mandible and the difficulty with perforation and needle placement at a distal site.

Onset of Anesthesia

The onset of anesthesia is immediate, which eliminates the waiting period.†

Site Selection: Attached Gingiva or Alveolar Mucosa

Both the Stabident and X-Tip IO systems instruct the user to locate the perforation site in attached gingiva. This gingival site allows the perforation to be made through a minimal thickness of cortical bone and generally is equidistant between adjacent root structures. However, because the guide sleeve remains in place with the X-Tip system, two studies have successfully used it in alveolar mucosa at a more apical location.[139,320] The X-Tip system has a definite clinical advantage over the Stabident system because the X-Tip perforation may be made at an apical location in unattached gingiva. If the Stabident system is used apically in alveolar mucosa, the hole created for delivering the anesthetic solution is almost impossible to find. The clinician may want to consider using the X-Tip system in an apical location in specific clinical situations. For example, when periodontal pocketing does not allow perforation into cancellous bone through the more coronal attached gingiva or when interproximal space is lacking (i.e., roots are too close together), the X-Tip system can be used to achieve pulpal anesthesia. If the Stabident system fails, the clinician may want to consider using the X-Tip apically to achieve pulpal anesthesia.

Care must be taken during IO injection to avoid insertion in areas of the roots and other critical structures, such as the mental foramen.

Injection Discomfort

When the IO injection is used as a primary injection, pain is experienced about a fourth of the time.[67,138,356-358] When the IO injection is used as a supplemental injection, fewer patients experience pain.[103,137,158,356,402]

Duration

With a primary IO injection, the duration of pulpal anesthesia declines steadily over an hour.[67,358] There is an even shorter duration with 3% mepivacaine compared with 2% lidocaine with 1:100,000 epinephrine.[358] With a supplemental IO injection of lidocaine after the inferior alveolar nerve block in patients without pain, the duration of pulpal anesthesia is very good for an hour.[103,158] A solution of 3% mepivacaine used as a supplemental IO injection results in a shorter anesthetic duration.[137]

Repeating the Intraosseous Injection

Repeating the IO injection, using 1.4 ml of 2% lidocaine with 1:100,000 epinephrine 30 minutes after the initial IO injection, provides an additional 15 to 20 minutes of pulpal anesthesia, similar to the duration of the initial IO injection.[198]

Use of Bupivacaine for Intraosseous Anesthesia

In an attempt to increase the duration of pulpal anesthesia with IO injections, some clinicians may consider using long-acting anesthetics. Bupivacaine (Marcaine) is a long-acting anesthetic, but only for IAN blocks. Long-acting anesthetics do not show an extended duration of anesthesia when injected by the IO or maxillary infiltration routes.[81,156,185,402] Bupivacaine has cardiotoxic effects[28] and for IO anesthesia basically is equivalent to 2% lidocaine with epinephrine in terms of efficacy, duration, and heart rate effects. Therefore, bupivacaine offers no advantage clinically and should not be used for IO anesthesia.

Systemic Effects of Intraosseous Injection

A transient increase in heart rate has been reported in 46% to 93% of cases involving Stabident and X-Tip IO injection of solutions containing epinephrine or levonordefrin.* Four clinical trials using techniques such as objective electrocardiographic recordings and pulse oximetry have shown that subjects experienced a transient tachycardia (mean increase of 12 to 32 beats/min) after Stabident IO injection of 1.8 ml of 2% lidocaine with 1:100,000 epinephrine, 1.8 ml of 2% mepivacaine with 1:20,000 levonordefrin, or 1.8 ml of 1.5% etidocaine with 1:200,000 epinephrine.[57,158,359,402] Another clinical trial reported transient tachycardia after IO injection, but not with infiltration injection, of 1.8 ml of 2% lidocaine with 1:100,000 epinephrine in the maxillary anterior region.[444] Generally, all these studies showed that the heart rate returned to baseline readings within 4 minutes in most patients. Therefore, injection of anesthetic solutions containing vasoconstrictors, using either the Stabident or X-Tip system, results in a transient tachycardia. No significant change in diastolic, systolic, or mean arterial blood pressure has been observed with IO injection of 2% lidocaine with 1:100,000 epinephrine.[57,359]

An IO injection of 1.4 ml of 2% lidocaine with 1:100,000 epinephrine with the CCLAD (CompuDent, Milestone Scientific, Livingston, New Jersey) at a fast rate resulted in a significantly higher heart rate compared to a slow solution deposition using either the CCLAD or a traditional syringe.[408]

Clinical Significance of Increased Heart Rate

Although the patient is likely to notice the transient tachycardia that occurs after Stabident or X-Tip IO injection of 2% lidocaine with 1:100,000 epinephrine, it generally is not clinically significant in healthy patients.[359] The clinical significance, cardiovascular effects, and contraindications to the use of vasoconstrictors in IO injections have been reviewed.[359]

Lack of Heart Rate Effect of 3% Mepivacaine in Intraosseous Anesthesia

No significant tachycardia occurs when 3% mepivacaine is used for IO anesthesia.[137,359] Clinicians should keep in mind that this anesthetic is an alternative for IO injection in

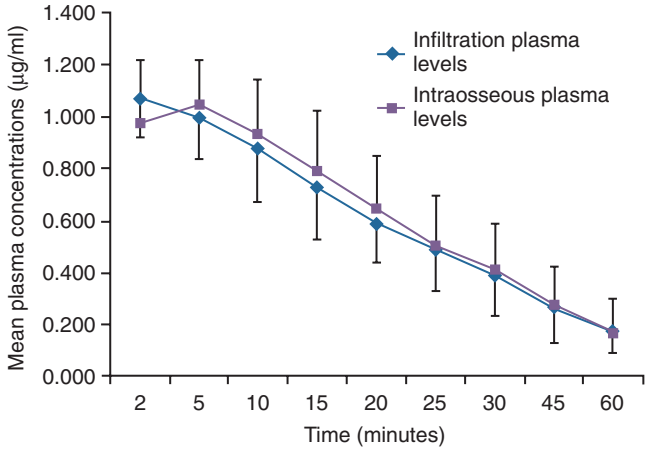

FIG. 4-23 Mean plasma concentrations of lidocaine for the intraosseous and infiltration injection techniques. No statistical differences were seen between the two techniques at any time period.

patients whose medical condition or drug therapy suggests caution in the use of solutions containing epinephrine or levonordefrin.[137,359]

Plasma Levels of Lidocaine After Intraosseous Injection

Some authors have cautioned that administration of an overly large volume of local anesthetic with an IO injection could lead to overdose reactions.[189] One experimental study using volunteers found that injection of 1.8 ml of 2% lidocaine with 1:100,000 epinephrine produced venous plasma levels of lidocaine that were the same for maxillary anterior IO and infiltration injections (Fig. 4-23).[444] Although systemic concentrations of vasoconstrictors have a short-lived effect on the heart rate, the plasma concentration of lidocaine delivered with IO injection is no more than that delivered with infiltration, so the IO technique should not be considered an intravascular injection with regard to lidocaine. Also, if it were an intravascular injection, little or no anesthetic effect would be demonstrated; that is, all the local anesthetic solution would be carried into the vascular system, with none left for pulpal anesthesia. Obviously, clinical and experimental studies have demonstrated clinical anesthesia with IO techniques.* Therefore, the precautions for the maximum amount of lidocaine for an infiltration injection would seem to apply to an IO injection.

Postoperative Discomfort

When IO injections are given with the Stabident system, either as a primary or a supplemental technique, most patients report no or only mild pain; approximately 2% to 15% report moderate pain.[67,158,356-358] Less postoperative discomfort is reported for the Stabident IO injection than for IL injection.[379]

One study found that significantly more men experienced postoperative pain with the X-Tip system than with the Stabident system.[138] The authors interpreted these results as being due to the denser, more mineralized bone in the posterior mandible in men and to the fact that the diameter of the X-Tip perforating system is larger than that of the Stabident perforator, meaning the X-Tip system generates more frictional heat during perforation.

*References 67, 103, 139, 320, 323, and 355-358.

Postoperative Problems

With the Stabident system, fewer than 5% of patients develop swelling or exudate at the site of perforation.[67,158,356-358] The X-Tip system may show a higher incidence of postoperative swelling clinically.[138] With both systems, swelling or exudate (or both) may persist for weeks after the injection, but this resolves with time.[67,138,158,356-358] Slow healing of perforation sites may be the result of overheating of the bone caused by pressure during perforation.

With both the Stabident and X-Tip systems, approximately 4% to 15% of patients report that for a few days, the tooth "feels high" during chewing.[67,138,158,356-358] This feeling most likely is an increased awareness to biting that results from soreness in the area caused by damage from perforation or inflammation of the bone. The incidence of this feeling for the IO injection is lower than that reported for the IL injection (36% to 49%).[79,379]

Medical Contraindications

Patients taking antidepressants, nonselective beta-blocking agents, medicine for Parkinson disease, and cocaine should not receive IO injections of solutions containing epinephrine or levonordefrin.[353] Three percent mepivacaine plain is preferred.

Intraligamentary Anesthesia

The IL injection is another technique that is used if a conventional injection is unsuccessful.[397,428] The technique for IL injection of anesthesia is reviewed in a number of published papers and textbooks.

Success

For use as a primary injection, IL injections have a reported success rate of about 75% in mandibular and maxillary posterior teeth, with a duration of pulpal anesthesia of 10 to 15 minutes.[379,436] Success rates are low in anterior teeth.[280,379,436]

For use as a supplemental injection (standard techniques have failed to provide adequate anesthesia), good success rates are achieved, but the duration of pulpal anesthesia is approximately 23 minutes.[61]

Mechanism of Action

An IL injection forces anesthetic solutions through the cribriform plate into the marrow spaces around the tooth.[101,129,352,396,430] The primary route is *not* via the periodontal ligament, and unlike the intrapulpal (IP) injection,[38,423] the mechanism of action is not a pressure anesthesia.[105,296] The IL injection should be considered an intraosseous injection.

Back-Pressure

Studies have shown that the most important factor for anesthetic success with an IL injection is injection under *strong back-pressure*.[396,428] Pressure is necessary to force the solution into the marrow spaces.

Anesthetic Solutions

A vasoconstrictor significantly increases the efficacy of an IL injection.[155,213,228,278,379] Injection of a vasoconstrictor alone (1:100,000 epinephrine) does not produce pulpal anesthesia.[379] Anesthetic solutions with reduced vasoconstrictor concentrations (bupivacaine with 1:200,000 epinephrine) are not very effective with this technique.[155,200,213] Articaine is equivalent to lidocaine.[34]

http://dentalebooks.com

Amount of Solution Delivered

Usually about 0.2 ml of solution is deposited with each mesial and distal injection, using a traditional or pressure syringe. The exact amount is not always known because some of the anesthetic solution may escape from the sulcus during the injection.

Injection Discomfort

When the IL injection is used as a primary injection, needle insertion and injection have the potential to be painful about a third of the time.[296,379,436] The IL injection may be quite painful in maxillary anterior teeth[436] and should not be used in these teeth; infiltration is preferred. The potential for pain with the IL technique is greatly reduced when the injection is used as a supplemental injection after an inferior alveolar nerve block.[61]

Onset of Anesthesia

The onset of anesthesia is immediate with an IL injection,* which means no waiting period is required for the anesthesia to take effect. If anesthesia is still not adequate, reinjection is necessary.

Duration

Experimental studies with the EPT have shown that when the IL injection is given as a primary injection, the duration of profound pulpal anesthesia is approximately 10 to 20 minutes.[296,379,436] When the injection is used as a supplemental technique in asymptomatic teeth after an IAN block, the duration of pulpal anesthesia is approximately 23 minutes.[61]

New Technology for Intraligamentary Injections: CCLAD

A computer-assisted local anesthetic delivery system, introduced by Milestone Scientific, can be used to administer an IL injection. The CCLAD (also called *CompuDent* or *The Wand*) accommodates a standard local anesthetic cartridge that is linked by sterile microtubing to a disposable, penlike handpiece with a Luer-Lok needle (Fig. 4-24). The device is activated by a foot control, which automates the infusion of local anesthetic solution at a controlled rate. The fast rate delivers 1.4 ml of solution in 1 minute. The slow rate delivers 1.4 ml of solution in approximately 4 minutes, 45 seconds. The slow rate is used for the IL injection.

Anesthetic Success of the IL Injection Using the CCLAD

An experimental study compared the anesthetic efficacy of primary IL injection of 1.4 ml of 4% articaine with 1:100,000 epinephrine and 1.4 ml of 2% lidocaine with 1:100,000 epinephrine administered with a CCLAD in the mandibular first molar.[34] Successful pulpal anesthesia (two consecutive maximum EPT readings) was obtained 86% of the time with the articaine solution and 74% of the time with the lidocaine solution. No significant difference was seen between the articaine and lidocaine solutions. The duration of pulpal anesthesia ranged from 31 to 34 minutes, longer than the 10 minutes recorded in a similar study using a pressure syringe and 0.4 ml of a lidocaine solution.[436] Therefore, the CCLAD system offers the advantage of increasing the duration of pulpal anesthesia; however, the anesthesia slowly decreases over 60 minutes.

FIG. 4-24 Wand computer-assisted local anesthetic delivery unit (The Wand/CompuDent). The handpiece assembly and microtubing are also shown. (Courtesy Milestone Scientific, Livingston, NJ.)

Postoperative Discomfort

When the IL injection is used as a primary technique, postoperative pain occurs in a third to three quarters of patients, with a duration of 14 hours to 3 days.[79,296,379,397,428,436] There is no difference between articaine and lidocaine.[34] The discomfort is related to damage from needle insertion rather than to the pressure of depositing the solution.[79] About a fourth of patients report that their tooth feels "high" in occlusion.[379,436]

Systemic Effects

When a high-pressure syringe was used in dogs, IL injection of solutions containing epinephrine caused cardiovascular responses similar to those seen with IV injections.[395] Clinical studies using a high-pressure syringe in human beings found that IL injections of such solutions did not significantly change the heart rate, rhythm, or amplitude or the blood pressure.[53,317] These studies support the conclusion that IL injections do not cause significant changes in heart rate in human beings.

Other Factors

Different needle gauges (25, 27, or 30 gauge) are equally effective.[428] Special pressure syringes have been marketed but have not been proven more effective than a standard syringe.[379,428,436]

Safety of the Periodontium

Clinical and animal studies have demonstrated the relative safety of the IL injection technique.* Minor transient damage occurs only at the site of needle penetration, and the tissue subsequently undergoes repair. In rare cases, periodontal abscesses and deep pocket formation have occurred after IL injections.[61,436] A small clinical risk of periodontal abscess formation and bone loss exists with this technique, and although these effects are rare, the clinician should be aware of them. Localized areas of root resorption after IL injections have also been reported.[339,361]

*References 45, 128, 129, 135, 255, 296, 340, 379, 428, and 436.

http://dentalebooks.com

Safety of the Pulp

Clinical and animal studies have shown that IL injections have no permanent effect on the pulp.* However, IL injection of a solution with epinephrine produces a rapid, prolonged decrease in blood flow.[228] Some have suggested that using this injection technique during restorative procedures could result in accumulation of inflammatory mediators that would not be effectively removed because of the reduced blood flow.[228] This hypothesis was directly tested, and the IL injection of an anesthetic solution containing a vasoconstrictor in conjunction with a deep cavity preparation did *not* produce a more severe reaction than in controls (cavity preparation only).[344] Rather, the depth of the cavity preparation was the most important factor dictating pulpal responses. IL injections are therefore unlikely to cause pulpal necrosis.

Safety in Primary Teeth

One study has shown that IL injection of primary teeth may cause enamel hypoplasia of the developing permanent teeth.[45] The effect noted was not caused by the injection technique, but by the anesthetics used; that is, the cytotoxic anesthetic agents bound to the enamel matrix in the developing tooth germ. The same effect seemingly would be produced by an infiltration injection next to the developing tooth, so the recommendation that IL injections be used with great care on primary teeth close to developing permanent teeth[45] may not be correct.

Safety in Periodontally Involved Sites

IL injections have been shown to be safe in cases of mild to moderate gingival inflammation or incipient periodontitis.[76]

Avulsion

In a letter to the editor of the *Journal of the American Dental Association,* Nelson[311] reported on the avulsion of a tooth after IL injections. However, *no* clinical or experimental study has reported avulsion or loosening of teeth with this technique.[296,379,436] Avulsion should not be a concern with IL injections.

LOCAL ANESTHESIA FOR ENDODONTICS

For an emergency patient presenting with a tooth diagnosed with symptomatic irreversible pulpitis, anesthesia is administered with a standard IAN block. The patient reports classic signs of anesthesia (lip numbness and a dull feeling of the tooth or quadrant). After isolation, access preparation is begun. When the bur is in enamel, the patient feels nothing. Once the bur enters dentin (or possibly not until the pulp is exposed), the patient feels sharp pain. Obviously, pulpal anesthesia is not profound, and additional anesthetic is required. The following discussion outlines useful information for anesthetizing these endodontic patients.

Success of the Inferior Alveolar Nerve Block in Patients Presenting with Symptomatic Irreversible Pulpitis

Endodontic clinical studies of mandibular posterior teeth in patients with irreversible pulpitis have shown success occurs 14% to 57% of the time.* Articaine is not superior to lidocaine in this group of patients.[64,364,415] Nor is bupivacaine statistically superior to lidocaine.[376]

Some authors have suggested that a two-cartridge volume is better than a one-cartridge volume.[7] However, others did not find a statistically significant difference between one- and two-cartridge volumes.[336] In addition, a number of studies have used a two-cartridge volume, and success rates are similar to those for a one-cartridge volume.[122,253,330,390]

The epinephrine concentration in 2% lidocaine does not seem to make a difference in success in patients with symptomatic irreversible pulpitis.[8]

Success of Maxillary Molar Infiltration in Patients Presenting with Irreversible Pulpitis

Endodontic clinical studies of maxillary posterior buccal infiltrations in patients presenting with irreversible pulpitis have shown success occurs 54% to 88% of the time.[6,207,323] Although some authors have found a difference between articaine and lidocaine,[401] others have not.[27,207,370,384]

Asymptomatic Irreversible Pulpitis Versus Symptomatic Irreversible Pulpitis

Patients who have spontaneous pain and have moderate to severe pain at an emergency visit (symptomatic irreversible pulpitis) have less successful anesthesia after an inferior alveolar nerve block than patients who do not have spontaneous pain or only have pain when the tooth is stimulated (asymptomatic irreversible).[23] It is important to distinguish between these patients, because the success rates differ.

Supplemental Techniques

Infiltrations

Supplemental Buccal, Lingual, or Buccal Plus Lingual Infiltrations of Articaine

Although the infiltration of articaine is effective in restorative dentistry as a supplemental technique (after the inferior alveolar nerve block),[163] its use in endodontically involved teeth does not result in predictable pulpal anesthesia.[273,330,390] Success rates in studies have ranged from 38% to 84%, with most studies reporting success rates less than 60%.† A buccal infiltration of lidocaine is also not effective (65% success).[336]

Buccal infiltration alone, buccal plus lingual infiltrations alone (or after an inferior alveolar nerve block) do not result in complete pulpal anesthesia.‡ Therefore, IO and IL injections are the preferred techniques for supplemental anesthesia, and the IP injection is indicated when the IO or IL injection is not successful.

Intraosseous Anesthesia

Success in Symptomatic Irreversible Pulpitis

High success rates (around 90%) have been reported when the IO injection was used as a supplemental injection with

*References 251, 296, 342, 361, 379, and 436.

‡References 3, 4, 10, 98, 109, and 346.

http://dentalebooks.com

irreversible pulpitis.[36,273,320,323,330] There is no difference between lidocaine and articaine.[36] Three percent mepivacaine has an 80% success rate, which increases to 98% with a second IO injection of 3% mepivacaine.[355]

An initial supplemental IO injection of 0.45 to 0.9 ml of 2% lidocaine with 1:100,000 epinephrine was successful in 79% of posterior mandibular teeth.[332] A second IO injection of the remaining cartridge increased the success rate to 91%. Therefore, initially giving a quarter to a half cartridge of 2% lidocaine with 1:100,000 epinephrine was less successful than initially giving a full cartridge.

Although some authors[338,354] have suggested an IO injection alone successfully anesthetizes patients presenting with irreversible pulpitis, it is very doubtful that this would be successful.[36,273,320,323,330]

Anesthetic Success in Symptomatic Teeth with Totally Necrotic Pulps and Radiolucent Areas

No study has investigated the use of IO anesthesia in patients with symptomatic teeth, totally necrotic pulps, and radiolucent areas. In a preliminary study performed at Ohio State, anesthetic solution deposition was very painful in these teeth, and the study had to be terminated.

Anesthetic Success in Partially Vital Teeth

The IO injection should work in teeth in which the chamber is necrotic, the canals are vital or partially vital, and widening of the periodontal ligament can be seen radiographically. A recent history of hot and cold sensitivity should differentiate this condition from that of a necrotic tooth experiencing an acute exacerbation (Phoenix abscess).

Injection Pain with Intraosseous Injection in Patients with Irreversible Pulpitis

Generally the Stabident system produces a very low incidence of moderate pain from perforation and solution deposition in asymptomatic patients.[67,138,356-358] A higher incidence was reported when the system was used to make IO injections in mandibular posterior teeth with symptomatic irreversible pulpitis. Up to 9% of patients reported moderate to severe pain after perforation, and 5% to 31% reported moderate to severe pain during deposition of the anesthetic solution.[323,355]

With the X-Tip system, 48% of patients with symptomatic irreversible pulpitis had moderate to severe pain with perforation, and 27% had moderate pain with solution deposition.[320] Patients with irreversible pulpitis may experience a transient but moderate to severe pain on perforation and solution deposition when either the Stabident or X-Tip system is used. The higher pain ratings, compared with those for asymptomatic teeth, are probably related to preexisting peripheral or central sensitization, which leads to increased pain responsiveness and preoperative anxiety.

Duration in Mandibular Teeth

In patients with irreversible pulpitis, supplemental IO injection using either the Stabident or X-Tip system provided anesthesia for the entire débridement appointment.[320,323,355]

Intraligamentary Anesthesia

Success

The overall success of supplemental IL injections in achieving pulpal anesthesia for endodontic procedures has been reported to be 50% to 96%.[68,260,397,428] As a primary anesthetic technique, IL injection produced a 50% to 79% success rate.[212,260] If a first IL injection fails, reinjection results in a success rate of 92%.[428] Similar results have been reported by other investigators.[397] IL injection is not successful in mandibular anterior teeth.[280,436] In addition, supplemental IL injections are not as successful as supplemental IO injections.[208,461]

Anesthetic Success of the IL Injection Using the CCLAD in Symptomatic Patients Presenting with Irreversible Pulpitis

A supplemental IL injection, administered with a CCLAD system in mandibular posterior teeth diagnosed with irreversible pulpitis after failure of an IAN injection, produced a 56% anesthesia success rate.[319] These results were somewhat disappointing because the CCLAD should have been capable of delivering approximately 1.4 ml of anesthetic solution with the IL injection by consistent maintenance of a precise flow rate.

Injection Discomfort

When the IL injection is given as a supplemental injection to anesthetize symptomatic vital teeth (i.e., in symptomatic irreversible pulpitis), the patient may have moderate pain.[100] Patients should be informed of this possibility.

Selective Anesthesia

Although some have reported that the IL injection can be used in the differential diagnosis of pulpally involved teeth,[256,386] experimental studies have shown that adjacent teeth may also become anesthetized with IL injection for a single tooth.[296,379,436] Therefore, the IL injection should *not* be used for differential diagnosis.

Duration

When the IL injection is used as a supplemental technique in endodontic therapy, the clinician must work fairly quickly and be prepared to reinject if profound anesthesia dissipates.

Intrapulpal Injection

In about 5% to 10% of mandibular posterior teeth with irreversible pulpitis, supplemental IO or IL injections, even when repeated, do not produce profound anesthesia; pain persists when the pulp is entered. This is an indication for an IP injection.

The major drawback of the IP injection technique is that the needle and injection are made directly into a vital and very sensitive pulp; this injection is often moderately to severely painful.[323] Because endodontic research offers more successful methods of supplemental anesthesia, the IP injection should be given only after all other supplemental techniques have failed. Another disadvantage of the technique is the possible duration of pulpal anesthesia (15 to 20 minutes). The bulk of the pulpal tissue must be removed quickly, at the correct working length, to prevent recurrence of pain during instrumentation. Yet another disadvantage is that the pulp obviously must be exposed to allow direct injection. Anesthetic problems frequently occur before exposure while the clinician is still working in dentin.*

*References 273, 319, 320, 323, 330, 355, and 390.

http://dentalebooks.com

The advantage of the IP injection is that it produces profound anesthesia if given under back-pressure.[38,423] The onset of anesthesia is immediate, and no special syringes or needles are required. The methods for this technique can be found in many excellent endodontic textbooks. As mentioned previously, strong back-pressure is a major factor in achieving successful IP anesthesia.[38,423] Depositing the anesthetic solution passively into the chamber is insufficient because the solution does not diffuse throughout the pulp.

MANAGEMENT OF ANESTHESIA IN ENDODONTIC CASES

Symptomatic Irreversible Pulpitis

When symptomatic irreversible pulpitis is a factor, the teeth that are most difficult to anesthetize are the mandibular molars, followed by the mandibular premolars, the maxillary molars and premolars, and the mandibular anterior teeth. The fewest problems arise in the maxillary anterior teeth.

In some teeth, irreversible pulpitis is the condition in the apical portion of the canals; the tissue in the chamber is necrotic and does not respond to pulp testing. The pulp chamber can be entered easily, but when attempts are made to place a file to length, severe pain results. IO or IL injections are helpful in these cases, and an IP injection may be used. However, irreversible pulpitis must be differentiated from a symptomatic necrotic tooth with a distinct apical abscess. In the latter condition, it is doubtful if IO or IL injections would be effective, and these injections may be quite painful, and bacteria may be forced into the periapical tissues by an IP injection.

Anesthetizing Mandibular Posterior Teeth

Until the 1980s, before supplemental IO and IL injections became popular, clinicians would administer the conventional IAN block and long buccal injection (molars). After signs of soft tissue anesthesia became evident, the pain abated and the patient relaxed. Local anesthesia produced the classic soft tissue signs and relieved the painful symptoms, but pain frequently resulted when the access opening was begun or the pulp was entered. Currently, this pain has been significantly reduced with supplemental techniques.

Timing of Supplemental IO Injection

Integration of the results of many clinical trials has changed the paradigm for anesthesia in patients with symptomatic irreversible pulpitis. Considering the high failure rate of the IAN block in patients with these teeth, now, after administering an anesthetic conventionally and observing signs of soft tissue anesthesia (which is required for a successful supplemental injection), the tooth is tested with cold refrigerant. If the result is negative, the clinician may proceed with access; if the result is positive, an IO injection is administered before the rubber dam is placed. The patient should be informed that the tooth is not as anesthetized as desired and that a little extra anesthetic will ensure his or her comfort. The clinician then explains that this extra anesthetic is placed next to the tooth and that the patient may feel some discomfort during the injection. Before the supplemental IO injection, a buccal infiltration of a cartridge of 4% articaine with 1:100,000 epinephrine is given over the tooth to reduce the pain of the IO injection. Because the supplemental IO injection is more successful than the supplemental IL injection for mandibular teeth with irreversible pulpitis,[208,461] the supplemental IO injection has replaced the IL injection. In addition, because negative testing with a cold refrigerant may not always indicate profound pulpal anesthesia, clinicians may proceed directly to an IO injection once soft tissue anesthesia is obtained. This technique significantly reduces pain and allows treatment to start sooner.

Many practitioners do not use this regimen because clinicians essentially do what they were taught in their initial clinical training, and sometimes change can be difficult. For example, a 1998 study in the *Journal of the American Medical Association* urged the use of anesthesia during circumcision[19]; nevertheless, up to 96% of baby boys don't receive anesthesia. Because many physicians were taught during their residencies not to administer anesthesia, changing their practice philosophy probably will be a slow process. This is a common problem in many health care disciplines, and it emphasizes the need for practitioners to stay current with recent advances.

Supplemental IO Injection: Use 3% Mepivacaine or 2% Lidocaine with 1:100,000 Epinephrine?

As a starting point, the authors recommend using 1.8 ml of 3% mepivacaine plain (e.g., 3% Carbocaine) for the IO injection. The basis for this recommendation is not the cardiovascular risks associated with anesthetic solutions containing a vasoconstrictor, but rather the results of clinical research, which indicate that 3% mepivacaine is reasonably effective and has no clinical side effect of increased heart rate.[137,359] A few patients may overreact to the heart rate increase produced by solutions containing epinephrine, making treatment difficult or time-consuming, because the patient must be calmed before treatment can begin. However, many clinicians also use 2% lidocaine with 1:100,000 epinephrine for IO anesthesia. Clinicians may want to experiment to determine which anesthetic solution (3% mepivacaine or 2% lidocaine with epinephrine) works best for them.

After anesthesia has been obtained, the rubber dam is placed, and the access preparation is slowly begun. The patient should be assured that the procedure will be stopped if he or she feels pain.

If the initial pain occurs in dentin, the rubber dam is removed and another cartridge of 3% mepivacaine is administered, which should be successful.[355] Again, the clinician should make sure that lip anesthesia has developed from the IAN block and that the anesthetic solution is deposited into medullary bone.

If the initial pain occurs when the pulp is entered, the rubber dam is removed and another cartridge of 3% mepivacaine is administered. If the patient still has pain, an IP injection is given. Some practitioners modify the access preparation under these conditions by creating a straight-line channel that directly opens the pulp tissue with little lateral access preparation (i.e., creating an entry hole the size of a #2 round bur). This provides quick access to the pulp, and the small size of the access facilitates IP injection with back-pressure if this technique is indicated. Usually, once the pulp is removed, further pain is minimal, owing to the longer duration of mandibular anesthesia.*

http://dentalebooks.com

Anesthetizing Mandibular Anterior Teeth

An inferior alveolar injection is given and the tooth is tested with cold refrigerant. If the result is negative, the clinician may proceed with access; if the result is positive, an IO injection is administered before access is begun (the IL injection does not work well in mandibular anterior teeth).[280,436] Before the supplemental IO injection, a labial infiltration of a cartridge of 4% articaine with 1:100,000 epinephrine is given over the tooth to reduce the pain of the IO injection. If pain is felt upon access, the IO injection is repeated. If this is unsuccessful, an IP injection is added.

Anesthetizing Maxillary Posterior Teeth

The initial anesthetic dose of 2% lidocaine with 1:100,000 epinephrine is doubled (to 3.6 ml) for the buccal infiltration.[287] A small amount of anesthetic solution is usually administered palatally for the rubber dam retainer. Although fewer anesthetic problems develop with the maxillary molars and premolars than with the mandibular posterior teeth, the clinician should be aware that they can occur.[6,323] The tooth is tested with cold refrigerant. If the result is negative, the clinician may proceed with access; if the result is positive, an IO or IL injection is administered before access is begun. If pain is felt during the access, the IO or IL injection is repeated. In some cases, an IP injection may be needed. Occasionally, pain is experienced in the palatal canal of molars. Infiltration over the palatal apex with 0.5 ml of anesthetic solution enhances pulpal anesthesia and may prove helpful.[157]

The duration of anesthesia in the maxilla is less than that in the mandible.[156,287,381] Therefore, if pain is experienced during instrumentation or obturation, additional primary and/or supplemental injections are necessary.

Anesthetizing Maxillary Anterior Teeth

Anesthetic is administered initially as a labial infiltration and occasionally as a palatal infiltration for the rubber dam retainer. The tooth is tested with cold refrigerant. If the result is negative, the clinician may proceed with access; if the result is positive, an IO injection is administered before access is begun. Rarely is an IO injection needed. The duration of anesthesia may be less than 1 hour. An additional infiltration injection may be necessary if the patient experiences pain during the later stages of instrumentation or obturation.[156,287,381]

Anesthetizing Symptomatic Teeth with Total Pulpal Necrosis and Periapical Abscess

Symptomatic teeth with total pulp necrosis and periapical radiolucencies are an indicator of pain in the periapical tissue. These teeth may be painful to manipulation and movement during treatment and require extra care. For mandibular teeth, the IAN block (and long buccal injection for molar teeth) is given in all situations. For maxillary teeth with no swelling, anesthetic is administered with conventional infiltration. If soft-tissue swelling is present (i.e., cellulitis or abscess), infiltration should be done on either side of the swelling, or a block could be administered (second division nerve block, PSA nerve block, or infraorbital nerve block). These provide some degree of bone and soft tissue anesthesia. After signs of anesthesia are observed, the rubber dam is placed, and the access is begun *slowly*. The pulp chamber usually can be entered without causing the patient discomfort if the tooth is not torqued excessively. Hand and rotary file shaping can be performed without causing much pain if instruments are used with gentleness and care.

Occasionally, the conventional injections do not provide profound anesthesia, particularly in the maxillary teeth. Although results from clinical trials are lacking for treatment of this region, anecdotal experience suggests that careful consideration of a supplemental injection, consisting of an additional palatal infiltration injection, may be helpful.[348]

In patients with severe preoperative pain, a long-acting anesthetic (e.g., bupivacaine) may help control postoperative pain in mandibular teeth but is not very successful in maxillary teeth.[81,156] However, the duration of analgesia in the mandible is usually not so long to preclude prescribing oral analgesics.[112]

Anesthetizing Asymptomatic Teeth with Total Pulp Necrosis and Periapical Radiolucencies

Asymptomatic teeth are the easiest to anesthetize. Although it may be tempting to proceed without anesthesia, vital sensitive tissue (ingrowth of periapical tissue into canal) may be encountered in the apical portion of canals or placement of files may cause pressure and extrusion of fluid periapically. The conventional injections are administered: IAN block and long buccal injection (for molars), infiltration injections for maxillary teeth. The clinician then proceeds with access and file placement. The patient usually is comfortable in such cases. Rarely, some discomfort may be felt during canal preparation, requiring an IO or IL injection. An IP injection should not be given, because bacteria and debris may be forced from the canal into the periapical tissue. Additional infiltration may be necessary in the maxilla if anesthesia begins to wear off.

Interim Treatment for Irreversible Pulpitis Using Pulpotomy

Patients often have to decide between extraction and endodontic treatment for irreversible pulpitis. Because of financial circumstances, patients may choose extraction if they are only presented with two choices. One study performed pulpotomies in patients with irreversible pulpitis and restored the teeth with intermediate restorative material (IRM) or IRM base/glass ionomer core.[274] They found pain was present in 10% of patients at 6 months and in 22% at 12 months. Although not ideal, the third option of pulpotomy and temporary restoration may allow the patient time to find the means to finance complete endodontic treatment.[87,218,274]

Pain Reduction in Irreversible Pulpitis When Endodontic Treatment Is Impossible

Endodontic débridement (pulpectomy or pulpotomy) most predictably relieves the pain of irreversible pulpitis.[240,329] When débridement is not possible, clinicians may prescribe strong analgesics and antibiotics in an attempt to relieve the pain. Unfortunately, the pain persists, and antibiotics have no effect on the pain of untreated irreversible pulpitis.[309] One clinical trial evaluated pain reduction in untreated irreversible pulpitis

http://dentalebooks.com

by giving an IO injection of Depo-Medrol (a long-acting methylprednisolone).[136] Clinically, the authors found that Depo-Medrol reduced the pain to manageable levels for up to 7 days before the patient received endodontic treatment, supporting this as a method for controlling a patient's pain until definitive endodontic treatment can be performed.

Oral Conscious Sedation with Triazolam (Halcion) and Alprazolam (Xanax)

Patients who are anxious have reduced pain tolerance[253] and may be harder to anesthetize. Oral conscious sedation is beneficial in reducing patient's anxiety. However, as shown by two studies, triazolam and alprazolam are *not* a way to reduce pain during endodontic or dental treatment.[226,253] Profound local anesthesia is still required to control the patient's pain.

Conscious Sedation with Nitrous Oxide

Nitrous oxide provides conscious sedation for apprehensive dental patients. Moreover, nitrous oxide provides a mild analgesic effect. A recent study showed administration of 30% to 50% nitrous oxide resulted in a statistically significant increase in the success of the IAN block in patients presenting with symptomatic irreversible pulpitis.[404]

Preemptive Nonsteroidal Antiinflammatory Drugs (NSAIDs)

Rationale for Preemptive NSAID Use in Patients Presenting with Irreversible Pulpitis

Administering NSAIDs 1 hour before anesthetic administration has been proposed to increase the success of the IAN block in patients presenting with irreversible pulpitis. The rationale is that prostaglandin induces sensitization of peripheral nociceptors.[174,327] Interventions with NSAIDs reduce the overall concentration of prostaglandins and lead to reduced activation of these receptors.[327] It has been shown that prostaglandin E_2 (PGE_2) is reduced in the pulps of patients presenting with irreversible pulpitis when NSAIDs were taken.[341]

Preemptive NSAID Use in Mandibular Posterior Teeth with Symptomatic Irreversible Pulpitis

An early study[291] of preemptive ibuprofen use found higher success rates of the IAN block using tooth sensitivity levels (TSLs). However, the assumption of pulpal anesthesia was not tested by accessing the endodontically involved teeth. Preemptive lornoxicam (8 mg) significantly improved the efficacy of the IAN block, but diclofenac (50 mg) did not.[347] The use of preemptive ketorolac had no significant effect on the success rate of the IAN block.[5,197,284] One study used preemptive oral ketamine and found that the requirements for the number of anesthetic cartridges were reduced when compared to a placebo.[216] However, the assumption of pulpal anesthesia was not tested by accessing the involved teeth.

A number of other studies[5,131,187,330,390] have demonstrated that preemptive administration of 600 mg or 800 mg ibuprofen, a combination of 800 mg ibuprofen and 1000 mg acetaminophen, or a combination of acetaminophen/hydrocodone did not statistically improve the success of the IAN block in patients presenting with symptomatic irreversible pulpitis.

However, preemptive NSAIDs have been shown to improve anesthesia in other studies.[316,333] In addition, a meta-analysis seemed to indicate an effect from preemptive NSAIDs in the treatment of irreversible pulpitis.[248] A simple explanation for these disparate findings is lacking, and more studies are needed on this topic.

Preemptive NSAID Use in Mandibular Posterior Teeth with Asymptomatic Irreversible Pulpitis

In one study[333] of patients presenting with no spontaneous pain at the endodontic appointment (asymptomatic irreversible pulpitis), preoperative administration of 600 mg ibuprofen or 75 mg indomethacin increased the success of the IAN block (78% and 62%, respectively) over a placebo (32%). However, as shown by Argueta-Figueroa et al.,[23] success rates are higher in patients with asymptomatic irreversible pulpitis. Another study of patients who presented with asymptomatic irreversible pulpitis[383] found that 400 mg of ibuprofen, 0.5 mg dexamethasone, and a placebo resulted in success rates of 25%, 38%, and 13%, respectively. However, the success rates with either ibuprofen or dexamethasone would not ensure profound pulpal anesthesia without supplemental injection of a local anesthetic.

Preemptive NSAID Use in Maxillary First Molars with Symptomatic Irreversible Pulpitis

One study[351] compared preemptive NSAIDs in maxillary teeth and found success rates of 93% for an 800-mg dose of ibuprofen, 90% for a 100-mg dose of aceclofenac, and 73% for 1000 mg of paracetamol. All these were significantly better than a placebo (26% success).

Patient Satisfaction with Painful Dental Procedures

Studies[131,253,404] have shown that patients were moderately or completely satisfied with endodontic treatment even though moderate to severe pain was experienced. Patient satisfaction may be related to the "bedside manner" of the dentist or to satisfaction with the emergency procedure, which they hoped would abate their discomfort. This is an important finding clinically because it helps explain why patients accept painful dental and medical procedures.

ANESTHESIA FOR SURGICAL PROCEDURES

Incision for Drainage

Clinicians should always attempt to achieve some degree of anesthesia before performing an incision and drainage procedure because patients tolerate such procedures better. In the mandible, a conventional IAN injection and long buccal injection are given. In the maxilla, 1.8 ml of 2% lidocaine with 1:100,000 epinephrine is infiltrated on both sides of the facial swelling. As an alternative, because we are mostly concerned with soft tissue anesthesia, a PSA or second division nerve block can be used for premolar and molar teeth and an infraorbital injection given for anterior teeth. For palatal swelling, 0.5 ml of 2% lidocaine with 1:100,000 epinephrine is infiltrated over the greater palatine foramen (molar and premolar teeth) or nasopalatine foramen (anterior teeth). These injections should not be given if swelling is present over the foramen; infiltration should be done on either side of the swelling. The Wand system reduces the pain of palatal injections. Generally, the computer-assisted injection system causes less

http://dentalebooks.com

pain than the conventional syringe technique for AMSA, palatal, and IAN block injections.*

Profound anesthesia is usually difficult to achieve in these cases,[29] and this must be explained to the patient. The swelling is not injected because traditionally it has been believed that injection directly into a swelling is contraindicated. Reasons for this included the possible spread of infection and the contention that the inflamed tissue's lower pH would make the anesthetic solution less effective. These ideas may have some merit, but swellings are not injected basically because it is *very* painful and relatively ineffective. An area of cellulitis has an increased blood supply, and an anesthetic injected into this area is largely carried away into the systemic circulation, which diminishes the anesthetic's local effectiveness. Also, edema and purulence may dilute the solution. (See Chapter 18 for additional information on incision and drainage procedures.)

Periapical Surgery

Most periapical surgery should be performed by an endodontist because he or she has received advanced training in the surgical procedures, periapical bone anatomy of the mandible and maxilla, use of magnification technologies, complex canal anatomy, and advanced microsurgical techniques for retrograde preparation and filling.

In the mandible, the inferior alveolar and long buccal injections are reasonably effective. Additional buccal infiltration injections in the vestibule may be useful to achieve vasoconstriction, particularly in the mandibular anterior region. In the maxilla, infiltration injections are generally effective; usually larger volumes are necessary to provide anesthesia over the surgical field. If the area of operation is inflamed, anesthesia may not be totally successful.

After the flap has been reflected, if anesthesia is inadequate, attempts to enhance or regain anesthesia (through additional infiltrations or injecting the sensitive area) are not particularly effective. The effectiveness of surgical anesthesia is decreased by half compared to anesthesia for nonsurgical procedures because when the clinician reflects a flap and opens into bone, the anesthetic solution is diluted by bleeding and removed by irrigation.[454]

Use of a long-acting anesthetic has been advocated for surgery.[84,371] In the mandible, this is reasonably effective. In the maxilla, long-acting agents have a shorter duration of anesthesia and decreased epinephrine concentrations, which result in more bleeding during surgery.[78,454]

Administration of a long-acting anesthetic after periapical surgery has been suggested.[262] However, postsurgical pain is usually not severe and can be managed by analgesics.[279]

SUMMARY AND FUTURE DIRECTIONS FOR EFFECTIVE ANESTHESIA

The emergence of evidence-based dentistry has rapidly drawn interest across all fields of dentistry. Fortunately, the large number of high-quality, randomized, controlled studies in anesthesia and analgesia provide a wealth of information supporting evidence-based recommendations. The practitioner must focus on high-quality research when making clinical decisions. This section of the chapter adopted the evidence-based approach in providing a comprehensive summary of local anesthetic clinical trials for the treatment of patients with endodontic pain.

The prudent practitioner knows that there is no "magic bullet" in pain control. Rather, the clinician must be knowledgeable about the advantages and disadvantages of several anesthetic-vasoconstrictor combinations and the various routes of injection. Clearly, judicious selection of local anesthetics, delivered through multiple sites of injection, is likely to provide predictable anesthesia with minimal exposure to side effects.

Research continues in the development of new or improved anesthetics. Investigations on extended-duration anesthetic formulations suggest that local anesthetics may prove useful for treating postprocedural pain.[141,462] In the future, clinicians may be able to provide anesthesia of a specific area for a day or maybe a number of days using liposomal-encapsulated anesthetic agents. The timing of anesthesia would be tailored by how the liposome is formulated to dissolve and the amount of drug in the liposome.

In addition, capsaicin and transient receptor potential vanilloid-1 (TRPV-1) agonists and antagonists may in the future be used in the clinical management of pain associated with inflammation.[144,232,237]

New modes of delivery of drugs are also being studied. Microneedles may be used in the future to deliver topical or local anesthetics across mucosal surfaces painlessly.[14,331,451]

II. ANALGESICS AND THERAPEUTIC RECOMMENDATIONS

NON-NARCOTIC ANALGESICS

Management of endodontic pain is multifactorial and directed at reducing the peripheral and central components of hyperalgesia through combined endodontic procedures and pharmacotherapy. A major class of drugs for managing endodontic pain is non-narcotic analgesics, which include both NSAIDs and acetaminophen. NSAIDs have been shown to be very effective in managing pain of inflammatory origin and, by virtue of their binding to plasma proteins, actually exhibit increased delivery to inflamed tissue via the extravasation of plasma proteins.[49,92,168,171] Although these drugs classically are thought to produce analgesia through peripheral mechanisms, the CNS is believed to be an additional site of action.[267,409] NSAIDs inhibit the synthesis of prostaglandins by blocking the enzyme cyclooxygenase (COX) which has two known isoforms, COX-1 and COX-2. Some researchers have proposed that a splice variant of COX-1 (i.e., COX-3) is expressed predominantly in the CNS and is the major site of action of acetaminophen.[59,231,325,380] However, recent studies[177] indicate that the antipyretic and analgesic effects of acetaminophen do not involve inhibition of COX-3; they are more likely exerted through effects of an active metabolite on CNS cannabinoid receptors,[18] and this metabolite appears to act by blocking a calcium channel ($Ca_V3.2$).[225]

Numerous NSAIDs are available for management of pain and inflammation (Table 4-4). Unfortunately, comparatively few studies (particularly for endodontic pain) directly compare one NSAID to another for analgesia and side-effect liability. The lack of comprehensive comparative studies in endodontic models means that only general recommendations can be made, and clinicians are encouraged to

TABLE 4-4
Summary of Selected Non-Narcotic Analgesics

Analgesic	Trade Name	Dose Range (mg)	Daily Dose (mg)
Acetaminophen	Tylenol and others	325-650	4000
Aspirin	Many	325-1000	4000
Diclofenac potassium	Cataflam	50-100	150-200
Diflunisal	Dolobid	250-1000	1500
Etodolac	Lodine	200-400	1200
Fenoprofen	Nalfon	200	1200
Flurbiprofen	Ansaid	50-100	200-300
Ibuprofen	Motrin et al.	200-800	2400 (Rx)
Ketoprofen	Orudis	25-75	300 (Rx)
Ketorolac*	Toradol Sprix	30-60 (oral) 31.5	60 126 mg
Naproxen	Naprosyn	250-500	1500
Naproxen Na	Anaprox and others	220-550	1650 (Rx)

Modified from Cooper SA: Treating acute dental pain, *Postgrad Dent* 2:7, 1995.
Note: Cyclooxygenase-2 (COX-2) inhibitors are not included (see text).
Rx, Prescription strength.
*A new package insert for ketorolac tablets includes the instructions that the drug should be used only as a transition from injectable ketorolac and for no longer than 5 days. The package insert for intranasal ketorolac states that for patients 65 years of age or older, renally impaired patients, and patients weighing less than 50 kg, the dose should be limited to 15.75 mg, and the maximum daily dose should be limited to 63 mg.

familiarize themselves with several of these drugs. Ibuprofen generally is considered the prototype of contemporary NSAIDs and has a well-documented efficacy and safety profile.[89] Other NSAIDs may offer certain advantages over ibuprofen. For example, etodolac (i.e., Lodine) has reduced gastrointestinal (GI) irritation,[25] and ketoprofen (i.e., Orudis) has been shown in some studies to be somewhat more analgesic than ibuprofen.[73] An intranasal formulation of ketorolac tromethamine (Sprix, Regency Therapeutics, Shirley, New York) is now available and provides significant pain relief within 30 minutes of administration in patients with endodontic pain.[420] Recent studies suggest that in addition to inhibiting cyclooxygenase, ketorolac and diclofenac inhibit peripheral *N*-methyl-D-aspartate (NMDA) receptors, which may contribute to their analgesic effects.[54,96] The advantages of NSAIDs include their well-established analgesic efficacy for inflammatory pain. Many of the NSAIDs listed in Table 4-4 have been shown to be more effective than traditional acetaminophen and opioid combinations such as acetaminophen with codeine.[72,89,417]

A 2002 paper represents the first systematic review comparing all endodontic pain studies evaluating oral NSAIDs.[184] This study also provides a framework for other investigators interested in conducting systematic reviews for endodontic research. The authors concluded that NSAIDs combined with other drugs (e.g., flurbiprofen with tramadol[97]) or pretreatment and posttreatment application of NSAIDs provides effective pain control. Although relatively new to endodontic research, systematic reviews of analgesic drugs in inflammatory pain models have been conducted for several years. Table 4-5 lists the results of a large ongoing systematic review of the relative efficacy of analgesics in inflammatory pain conditions. Importantly, the data are generated based on postoperative patients having moderate to severe pain, and the number needed to treat (NNT) is based on the relative superiority of the analgesic over placebo for producing a 50% relief in pain. These data, therefore, constitute important, clinically relevant information for clinicians who want to compare the relative efficacy of posttreatment analgesics. Of course, other issues, such as the potential adverse effects of drugs and the patient's medical history, must be considered when a treatment plan for postendodontic pain is developed.

The introduction of selective inhibitors of COX-2 offered the potential for both analgesic and antiinflammatory benefits and reduced GI irritation.[91,227] Oral surgery pain studies evaluating COX-2 inhibitors have indicated that rofecoxib (i.e., Vioxx) has significant analgesic efficacy in this model.[106] In one study, a 50-mg dose of rofecoxib produced analgesia equivalent to 400 mg of ibuprofen, with the two drugs displaying similar times for onset of analgesia.[106] Expression of COX-2 is increased in inflamed human dental pulp,[310] and a COX-2 inhibitor (rofecoxib) is analgesic in patients with endodontic pain. However, most selective COX-2 inhibitors have been withdrawn from the market due to prothrombic adverse effects, and the only coxib still available, celecoxib, has not received approval by the U.S. Food and Drug Administration (FDA) for treatment of acute inflammatory pain. Concern has been raised that the COX-2 inhibitors may also display at least some GI irritation in patients with preexisting GI disease.[426]

Another major concern centers on the recognized prothrombic adverse effects of the COX-2 inhibitors. This debate originally started when patients randomized to 50 mg/day of rofecoxib in the VIGOR study had a fivefold increase in thromboembolic cardiovascular (CV) events compared to 1000 mg/day of naproxen.[40] The debate continued until the demonstration of an increased risk for prothrombic events after long-term administration of rofecoxib, which led to the withdrawal of this drug from the market in 2004.[110] Two meta-analyses have examined the CV safety of traditional NSAIDs and COX-2 inhibitors. Kearney et al.[217] conducted a meta-analysis of 138 randomized trials, and McGettigan and Henry[276] conducted a meta-analysis of 23 controlled observational studies.[217,276] Kearney et al.[217] estimated a relative risk for CV events associated with COX-2 to be 1.42 (95% CI, 1.64 to 2.91). Naproxen was found to have no significant adverse effects on the CV system in both meta-analyses. Diclofenac (Voltaren) is a relatively COX-2–selective drug and seems to have a degree of COX-2 selectivity similar to that of celecoxib. Diclofenac was associated with increased CV events. In the randomized trial analysis, there was an increase in CV risk with high-dose ibuprofen. Based on the available data, the FDA has requested that manufacturers of all prescription products containing nonselective NSAIDs revise their product labeling to include (1) a boxed warning regarding the potential serious adverse CV events and the serious, potentially life-threatening GI adverse events associated with the use of this class of drugs; (2) a contraindication to use in patients who have recently undergone coronary artery bypass surgery; and (3) a medication guide for patients regarding the potential for CV and GI adverse events associated with the use of this class of drugs.

IM, Intramuscular; NA, not applicable; NNT, number needed to treat.
*Analgesics are listed in descending order from most to least effective based on the number needed to treat (NNT). The NNT reflects the superiority of an analgesic over a placebo treatment; therefore an analgesic with a lower NNT has greater efficacy than an analgesic with a higher NNT. The NNT is calculated for the proportion of patients with at least 50% pain relief over 4 to 6 hours compared with placebo in randomized, double-blind, and single-dose studies in patients with moderate to severe pain. The 95% confidence interval contains the upper and lower estimates of the NNT with a 95% chance of accuracy.
†Drugs were given orally except where noted.

http://dentalebooks.com

The available data do not suggest an increased risk of serious CV events for the short-term, low-dose use of NSAIDs available over the counter, but the FDA has requested changes to the label to better inform consumers about the safe use of these products. Given this situation and reasonable alternative NSAIDs, we recommend against the use of COX-2 inhibitors for the treatment of patients with routine endodontic pain.

Limitations and Drug Interactions

Clinicians should educate themselves not only on the efficacy of the non-narcotic analgesics, but also on their limitations and interactions with other drugs.[52] For example, NSAIDs exhibit an analgesic ceiling that limits the maximal level of analgesia and induces side effects, including those affecting the GI system (3% to 11% incidence) and the CNS (1% to 9% incidence of dizziness and headache). NSAIDs are contraindicated in patients with ulcers and aspirin hypersensitivity.[63,65,125,396] They also are associated with severe GI complications, and the risk of adverse effects increases with an increasing lifetime-accumulated dose of these drugs and concurrent intake of aspirin, steroids, or coumadin.[24,93,242,442] A strategy for avoiding GI bleeding associated with NSAIDs is to use a proton pump inhibitor (PPI). A combination of a PPI (esomeprazole magnesium) with naproxen (Vimovo, Patheon/Astrozenica, Wilmington, Delaware) is now available. Although this is a cost-effective approach, it does not protect the lower GI tract.[400] Another approach is to use a histamine receptor H_2 antagonist in combination with an NSAID. The combination of famotidine (an H_2-receptor antagonist) and ibuprofen (Duexis, Horizon Pharma, Northbrook, Illinois) was recently approved by the FDA. The NSAIDs have been reported to interact with a number of other drugs (Table 4-6).

Acetaminophen and opioid combination drugs are alternatives for patients unable to take NSAIDs.[71] Further information is available on the pharmacology and adverse effects of this important class of drugs.[52,69,93,133,452] Other resources are also available for evaluation of drug interactions, including Internet drug search engines, such as *rxlist.com*, *Epocrates.com*, and *Endodontics.UTHSCSA.edu*.

TABLE 4-6

Summary of Selected Drug Interactions with Nonsteroidal Antiinflammatory Drugs (NSAIDs)

Drug	Possible Effect
Angiotensin-converting enzyme (ACE) inhibitors	Reduced antihypertensive effectiveness of captopril (and especially indomethacin)
Anticoagulants	Increase in prothrombin time or bleeding with anticoagulants (e.g., coumarins)
Beta-blockers	Reduced antihypertensive effects (e.g., propranolol, atenolol, pindolol)
Cyclosporine	Increased risk of nephrotoxicity
Digoxin	Increase in serum digoxin levels (especially ibuprofen, indomethacin)
Dipyridamole	Increased water retention (especially indomethacin)
Hydantoins	Increased serum levels of phenytoin
Lithium	Increased serum levels of lithium
Loop diuretics	Reduced effectiveness of loop diuretics (e.g., furosemide, bumetanide)
Methotrexate	Increased risk of toxicity (e.g., stomatitis, bone marrow suppression)
Penicillamine	Increased bioavailability (especially indomethacin)
Sympathomimetics	Increased blood pressure (especially indomethacin with phenylpropanolamine)
Thiazide diuretics	Reduced antihypertensive effectiveness

Acetaminophen

Acetaminophen (*N*-acetyl *p*-aminophenol) is one of the most commonly used analgesic and antipyretic drugs. Acetaminophen alone is not comparable to ibuprofen in relieving moderate to severe pain; however, a combination of ibuprofen and acetaminophen may provide greater pain relief than either drug alone. In a randomized, double-blind, placebo-controlled study, patients who had undergone pulpectomy were administered a single dose of either a combination of acetaminophen (1000 mg) and ibuprofen (600 mg) or ibuprofen (600 mg) alone. The combination of the two analgesics provided greater pain relief in the immediate postoperative period (8 hours) than ibuprofen (600 mg) alone.[285]

Acetaminophen is one of the most common drugs found in combination products for the relief of pain and symptoms of cold or flu. It is considered safe when taken at normal doses, but in higher doses, acetaminophen causes liver toxicity and is associated with nearly half of the cases of acute liver failure in the United States.[244] Most acetaminophen is conjugated in the liver to form inactive metabolites. A small portion is metabolized by the cytochrome P450 system to form *N*-acetyl-*p*-benzoquinone imine (NAPQI), which is very toxic but is generally detoxified by glutathione and converted into nontoxic compounds. Large doses of acetaminophen saturate the main route of metabolism, causing more acetaminophen to be converted to NAPQI. Liver injury occurs once glutathione becomes depleted and NAPQI is allowed to accumulate. To minimize this risk, it has been recommended that healthy adults not take more than 3 g (3000 mg) of acetaminophen in a 24-hour period (*www.tylenolprofessional.com/extra-strength-tylenol-dosage-faq.html*). The FDA mandated that by 2014, manufacturers of oral prescription acetaminophen combination medicines limit the maximum amount of acetaminophen to 325 mg per tablet. The FDA also requires a boxed warning to be added to the label of all oral prescription drug products that contain acetaminophen. (A boxed warning, the strongest warning that the FDA requires, indicates that the drug carries a significant risk of serious adverse effects).

OPIOID ANALGESICS

Opioids are potent analgesics and are often used in dentistry in combination with acetaminophen, aspirin, or ibuprofen. Most clinically available opioids activate mu opioid receptors at several important sites in the brain and on afferent neurons. Studies indicate that they activate peripheral opioid receptors in dental pulp and that IL injection of morphine significantly

TABLE 4-7
Selected Opioid Combination Analgesic Drugs

Formulation	Trade Name*	Possible Rx
APAP 300 mg and codeine 30 mg	Tylenol with codeine no. 3	2 tabs q4h
APAP 500 mg and hydrocodone 5 mg	Vicodin, Lortab 5/500	1-2 tabs q6h
APAP 325 mg and oxycodone 5 mg	Percocet	1 tab q6h
APAP 500 mg and oxycodone 5 mg	Tylox	1 tab q6h
ASA 325 mg and codeine 30 mg	Empirin with codeine no. 3	2 tabs q4h
ASA 325 mg and oxycodone 5 mg	Percodan	1 tab q6h

APAP, Acetaminophen; *ASA*, aspirin; *Rx*, prescription.
*Several generics are available for most formulations.

TABLE 4-8
Analgesic Doses of Representative Opioids

Opioid	Dose Equivalent to Codeine 60 mg
Codeine	60 mg
Oxycodone	5-6 mg
Hydrocodone	10 mg
Dihydrocodeine	60 mg
Propoxyphene HCl	102 mg
Propoxyphene-N	146 mg
Meperidine	90 mg
Tramadol	50 mg

Modified from Troullos E, Freeman R, Dionne RA: The scientific basis for analgesic use in dentistry, *Anesth Prog* 33:123, 1986.
HCl, Hydrochloride; *N*, napsylate.

reduces pain in endodontic patients and in other inflammatory pain states.[94,111,167] Gender-dependent differences appear to exist in responsiveness to at least the kappa opioid agonists.[142] In a randomized, controlled clinical trial, women taking a combination of pentazocine and naloxone had significantly less postoperative endodontic pain than men taking the same medications.[374]

Although opioids are effective as analgesics for moderate to severe pain, their use is generally limited by their adverse side effects, which can include nausea, emesis, dizziness, drowsiness, and the potential for respiratory depression and constipation. Chronic use is associated with tolerance and dependence. Because the dosage is limited by side effects, these medications are almost always used in combination drugs to manage dental pain. A combination formulation is preferred because it permits a lower dose of the opioid, thereby reducing side effects (Table 4-7).

Codeine is often considered the prototype opioid for orally available combination drugs. Most studies have found that the 60-mg dose of codeine (the amount in two tablets of Tylenol with codeine no. 3) produces significantly more analgesia than placebo, although it often produces less analgesia than either aspirin 650 mg or acetaminophen 600 mg.[71,72,168] In general, patients taking only 30 mg of codeine report about as much analgesia as those taking a placebo.[31,417] Table 4-8 provides comparable doses of other opioids equivalent to 60 mg of codeine.

CORTICOSTEROIDS

Posttreatment pain or flare-up after endodontic treatment can be attributed to inflammation, infection, or both in the periradicular tissues. Establishing patency and subsequently débriding and shaping the root canal system may irritate the periradicular tissues and inadvertently introduce bacteria, bacterial products, necrotic pulp tissue, or caustic irrigating solution through apical foramina.

In response to this irritation, inflammatory mediators (e.g., prostaglandins [PGs], leukotrienes, bradykinin, platelet-activating factor, substance P) are released into the tissues surrounding the apical area of the tooth. As a result, pain fibers are directly stimulated or sensitized, and an increase in vascular dilation and permeability results in edema and increased interstitial tissue pressure.

Glucocorticosteroids are known to reduce the acute inflammatory response by suppressing vasodilation, migration of polymorphonuclear (PMN) leukocytes, and phagocytosis and by inhibiting formation of arachidonic acid from neutrophil and macrophage cell membrane phospholipids, thus blocking the COX and lipoxygenase pathways and respective synthesis of PGs and leukotrienes. It is not surprising that a number of investigations have evaluated the efficacy of corticosteroids (administered via either intracanal or systemic routes) in the prevention or control of postoperative endodontic pain or flare-ups.[268]

Intracanal Administration

Several studies have evaluated intracanal administration of steroids. In 50 consecutive patients requiring nonsurgical root canal treatment of vital teeth, one investigator alternately placed a dexamethasone solution or saline placebo as intracanal medicaments after the root canals had been cleaned and shaped.[307] Pretreatment pain ratings were collected, as were ratings at 24, 48, and 72 hours after treatment. Results indicated a significant reduction in pain at 24 hours but no significant difference at 48 and 72 hours. In a similar double-blind clinical trial, intracanal placement of a 2.5% steroid solution or saline placebo on completion of instrumentation resulted in a significant reduction of the incidence of postoperative pain in teeth in which the pulp was vital.[58] When the pulp was necrotic, however, there was no significant difference between the steroid and placebo in reducing postoperative discomfort.

Another study found no significant difference in the flare-up rate when either formocresol, Ledermix (a corticosteroid antibiotic paste), or calcium hydroxide was placed as an intracanal medicament in strict sequence, irrespective of the presence or absence of symptoms or radiographic signs of apical periodontitis.[416] However, a large-scale clinical trial of 223 patients reported significantly less posttreatment pain in patients after intracanal administration of Ledermix compared with either calcium hydroxide or no intracanal dressing.[107] Intracanal steroids appear to have significant effects for reducing postoperative pain.[365]

http://dentalebooks.com

Systemic Administration

Some studies have evaluated the systemic route of administration of corticosteroids on posttreatment pain or flare-ups. In one double-blind, randomized, placebo-controlled study, dexamethasone (4 mg/ml) or saline was injected intramuscularly at the conclusion of a single-visit endodontic appointment or at the first visit of a multivisit procedure.[269] The results indicated that the steroid significantly reduced the incidence and severity of pain at 4 hours when compared with the placebo. No difference in pain was seen at the 24- and 48-hour time points.

In a similar study, 106 patients with irreversible pulpitis and acute periradicular periodontitis were given an intraoral intramuscular injection of dexamethasone at different doses, either on completion of a single-visit endodontic treatment or after the first visit of a multivisit procedure.[250] Systemic administration of dexamethasone was shown to significantly reduce the severity of pain at 4 and 8 hours, with an optimum dose between 0.07 and 0.09 mg/kg. However, no significant reduction in the severity of pain was noted at 24, 48, and 72 hours, and no overall effect was seen on the incidence of pain. Another study compared the effect an IL injection of methylprednisolone, mepivacaine, or placebo in preventing posttreatment endodontic pain.[215] The results showed that methylprednisolone significantly reduced postoperative pain within a 24-hour follow-up period.

In a double-blind placebo-controlled study, patients with irreversible pulpitis were given 4 mg of dexamethasone or placebo by means of a supraperiosteal injection at the apex of the treated tooth after pulpectomy.[283] This is an injection technique that most clinicians would be familiar with (as opposed to intramuscular injection). Posttreatment pain was significantly reduced in the steroid group during the first 24 hours. There was no difference at 48 hours.

Yet another study evaluated the effect of IO injection of methylprednisolone or placebo in patients with irreversible pulpitis. Highly significant pain reduction in the steroid group was maintained for 7 days after a single injection.[143]

Animal studies have histologically evaluated the antiinflammatory effects of corticosteroids on inflamed periradicular tissues. In one study, after an acute inflammatory reaction was induced in the molar teeth of rats by overextending endodontic instruments, sterile saline or dexamethasone was infiltrated supraperiosteally into the buccal vestibule adjacent to the treated teeth. Dexamethasone significantly reduced the number of neutrophils present and thus had an antiinflammatory effect on the periradicular tissues of the treated teeth.[315]

Other studies of systemic administration have evaluated the effect of oral administration of corticosteroids on the incidence and severity of posttreatment endodontic pain. In a double-blind, controlled clinical trial, 50 patients randomly received either 0.75 mg of dexamethasone or a placebo tablet orally after initial endodontic treatment.[238] Oral dexamethasone significantly reduced posttreatment pain after 8 and 24 hours compared with placebo. A follow-up study evaluated the effect a larger oral dose of dexamethasone (i.e., 12 mg given every 4 hours) on the severity of posttreatment endodontic pain.[147] Results showed that dexamethasone was effective in reducing posttreatment endodontic pain up to 8 hours after the treatment was completed; no effect on the severity of pain was seen at 24 and 48 hours after treatment. In a double-blind study comparing etodolac and dexamethasone, the perioperative administration of oral dexamethasone was comparable to that of etodolac in reducing pain after endodontic surgery. In a randomized clinical trial,[252] 40 patients received a single dose of prednisolone (30 mg) or placebo 30 minutes before initiation of endodontic treatment. Prednisolone significantly reduced posttreatment pain at 6, 12, and 24 hours compared to placebo.[194]

Collectively, these studies on systemic steroid administration indicate that corticosteroids reduce the severity of posttreatment endodontic pain compared with placebo treatment. However, given the relative safety/efficacy relationship between steroids and NSAIDs, most investigators choose an NSAID as the drug of first choice for postoperative pain control.

ANTIBIOTICS

Because bacteria are involved in endodontic cases with apical periodontitis, the incidence of a posttreatment infection or flare-up is a concern to clinicians providing endodontic treatment. Prescribing an antibiotic to prevent such an occurrence might make sense, but use of antibiotics is controversial for several reasons.[119] First, overprescribing of antibiotics, especially when these drugs are not indicated, has led to increased bacterial resistance and patient sensitization. Second, antibiotics have been mistakenly prescribed for patients with severe pain who have a vital tooth (i.e., when bacteria are unlikely to be a causative factor in periradicular pain).[457] Third, even when bacteria are likely to be present, data from controlled clinical trials provide little or no support for the hypothesis that antibiotics reduce pain.[218]

A series of clinical studies evaluated the efficacy of prophylactically administered systemic antibiotics for preventing posttreatment endodontic flare-ups. Working on the premise that the incidence of infectious flare-ups after endodontic treatment is 15%, Morse et al.[305] randomly prescribed a prophylactic dose of either penicillin or erythromycin to patients after endodontic treatment of teeth with a diagnosis of necrotic pulp and chronic periradicular periodontitis (no placebo was used). The results showed that the overall incidence of flare-ups was 2.2%, with no difference between penicillin and erythromycin. Similar results were obtained in a study in which dental students (instead of private practitioners) provided the endodontic treatment.[1] Outcomes found a 2.6% incidence of flare-up, with no statistically significant differences between penicillin and erythromycin. However, neither the original nor the follow-up study was a randomized, placebo-controlled clinical trial. This observation appears to be highly significant for clinical recommendations because in general, randomized controlled studies fail to detect any analgesic benefit to antibiotics, whereas open-label or historical control studies often report profound effects.[119]

To determine whether the timing of administration of an antibiotic altered the occurrence of flare-ups and pain unassociated with flare-ups, researchers analyzed components of two separate prospective studies of patients undergoing endodontic treatment for teeth with necrotic pulps and chronic periradicular periodontitis. In the first study, prophylactic penicillin was provided; in the second study, patients were instructed to take penicillin (or erythromycin if they were allergic to penicillin) at the first sign of swelling.[304,305] The authors concluded that prophylactic administration of antibiotics is preferable to having the patient take antibiotics at the first sign of an infection.

http://dentalebooks.com

Another study of similar design compared the incidence of flare-up when a cephalosporin or erythromycin was given prophylactically.[306] When the data from previous studies were pooled and retrospectively compared, the authors concluded that prophylactically administered antibiotics, including cephalosporins, significantly reduced the incidence of flare-ups in endodontic cases involving necrotic pulp and chronic periradicular periodontitis. However, these studies have been questioned because of the lack of concurrent placebo-treated groups and the use of historical controls.

In a multicenter, two-part clinical study, 588 consecutive patients received one of nine medications or placebos and were monitored for 72 hours after treatment.[414] The results showed that ibuprofen, ketoprofen, erythromycin, penicillin, and penicillin plus methylprednisolone significantly reduced the severity of pain within the first 48 hours after treatment. The second part of the study then evaluated the incidence of posttreatment pain after obturation of the same teeth in the first phase of the study.[414] Although only 411 of the original 588 patients participated in this phase, they were randomly given the same medications or placebo after completion of the obturation appointment. The incidence of posttreatment pain was lower after obturation (5.83%) than after cleaning and shaping (21.76%) of the root canal system, and no significant difference was found in the effectiveness of the various medications and placebo in controlling posttreatment pain after obturation.

Walton and Chiappinelli[429] were concerned that previous studies were uncontrolled, retrospective, or carried out on different patient groups at different times and with different treatment modalities. They conducted a randomized, prospective, double-blind clinical trial to test the hypothesis that an antibiotic (e.g., penicillin) can prevent a posttreatment endodontic flare-up.[429] Eighty patients with teeth that had necrotic pulp and chronic periradicular periodontitis were randomly divided into three groups. In the first two groups, either penicillin or a placebo was administered 1 hour before and 6 hours after the individual appointments on a double-blind basis. Upon completion of the individual appointments, which included débridement, shaping, and possibly obturation of the root canal system, the patients completed questionnaires at 4, 8, 12, 24, and 48 hours. No significant difference was found among the three groups in the incidence of flare-ups, pain, or swelling. The authors concluded that the use of prophylactic penicillin offers no benefit for postoperative pain or flare-up, and prophylactic administration of penicillin should not be used routinely in patients undergoing endodontic treatment of necrotic teeth and chronic periradicular periodontitis.

In another randomized, prospective, placebo-controlled clinical study, a group of investigators examined whether supplemental penicillin reduced symptoms or shortened the course of recovery of emergency patients diagnosed with necrotic pulp and acute apical abscess.[120] Patients were randomly given penicillin, a placebo, or no medication. Using a visual analog scale, the subjects then evaluated their postoperative pain and swelling for up to 72 hours. No significant difference was found among the three groups. Recovery occurred as a result of endodontic treatment alone.

It is well recognized that antibiotics may be indicated for the management of infections of endodontic origin. However, a review of the available literature indicates that prophylactic use is contraindicated in immunocompetent patients with no systemic signs of infection and with swelling localized to the vestibule. Controlled clinical studies indicate that antibiotics offer little or no benefit for pain reduction under these circumstances, but they may be indicated for immunocompromised patients and for patients with systemic signs and symptoms of an infection or an infection that has spread into the fascial spaces of the head and neck.

PAIN MANAGEMENT STRATEGIES

When managing pain in an individual patient, the skilled clinician must customize the treatment plan, balancing the general principles of endodontics, mechanisms of hyperalgesia, and pain management strategies with the particular factors of the individual patient (e.g., medical history, concurrent medications).[171,219,220,369,393]

Effective management of endodontic pain starts with the "three Ds": *diagnosis*, *definitive* dental treatment, and *drugs* (Box 4-1). Comprehensive reviews on *diagnosis* and *definitive* dental treatment (e.g., incision and drainage, pulpectomy) are provided elsewhere in this text (Chapters 1, 6, 9, and 18). As described earlier in this chapter, the management of endodontic pain should focus on the removal of peripheral mechanisms of hyperalgesia and allodynia (see Box 4-1). This generally requires treatment that removes and reduces causative factors (e.g., bacterial and immunologic factors). For example, both pulpotomy and pulpectomy have been associated with substantial reduction in patient reports of pain compared to pretreatment pain levels.[97,173,274,337] However, pharmacotherapy often is required to reduce continued nociceptor input (e.g., NSAIDs, local anesthetics) and suppress central hyperalgesia (e.g., NSAIDs, opioids).

Pretreatment

Treatment with an NSAID before a procedure has been shown to have a significant benefit in many studies[89,191] but not all.[314] The rationale for pretreatment is to block the development of hyperalgesia by reducing the input from peripheral nociceptors. For patients who cannot take NSAIDs, pretreatment with acetaminophen also has been shown to reduce postoperative pain.[298] Patients can be pretreated 30 minutes before the procedure with either an NSAID (e.g., ibuprofen 400 mg or flurbiprofen 100 mg) or with acetaminophen 1000 mg.[97,191,298]

Long-Acting Local Anesthetics

A second pharmacologic approach for pain management is the use of long-acting local anesthetics, such as bupivacaine and ropivacaine. Clinical trials indicate that long-acting local anesthetics not only provide anesthesia during the procedure, but

BOX 4-1

Considerations for Effective "Three D" Pain Control

1. Diagnosis
2. Definitive dental treatment
3. Drugs
   - Pretreat with nonsteroidal antiinflammatory drugs (NSAIDs) or acetaminophen when appropriate.
   - Use long-acting local anesthetics when indicated.
   - Use a flexible prescription plan.
   - Prescribe "by the clock" rather than as needed.

http://dentalebooks.com

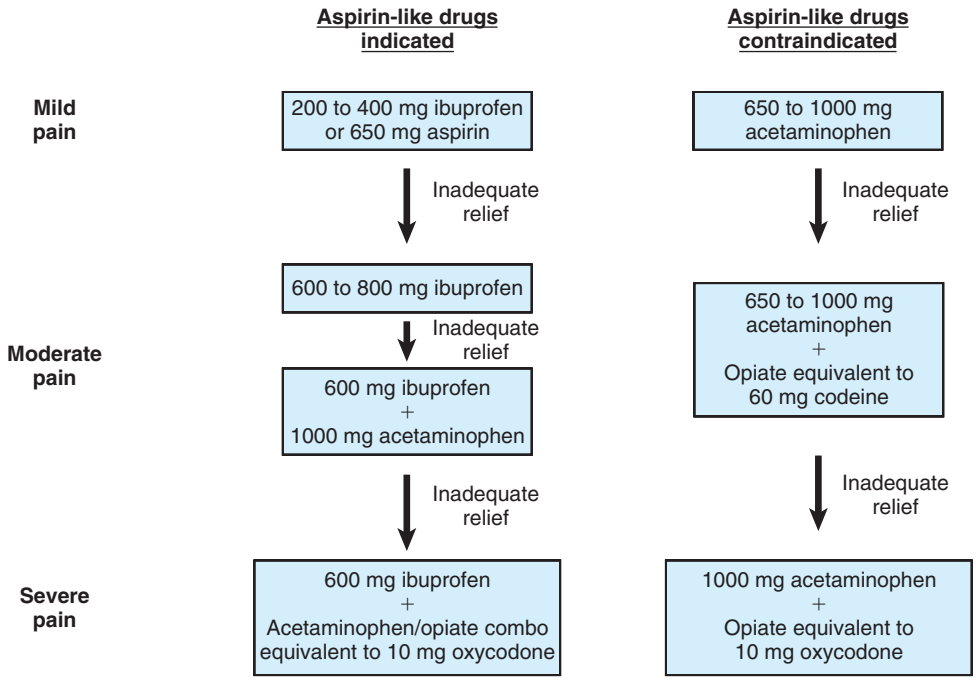

FIG 4-25 A flexible analgesic strategy.

also significantly delay the onset of posttreatment pain compared with local anesthetics that contain lidocaine.[77,89,152,153,196] Administration of long-acting local anesthetics by block injection has been shown to reduce posttreatment pain for 2 to 7 days after the oral procedure[152,153,196] because an afferent barrage of nociceptors can induce central hyperalgesia.[445-447] The analgesic benefit of long-acting local anesthetics is more prominent with block injections than infiltration injections, but the clinician should also be aware of adverse effects attributed to these agents.[28,297]

Flexible Plan

A third pharmacologic approach is the use of a flexible plan for prescribing analgesics (Fig. 4-25).* A flexible prescription plan serves to minimize both postoperative pain and side effects. Given these goals, the clinician's strategy is twofold: (1) to achieve a maximally effective dose of the non-narcotic analgesic (either an NSAID or acetaminophen for patients who cannot take NSAIDs); and (2) in the rare cases in which the patient still has moderate to severe pain, to consider adding drugs that increase the NSAID's analgesia. Because of its predictive value, the presence of preoperative pain or mechanical allodynia may be an indicator that such NSAID combinations should be considered.

Most, but not all, studies report that combining an NSAID with acetaminophen 1000 mg alone (i.e., no opioid) produces nearly twice the analgesic response as just the NSAID.[46,74,285,434] Administration of ibuprofen 600 mg with acetaminophen 1000 mg produced significant relief of posttreatment endodontic pain compared to ibuprofen alone or placebo (Fig. 4-26). However, in a recent study, the analgesic effect of a combination of ibuprofen 600 mg with acetaminophen 1000 mg did not differ from that of acetaminophen alone.[434] Studies have also shown that concurrent administration of an NSAID and an acetaminophen-opioid combination drug provided significantly greater analgesia than an NSAID alone.[46,403] The concurrent administration of acetaminophen and NSAIDs appears to be well tolerated, with no detectable increase in side effects or alterations in pharmacokinetics.[46,243,403,448]

In cases of moderate to severe pain, an NSAID may need to be administered with an opioid. Two general methods are used to combine NSAIDs and opioids to achieve the analgesic benefits of both. The first involves an alternating regimen of an NSAID followed by an acetaminophen-opioid combination.[17,72] Aspirin and opioid combinations are not used in this alternating schedule because of the potential for NSAID/aspirin interactions. The second method involves administration of a single drug consisting of an NSAID-opioid combination. For example, a tablet of Vicoprofen contains both ibuprofen (200 mg) and hydrocodone (7.5 mg). Postoperative pain studies have shown that this combination was about 80% more effective for analgesia than ibuprofen (200 mg) alone, with about the same incidence of side effects.[438] Other opioids can be added to an NSAID for increased analgesia. Ibuprofen 400 mg with a 10-mg oxycodone tablet produces significantly greater analgesia than ibuprofen alone.[90] A study on posttreatment endodontic pain demonstrated short-term benefits of the combination of flurbiprofen and tramadol.[97] Other NSAID and opioid combinations have also been evaluated.[93] However, the results of clinical trials on the use of NSAIDs alone and combined with acetaminophen (see Fig. 4-26) suggest that opioid combinations may be required only rarely.

Not all patients require concurrent use of NSAIDs with acetaminophen-opioid combinations or combinations of an NSAID and opioid. The basic premise of a flexible prescription plan is that the analgesic prescribed is matched to the patient's need. The major advantage of a flexible plan is that the clinician is prepared for those rare cases when additional pharmacotherapy is indicated to increase the efficacy of pain control. As mentioned, preoperative hyperalgesia may be an indicator

*References 17, 72, 166, 168, 171, 219, 221, and 417.

http://dentalebooks.com

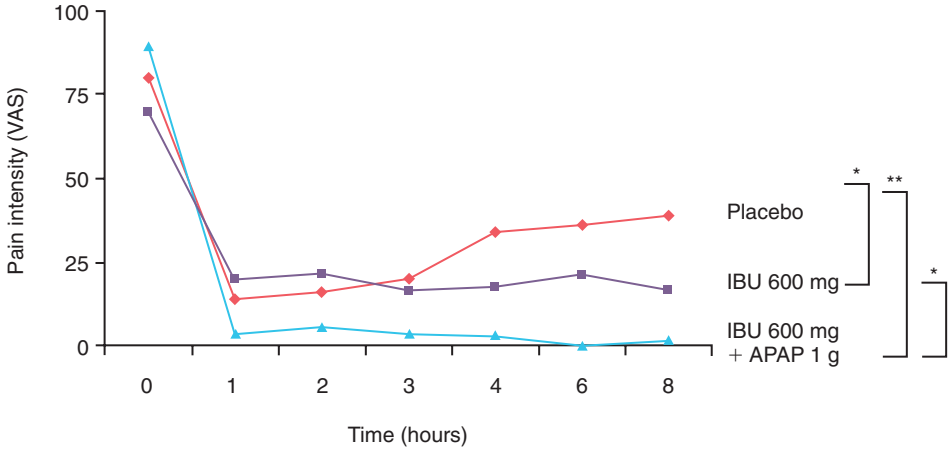

FIG. 4-26 Comparison of ibuprofen 600 mg with acetaminophen 1000 mg to ibuprofen alone or to placebo treatment in postendodontic pain patients. (From Menhinick KA, Gutmann JL, Regan JD, et al: The efficacy of pain control following nonsurgical root canal treatment using ibuprofen or a combination of ibuprofen and acetaminophen in a randomized, double-blind, placebo-controlled study, *Int Endod J* 37:531, 2004.)

for more comprehensive pharmacotherapy. When considering the combination of various analgesics, the clinician must make sure to use dosing regimens that do not exceed any of the drugs' maximum daily dosage.

FUTURE DIRECTIONS

COX-inhibiting nitric oxide (NO) donators (CINODs), a new class of NSAIDs, have an NO-donating moiety. These drugs, also known as NO-NSAIDs, were developed with the idea that the released NO would lead to improved vascular tone and mucosal blood flow, thus attenuating the adverse effects of NSAIDs on GI mucosa and blood pressure. Although none of the CINODS have been approved by the FDA yet, they may be available in the near future.

Current use of analgesics has been driven by clinical trials to arrive at doses that obtain the desired level of pain relief with acceptable side-effect profiles. After administration, drugs are absorbed and distributed to their site of action, where they interact with functional targets. They then undergo metabolism and eventual excretion. All of the steps along the way are influenced by a variety of environmental and genetic factors. The ability to predict how a patient's genome may affect the efficacy of a given analgesic drug is being discovered in the field of pain pharmacogenomics (for a review, see Rollason et al.[366]).

One example relevant to pain control in dentistry is the variable efficacy of codeine in a specific population. Many analgesic drugs are metabolized by the cytochrome P450 (CYP) family of hepatic enzymes, and the genes that encode for their biosynthesis have been identified. Codeine is a prodrug that is demethylated to produce morphine, which is responsible for its analgesic action. This demethylation is catalyzed by the enzyme cytochrome P402D6. It has been estimated that 6% to 7% of the Caucasian population has a nonfunctional CYP2D6 mutant allele, making them poor metabolizers of codeine to morphine.[88] These patients may be aware that codeine is ineffective in their systems from past experience and may request a different (usually more potent) form of narcotic. The clinician may suspect drug-seeking behavior, when in fact there is a biochemical reason for their request. Given the current state of clinical DNA analysis, it is not incomprehensible to envision a time when rapid (chairside) genomic evaluation will lead to specific recommendations for analgesic prescription.

SUMMARY

The information and recommendations provided in this chapter were selected to aid the clinician in the management of acute endodontic pain. Clinical judgment must also take into account other sources of information—the patient history, concurrent medications, the nature of the pain, and the overall treatment plan—when determining the best means of alleviating patient pain. An effective approach to managing endodontic pain demands integration of general principles of pain mechanisms and management with thorough, individualized clinical assessment.

CHAPTER 5

Tooth Morphology, Isolation, and Access

JAMES L. GUTMANN | BING FAN

CHAPTER OUTLINE

Components of the Root Canal System
Root Canal Anatomy
Clinical Determination of the Root Canal Configuration
Objectives and Guidelines for Access Cavity Preparation
Objectives
Key Steps to Consider in Access Preparation
Visualization of the Likely Internal Anatomy
Evaluation of the Cementoenamel Junction and Occlusal Tooth Anatomy
Preparation of the Access Cavity Through the Lingual and Occlusal Surfaces
Removal of All Defective Restorations and Caries Before Entry into the Pulp Chamber
Removal of Unsupported Tooth Structure
Preparation of Access Cavity Walls that Do Not Restrict Straight- or Direct-Line Passage of Instruments to the Apical Foramen or Initial Canal Curvature
Inspection of the Pulp Chamber Walls and Floor
Tapering of Cavity Walls and Evaluation of Space Adequacy for a Coronal Seal
Mechanical Phases of Access Cavity Preparation
Magnification and Illumination
Handpieces
Burs
Endodontic Explorer and Spoon
Ultrasonic Unit and Tips
Access Cavity Preparations
Anterior Teeth
Posterior Teeth
Challenging Access Preparations
Teeth with Minimal or No Clinical Crown
Heavily Restored Teeth (Including Those with Full Coronal Coverage)
Access in Teeth with Calcified Canals
Crowded or Rotated Teeth
Errors in Access Cavity Preparation
Morphology of and Access Cavity Preparations for Individual Teeth

Mandibular Third Molar
Teeth with C-Shaped Root Canal Systems

The dental pulp presents with a variety of configurations and shapes throughout the dentition. Therefore, a thorough knowledge of tooth morphology, careful interpretation of radiographic documentation, and adequate access to and exploration of the pulpal space are prerequisites for all root canal procedures, whether nonsurgical or surgical.[182] To enhance this exploration and interpretation, magnification and illumination are indispensable. This chapter describes and illustrates tooth morphology and explains the techniques necessary to achieve unobstructed, direct access to the root canal system. The clinician is challenged to perform adequate enlarging, shaping, cleaning, disinfection, and obturation of the pulpal space to achieve predictable outcomes with root canal procedures. However, the optimal result is difficult to achieve if the access is not prepared properly. Therefore, knowledge of the complexity of the root canal system is essential to understand the principles and problems encountered in access preparation.

The complexity of the root canal system is best understood by the integration of formative knowledge of tooth anatomy and the interpretation of radiographic documentation. Careful evaluation of two or more periapical radiographs, exposed at different horizontal angulations of the x-ray cone, is essential.

http://dentalebooks.com

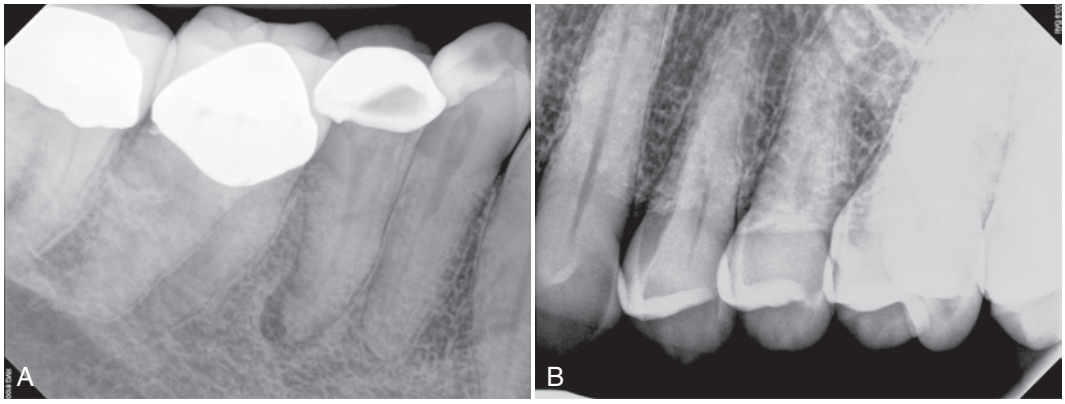

FIG. 5-1 A, Abrupt disappearance of the large canal in the mandibular first premolar indicates a canal bifurcation. B, The same is true for the maxillary first premolar.

These divergently exposed radiographs along with cone-beam computed tomography (CBCT) scans in some clinical situations (see Chapter 2) provide important information about root canal morphology. However, the inclination of the x-ray tube significantly influences the ability to detect variable root canal systems present in many teeth. For example, in premolars, if the horizontal angle is varied by either 20 or 40 degrees, the number of root canals seen in the maxillary first and second premolars and the mandibular first premolars coincides with the number of canals actually present.[134] However, in the mandibular second premolar, only the 40-degree horizontal angle correctly identifies the root canal morphology. The careful reading and interpretation of each radiograph before and during root canal procedures is necessary because many teeth present with unusual canal morphology. Unfortunately, the interpretation of traditional radiographs may not always result in the correct morphologic assessment, particularly when only a buccolingual view is taken. In one study, 790 extracted mandibular incisors and premolars were radiographed to assess the incidence of canal bifurcation in a root.[147] When the *fast break* guideline was used (i.e., interpreting a sudden disappearance or narrowing of a canal as a sign of canal division, such as bifurcation [Fig. 5-1]), the result was failure to identify one third of these divisions from a single radiographic view. Thus, evaluation of the root canal system is most accurate when the information from several radiographic views is integrated with a thorough clinical exploration of the interior and exterior of the tooth. Alternatively, the recent development of micro-computed tomography (μCT) scanning of teeth has greatly increased clinical assessment of these complexities and three-dimensional (3D) relationships found in root canal systems.

The main objectives of root canal procedures are adequate enlargement, shaping, cleaning, and disinfection of all pulpal spaces, along with obturation of these spaces with an acceptable filling material. At times a root canal or its elaborate, complex system may go undetected, which results in failure to achieve the stated objectives. Therefore, the use of a vast array of tools, in particular magnification and illumination, is essential to accomplish these objectives on a more predictable basis.

Initially important aids for determining pulp space morphology, in particular the pulp chamber and location of root canal orifices, include multiple pretreatment radiographs, CBCTs, examination of the pulp chamber floor with a sharp explorer, visual assessment of color changes in the dentin,

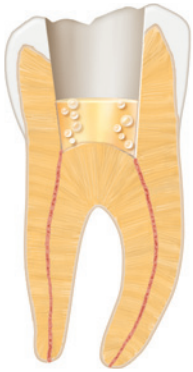

FIG. 5-2 Allowing sodium hypochlorite (NaOCl) to remain in the pulp chamber may help locate a calcified root canal orifice. Tiny bubbles may appear in the solution, indicating the position of the orifice. This is best observed through magnification.

troughing of anatomic grooves with ultrasonic tips, staining the chamber floor with 1% methylene blue dye, performing a sodium hypochlorite "champagne bubble" test (Fig. 5-2), visualizing the pulp chamber anatomy from established documents,[107] and root canal bleeding points. Sequential application of 17% aqueous ethylene diaminetetraacetic acid (EDTA) and 95% ethanol has been recommended for effective cleaning and drying of the pulp chamber floor before visual inspection.[207]

Specifically, the use of the dental operating microscope (DOM), which is intended to provide superior magnification, increased lighting, and enhanced visibility,[182] is recommended to determine the location of root canal orifices in the properly prepared coronal access (Fig. 5-3). Removal of dentin that may obscure the location of these orifices is also enhanced with better visualization with the DOM. The DOM also improves the identification of extra canals (e.g., the mesiopalatal canal found in many first and second maxillary molars) and has been shown to be superior to the use of the naked eye and magnifying loupes for this assessment.[14,187] Additional studies have noted that use of the DOM improves the detection of mesiopalatal canals to more than 90% in maxillary first molars and 60% in maxillary second molars.[108,207] These evaluative studies demonstrate that magnification and illumination greatly enhance the identification of the pulp chamber morphology and ultimately enable the clinician to achieve better outcomes within each of the stated objectives for root canal procedures.

http://dentalebooks.com

As with all advances in technology, however, there are varying points of concurrence and disagreement. For example, one group of investigators determined that dental loupes and the DOM were equally effective for locating mesiopalatal canals in maxillary molars,[29] whereas other studies determined that the DOM did not significantly enhance the ability to locate canals.[80] However, there appears to be consensus that the DOM enhances the locating of canals by magnifying and illuminating the grooves in the pulpal floor and by distinguishing the color differences in the dentin of the floor and walls.[41,107]

COMPONENTS OF THE ROOT CANAL SYSTEM

The dental pulp is often referred to as the root canal system, as opposed to a simple tube or circular space, due to its complexity (Fig. 5-4). The outline of this system generally corresponds to the external contour of the tooth. However, factors such as physiologic aging, pathosis, trauma, and occlusion all can modify its dimensions through the production of dentin or reparative (irregular secondary, irritation, and tertiary) dentin (Fig. 5-5).[199] The root canal system is divided into two portions: the pulp chamber, located in the anatomic crown of the tooth, and the pulp or root canal (or canals), found in the anatomic root. Other notable features are the pulp horns; accessory, lateral, and furcation canals; canal orifices; apical deltas; and apical foramina. The pulp horns are important because the pulp in them is often exposed by caries, trauma, or mechanical invasion, which usually necessitates vital pulp or root canal procedures. Also, the pulp horns undergo rapid mineralization, along with reduction of the size and shape of the pulp chamber because of the formation of reparative dentin over time.

The root canal begins as a funnel-shaped canal orifice, generally at or just apical to the cervical line, and ends at the apical foramen, which opens onto the root surface at or within 3 mm of the center of the root apex.* Nearly all root canals are curved, particularly in a faciolingual direction. These curves may pose problems during enlargement and shaping procedures because they are not evident on a standard two-dimensional (2D) radiograph. Angled views are often necessary to determine their presence, direction, and severity. A curvature may be a gradual curve of the entire canal or a sharp curvature near the apex. Double S-shaped canal curvatures also can occur. In most cases, the number of root canals corresponds to the number of roots; however, an oval root may have more than one canal.

Accessory canals are minute canals that extend in a horizontal, vertical, or lateral direction from the pulp space to the periodontium. In 74% of cases they are found in the apical third of the root, in 11% in the middle third, and in 15% in the cervical third.[223] Accessory canals contain connective tissue and vessels but do not supply the pulp with sufficient circulation to form a collateral source of blood flow. They are formed by the entrapment of periodontal vessels in Hertwig's epithelial root sheath during calcification.[46] They may play a significant role in the communication of disease processes, serving as avenues for the passage of irritants, primarily from the pulp to

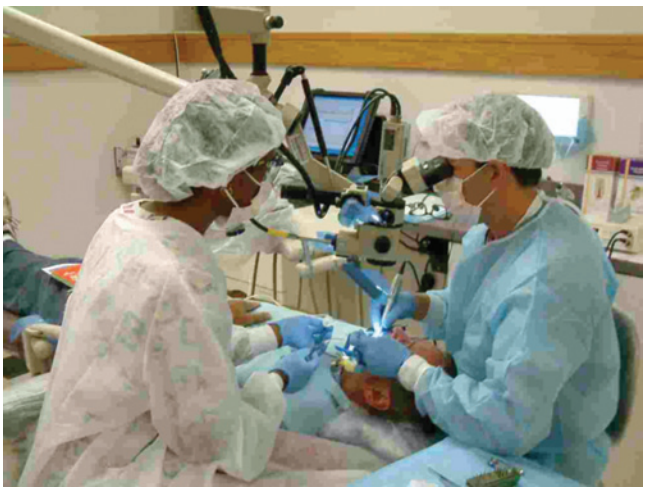

FIG. 5-3 The dental operating microscope (DOM) has vastly improved locating the position of the coronal canal anatomy.

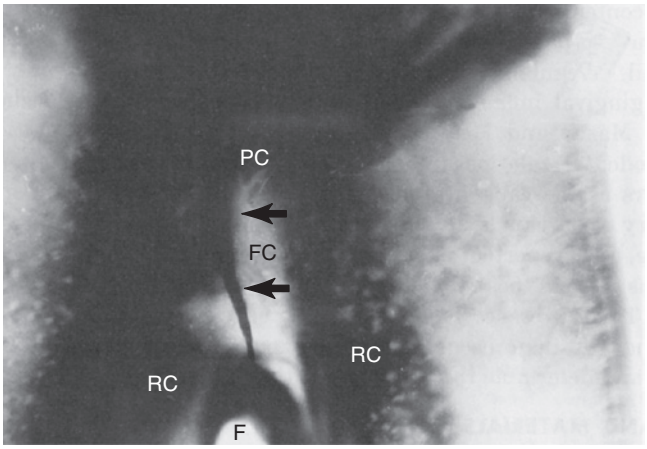

FIG. 5-6 Mandibular first molar showing a furcation canal *(FC, arrows). F,* Furcation; *PC,* pulp chamber floor; *RC,* root canal.

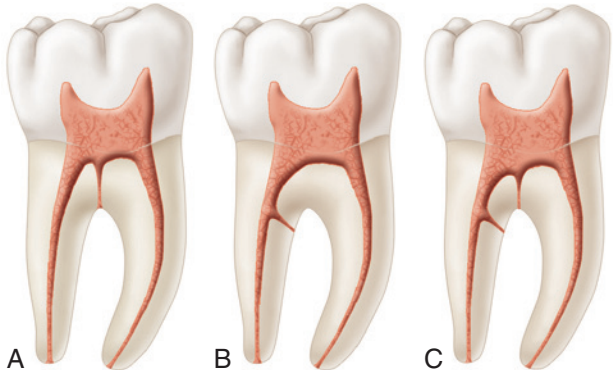

FIG. 5-7 Accessory canals occur in three distinct patterns in the mandibular first molars. A, In 13% a single furcation canal extends from the pulp chamber to the intraradicular region. B, In 23% a lateral canal extends from the coronal third of a major root canal to the furcation region (80% extend from the distal root canal). C, About 10% have both lateral and furcation canals.

the periodontium, although communication of inflammatory processes may occur from either tissue.

Accessory canals that are present in the bifurcation or trifurcation of multirooted teeth are referred to as *furcation canals* (Fig. 5-6).[223,226] These channels form as a result of the entrapment of periodontal vessels during the fusion of the diaphragm, which becomes the pulp chamber floor.[46] In mandibular molars these canals occur in three distinct patterns (Fig. 5-7). Tables 5-1 and 5-2 present the incidence of furcation canals for each tooth.

Based on scanning electron microscopy (SEM) studies, the diameter of furcation openings in mandibular molars varies from 4 to 720 m.[224] The number of furcation canals ranges from none to more than 20 per specimen. Foramina on both the pulp chamber floor and the furcation surface were found in 36% of maxillary first molars, 12% of maxillary second molars, 32% of mandibular first molars, and 24% of mandibular second molars (Fig. 5-8). Mandibular teeth have a higher incidence of foramina involving both the pulp chamber floor and the furcation surface (56%) than do maxillary teeth (48%). No relationship was found between the incidence of accessory foramina and the occurrence of pulp chamber calcification or the distance from the chamber floor to the furcation. Radiographs usually fail to show the presence of furcation and lateral canals in the coronal portion of these roots. In one study involving 200 permanent molars, the pulp chamber floor was stained with 0.5% basic fuscin dye. Patent furcation canals were detected in 24% of maxillary and mandibular first molars, 20% of mandibular second molars, and 16% of maxillary second molars.[87] Pulpal inflammation can communicate to the periodontium via these canals, and the result is furcation lesions in the absence of demonstrable periodontal disease. Likewise, the long-term presence of periodontal furcation lesions may influence the viability of the coronal or radicular pulp tissue when these aberrant channels are present.[84]

ROOT CANAL ANATOMY

The knowledge of common root canal morphology and its frequent variations is a basic requirement for success during root canal procedures. The significance of canal anatomy has been underscored by studies that demonstrated that the natural variations in canal geometry had a greater effect on the changes that occurred during enlargement and shaping than did the instrumentation techniques used to achieve these objectives.[167-169]

From the early works of Preiswerk[175] in 1912, Fasoli and Arlotta[67] in 1913, and Hess and Zurcher[90] in 1917, to more recent studies[33,82,100,190] demonstrating the anatomic complexities of the root canal system, data indicate that a root with a

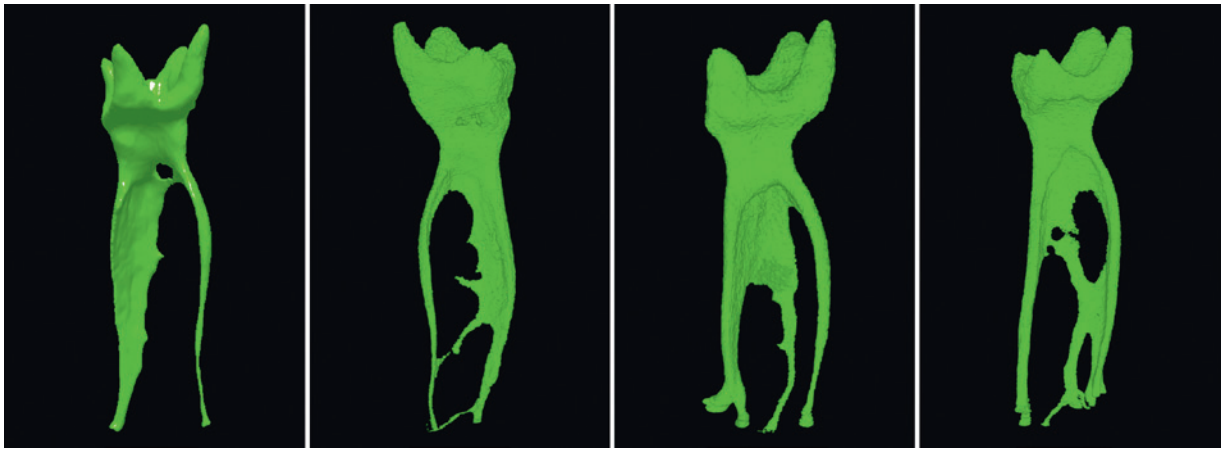

FIG. 5-9 Microcomputed tomography (μCT) scans show multiple canal configurations, depicting the complexity of the root canal system.

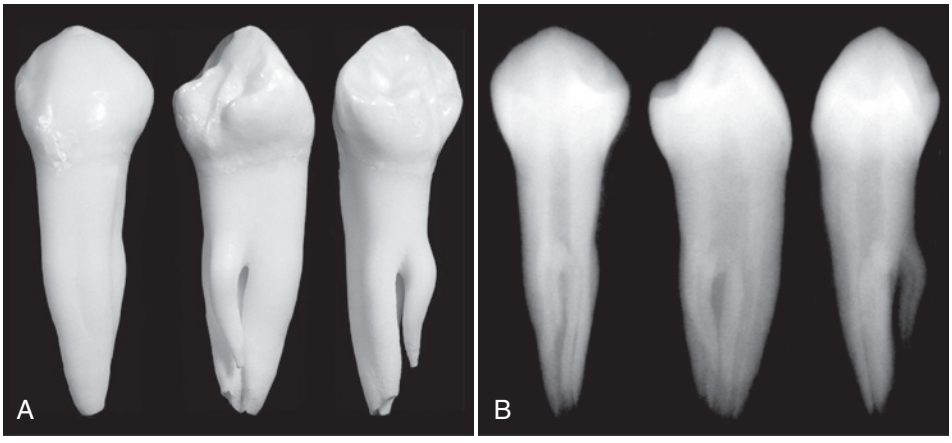

FIG. 5-10 A, Mandibular first premolar with three separate roots trifurcating in the midroot. B, Radiograph of the three views. Small canals diverging from the main canal create a configuration that is difficult to prepare and obturate biomechanically.

tapering canal and a single foramen is the exception rather than the rule. Investigators have shown multiple foramina, additional canals, fins, deltas, intercanal connections, loops, C-shaped canals, and furcation and lateral canals in most teeth (Fig. 5-9).* Consequently, complex anatomy must be considered the norm. The first premolar in Fig. 5-10, *A*, is a good example of complex anatomy. The extra root is not obvious in a pretreatment radiograph (Fig. 5-10, *B*). Figure 5-11 shows a cross-section of a similar tooth. This tooth has a fine, ribbon-shaped canal system instead of two distinct canals. Both these teeth present challenges for locating the canal and for achieving the previously stated objectives for root canal procedures.

Typically, root canals take variable pathways throughout, coursing from the orifice to the apex. The pulp canal system is complex, and canals may branch, divide, and rejoin. Weine[238]

*References 48, 53, 154, 170, 196, and 223.

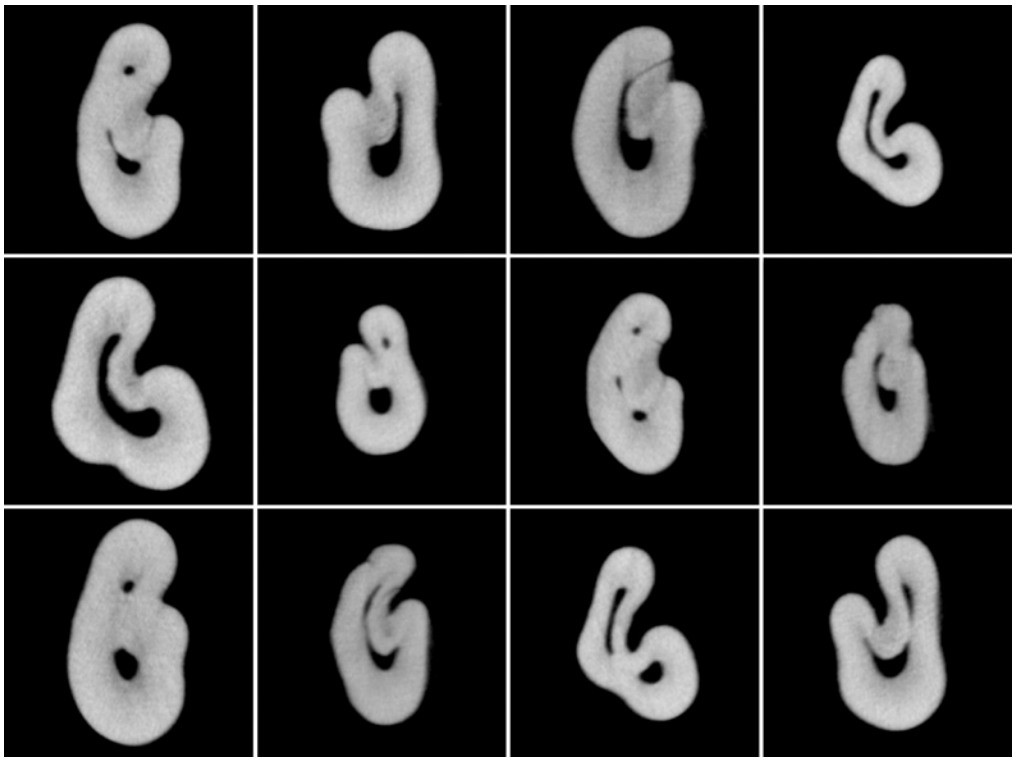

FIG. 5-11 Cross sections of teeth similar to those seen in Fig. 5-10 amplify the unique nature of the root canal system, particularly its ribbon and C-shaped configurations.

categorized the root canal systems in any root into four basic types. Other studies,[225] using cleared teeth in which the root canal systems had been stained with hematoxylin dye, found a much more complex canal system. In doing so the authors identified eight pulp space configurations, which can be briefly described as follows (Fig. 5-12):

Type I: A single canal extends from the pulp chamber to the apex (1).

Type II: Two separate canals leave the pulp chamber and join short of the apex to form one canal (2-1).

Type III: One canal leaves the pulp chamber and divides into two in the root; the two then merge to exit as one canal (1-2-1).

Type IV: Two separate, distinct canals extend from the pulp chamber to the apex (2).

Type V: One canal leaves the pulp chamber and divides short of the apex into two separate, distinct canals with separate apical foramina (1-2).

Type VI: Two separate canals leave the pulp chamber, merge in the body of the root, and separate short of the apex to exit as two distinct canals (2-1-2).

Type VII: One canal leaves the pulp chamber, divides and then rejoins in the body of the root, and finally separates into two distinct canals short of the apex (1-2-1-2).

Type VIII: Three separate, distinct canals extend from the pulp chamber to the apex (3).

The anatomic variations present in these teeth are listed in Tables 5-1 and 5-2. The only tooth that showed all eight possible configurations was the maxillary second premolar.

The percentages of human permanent teeth with these variable canal configurations are presented in Tables 5-3 and 5-4.

Similar observations have been described in large population studies with the exceptions that one canal was found in 23% of maxillary laterals, 55% of mesiobuccal roots of maxillary second molars, and 30% of distal roots of mandibular second molars.[33,242] Differences in these studies, from the types described by Weine, may be due to variations in the ethnic and racial populations studied. Other studies that were ethnic, racial, or gender-specific based have indicated wide variations in canal morphology, which sometimes appeared more often in specific teeth.* These authors concluded that gender, racial, and ethnic aspects should be considered in the pretreatment evaluation for root canal procedures (Fig. 5-13).

In addition to in vitro morphologic studies, a large number of case reports has described a variety of complex canal configurations (see Tables 5-8 to 5-27 online at the Expert Consult site). Reports of complex anatomy from both in vitro and in vivo investigations contribute to the adage that it is easier to recognize an anatomic feature if one is already prepared to see it. With the availability of CBCT, many more irregular and challenging root canal anatomies have been identified.[168,217]

One well-recognized ethnic variant is the higher incidence of single-rooted and C-shaped mandibular second molars in Native American and Asians populations (Fig. 5-14).[62,63,130,131] However, this is not always the case, as the occurrence of two canals in the mesiobuccal root of maxillary first molars in Japanese patients is similar to that described for other ethnic groups.[239] All this information makes it clear that the clinician is confronted daily with highly complex and variable root canal systems.

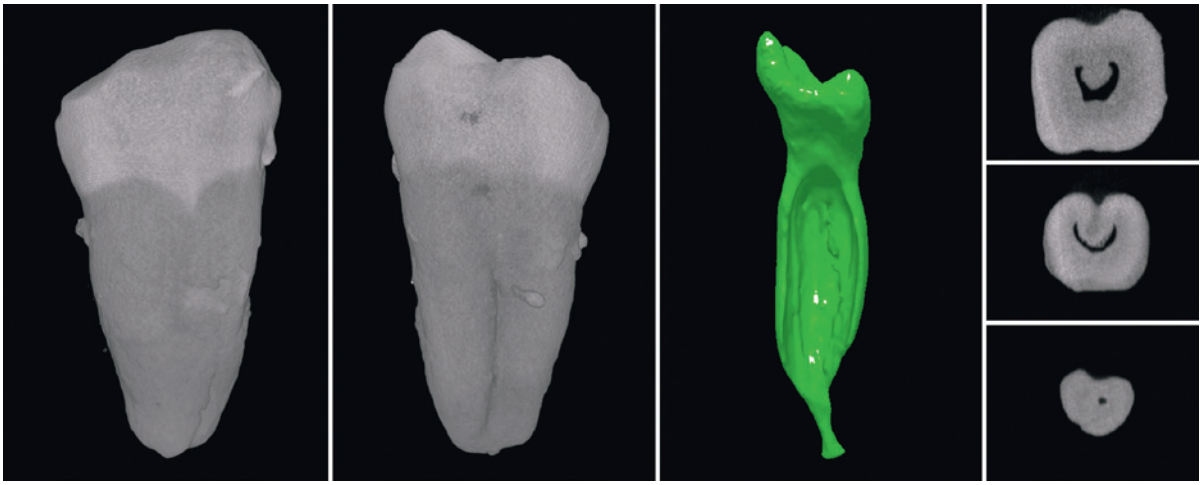

FIG. 5-14 Common variant of a C-shaped canal anatomy found in Native Americans and Asian populations.

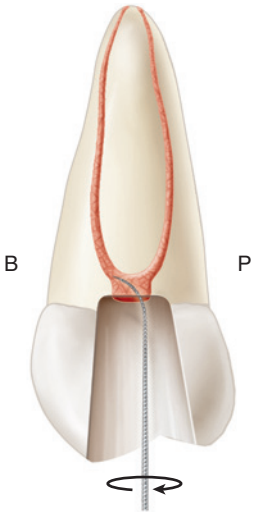

FIG. 5-15 An oval orifice must be explored with apically curved small instruments. When trying to locate the buccal canal, the clinician should place the file tip in the orifice with the tip curved to the buccal side. To explore for the palatal canal, a curved file tip is placed toward the palate. *B,* Buccal; *P,* palatal.

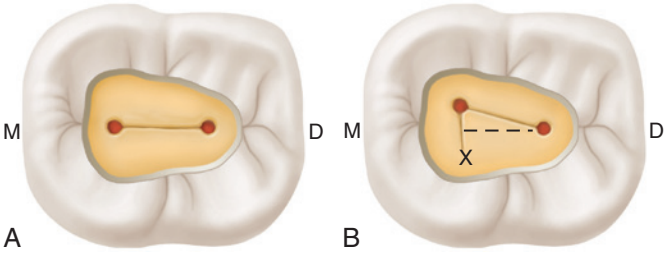

FIG. 5-16 A, In a mandibular second molar with two canals, both orifices are in the mesiodistal midline. B, If two orifices are not directly in the mesiodistal midline, a search should be made for another canal on the opposite side in the area of "X." *D,* Distal; *M,* mesial.

Clinical Determination of the Root Canal Configuration

Coronal Considerations

Examination of the pulp chamber floor can reveal clues to the location of orifices and to the type of canal system present. It is important to note that if only one canal is present, it usually is located in the center of the access preparation. All such orifices, particularly if oval shaped, should be explored thoroughly with small, stiff K-files that have a smooth to sharp bend in the apical 1 to 2 mm (C files and C+ files, Dentsply Tulsa Dental Specialties, Tulsa, Oklahoma, and Dentsply Maillefer, Ballaigues, Switzerland, respectively). If only one orifice is found and it is not in the center of the root, another orifice probably exists, and the clinician should search for it on the opposite side (Fig. 5-15). The relationship of the two orifices to each other is also significant (Fig. 5-16). The closer they are, the greater the chance the two canals join at some point in the body of the root. As the distance between orifices in a root increases, the greater is the chance the canals will remain separate. The more separation between orifices, the less the degree of canal curvature.[40] The direction a file takes when introduced into an orifice is also important. If the first file inserted into the distal canal of a mandibular molar points either in a buccal or lingual direction, a second canal is present. If two canals are present, they will be smaller than a single canal. (See μCTs and cross sections of all tooth groups later in this chapter. In addition, rotational videos of these groups can be found online as Videos 5-1 through 5-16 at the Expert Consult site.)

Midroot Considerations

As the canal leaves the coronal portion of the root and blends into the midroot portion, many changes can occur, including fins, webs, culs-de-sac, and isthmuses (also called *anastomoses*). These structures are narrow, ribbon-shaped communications between two root canals that contain pulp or pulpally derived tissue, or they may represent a communication between two canals that split in the midroot portion of the canal. These structures contain variable amounts of tissue, and when the pulp is infected, they often contain bacteria and their byproducts. In one study, isthmuses in the mesiobuccal root of maxillary first molars were found most often 3 to 5 mm from the root apex.[244] A complete or partial isthmus was found at the 4-mm level 100% of the time. In another study, partial isthmuses were found more often than complete ones.[213]

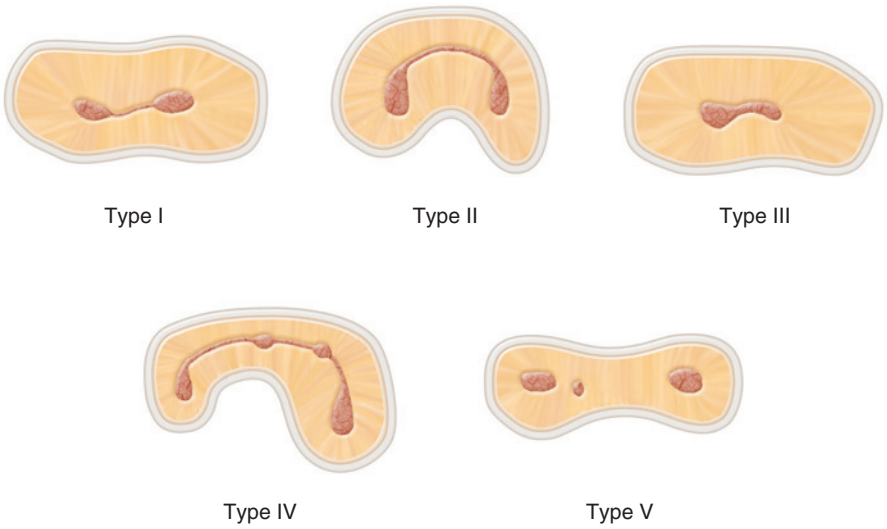

FIG. 5-17 Schematic representation of isthmus classifications described by Kim and colleagues. Type I is an incomplete isthmus; it is a faint communication between two canals. Type II is characterized by two canals with a definite connection between them (complete isthmus). Type III is a very short, complete isthmus between two canals. Type IV is a complete or incomplete isthmus between three or more canals. Type V is marked by two or three canal openings without visible connections. (From Kim S, Pecora G, Rubinstein R, Dorscher-Kim J: *Color atlas of microsurgery in endodontics,* Philadelphia, 2001, Saunders.)

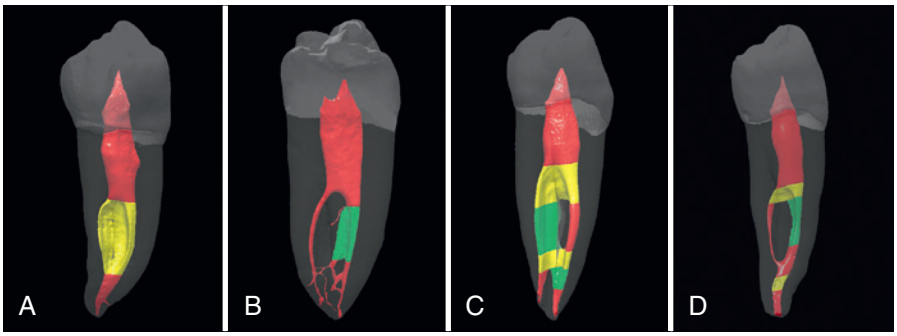

FIG. 5-18 μCT scans of mandibular premolars reflect a wide variation in canal morphology, moving from coronal to apical sections The red color indicates a non–C-shaped canal space; yellow indicates a semilunar canal shape; and green indicated a continuous C-shaped configuration.

Isthmuses are found in 15% of anterior teeth; in maxillary premolar teeth, they are found in 16% at the 1-mm level from the apex and in 52% at the 6-mm level, which puts them primarily in the middle third of the canal (Fig. 5-17). The prevalence of an isthmus increases in the mesiobuccal root of the maxillary first molar, from 30% to 50% near the junction of middle and apical thirds of the root. Eighty percent of the mesial roots of mandibular first molars have these communications at the apical to middle third junction, with the distal root display more in the apical third.

Another change that often occurs in the midroot portion is the splitting of a single canal into two or more canals, along with a wide variation in canal morphology. Likewise, canals often join in this area, starting as coronally two separate canals (Fig. 5-18).

Whenever a root contains two canals that join to form one, the lingual/palatal canal generally is the one with direct access to the apex, although this may require radiographic verification. When one canal separates into two, the division is buccal and palatal/lingual, and the lingual canal generally splits from the main canal at a sharp angle, sometimes nearly a right angle (Fig. 5-19). One study[197] recommended visualizing this configuration as a lower case letter "h". The buccal canal is the straight-line portion of the h; the lingual canal exists about midroot at a sharp angle from the buccal canal. In these situations modification of the access to develop an unobstructed passage of instruments into the lingual canal is indicated.

Although the splitting of one canal into two presents challenges for the clinician, of greater concern is the very small canal that may split off, at times at almost a 90 degree angle, and cannot be located tactilely or even under magnification with the DOM. Although these canals may join the main canal at some point apically, some of them exit separately. This is not uncommon in teeth with C-shaped canals.

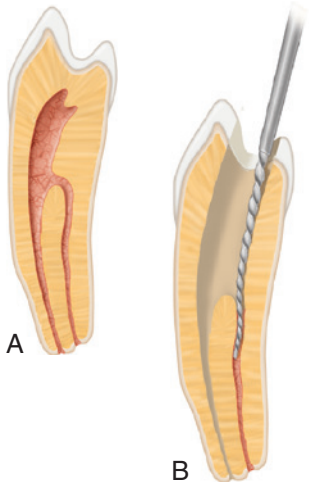

FIG. 5-19 A, Mesial view of a mandibular premolar with a type V canal configuration. The lingual canal separates from the main canal at nearly a right angle. B, This anatomy requires widening of access in a lingual direction to achieve straight-line access to the lingual canal. This should be done with a DOM.

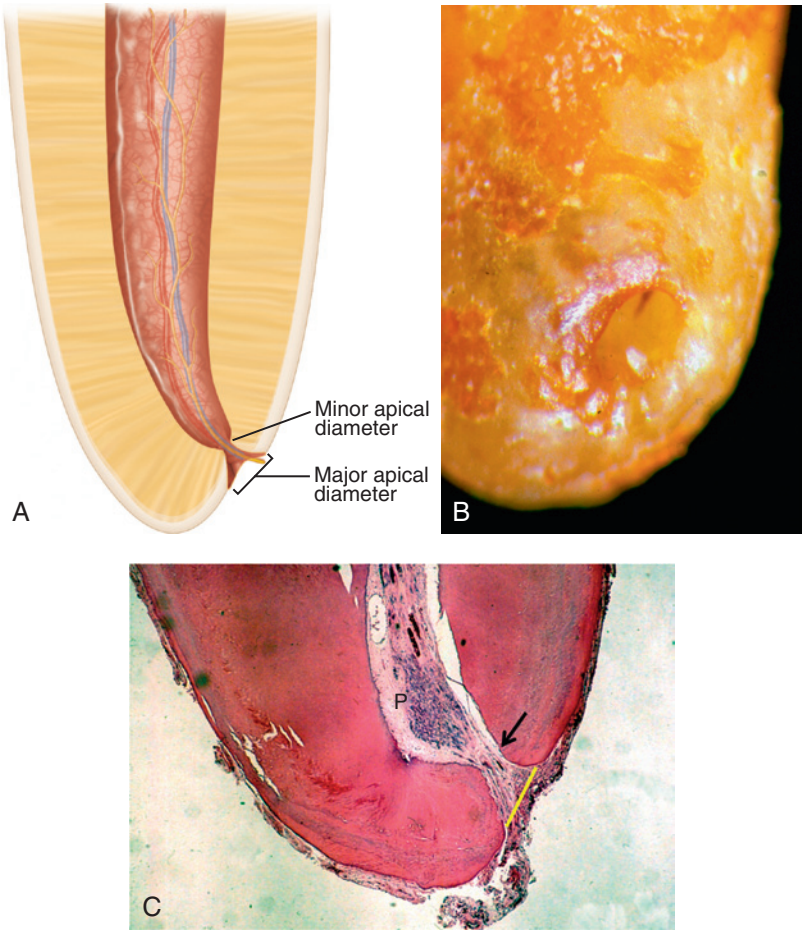

FIG. 5-20 A, Morphology of the root apex. From its orifice the canal tapers to the apical constriction, or minor apical diameter, which generally is considered the narrowest part of the canal. From this point the canal widens as it exits the root at the apical foramen, or major apical diameter. The space between the minor and major apical diameters is funnel shaped. B, Clinical view of major apical foramen. C, Histologic view of the canal constriction and canal foramen. (B and C from Gutmann JL, Lovdahl PE: *Problem solving in endodontics,* ed 5, St Louis, 2011, Elsevier.)

Apical Considerations

The classic concept of apical root anatomy is based on three anatomic and histologic landmarks in the apical region of a root: the apical constriction (AC), the cementodentinal junction (CDJ), and the apical foramen (AF). Kuttler's description of the anatomy of the root apex has the root canal tapering from the canal orifice to the AC, which generally is 0.5 to 1.5 mm coronal to the AF (Fig. 5-20).[109] The AC generally is considered the part of the root canal with the smallest diameter; it also is the reference point clinicians use most often as the apical termination for enlarging, shaping, cleaning, disinfecting, and filling. Violation of this area with instruments or filling materials is not recommended for long-term, successful outcomes.

The CDJ is the point in the canal where cementum meets dentin; it is also the point where pulp tissue ends and periodontal tissues begin. The location of the CDJ in the root canal varies considerably. It generally is not in the same area as the AC, and estimates place it approximately 1 mm from the AF.[184,200]

From the AC, or minor apical diameter, the canal widens as it approaches the AF, or major apical diameter. The space between the major and minor diameters has been described as funnel shaped or hyperbolic, or as having the shape of a morning glory. The mean distance between the major and minor apical diameters is 0.5 mm in a young person and 0.67 mm in an older individual.[109] The distance is greater in older individuals because of the buildup of cementum.

The AF is the "circumference or rounded edge, like a funnel or crater, that differentiates the termination of the cemental canal from the exterior surface of the root."[109] The diameter of the foramen is 502 µm in individuals 18 to 25 years of age and 681 µm in those over age 55, which demonstrates the growth of the AF with age.[109] By comparison, these sizes are larger than the cross-sectional diameter of #50 and #60 root canals files, respectively. The AF does not normally exit at the anatomic apex, but rather is offset 0.5 to 3 mm. This variation is more marked in older teeth through cementum apposition. Studies have shown that the AF coincides with the apical root vertex in 17% to 46% of cases.*

The location and diameter of the CDJ differ from those of the AF in maxillary anterior teeth.[174] Extension of cementum from the AF into the root canal differs considerably, even when opposite canal walls are compared. Cementum reaches the same level on all canal walls in only 5% of cases. The greatest extension generally occurs on the concave side of the canal curvature. This variability confirms that the CDJ and the AC generally are not in the same area and that the CDJ should be considered just a variable junction at which two histologic tissues meet in the root canal (Fig. 5-21). The diameter of the canal at the CDJ varies considerably; it was determined to be 353 µm for the central incisors, 292 µm for the lateral incisors, and 298 µm for the canines.[167] These measures approximate the size of #30 to #35 root canal files.

In maxillary anterior teeth, the root apex and main AF coincided in 17% of examined central incisors and canines and

Mean Perpendicular Distance from Root Apex to Apical Constriction with Mesiodistal and Labiolingual Diameters at Constriction

Tooth	Mesiodistal (mm)	Labiolingual (mm)	Vertical (mm)
Central incisor	0.37	0.428	0.863
Lateral incisor	0.307	0.369	0.825
Canine	0.313	0.375	1.01

From Mizutani T, Ohno N, Nakamura H: Anatomical study of the root apex in the maxillary anterior teeth, *J Endod* 18:344, 1992.

in 7% of lateral incisors.[139] Both the root apex and the AF of the central incisors and canines were displaced distolabially, whereas those of the lateral incisors were displaced distolingually. The perpendicular distance from the root apex to the AC and both mesiodistal and labiolingual root canal diameters at the AC are shown in Table 5-5. The labiolingual diameter in all maxillary anterior teeth is approximately 50 µm more than the mesiodistal diameter. This has definite implications for intracanal root canal procedures because only the mesiodistal diameter is evident on radiographs.

Scanning electron microscopy has been used to determine the number and size of main apical foramina, their distance from the anatomic apex, and the size of accessory foramina. Morfis et al.[145] observed that more than one main foramen was found in all teeth except the palatal root of maxillary molars

TABLE 5-6

and the distal root of mandibular molars. No main foramen was seen in 24% of maxillary premolars and 26% of maxillary incisors. The mesial roots of mandibular molars (50%) and maxillary premolars (48%) and the mesial roots of maxillary molars (42%) had the highest percentage of multiple main foramina. This finding is consistent with observations that blunted roots usually have more than one root canal. The mean values for the size of the main foramen are listed in Table 5-6. Sizes ranged from 210 µm for the maxillary premolars to 392 µm for the distal roots of the mandibular molars. All groups of teeth had at least one accessory foramen. The maxillary premolars had the most and the largest accessory foramina (mean value, 53 µm) and the most complicated apical morphologic makeup. The mandibular premolars had strikingly similar characteristics, a possible reason root canal procedures may fail in premolar teeth.

The morphology of the apical third of the root reflects multiple anatomic variations, including numerous accessory canals; areas of resorption and repaired resorption; attached, embedded, and free pulp stones; varying amounts of reparative dentin; and varying root canal diameters (Table 5-7).[140,141] Primary dentinal tubules are found less often than in the coronal dentin and are more or less irregular in direction and density. Some areas are completely devoid of tubules. Fine tubular branches (300 to 700 µm in diameter) that run at a 45-degree angle to the main tubules and microbranches (25 to 200 µm in diameter) that run at a 90-degree angle to the main tubules are often present (Fig. 5-22). This variable nature of the apical structure and significant absence of dentinal tubules may lead to reduced chances of bacterial invasion into the dentinal walls; however, it also presents challenges for all root canal procedures, from cleaning and disinfection to obturation.

Clinically, considerable controversy exists over the exact termination point for root canal procedures in the apical third of the root; clinical determination of apical canal morphology is difficult at best.[84,193] The existence of an AC may be more conceptual than real. Several studies have reported that a traditional single AC was present less than half the time, particularly when apical root resorption and periradicular pathosis were factors.[44,55,192,238] The apical portion of the root canal often

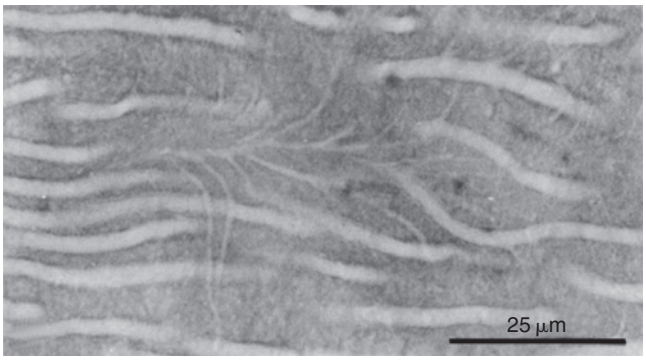

FIG. 5-22 Fine tubules and microbranches can be seen in the apical part of the root. (From Mjör IA, Nordahl I: The density and branching of dentinal tubules in human teeth, *Arch Oral Biol* 41:401, 1996.)

is tapered, or the walls are parallel to each other, or the canal has multiple constrictions.[55] Weine[238] recommended the following termination points: 1 mm from the apex when no bone or root resorption has occurred; 1.5 mm from the apex when only bone resorption has occurred; and 2 mm from the apex when both bone and root resorption are present.

Locating the AC and AF is difficult clinically; for this reason, some researchers contend that the radiographic apex is a more reliable reference point.[250] These authors recommend that root canal procedures terminate at or within 3 mm of the radiographic apex, depending on the pulpal diagnosis. For vital cases, clinical and biologic evidence indicates that a favorable point at which to terminate therapy is 2 to 3 mm short of the radiographic apex.[103,195] This leaves an apical pulp stump, which prevents extrusion of irritating filling materials into the periradicular tissues. However, what is not recognized commonly among clinicians is that this so-called pulp stump is actually not pulp tissue, but rather periodontal tissue that can ensure apical healing with cementum over the root end (see Fig. 5-21). On the other hand, pulp necrosis, bacteria and their byproducts, and biofilms may be present in the apical root canal, which may negate healing if they are not removed thoroughly during root canal procedures. Studies have shown that in these cases, a better success rate is achieved when therapy ends at or within 2 mm of the radiographic apex.[102,103,195] When the intracanal procedures ended short of the 2-mm point or extended past the radiographic apex, the success rate declined by 20%. For revision of procedural failures, apical procedures should extend to or preferably 1 to 2 mm short of the radiographic apex to prevent overextension of instruments and filling materials into the periradicular tissues (see Chapters 6 and 8).

Many investigators who have evaluated apical and periradicular tissues after root canal procedures concluded that the most favorable prognosis was obtained when procedures were terminated at the AC, and the worst prognosis was produced by treatment that extended beyond the AC.[113-116,180] Procedures terminated more than 2 mm from the AC had the second worst prognosis. These findings occurred with root canal procedures in teeth with both vital and necrotic pulps and when bacteria were present beyond the AF. Sealer or gutta-percha (or both) in the periradicular tissues, lateral canals, and apical ramifications may cause a severe inflammatory reaction. However, it is difficult to locate the AC clinically, which is why some studies direct clinicians to terminate all procedures at or beyond the radiographic apex, thereby filling all apical ramifications and lateral canals.[186] This dictate is empirically based, and CBCT evaluation of procedures previously thought to be successful has allowed identification of more posttreatment disease.[158]

Although the apical limit of instrumentation and obturation during root canal procedures continues to be the subject of major controversy, modern electronic apex locators can help the clinician determine the approximate working length of the root canal with greater assuredness. The ultimate challenges are that the two hallmarks of the apical region are its variability and unpredictability. The tremendous variation in canal shapes and diameters complicates enlargement and shaping procedures in all dimensions. Success in these goals depends on the anatomy of the root canal system, the dimensions of the canal walls, use of the appropriate instruments within these confines, and the operator's skill and experience.

OBJECTIVES AND GUIDELINES FOR ACCESS CAVITY PREPARATION

Objectives

Access to the complex root canal system is the first and arguably the most important phase of any nonsurgical root canal procedure.[84,212] The objectives of access cavity preparation are to (1) remove all caries when present, (2) conserve sound tooth structure, (3) unroof the pulp chamber completely, (4) remove all coronal pulp tissue (vital or necrotic), (5) locate all root canal orifices, and (6) achieve straight- or direct-line access to the apical foramen or to the initial curvature of the canal. If done properly, a thorough assessment of the restorative needs of every tooth can be made (e.g., the need for crown lengthening, a post, or simply a bonded core or composite to ensure the structural integrity of the tooth after root canal procedures).

A properly prepared access cavity creates a smooth, straight-line path to the canal system and ultimately to the apex or position of the first curvature (Fig. 5-23, *A*). Straight-line access provides the best chance of débridement of the entire canal space; it reduces the risk of instrument breakage[143]; and it results in straight entry into the canal orifice, with the line angles forming a funnel that drops smoothly into the canal (or canals). Projection of the canal center line to the occlusal surface of the tooth indicates the location of the line angles (Fig. 5-23, *B*). Connection of the line angles creates the outline form. Modifications of the access outline form may be needed to facilitate location of canals and to create a convenient form for the planned procedures.

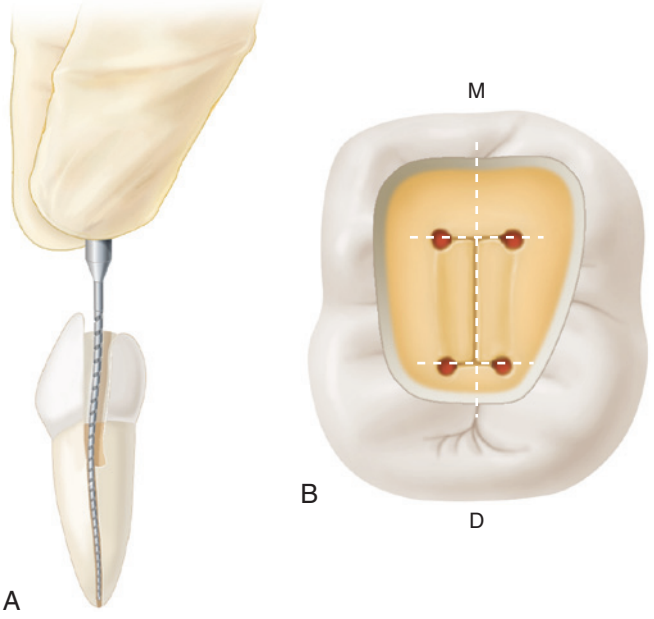

FIG. 5-23 A, Straight-line access to a canal. The instrument should not be deflected until it reaches the initial canal curvature. In some cases coronal tooth structure must be sacrificed to obtain direct access to the pulp chamber. B, Diagrammatic representation of centrality and concentricity of symmetry and location of canal orifices. *D,* Distal; *M,* mesial.

KEY STEPS TO CONSIDER IN ACCESS PREPARATION

Visualization of the Likely Internal Anatomy

Internal tooth anatomy dictates access shape; therefore, the first step in preparing an access cavity is visualization of the position of the pulp space in the tooth. This visualization requires evaluation of angled periapical radiographs and examination of the tooth anatomy at the coronal, cervical, and root levels. Although only two-dimensional, diagnostic radiographs help the clinician estimate the position of the pulp chamber, the degree of chamber calcification, the number of roots and canals, and the approximate canal length. Palpation along the attached gingiva may aid in the determination of root location and direction. This information, when considered together, guides the clinician in the direction of the bur that is chosen to begin cutting the access cavity.

Evaluation of the Cementoenamel Junction and Occlusal Tooth Anatomy

Traditionally, access cavities have been prepared in relation to the occlusal anatomy. However, complete reliance on the occlusal/lingual anatomy is dangerous because this morphology can change as the crown is destroyed by caries and reconstructed with various restorative materials. Likewise, the root may not be perpendicular to the occlusal surface of the tooth; thus complete dependence on the occlusal or lingual anatomy may explain the occurrence of some procedural errors, such as coronal perforations along the cervical line or into the furcation. Krasner and Rankow[107] found that the cementoenamel junction (CEJ) was the most important anatomic landmark for determining the location of pulp chambers and root canal orifices. Their study demonstrated the existence of a specific and consistent anatomy of the pulp chamber floor. These authors proposed guidelines, or spatial concepts, that apply to the 3D assessment of the pulp chamber anatomy and that can help the clinician determine the number and location of orifices on the chamber floor (see Fig. 5-23, *B*).

- *Centrality:* The floor of the pulp chamber is always located in the center of the tooth at the level of the CEJ.
- *Concentricity:* The walls of the pulp chamber are always concentric to the external surface of the tooth at the level of the CEJ; that is, the external root surface anatomy reflects the internal pulp chamber anatomy.
- *Location of the CEJ:* The distance from the external surface of the clinical crown to the wall of the pulp chamber is the same throughout the circumference of the tooth at the level of the CEJ, making the CEJ the most consistent repeatable landmark for locating the position of the pulp chamber.
- *Symmetry:* Except for the maxillary molars, canal orifices are equidistant from a line drawn in a mesiodistal direction through the center of the pulp chamber floor. Except for the maxillary molars, canal orifices lie on a line perpendicular to a line drawn in a mesiodistal direction across the center of the pulp chamber floor.
- *Color change:* The pulp chamber floor is always darker in color than the walls.
- *Orifice location:* The orifices of the root canals are always located at the junction of the walls and the floor; the

orifices of the root canals are always located at the angles in the floor-wall junction; and the orifices of the root canals are always located at the terminus of the roots' developmental fusion lines.

More than 95% of the teeth these investigators examined conformed to these spatial relationships.[107] Slightly less than 5% of mandibular second and third molars did not conform because of the occurrence of C-shaped anatomy.

Preparation of the Access Cavity Through the Lingual and Occlusal Surfaces

Access cavities on anterior teeth usually are prepared through the lingual tooth surface, and those on posterior teeth are prepared through the occlusal surface. These approaches are the best for achieving straight-line access while reducing esthetic and restorative concerns. Some authors have recommended that the traditional anterior access for mandibular incisors be moved from the lingual surface to the incisal surface in selected cases[135]; this allows better access to the lingual canal and improves canal débridement (Fig. 5-24). In teeth that are lingually inclined or rotated, this is often the preferred choice for access and is performed before the dental dam is placed, or careful alignment of the root is determined before a bur is used.[84] Likewise, initial access through crowns may be better achieved without a dental dam in place so that the inclination of the root can be visualized; this information can be used as an indicator of the direction of the long axis of the treated tooth. Furthermore, canal identification and partial enlargement before dental dam placement may be beneficial in some cases. The Micro-Opener (Dentsply Maillefer) (Fig. 5-25, *A*) and EndoHandle with Find and File instruments (Venta Innovative Dental Products, Logan, Utah) (Fig. 5-25, *B*) are excellent instruments for locating canal orifices and developing the canal pathway when a dental dam has not been placed. These flexible, stainless steel hand instruments have variably tapered tips and permit not only canal identification, but also initial pathway formation when indicated. The former has offset handles that provide enhanced visualization of the pulp chamber, whereas the latter permits the use of a wide variety of instruments of different sizes.

FIG. 5-24 An incisal access cavity on mandibular anterior teeth may allow for improved straight-line access and canal débridement.

Removal of All Defective Restorations and Caries before Entry Into the Pulp Chamber

Removal of all defective restorations and caries before entering the root canal system is essential for many reasons.[84] Hidden caries or fractures are often identified, and the ability to determine the restorability of the tooth is enhanced. In this respect it is not uncommon, before entering the pulp chamber, to stop with the access opening preparation in favor of a crown lengthening procedure or adding a bonded buildup. Subsequently, the tooth will be much easier to isolate before entry into the pulp chamber, and sound restorative margins will have been identified. In some cases, an extraction may be indicated because of tooth fracture or unrestorability (Fig. 5-26). Ultimately, with an open preparation, canals are much easier to locate, especially under enhanced illumination and magnification, and intracanal procedures are facilitated. Studies have indicated that clinicians were about 40% more likely to miss fractures, caries, and marginal breakdown if restorations were not completely removed.[1] Working through a clean access also

prevents restorative debris from becoming dislodged and inadvertently pushed into the canal system.

Removal of Unsupported Tooth Structure

Along with the removal of caries and restorations, unsupported tooth structure should be removed to prevent tooth fracture during or between procedures. Although unnecessary removal of sound tooth structure should be avoided, oftentimes the access shape may have to be modified to facilitate canal location and intracanal procedures.

Preparation of Access Cavity Walls that Do Not Restrict Straight- or Direct-Line Passage of Instruments to the Apical Foramen or Initial Canal Curvature

Sufficient tooth structure must be removed to allow instruments to be placed easily into each canal orifice without interference from canal walls, particularly when a canal curves severely or leaves the chamber floor at an obtuse angle. Hence, access design depends not only on the orifice location, but also on the position and curvature of the entire canal. The walls of the root canal, rather than the walls of the access preparation, must guide the passage of instruments into the canal. Failure to follow this guideline results in treatment errors, including root perforation, misdirection of an instrument from the main canal (ledge formation), instrument separation, or creation of an incorrect canal shape (apical transportation).

Inspection of the Pulp Chamber Walls and Floor

Magnification is particularly important during initial root canal procedures, especially for determining the location of canals and removing tissue and calcifications from the pulp chamber. Illumination provided by the use of many magnification tools, in particular the DOM, aids in the initial negotiation of constricted, curved, and partially calcified canals. Enhanced vision allows the clinician to see internal dentin color changes and subtle landmarks that may not be visible to the unaided eye, including previously hidden cracks and decay. Surgical loupes and endodontic endoscopes[12] are also available to help in locating intricate root canal systems. In most cases, after dental dam placement, in addition to magnification, a sharp endodontic explorer (DG-16) is used to locate canal orifices and to determine their angle of departure from the pulp chamber.

Tapering of Cavity Walls and Evaluation of Space Adequacy for a Coronal Seal

A proper access cavity generally has tapering walls, with its widest dimension at the occlusal surface. In such a preparation, occlusal forces do not push the temporary restoration into the cavity and disrupt the seal. A minimum 3.5 mm of temporary filling material (e.g., Cavit; 3M ESPE, St. Paul, Minnesota) is needed to provide an adequate coronal seal for a short time.[237] Recently, canal orifice plugs of composite, glass ionomer, and mineral trioxide aggregate (ProRoot MTA, Dentsply Tulsa Dental Specialties) have shown promise in reducing the risk of bacterial contamination of the canal system when microleakage occurs at the coronal-restorative margins.[96]

MECHANICAL PHASES OF ACCESS CAVITY PREPARATION

The preparation of an access cavity requires the following equipment:

- Magnification and illumination
- Handpieces
- Burs
- Endodontic explorers
- Endodontic spoon
- Ultrasonic unit and tips

Magnification and Illumination

The access cavity is best prepared with the use of magnification and an appropriate light source. In lieu of a DOM, surgical loupes with an auxiliary light source are highly recommended.

Handpieces

Good tactile awareness is essential to perform most phases of access preparation with a high-speed handpiece. In many cases,

FIG. 5-27 Access burs: #2, #4, and #6 round carbide burs.

the use of a slow-speed handpiece is indicated, which is especially helpful in the careful excavation of caries located in the area of the anticipated access opening. For challenging access cavity preparations, especially those involving calcified and receded pulp chambers, even experienced clinicians may sacrifice cutting speed and efficiency in favor of the increased cutting control of the slow-speed handpiece or an ultrasonic tip.

Burs

Numerous burs have been developed exclusively for access cavity preparation. Providing a detailed, unabridged list of these burs would be difficult, and most clinicians have their own set of preferred access burs. To meet the overall needs in this regard, various companies have developed access kits with a large variety of burs (Dentsply Tulsa Dental Specialities; SS White, Lakewood, New Jersey; SybronEndo, Orange, California; Ultradent Products, Inc., South Jordan, Utah). In reality, creating an access cavity that meets the previously stated guidelines is more important than worrying about which burs are used in the process. This discussion, therefore, covers some of the more common access burs.

Round carbide burs (sizes #2, #4, and #6) (Fig. 5-27) are used extensively in the preparation of access cavities. They are used to excavate caries and to create the initial external outline shape. They also are useful for penetrating through the roof of the pulp chamber and for removing the roof. Some clinicians prefer to use a fissure carbide bur (Fig. 5-28) or a diamond bur with a rounded cutting end (Fig. 5-29) to perform these procedures. The advantage of the fissure carbide and diamond round-end burs is that they also can be used for some of the axial wall extensions of the access cavity preparation. However, when these burs are used for this purpose by inexperienced clinicians, their cutting ends can gouge the pulp floor and axial walls.

Fissure carbide and diamond burs with safety tips (i.e., noncutting ends) (Fig. 5-30) are safer choices for axial wall extensions. They can be used to extend and favorably orient the axial walls of the pulp chamber. Because they have no cutting end, the burs can be allowed to extend to the pulp floor, and the entire axial wall can be moved and oriented all in one plane from the enamel surface to the pulp floor. Such a technique produces axial walls free of gouges as the final access extensions are created. Fissure carbide and diamond burs also can be used to level off cusp tips and incisal edges,

FIG. 5-28 Access bur: #57 fissure carbide bur.

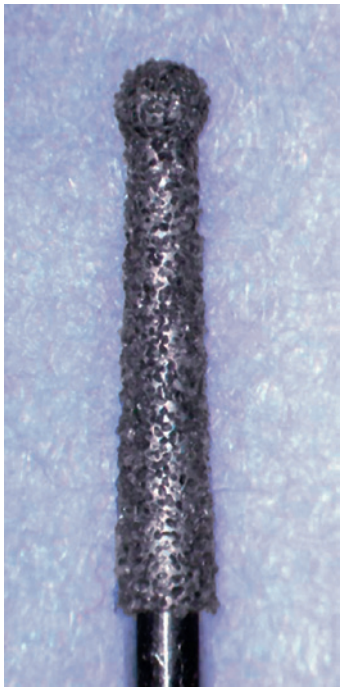

FIG. 5-29 Access bur: Round-end cutting tapered diamond bur.

which are used as reference points for the working length determination.

Round diamond burs (sizes #2 and #4) (Fig. 5-31) are needed when the access must be made through porcelain or metalloceramic restorations.[84] Diamond burs are less traumatic to porcelain than carbide burs and are more likely to penetrate the porcelain without cracking or fracturing it. They should always be used with water spray to control heat buildup in porcelain restorations. After penetrating the porcelain with a diamond bur, a carbide bur, such as a transmetal bur (Dentsply Maillefer) (Fig. 5-32), is used for metal or dentin penetration because of this bur's greater cutting efficiency.[84]

FIG. 5-30 Access burs: Safety-tip tapered diamond bur *(left);* safety-tip tapered carbide bur *(right).*

FIG. 5-31 Access burs: #2 and #4 round diamond burs.

FIG. 5-32 Access bur: Transmetal bur.

A significant trend in restorative dentistry is the increased use of zirconia-based crowns and onlays. Zirconia has different mechanical and thermal characteristics than metal. Carbide burs do not cut zirconia efficiently or safely. Zirconia is a brittle material and when cut can develop cracks that propagate through the framework and lead to eventual failure of the crown or onlay. Diamond bur manufacturers are aware of these issues, and they are currently introducing medium- and

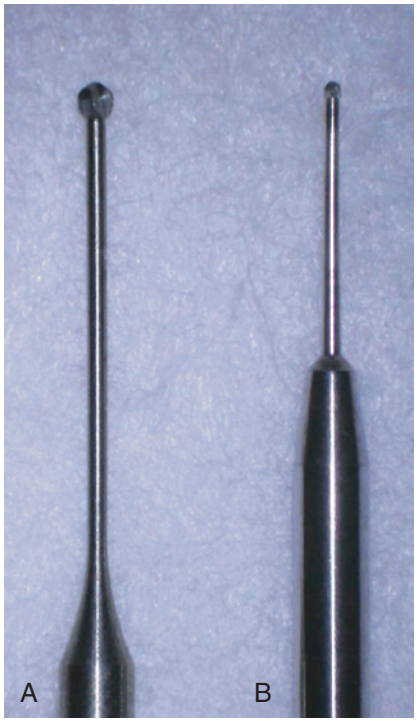

FIG. 5-33 Access burs. **A,** Mueller bur. **B,** LN bur or Extendo Bur.

fine-grit diamond burs that efficiently cut zirconia (Komet USA, Savannah, Georgia; Prima Dental Gloucester, England; SS White). These diamond burs should be used with copious water spray to minimize heat buildup in the zirconia crowns during access preparations.[84] Also, some diamond burs may degrade rapidly when cutting through zirconia and should be thrown away after one use.

Many teeth requiring access cavity preparations have metal restorations that must be penetrated. These restorations may be amalgams, all-metal cast restorations, or metal copings of porcelain fused to metal crowns. As previously mentioned, a transmetal bur is excellent for cutting through metal because of its exceptional cutting efficiency. To penetrate a metallic restoration, a new transmetal bur is recommended for each restoration, together with copious water spray for maximal cutting effect.

When a receded pulp chamber and calcified orifice are identified, or to locate and identify the canal orifice, countersinking or cutting into the root is often indicated. Extended-shank round burs, such as the Mueller bur (Brasseler USA, Savannah, Georgia) (Fig. 5-33, *A*) or Extendo Bur (Dentsply Tulsa Dental Specialties), also known as the LN bur (Dentsply Maillefer) (Fig. 5-33, *B*), can be used. The Munce Discovery bur (CJM Engineering, Santa Barbara, California) is similar to the Mueller bur but has a stiffer shaft and is available in smaller head sizes. The extra-long shank of these burs moves the head of the handpiece away from the tooth, improving the clinician's visibility during this delicate procedure. As an alternative, ultrasonic units offer good visibility with precision cutting.

Once the orifices have been located, they should be flared or enlarged and blended into the axial walls of the access cavity. This process permits the intracanal instruments used during the enlargement and shaping procedures to penetrate the canal effortlessly. Some clinicians might consider this task part of the

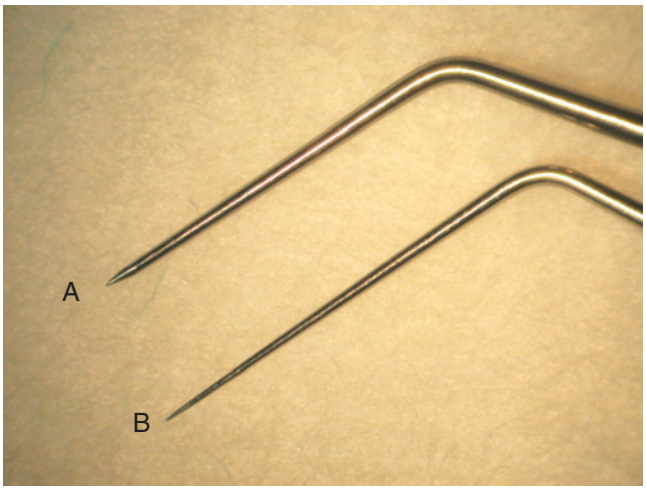

FIG. 5-34 A, Access instruments: DG-16 endodontic explorer. B, JW-17 endodontic explorer.

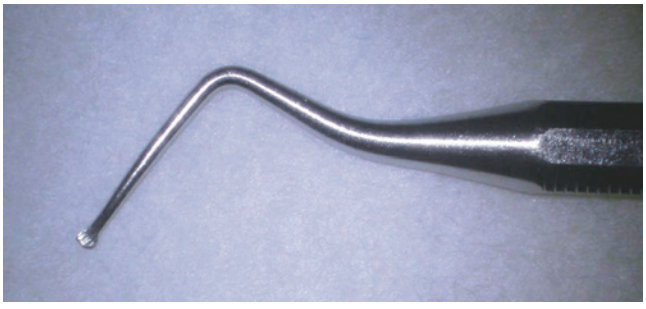

FIG. 5-35 Access instrument: Endodontic spoon.

canal enlargement and shaping phase; however, when done before deep canal penetration, it establishes a well-prepared access opening and may prevent subsequent error.

Endodontic Explorer and Spoon

Various hand instruments are useful for preparing access cavities. The DG-16 endodontic explorer (Fig. 5-34, *A*) is used to identify canal orifices and to determine canal angulation. An alternative, the JW-17 endodontic explorer (Fig. 5-34, *B*) (CK Dental Industries, Orange, California) serves the same purpose, but its thinner, stiffer tip can be useful for identifying the possible location of a calcified canal. A sharp endodontic spoon, which comes in different sizes (Fig. 5-35) can be used to remove coronal pulp and carious dentin. A #17 operative explorer, which can also be found as a doubled-ended instrument with the DG-16, is useful for detecting any remaining overhang from the pulp chamber roof, particularly in the area of a pulp horn of anterior teeth (Fig. 5-36). Failure to remove this overhang, along with the propensity for it to harbor tissue debris, often leads to tooth discoloration, especially in teeth restored only with bonded palatal composite.

Ultrasonic Unit and Tips

Ultrasonic units (Fig. 5-37) and tips specifically designed for activities during access opening preparation are extremely valuable. Ultrasonic tips from various manufacturers can be used to trough and deepen developmental grooves, remove tissue, and explore for canals. Ultrasonic systems provide

FIG. 5-36 Removal of the pulp horn is evaluated with a #17 operative explorer.

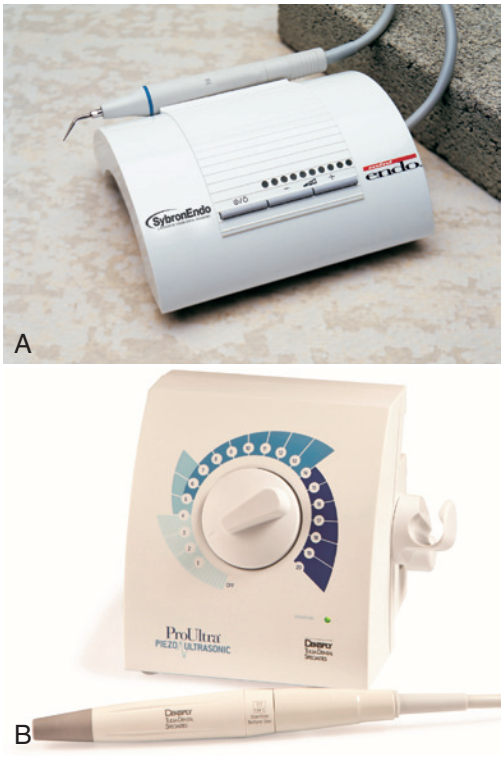

FIG. 5-37 A, Endo ultrasonic unit (MiniEndo II). B, ProUltra Piezo Ultrasonic. (A courtesy SybronEndo, Orange, Calif; B courtesy DENTSPLY Tulsa Dental Specialties, Tulsa, Okla.)

outstanding visibility compared with traditional handpiece heads, which typically obstruct vision. Fine ultrasonic tips, such as Sine Tips, ProUltra Tips, and Smart X BUC Tips (Dentsply Tulsa Dental Specialties; Dentsply Maillefer; and SybronEndo, respectively), are smaller than round burs, and their abrasive coatings or variable surfaces permit careful shaving away of dentin and calcifications during exploration for canal orifices.

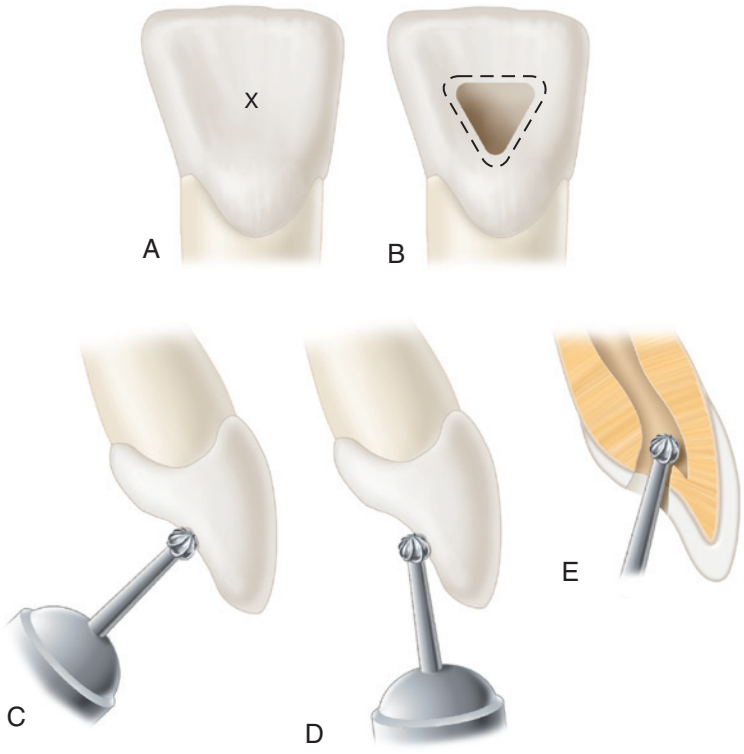

FIG. 5-38 **A,** In anterior teeth the starting location for the access cavity is the center of the anatomic crown on the lingual surface *(X).* **B,** Preliminary outline form for anterior teeth. The shape should mimic the expected final outline form, and the size should be half to three fourths the size of the final outline form. **C,** The angle of penetration for the preliminary outline form is perpendicular to the lingual surface. **D,** The angle of penetration for initial entry into the pulp chamber is nearly parallel to the long axis of the root. **E,** Completion of removal of the pulp chamber roof; a round carbide bur is used to engage the pulp horn, cutting on a lingual withdrawal stroke.

ACCESS CAVITY PREPARATIONS

Anterior Teeth

The following discussion outlines the steps for maxillary and mandibular anterior teeth. Tooth-specific access concerns are illustrated and discussed in the section Morphology of and Access Cavity Preparations for Individual Teeth, later in the chapter.

External Outline Form

Once caries and restorations have been removed as necessary to establish sound tooth margins, an initial external outline opening is cut on the lingual surface of the anterior tooth. This step may also be performed during the removal of caries and restorations. For an intact tooth, cutting commences at the center of the lingual or palatal surface of the anatomic crown (Fig. 5-38, *A*). A #2 or #4 round bur or a tapered fissure bur may be used to penetrate the enamel and slightly into the dentin (approximately 1 mm). An outline form is developed that is similar in geometry to an ideal access shape for the particular anterior tooth (Fig. 5-38, *B*); it is half to three quarters the projected final size of the access cavity. Because most of this step involves removal of enamel, the high-speed handpiece is used for cutting efficiency. The bur is directed perpendicular to the lingual surface as the external outline opening is created (Fig. 5-38, *C*).

Penetration of the Pulp Chamber Roof

Experienced clinicians usually penetrate the pulp chamber roof using a high-speed handpiece; however, less experienced clinicians may find the increased tactile sensation of a slow-speed handpiece a safer option. Continuing with the same round or tapered fissure bur, the angle of the bur is rotated from perpendicular to the lingual/palatal surface to parallel to the long axis of the root (see Fig. 5-38, *D*). Penetration into the tooth continues along the root's long axis until the roof of the pulp chamber is penetrated; frequently, a drop into the chamber effect is felt when this occurs. Measuring the distance from the incisal edge to the roof of the pulp chamber on a dimensionally accurate pretreatment radiograph may serve as guide in limiting penetration and possibly preventing a perforation. If the drop-in effect is not felt at this depth, an endodontic explorer can be used to probe the depth of the access, using magnification or the DOM. Often a small opening into the chamber is present, or the dentin is very thin and the explorer penetrates into the chamber. The depth and angle of penetration should be assessed for any deviation away from the long axis of the root in both the mesiodistal and buccolingual dimensions, and the penetration angle should be realigned if necessary. Angled radiographs can be used to assess progress at any time if any confusion or doubt exists. A little caution and concern at this stage can prevent a mishap.

Removal of the Chamber Roof

Once the pulp chamber has been penetrated, the remaining roof is removed by catching the end of a round bur under the lip of the dentin roof and cutting on the bur's withdrawal stroke (see Fig. 5-38, *E*). Because each tooth has a unique pulp chamber anatomy, working in this manner enables the internal pulp anatomy to dictate the external outline form of the access opening. In teeth with irreversible pulpitis, pulp tissue hemorrhage can impair vision during this process. In such cases, as soon as sufficient roof structure has been removed to allow instrument access, the coronal pulp should be amputated at the orifice level with a spoon or round bur and the chamber irrigated copiously with sodium hypochlorite. If the hemorrhage continues, a tentative canal length can be established by measuring the pretreatment radiograph. A small broach coated

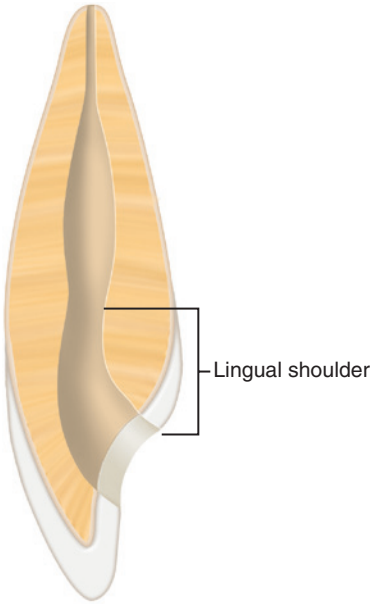

FIG. 5-39 Lingual shoulder of the anterior tooth, extending from the cingulum to 2 mm apical to the orifice.

FIG. 5-40 Placing an incisal bevel on the lingual surface of a maxillary anterior tooth can lead to fracture of the permanent restoration during occlusal function.

with a chelating agent then can be used loosely in the canal to grasp and sever the pulp at a more apical level. Copious irrigation with sodium hypochlorite helps control hemorrhage. Subsequently, the chamber roof, including the pulp horns, is removed and all internal walls are flared to the lingual surface of the tooth. Complete roof removal is confirmed with a #17 operative explorer if no "catches" are identified as the explorer tip is withdrawn from the pulp chamber along the mesial, distal, and facial walls.

Removal of the Lingual Shoulder and Coronal Flaring of the Orifice

Once the orifice or orifices have been identified and confirmed, the lingual shoulder or ledge is removed. This is a shelf of dentin that extends from the cingulum to a point approximately 2 mm apical to the orifice (Fig. 5-39). Its removal improves straight-line access and allows for more intimate contact of files with the canal's walls for effective shaping and cleaning. In addition, its removal from mandibular anterior teeth may often expose an extra orifice and canal.

The contemporary approach to flaring the orifice involves the use of rotary nickel-titanium (NiTi) orifice openers that allow rapid, safe removal of the lingual ledge, following the manufacturer's directions for use (DFUs). When used properly, these openers allow refinement of the orifice shape or help to enhance straight-line access to the canal with minimal removal of dentin. Although there may be subtle differences in these instruments from manufacturer to manufacturer, proper application achieves the same objective. A time-tested and traditional way to achieve the same goal involves the use of a tapered, safety-tip diamond or carbide bur or a Gates-Glidden bur. However, use of these instruments may result in excessive removal of cervical dentin. When a fine, safety-tip diamond bur is used, the tip is placed approximately 2 mm apical to the canal orifice and inclined to the lingual during rotation to slope the lingual shoulder. The bur should be placed so as to avoid putting a bevel on the incisal edge of the access preparation (Fig. 5-40). When Gates-Glidden burs are used, the largest that can be placed passively 2 mm apical to the orifice is used first. During rotation, gentle pressure is applied on the bur as it cuts against the lingual shoulder and then is withdrawn. The size of these burs can be increased sequentially, depending on the size of the canal, with repeated shaping of the lingual wall until the lingual shoulder of dentin has been eliminated in anterior teeth. During this process, the orifice is often concomitantly flared so that it is contiguous with all walls of the access preparation. If this is not achieved, use of the orifice openers is recommended.

Straight-Line Access Determination

After removal of the lingual shoulder and flaring of the orifice, straight-line access must be determined. Ideally, a small intracanal file can reach the apical foramen or the first point of canal curvature with no deflections. Unnecessary deflection of the file can result in numerous consequences related to loss of instrument control. Deflected instruments function under more stress than those with minimal or no deflection pressure and are more susceptible to separation during enlargement and shaping (Fig. 5-41). Deflected instruments also lack access to critical areas of the canal and therefore do not function effectively. Without straight-line access, procedural errors (e.g., ledging, transportation, and zipping) may occur, but this is primarily seen with the use of hand files or larger NiTi instruments (Fig. 5-42).

If the lingual shoulder has been removed properly and a file still binds on the incisal edge, the access cavity should be extended further incisally until the file is not deflected (Fig. 5-43). The final position of the incisal wall of the access cavity is determined by two factors: (1) complete removal of the pulp horns and (2) straight-line access.

Visual Inspection of the Access Cavity

Appropriate magnification and illumination should be used to inspect and evaluate the completed access cavity. Although this

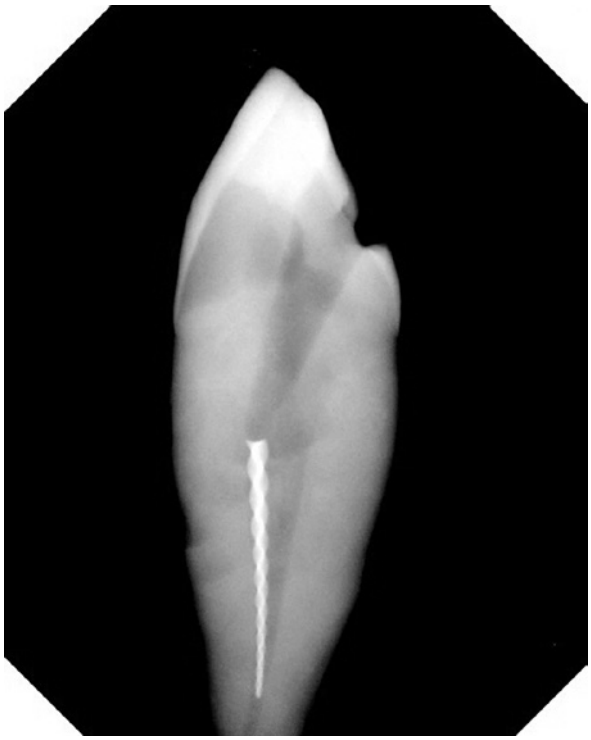

FIG. 5-41 Separation of a rotary endodontic instrument as a result of underextended access preparation rather than canal binding.

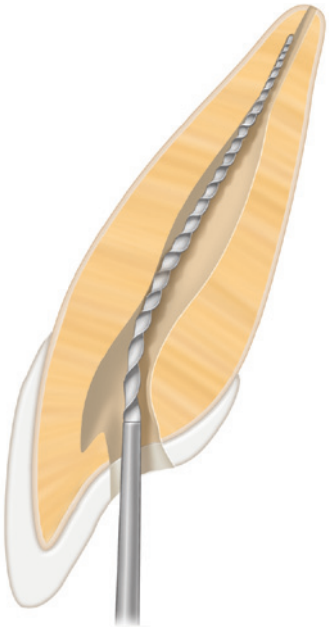

FIG. 5-42 Inadequate access preparation. The lingual shoulder was not removed, and incisal extension is incomplete. The file has begun to deviate from the canal in the apical region, creating a ledge.

can be done during any stage of the preparation, it should always be done at this point. The axial walls at their junction with the orifice must be inspected for grooves that might indicate an additional canal. The orifice and coronal portion of the canal must be evaluated for a bifurcation.

FIG. 5-43 A, The lingual ledge of dentin remains, deflecting the file toward the labial wall. As a result, portions of the lingual canal wall will not be shaped and cleaned. B, Removal of the lingual ledge results in straight-line access.

Refinement and Smoothing of Restorative Margins

The final step in the preparation of an access cavity is to refine and smooth the cavosurface margins. Rough or irregular margins can contribute to coronal leakage through a permanent or temporary restoration. Proper restorative margins are important because anterior teeth may not require a crown as the final restoration. Smooth cavosurface margins allow the placement of a composite resin restoration with the precision necessary to minimize coronal leakage. Such leakage could jeopardize the success of the root canal procedure.

Another factor to consider regarding the access margin of a maxillary anterior tooth is that the final composite resin restoration will be placed on a functional tooth surface. The incisal edges of the mandibular anterior teeth slide over these maxillary lingual surfaces during excursive jaw movements. Therefore, the restorative margins of an access cavity in maxillary anterior teeth should be created to allow a bulk of restorative material at the margin. Butt joint margins are indicated, rather than beveled margins, which produce thin composite edges that can fracture under functional loads and ultimately result in coronal leakage. If the anterior tooth requires a crown as the final restoration, the cavosurface margin becomes a less critical factor, although if it is not restored in a timely fashion, breakdown and leakage may occur.

Individual Anterior Teeth

See the figures in the section Morphology of and Access Cavity Preparations for Individual Teeth, later in this chapter.

Posterior Teeth

Preparing access cavities on posterior teeth is similar to the process for anterior teeth, but significant differences warrant a separate discussion.[84] Posterior teeth requiring root canal procedures typically have been heavily restored or the carious process was extensive. Such conditions, along with the complex pulp anatomy and position of posterior teeth in the oral cavity, can make the access process challenging.

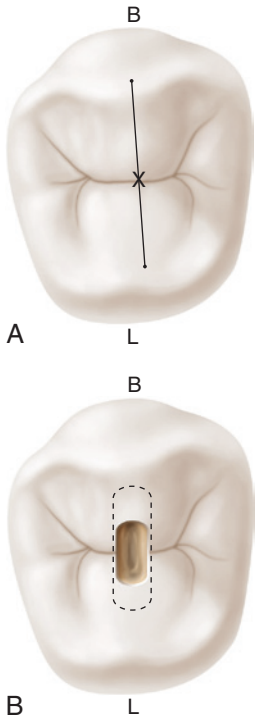

FIG. 5-44 A, Starting location for access to the maxillary premolar *(X)*. B, Initial outline form *(dark area)* and projected final outline form *(dashed line)*. *B,* Buccal; *L,* lingual.

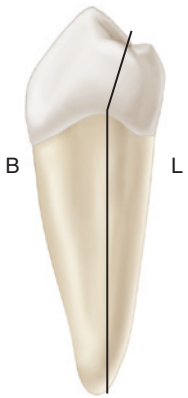

FIG. 5-45 The crown of a mandibular premolar is tilted lingually relative to the root. *B,* Buccal; *L,* lingual.

External Outline Form

Removal of caries and existing restorations from a posterior tooth requiring a root canal procedure often results in the development of an acceptable access outline form. However, if the tooth is intact, the access starting location must be determined for an intact tooth. The pulp chamber of posterior teeth is positioned in the center of the tooth at the level of the CEJ. Therefore, in maxillary premolars, the point of entry that determines the external outline form is on the central groove between the cusp tips (Fig. 5-44). Crowns of mandibular premolars are tilted lingually relative to their roots (Fig. 5-45); therefore, the starting location must be adjusted to compensate for this tilt (Fig. 5-46). In mandibular first premolars, the starting location is halfway up the lingual incline of the buccal cusp on a line connecting the cusp tips. Mandibular second premolars require less of an adjustment because they have less lingual inclination. The starting location for this tooth is one third the way up the lingual incline of the buccal cusp on a line connecting the buccal cusp tip and the lingual groove between the lingual cusps.

To determine the starting location for molar access cavity preparations, the mesial-distal and apical-coronal boundary limitations for this outline must be determined (Fig. 5-47). Evaluation of bite-wing radiographs is an accurate method of assessing the mesiodistal extensions of the pulp chamber (Fig. 5-48). The mesial boundary for both the maxillary and mandibular molars is a line connecting the mesial cusp tips. Pulp chambers are rarely found mesial to this imaginary line. A good initial distal boundary for maxillary molars is the oblique ridge. For mandibular molars, the initial distal boundary is a line connecting the buccal and lingual grooves. For molars the correct starting location is on the central groove halfway between the mesial and distal boundaries.

Penetration through the enamel into the dentin (approximately 1 mm) is achieved with a #2 or #4 round bur for premolars and a #4 or #6 round bur for molars. A tapered fissure bur may be used instead of round burs. The bur is directed perpendicular to the occlusal table, and an initial outline shape is created at about half to three fourths its projected final size. The premolar shape is oval and widest in the buccolingual dimension. The molar shape is also oval initially; it is widest in a buccolingual dimension for maxillary molars and in a mesiodistal direction for mandibular molars. The final outline shape for molars is approximately triangular (for three canals) or rhomboid (for four canals); however, the canal orifices dictate the position of the corners of these geometric shapes. Therefore, until the orifices have been located, the initial outline form should be left as roughly oval.

Penetration of the Pulp Chamber Roof

Once initial penetration into the pulp chamber has been achieved, the angle of penetration changes from perpendicular to the occlusal table to an angle appropriate for penetration through the roof of the pulp chamber. In premolars the angle is parallel to the long axis of the root or roots, both in the mesiodistal and buccolingual directions. Failure to analyze this penetration angle carefully can result in gouging or perforation because premolar roots often are tilted relative to the occlusal plane. In molars the penetration angle should be toward the largest canal because the pulp chamber space usually is largest just occlusal to the orifice of this canal. Therefore, in maxillary molars, the penetration angle is toward the palatal orifice, and in mandibular molars, it is toward the distal orifice (Fig. 5-49).

As with anterior teeth, penetration is limited to the distance measured on a pretreatment radiograph to just penetrate the roof of the pulp chamber. If the drop-in effect is not felt at this depth, a careful evaluation of the angle of penetration is necessary before going deeper into the chamber. In multirooted posterior teeth, lateral and furcation perforations may occur rapidly without attention to 3D detail during this penetration. As with anterior teeth, aggressive probing with an endodontic explorer at any time during the penetration often can help locate the pulp chamber.

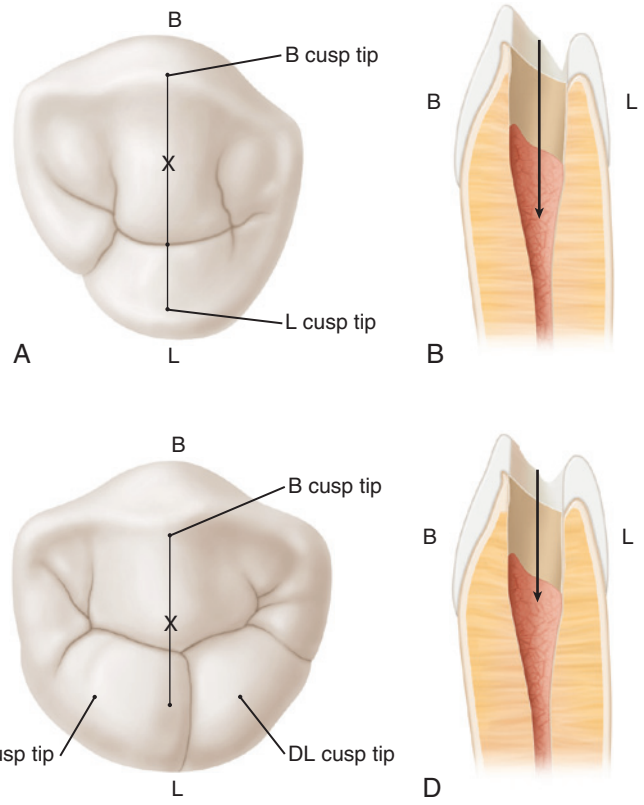

FIG. 5-46 **A,** Mandibular first premolar and access starting location *(X)* (occlusal view). **B,** Mandibular first premolar and starting location (proximal view). **C,** Mandibular second premolar and access starting location *(X)* (occlusal view). **D,** Mandibular second premolar and starting location (proximal view). *B,* Buccal; *DL,* distolingual; *L,* lingual; *ML,* mesiolingual.

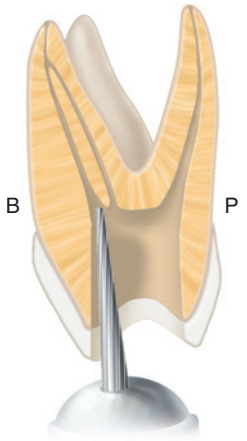

FIG. 5-51 Safety-tip carbide bur is used to shape the axial wall in one plane from the orifice to the cavosurface margin. *B,* Buccal; *P,* palatal.

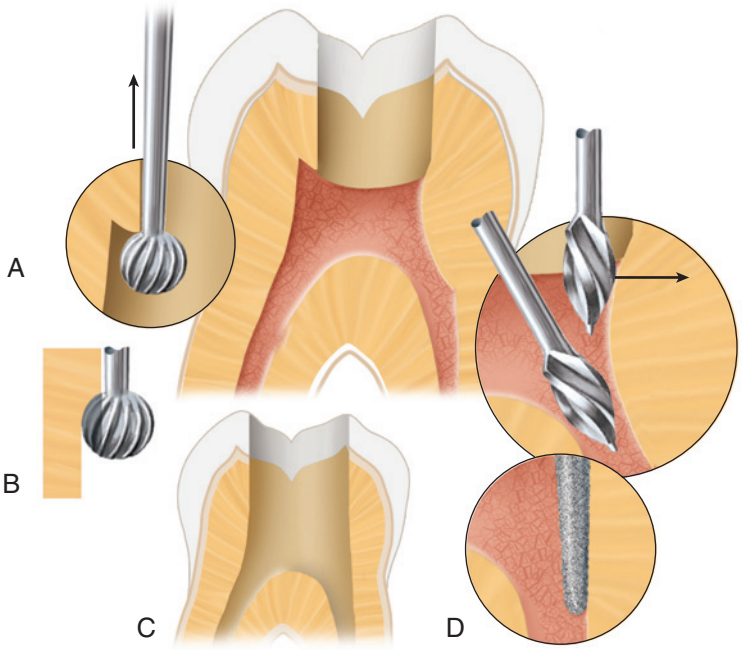

FIG. 5-50 **A,** Pulp roof/pulp horn removal. The round bur hooks under the lip of the pulp horn. **B,** The bur is rotated and withdrawn in an occlusal direction to remove the lip. **C,** Removal of a cervical dentin bulge. A Gates-Glidden bur is placed just apical to the orifice and withdrawn in a distoocclusal direction. **D,** A safety-tip tapered diamond bur is used to blend and funnel the axial wall from the cavosurface margin to the orifice.

Removal of the Chamber Roof

The bur of choice is used to remove the roof of the pulp chamber completely, including all pulp horns (Fig. 5-50, *A* and *B*). Visibility problems caused by pulpal hemorrhage should be handled as described in the previous section for anterior teeth. The goal is to funnel the corners of the access cavity directly into the orifices, and a safety-tip diamond or carbide bur (Multi Bur, Dentsply Tulsa Dental Specialties) performs this task nicely (Fig. 5-50, *C* and *D*); it can be set on the pulp floor and the entire axial wall shaped at one time, with little or no apical pressure (Fig. 5-51). These burs are passed between the orifices along the axial walls to remove the roof, taper the internal walls, and create the desired external outline shape simultaneously.

Identification of All Canal Orifices

In posterior teeth with multiple canals, the canal orifices play an important role in determining the final extensions of the external outline form of the access cavity. Ideally, the orifices are located at the corners of the final preparation to facilitate all of the root canal procedures (Fig. 5-52). Internally, the access cavity should have all orifices positioned entirely on the pulp floor and should not extend into an axial wall. Extension of an orifice into the axial wall creates a "mouse hole" effect (Fig. 5-53), which indicates internal underextension and impedes straight-line access. In such cases the orifice must be repositioned onto the pulp floor without interference from axial walls.

Removal of the Cervical Dentin Bulges and Orifice and Coronal Flaring

In posterior teeth the internal impediments to an ideal access opening are the cervical dentin ledges or bulges and the natural coronal canal constriction.[84] The cervical bulges are shelves of dentin that frequently overhang orifices in posterior teeth, restricting access into root canals and accentuating existing

canal curvatures.[117] They can develop from mesial, distal, buccal, and lingual walls inward. These bulges can be removed safely with burs or ultrasonic instruments. The removal instruments should be placed at the orifice level, and light pressure should be used to cut laterally toward the dentin bulge to remove the overhanging ledge (Fig. 5-54). After removal of the ledge, the orifice and constricted coronal portion of the canal can be flared with NiTi orifice openers, Gates-Glidden burs, or large, tapered rotary instruments (.10/.12), which are used in a sweeping upward motion with minimal lateral pressure away from the furcation. As the orifice is enlarged, it should be tapered and blended into the axial wall so that an explorer can slide down the corner of the external outline form, down the axial wall, and into the orifice without encountering any obstructions (see Fig. 5-54).

FIG. 5-52 An endodontic explorer is used to search for canal orifices.

Straight-Line Access Determination

Straight-line access is paramount to successful shaping, especially given the complexity of the root canal systems in posterior teeth. Files must have unimpeded access to the apical foramen or the first point of canal curvature to perform properly. Therefore, each canal must have straight-line access, and adjustments must be made accordingly (see Fig. 5-54, *O*).

Visual Inspection of the Pulp Chamber Floor

The floor and walls must be inspected, using appropriate magnification and illumination, to ensure that all canal orifices are visible and no roof overhangs are present (Fig. 5-55).

Refinement and Smoothing of the Restorative Margins

In both temporary and interim permanent restorations, the restorative margins should be refined and smoothed to minimize the potential for coronal leakage. The final permanent restoration of choice for posterior teeth that have undergone a root canal procedure is generally a crown or onlay, although this may vary, depending on the opposing dentition and patient function.

Individual Posterior Teeth

See the figures in the section Morphology of and Access Cavity Preparations for Individual Teeth, later in the chapter.

CHALLENGING ACCESS PREPARATIONS

Teeth with Minimal or No Clinical Crown

Forming an access cavity on a tooth with little or no clinical crown might seem to be a simple procedure. For example, in young teeth, traumatic fractures often expose the pulp chamber, making access preparation easy. However, in older teeth with previous caries or large restorations, the pulp chambers typically have receded or calcified (Fig. 5-56). Loss of significant coronal anatomy to guide penetration angles can make access quite difficult. A thorough evaluation of these teeth clinically and their root angulation on pretreatment radiographs is essential. Pulp chambers are located at the center of the crown at the level of the CEJ. Access often is started without a dental dam in place so that root eminences can be visualized and palpated as access preparation progresses (Fig. 5-57). Every effort is made to stay centered within the root for the best

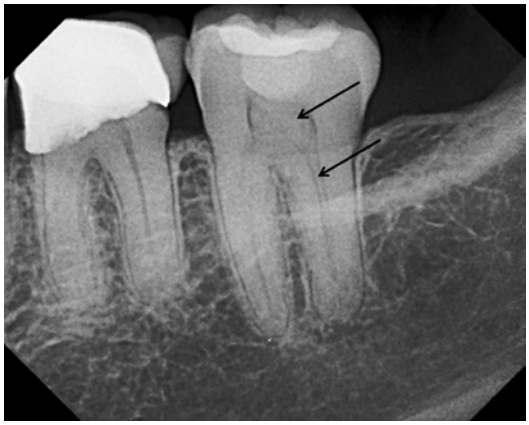

FIG. 5-56 Mandibular molar with significant calcification of the pulp chamber and canal spaces *(arrows).*

chance of locating the pulp canal.[25] The depth of penetration needed to reach the pulp canal is measured on a pretreatment radiograph. If this depth is reached without locating the canal, two radiographs should be taken before the process proceeds. A straight-on radiograph shows whether the preparation is deviating in a mesial or distal direction. Applying the buccal object rule, an angled radiograph shows a buccal or lingual deviation in penetration. After checking these radiographs, the operator can alter the penetration angle, if necessary, while penetrating apically. As soon as the pulp canal is identified, the dental dam must be placed and the access preparation finalized, using the guidelines discussed previously.

Heavily Restored Teeth (Including Those with Full Coronal Coverage)

Restorative materials often alter the external anatomic landmarks on the crown of a tooth, making access preparation difficult. Restorative materials and full crowns rarely reproduce the original tooth anatomy in the exact same position. The crown-to-root angulation often is altered when large restorations or crowns correct occlusal discrepancies (Fig. 5-58). Most restorative materials block the passage of light into the internal aspects of the tooth, resulting in poor visibility during preparation of the access cavity. All these factors, singly or together, complicate the preparation of access cavities on heavily restored teeth (Fig. 5-59).[1] The DOM and transillumination of the cervical area of a heavily restored tooth can greatly improve visibility and reveal landmarks that otherwise would be missed (see Fig. 5-55).

In most cases, complete removal of large restorations is the wisest course, and treatment should be planned accordingly (Fig. 5-60). These restorations often have leaking, defective margins or recurrent caries, or both. Removing the restoration enhances visibility of the internal anatomic structures through direct visualization and increased light penetration. With increased visibility, recurrent caries and fracture lines on the pulp chamber walls or floor can be seen, especially with the DOM. Clinicians are 40% more likely to miss these anomalies when restorations are not removed completely.[1] Better visibility also makes locating receded or calcified canals easier.

Coronal leakage often occurs when parts of large restorations are left in the tooth because the restorations are loosened by the vibration of the access drilling. Furthermore, removal of these restoration remnants prevents pieces of the restorative material from falling into the root canal. Instruments can rub against restoration fragments during the root canal procedures, creating filings that can be carried into the canal system. Thorough removal prevents these problems.

Complete removal of an extensive restoration from the cervical region of the tooth permits more direct access to the root canal or canals. For example, class V restorations often cause calcifications in the coronal portion of the canal, making location of the canal through the occlusal approach quite difficult. Removal of the class V restoration allows more direct access to the canal, which makes location and penetration much easier. Any remaining canals can be managed through the traditional occlusal access cavity (Fig. 5-61).

When an extensive restoration is a full metalloceramic or partial veneer crown, the restoration must be evaluated thoroughly. If any concerns arise about recurrent decay or leaking margins, the crown should be removed before an access cavity is formed. Removal of the crown allows elimination of all recurrent caries and improves the visibility of the pulp spaces.

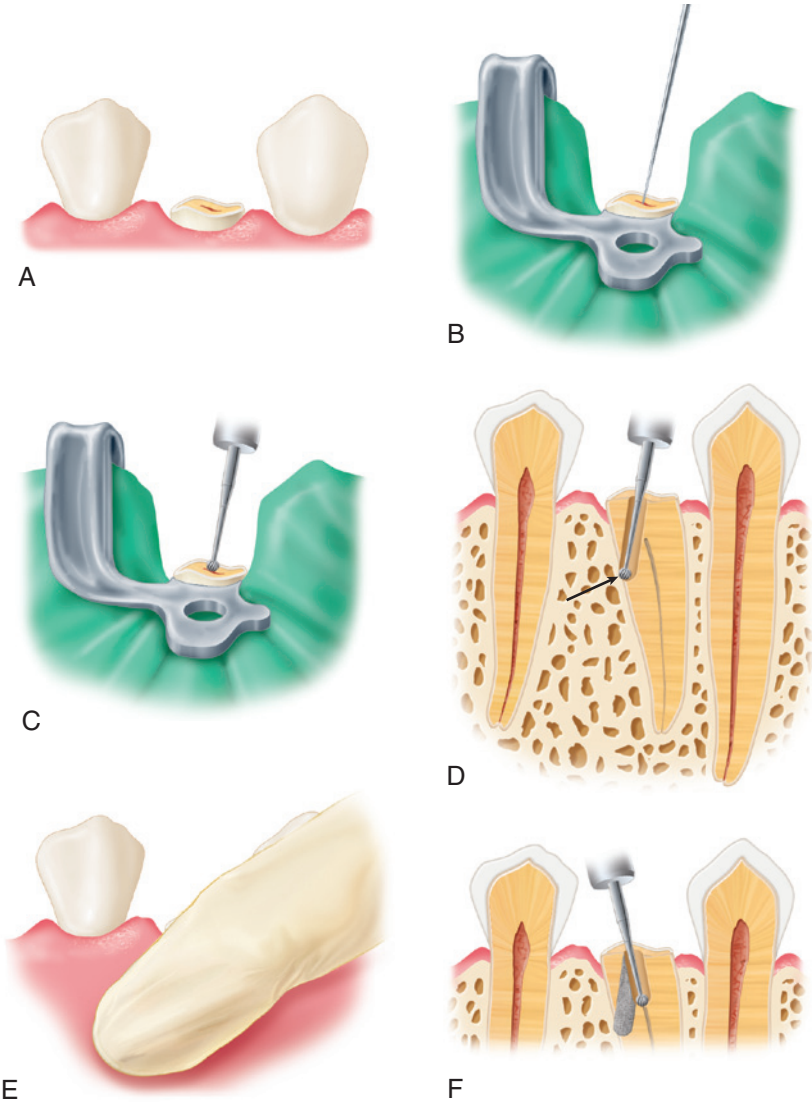

FIG. 5-57 Access cavity preparation when the anatomic crown is missing. **A**, Mandibular first premolar with the crown missing. **B**, An endodontic explorer fails to penetrate the calcified pulp chamber. **C**, A long-shank round bur is directed in the assumed long axis of the root. **D**, Perforation of the root wall *(arrow),* resulting from failure to consider root angulation. **E**, Palpation of the buccal root anatomy without a dental dam in place to determine root angulation. **F**, Correct bur angulation after repair of the perforation with mineral trioxide aggregate (MTA). The dental dam is placed as soon as the canal has been identified.

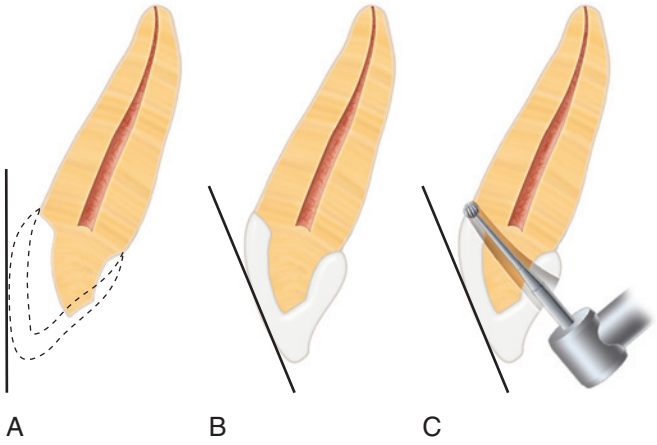

FIG. 5-58 Access cavity error resulting from alteration of the original tooth contours by a full veneer crown. **A**, Original crown contour of the tooth. **B**, A full veneer crown is used to change the original crown contour for esthetic purposes. **C**, Access perforation resulting from reliance on the full veneer crown contour rather than the long axis of the root.

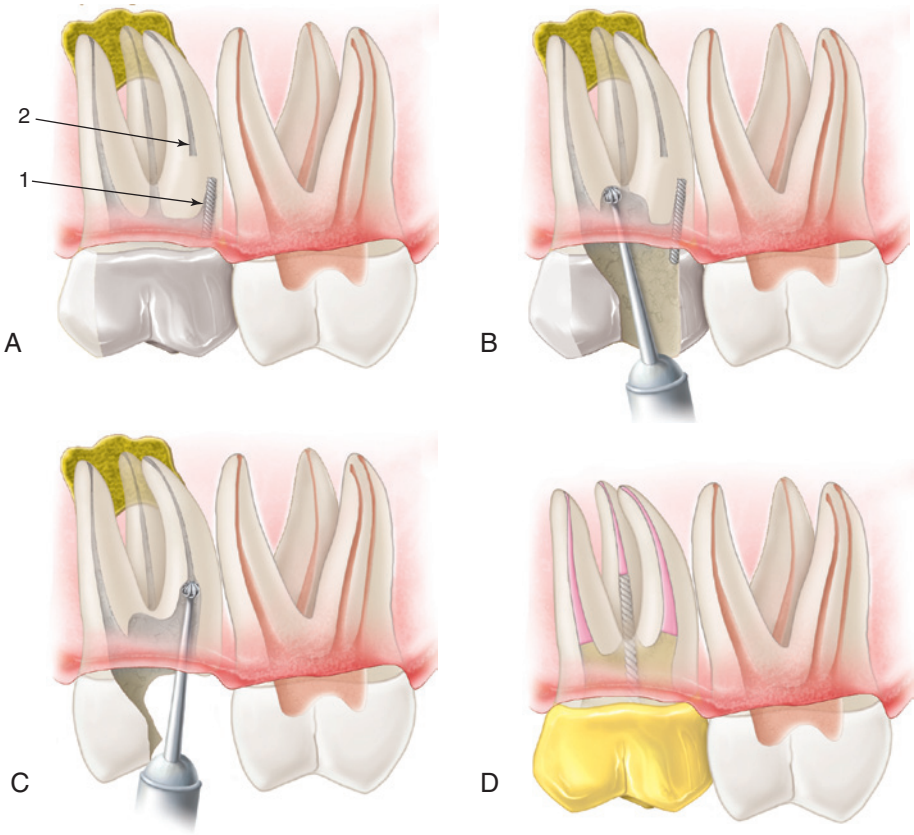

FIG. 5-59 **A,** In a heavily restored maxillary second molar that requires root canal therapy, the clinician may attempt access to the canals. Pretreatment radiographs demonstrate three important factors: (1) a reinforcing pin is in place *(arrow);* (2) at least two thirds of the coronal portion is restorative material; and (3) the mesiobuccal canal appears calcified *(arrow)*. These factors suggest complete excavation. **B,** A patient may ask the clinician to attempt an unexcavated search for the canals; this may result in a furcal perforation, compromising the prognosis. In such cases the patient should be engaged in the decision to continue treatment, which unquestionably involves removal of the existing restoration. **C,** A safer, more conservative approach is to remove the amalgam, the pin, and any old cements. Careful excavation, using enhanced vision, results in access to the pulp chamber. **D,** The clinician now can perform sound root canal therapy, followed by internal reinforcement and full coverage.

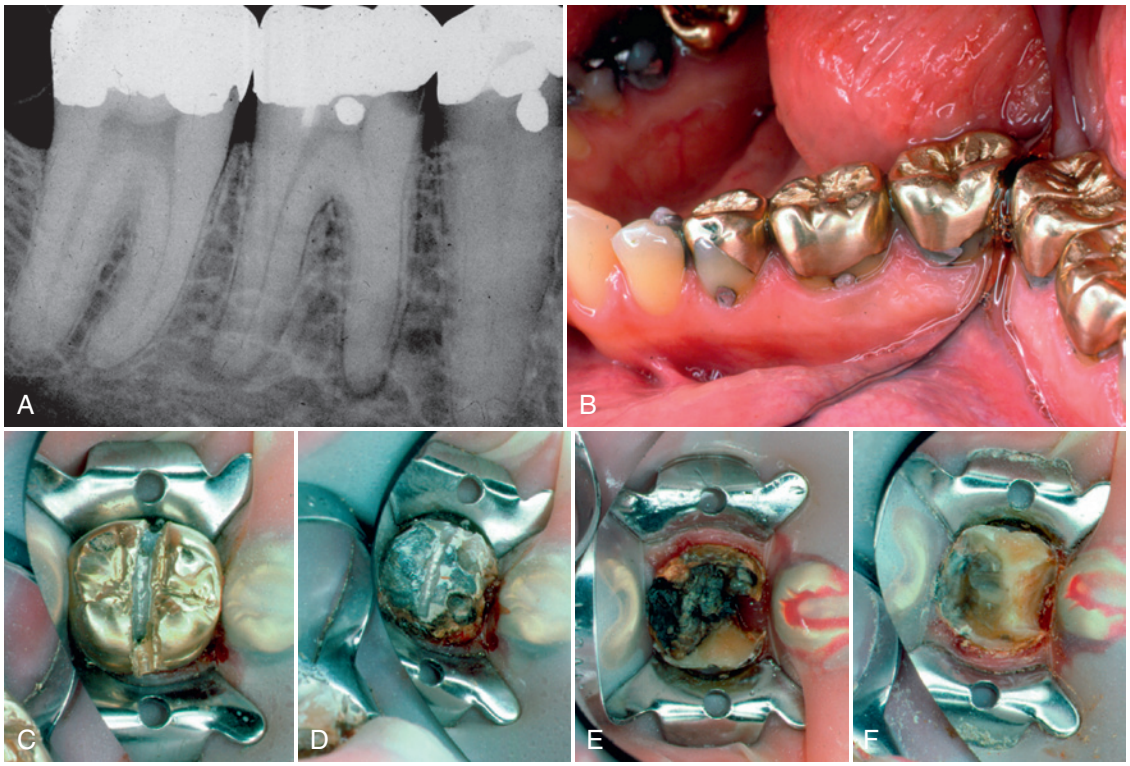

FIG. 5-60 **A**, Radiograph showing apical lesions on both roots and recurrent caries under the mesial margin of the crown. **B,** Clinical photograph of the crown and tissues that appear normal. **C,** Cutting of the crown from the tooth. **D,** Crown has been removed, and decay is evident around the core restoration. **E,** Removal of the old restoration shows significant decay. **F,** Final excavation, which allows for evaluation of the tooth structure and facilitates direct access to the pulp chamber. (From Gutmann JL, Lovdahl PE: *Problem solving in endodontics,* ed 5, St Louis, 2011, Elsevier.)

Development of an access through an intact metalloceramic crown should be done with caution. When such restorations are placed, they often change the crown-to-root angulation to correct preexisting occlusal discrepancies. Metalloceramic crowns often alter previous tooth rotation. Both these situations make the preparation of access cavities challenging. Pretreatment radiographs can be helpful, but the metal in the full veneer crown usually masks the underlying pulp chamber. In these situations the best approach is to stay as centered in the tooth as possible, using all available clinical and radiographic information. The DOM and transillumination of the CEJ are valuable aids in this process.

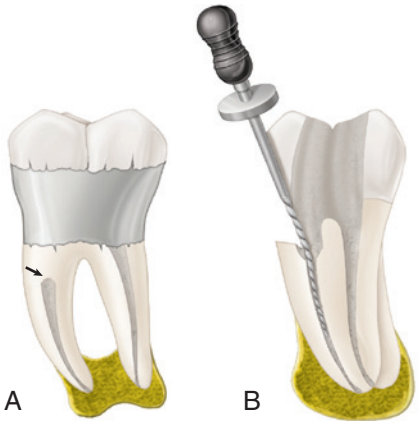

FIG. 5-61 A, Extensive class V restoration necessitated by root caries and periodontal disease that led to canal calcification *(arrow)*. B, Access to the canal is occluded by calcification. Removal of the facial restoration may be required to obtain access from the buccal surface.

Metalloceramic crowns are best penetrated with new, sharp carbide burs. Round burs work well, but tungsten carbide transmetal burs are more efficient. These crosscut fissure burs are specifically designed to cut through metal restorative materials. Porcelain or metalloceramic restorations must be handled delicately to minimize the potential for fracture (Fig. 5-62). Whatever the nature of the crown, efforts should be made to avoid being too conservative. Attempting to save the crown often leads to an underextended preparation. All the guidelines for access cavity preparations discussed earlier must be followed. When the preparation is complete, the margins and internal spaces must be evaluated for caries, leakage, and fractures.

Access in Teeth with Calcified Canals

Often a 2D pretreatment radiograph may be interpreted as showing total or nearly total calcification of the pulp chamber and radicular canal spaces (see Fig. 5-56). Unfortunately, these spaces have adequate room to allow passage of millions of microorganisms. Chronic inflammatory processes (e.g., caries, medications, occlusal trauma, and aging) often cause pulpal degeneration and concomitant narrowing of the root canal system.[84] Although the coronal portion of the canal may appear diminished significantly, canals often become less calcified as they approach the root apex. Despite these perceived 2D anatomic alterations, many canals do exist, and attempts must be made to manage them to the canal terminus.

Chambers and roots that demonstrate significant calcifications may present problems with locating, penetrating, and

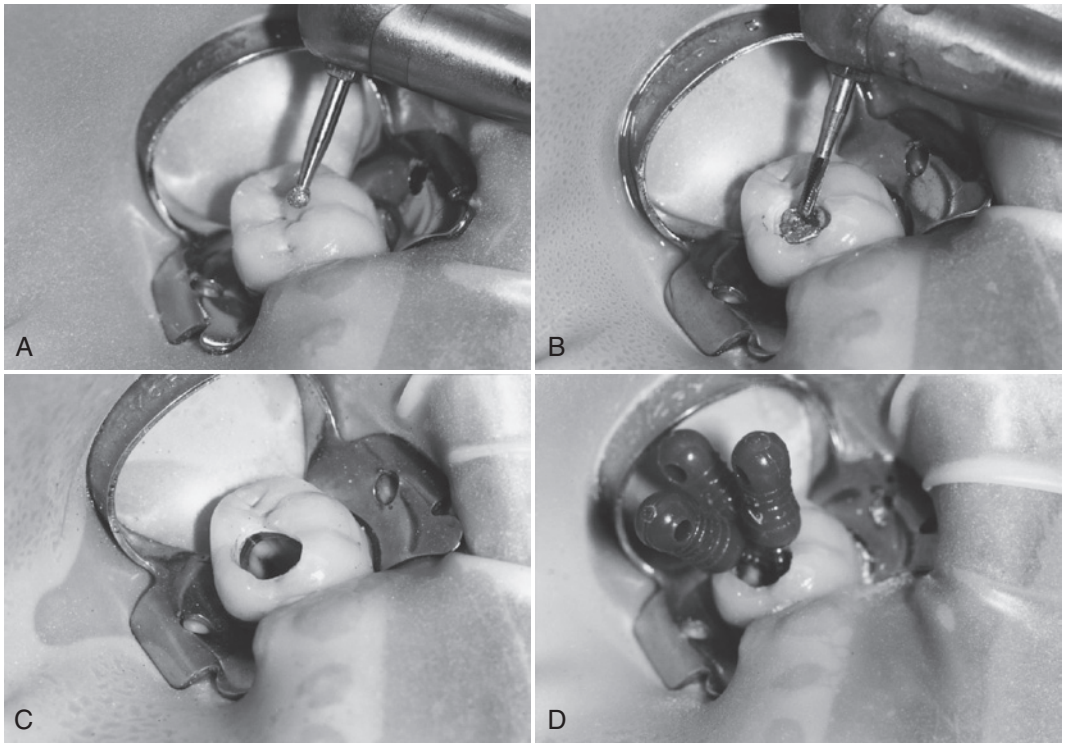

FIG. 5-62 Access cavity preparation through a metalloceramic crown. A, A round diamond bur is used to penetrate the porcelain. B, Following the access outline with the round diamond bur, a transmetal bur is used to cut through the metal. C, Prepared access cavity allowing direct approach to the canals. D, Files are placed on the access cavity walls without impingement.

FIG. 5-63 Mandibular molar with what appears to be almost complete calcification of the pulp chamber and root canals. However, pathosis is present, which indicates the presence of bacteria and some necrotic tissue in the apical portion of the roots.

negotiating the pulpal spaces.[84] The use of magnification and transillumination, as well as careful examination of color changes and pulp chamber shapes, assists in locating the canals (Fig. 5-63). However, the search for the root canal orifices should be made only after the pulp chamber has been completely prepared and its floor has been cleaned and dried (95% denatured ethanol may be useful for drying the floor and enhancing visibility). A fiberoptic light directed through the CEJ can reveal subtle landmarks and color changes that may not otherwise be visible. The chamber floor is darker in color than its walls, and developmental grooves connecting orifices are lighter in color than the chamber floor. Awareness of these color differences when searching for calcified orifices is essential, especially when searching for canal orifices that are located at the angles formed by the floor and walls and at the end points of developmental grooves. Additional methods to help locate calcified root canals include staining the pulp chamber floor with 1% methylene blue dye, performing the sodium hypochlorite "champagne bubble" test (see Fig. 5-2) and searching for canal bleeding points. These approaches are enhanced when the area is viewed through magnification.

In teeth with significant calcifications that obscure and block the root canal, the calcified material must be removed slowly down the root. Long, thin ultrasonic tips should be used under the high magnification of a DOM to avoid removing too much tooth structure. As the clinician proceeds apically, exposure of two radiographs should be considered, one from the straight-on direction and the other from an angled direction. A very small piece of lead foil placed at the apical extent of the penetration can provide a radiographic reference.

Uncovering canals that contain calcified material is a challenge. When the canal is located, a small K-file (#6, #8, or #10 or, preferably, a C or C+ file [Dentsply Tulsa and Maillefer, respectively]) coated with a chelating agent should be introduced into the canal to determine patency. These instruments provide added stiffness to the shaft for better penetration. The file should not be removed until some canal enlargement has occurred. The file should be used in short up-and-down movements and in a selective circumferential filing motion, with most of the lateral pressure directed away from the furcation. This enlarges the coronal aspect of the canal safely and moves it laterally, to avoid thinning of the dentin wall adjacent to the furcation. It also creates a path of insertion for larger files and for preflaring burs. Figs. 5-64 through 5-69 illustrate several methods that can be used to locate calcified spaces. For the most successful results, the sequence should be followed as shown.

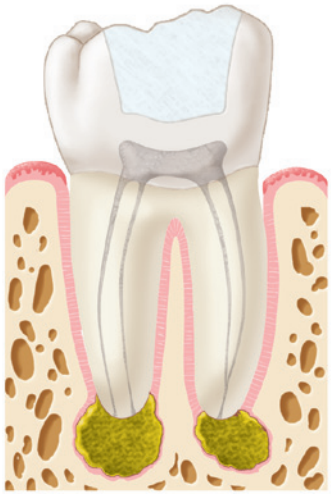

FIG. 5-64 Mandibular first molar with a class I restoration, calcified canals, and periradicular radiolucencies. Presumably a pulp exposure has occurred, resulting in calcification and ultimate necrosis of the pulp tissue.

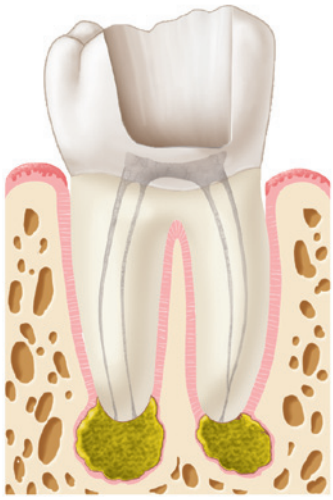

FIG. 5-65 Excavation of a restoration and base material. The cavity preparation is extended toward the assumed location of the pulp chamber, keeping in mind that pulp chambers are located in the center of the tooth at the level of the cementoenamel junction *(CEJ)*.

If the canal orifice cannot be found, it is wise to stop excavating the dentin to avoid weakening the tooth structure or perforating into the periodontal ligament. Management of these problems can be found in Chapter 19. There is no rapid technique or solution for dealing with calcified root canals.[84] Painstaking removal of small amounts of dentin with the aid of the DOM and radiographic confirmation has proved to be the safest approach.

Crowded or Rotated Teeth

Traditional access preparations may not be possible in patients with crowded teeth. The decision about an alternative approach

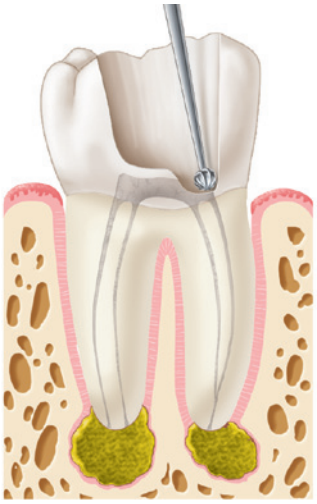

FIG. 5-66 Use a long-shank #2 or #4 round bur to remove dentin and attempt to locate calcified canals.

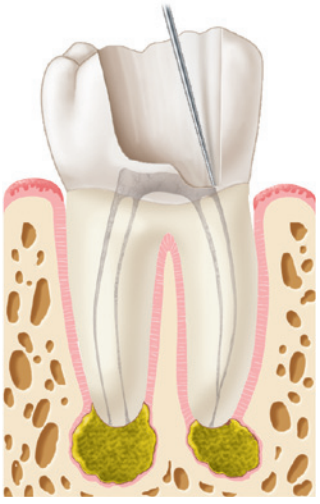

FIG. 5-67 An endodontic explorer is used to probe the pulp floor. A straight ultrasonic tip may be used to remove dentin. Angled radiographs must be taken to monitor progress.

must be based on straight-line access principles and conservation of tooth structure. In certain circumstances a buccal access preparation may be the treatment of choice (Fig. 5-70).[84] Modern restorative materials have made repair of this access esthetically acceptable.

Rotated teeth can present problems during access cavity preparation because of the altered crown-to-root relationships. According to a study by Moreinis,[144] diagnostic periapical radiographs, although only 2D, are indispensable for "determining the anatomic relationship of the crown to the root and the angle of the root in the arch." When these factors are identified, reasonable variations in the access opening must be visualized before the tooth is entered. Perforations in rotated teeth during access preparation usually occur because of faulty angulation of the bur with respect to the long axis of the root.

Other problems can occur when tooth angulations are not considered during preparation of an access cavity. Such problems include the following:

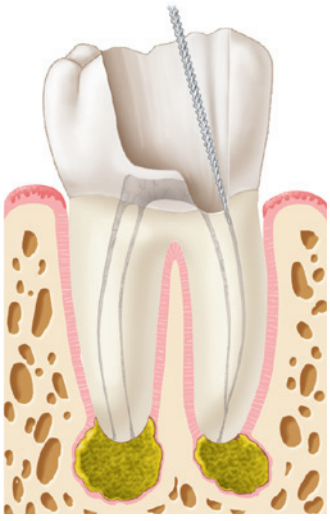

FIG. 5-68 At the first indication of a canal space, the smallest instrument (i.e., a #.06 or #.08 C or C+ file or micro openers) should be introduced into the canal. Gentle passive movement, both apical and rotational, often produces some penetration. A slight pull, signaling resistance, usually is an indication that the canal has been located. This should be confirmed by radiographs.

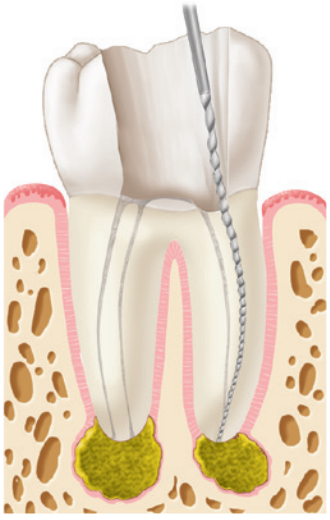

FIG. 5-69 A small K-file negotiates the canal to its terminus. An apex locator or radiograph is used to confirm the file's position.

- Mistaken identification of an already located canal, resulting in a search in the wrong direction for additional canals. Whenever a difficult canal is located, a file should be placed in the canal and an angled radiograph taken. This determines which canal has been located. A search for another canal orifice can then begin in the correct direction.
- Failure to locate a canal or extra canals.
- Excessive gouging of coronal or radicular tooth structure.
- Instrument separation during attempts to locate an orifice.
- Failure to débride all pulp tissue from the chamber.

The best way to handle any these problems is to prevent them from occurring. A thorough radiographic examination is

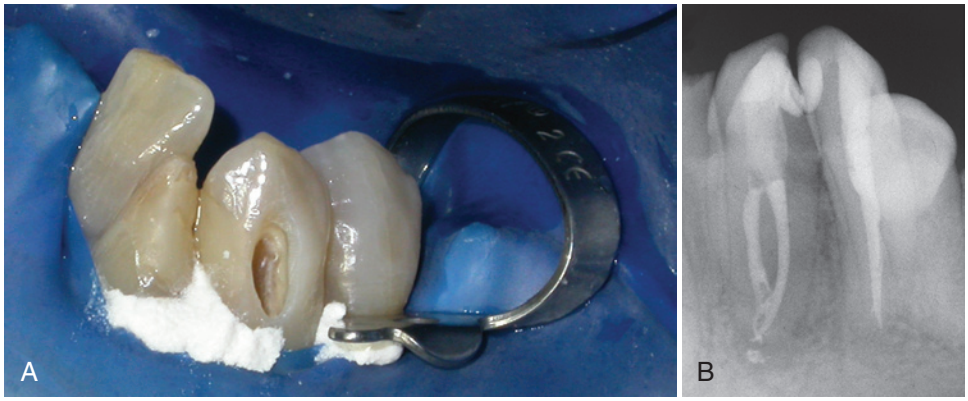

FIG. 5-70 A, Access cavity on crowded mandibular anterior teeth. The access preparation is cut through the buccal surface on the canine. The lateral incisor has also been accessed through the buccal surface; root canal procedures were performed, and the access cavity was permanently restored with composite. B, Obturation.

crucial. The initial outline form occasionally can be created without the dental dam, which facilitates positioning of the bur with the long axis of the tooth. Bur penetration for both depth and angulation should be confirmed frequently with radiographs.

ERRORS IN ACCESS CAVITY PREPARATION

Unfortunately, errors can occur in the preparation of an access cavity. Most are the result of failure to follow the access guidelines; others reflect a lack of understanding of the internal and external tooth morphology. Common errors are discussed and illustrated in Figs. 5-71 through 5-73 and detailed extensively elsewhere in this text and other publications.[84]

MORPHOLOGY OF AND ACCESS CAVITY PREPARATIONS FOR INDIVIDUAL TEETH

The anatomy shown in the following figures was obtained from human teeth through the use of recently developed 3D imaging techniques. The teeth were scanned in a high-resolution, microcomputer-assisted tomographic scanner. The data were then manipulated with proprietary computer programs to produce the 3D reconstructions and visualization. The following individuals and sources are recognized to have contributed greatly to this endeavor.

The 3D reconstructed images in this chapter were obtained from the tooth and canal morphology database at the School of Stomatology, Wuhan University, China. The database was established by Dr. Bing Fan's group and supported by the National Natural Science Foundation of China (grant no. 30572042, 30872881, 81070821) and the Key Technologies R&D Programme of Hubei Province of China (grant no. 2007AA302B06). The microcomputed tomography machine used for scanning was the μCT-50, Scanco Medical, Bassersdorf, Switzerland. The multiple softwares used for 3D reconstruction included 3D-Doctor (Able Software Corp., Lexington, Massachusetts) and VGStudio MAX (Volume Graphics GmbH, Heidelberg, Germany).

Access cavity illustrations: Designed and formatted by Dr. Richard Burns, San Mateo, California; and Dr. Eric Herbranson, San Leandro, California.

All tables in this section that provide literature documentation for the studies on root canal anatomy are available online at the Expert Consult site and can be accessed accordingly.

Maxillary Central Incisor

The root canal system outline of the maxillary central incisor reflects the external surface outline (Fig. 5-74). A newly erupted central incisor has three pulp horns, and the pulp chamber is wider mesiodistally than buccolingually. A lingual shoulder usually is present, and it must be removed to gain access to the lingual wall of the root canal. The lingual shoulder prevents direct access to the root canal and deflects files labially, often resulting in a ledge or perforation. In cross section, the root canal at the CEJ is triangular in young teeth and oval in older teeth. It gradually becomes round as it approaches the apical foramen (see Table 5-8 online at the Expert Consult site). The μCT scans of this tooth are seen in Fig. 5-75. (See Video 5-1 online at the Expert Consult site for rotational views of these teeth.)

The external access outline form for the maxillary central incisor is a rounded triangle with its base toward the incisal aspect (Figs. 5-76 through 5-79). The width of the triangular base is determined by the distance between the mesial and distal pulp horns. The mesial and distal external walls should converge toward the cingulum. All internal walls should funnel to the root canal orifice. If the lingual shoulder has been removed properly, the entire orifice should be seen through the access opening. The incisal internal wall should approach the lingual surface of the tooth in a near butt joint to allow for a bulk of restorative material on this functional surface.

Variation

The outline form of the access cavity changes to a more oval shape as the tooth matures and the pulp horns recede because the mesial and distal pulp horns are less prominent.

Maxillary Lateral Incisor

The pulp chamber outline of the maxillary lateral incisor is similar to that of the maxillary central incisor; however, it is

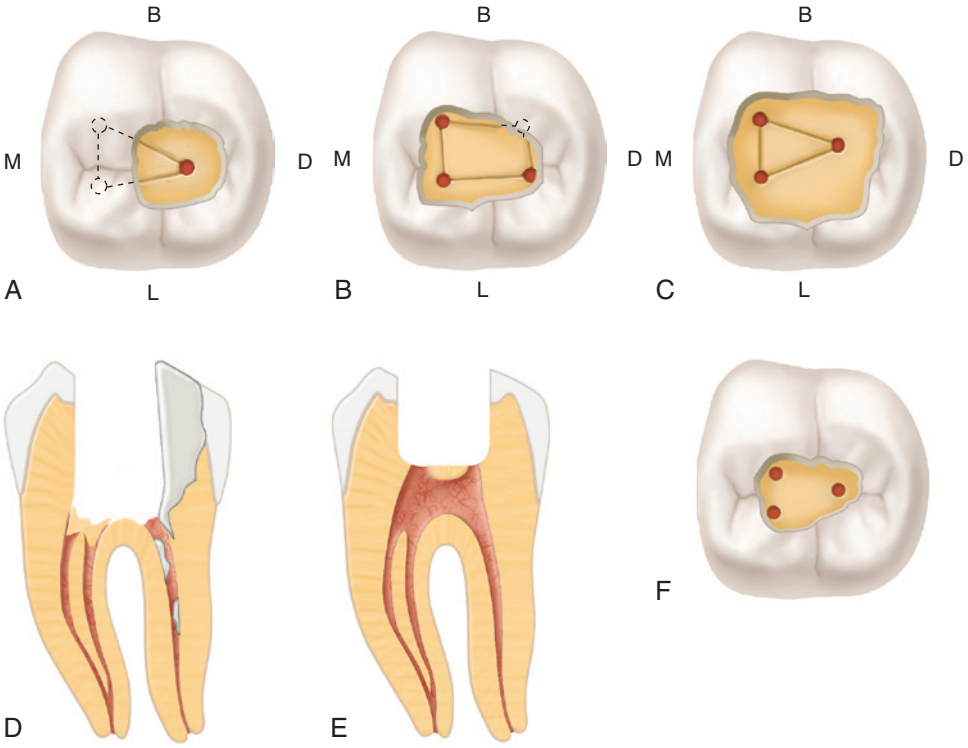

FIG. 5-71 **A,** Poor access placement and inadequate mesial extension leave both mesial orifices uncovered. Information about the position and location of pulp chambers can be obtained through evaluation of pretreatment radiographs, especially bite-wing radiographs, and assessment of the tooth anatomy at the cementoenamel junction (CEJ). **B,** Inadequate extension of the distal access cavity leaves the distobuccal canal orifice unexposed. All developmental grooves must be traced to their termination and must not be allowed to disappear into an axial wall. **C,** Gross overextension of the access cavity weakens the coronal tooth structure and compromises the final restoration. This mistake results from failure to determine correctly the position of the pulp chamber and the angulation of the bur. **D,** Allowing debris to fall into canal orifices results in an iatrogenic mishap. Amalgam fillings and dentin debris block canal orifices, preventing proper shaping and cleaning. Complete removal of the restoration and copious irrigation help prevent this problem. **E,** Failure to remove the roof of the pulp chamber is a serious underextension error; the pulp horns have been exposed. Bite-wing radiographs are excellent aids in determining vertical depth. **F,** Access preparation in which the roof of the pulp chamber remains and the pulp horns have been mistaken for canal orifices. The whitish color of the roof, the depth of the access cavity, and the lack of developmental grooves are clues to this underextension. Root canal orifices generally are positioned at or slightly apical to the CEJ. *B,* Buccal; *D,* distal; *L,* lingual; *M,* mesial.

smaller, and two or no pulp horns may be present (Fig. 5-80). This tooth is wider mesiodistally than buccolingually. A cross section at the CEJ shows a pulp chamber centered in the root, and its shape may be triangular, oval, or round. From the CEJ the pulp canal becomes round in cross section in the midroot and apical areas. The lingual shoulder of dentin must be removed before instruments can be used to explore the canal (see Table 5-9 online at the Expert Consult site). The μCT scans of this tooth are shown in Fig. 5-81. (See Video 5-2 online at the Expert Consult site for rotational views of these teeth.) Normally only one root canal is present, but other variations have been reported.

The external access outline form for the maxillary lateral incisor may be a rounded triangle or an oval, depending on the prominence of the mesial and distal pulp horns (Figs. 5-82 through 5-84). When the horns are prominent, the rounded triangular shape is compressed mesiodistally relative to a central incisor, producing a more slender triangle. The outline form usually is oval if the mesial and distal pulp horns are not prominent. All other aspects of the access preparation are the same as those for the central incisor.

The maxillary lateral incisor often has anomalies. One such variation in form is the presence of a palatal radicular or developmental groove (Fig. 5-85).[121,153-155,161-164] Although this groove may be present on the roots of all anterior teeth, it is more common in the maxillary lateral incisor. There is generally direct communication between the groove and the pulp cavity, and this occurs primarily through dentinal tubules.

Dens invaginatus, another anomaly, has been classified into three types based on severity, ranging from simple to more complex.[194] Type 1 is an invagination that is confined to the crown. Type 2 is an invagination that extends past the CEJ but does not involve the periradicular tissues. Type 3 is an invagination that extends beyond the CEJ and can have a second apical foramen. Often both surgical and nonsurgical root canal procedures are necessary to properly manage this condition.*

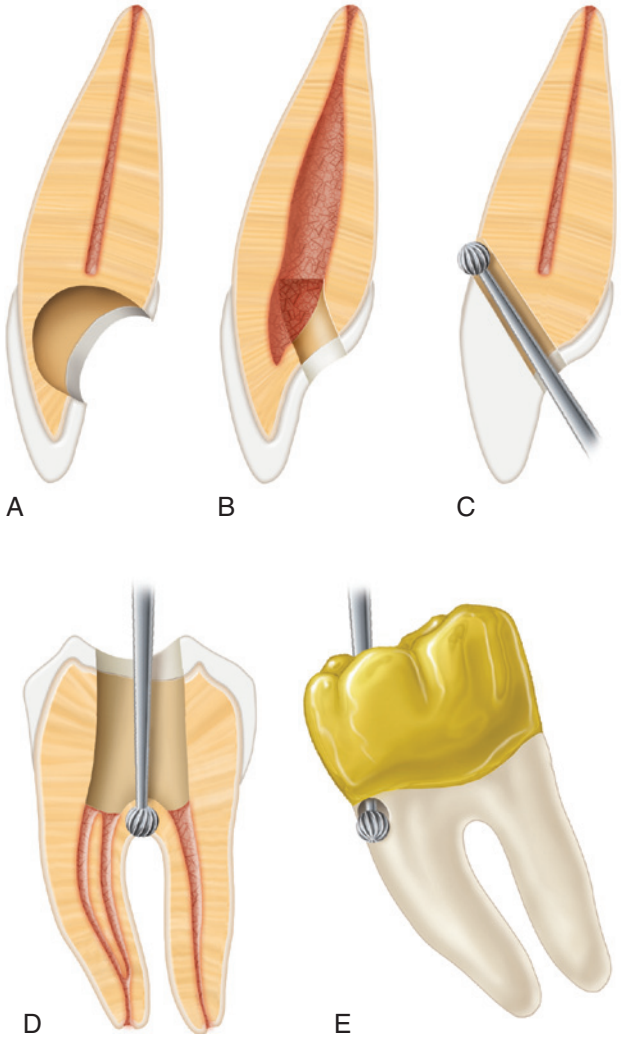

FIG. 5-72 A, Overzealous tooth removal caused by improper bur angulation and failure to recognize the lingual inclination of the tooth. This results in weakening and mutilation of the coronal tooth structure, which often leads to coronal fractures. B, Inadequate opening; the access cavity is positioned too far to the gingival, with no incisal extension. This can lead to bur and file breakage, coronal discoloration because the pulp horns remain, inadequate instrumentation and obturation, root perforation, canal ledging, and apical transportation. C, Labial perforation caused by failure to extend the preparation to the incisal before the bur shaft entered the access cavity. D, Furcation perforation caused by failure to measure the distance between the occlusal surface and the furcation. The bur bypasses the pulp chamber and creates an opening into the periodontal tissues. Perforations weaken the tooth and cause periodontal destruction. To ensure a satisfactory result, they must be repaired as soon as they are made. E, Perforation of the mesial tooth surface caused by failure to recognize that the tooth was tipped and failure to align the bur with the long axis of the tooth. This is a common error in teeth with full crowns. Even when these perforations are repaired correctly, they usually cause a permanent periodontal problem because they occur in a difficult maintenance area.

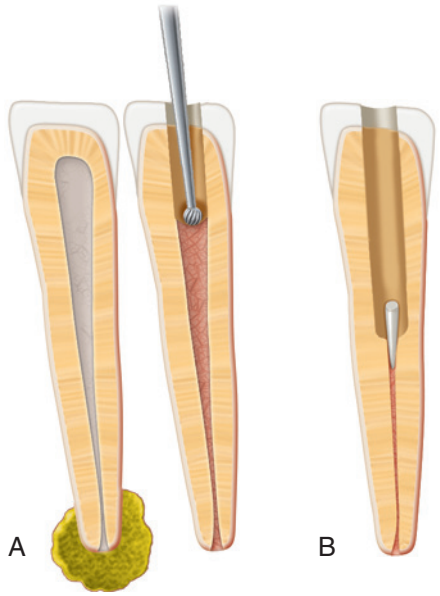

FIG. 5-73 A, The most embarrassing error, with the greatest potential for medical and legal damage, is entering the wrong tooth because of incorrect dental dam placement. When the crowns of teeth appear identical, the clinician should mark the tooth with a felt-tip marker before placing the dental dam. B, Burs and files can be broken if used with an improper motion, excessive pressure, or before the access cavity has been properly prepared. A broken instrument may lock into the canal walls, requiring excessive removal of tooth structure to retrieve it. On occasion, fragments may not be retrievable.

Maxillary Canine

The root canal system of the maxillary canine is similar in many ways to that of the maxillary incisors (Fig. 5-86). A major difference is that it is wider labiolingually than mesiodistally. Another difference is that it has no pulp horns. Its smallest pointed incisal edge corresponds to the single cusp. The pulp chamber outline at the CEJ is oval. A lingual shoulder is present, which may prevent shaping and cleaning of the root canal in its lingual dimension. From this point, the root canal remains oval until it approaches the apical third of the root, where it becomes constricted. Because of this oval shape, the clinician must take care to circumferentially file labially and palatally to shape and clean the canal properly.[124] Usually one root canal is present, although two canals have been reported (see Table 5-10 online at the Expert Consult site). The μCT scans for the maxillary canine can be seen in Fig. 5-87. (See Video 5-3 online at the Expert Consult site) for rotational views of these teeth. The thin buccal bone over the canine eminence often disintegrates, and fenestration is an occasional anatomic finding.

The external access outline form is oval or slot shaped because no mesial or distal pulp horns are present (Figs. 5-88 through 5-90). The mesiodistal width of the slot is determined by the mesiodistal width of the pulp chamber. The incisogingival dimension is determined by straight-line access factors and removal of the lingual shoulder. The incisal extension often approaches to within 2 to 3 mm of the incisal edge to allow for straight-line access. The incisal wall meets the lingual surface of the canine in a butt joint to provide adequate thickness for restorative material because this tooth is heavily involved in excursive occlusal guidance and function. All internal walls funnel to the orifice.

Maxillary First Premolar

Most maxillary first premolars have two root canals, regardless of the number of roots (Fig. 5-91). Ethnicity plays a factor in that Asian people have a higher incidence of one canal than do other ethnic groups.[120,156]

A furcation groove or developmental depression on the palatal aspect of the buccal root is another anatomic feature. Its prevalence has been reported as 62% to 100%.[97,112,211] This groove may pose a risk to root canal and restorative procedures in this tooth.[118] At the deepest part of the invagination, the average dentin thickness was found to be 0.81 mm.

The pulp chamber of the maxillary first premolar is considerably wider buccolingually than mesiodistally. In the buccolingual dimension, the chamber outline shows a buccal and a

palatal pulp horn. The buccal pulp horn usually is larger. From the occlusal level, the chamber maintains a width similar that of the floor, which is located just apical to the cervical line. The palatal orifice is slightly larger than the buccal orifice. In cross section at the CEJ, the palatal orifice is wider buccolingually and kidney shaped because of its mesial concavity. From the floor, two root canals take on a round shape at midroot and rapidly taper to their apices, usually ending in extremely narrow, curved root canals. The palatal canal usually is slightly larger than the buccal canal. The maxillary first premolar may have one, two, or three roots and canals; it most often has two (see Table 5-11 online at the Expert Consult site). The μCT scans for the maxillary first premolar can be seen in Fig. 5-92. (See Video 5-4 available online at the Expert Consult site for rotational views of these teeth.)

If two canals are present, they are labeled buccal and palatal; three root canals are designated mesiobuccal, distobuccal, and palatal. Directional positioning of small files can help identify the anatomy. The roots are considerably shorter and thinner than in the canines. In double-rooted teeth, the roots most often are the same length. The buccal root is often found to be fenestrated through the cortical plate of bone; this can pose both nonsurgical and surgical treatment challenges.

The access preparation for the maxillary first premolar is oval or slot shaped (Figs. 5-93 through 5-96). It also is wide buccolingually, narrow mesiodistally, and centered mesiodistally between the cusp tips. In fact, the mesiodistal width should correspond to the mesiodistal width of the pulp chamber. The buccal extension typically is two thirds to three fourths up the buccal cusp incline. The palatal extension is approximately halfway up the palatal cusp incline. The buccal and palatal walls funnel directly into the orifices. Because of the mesial concavity of the root, the clinician must take care

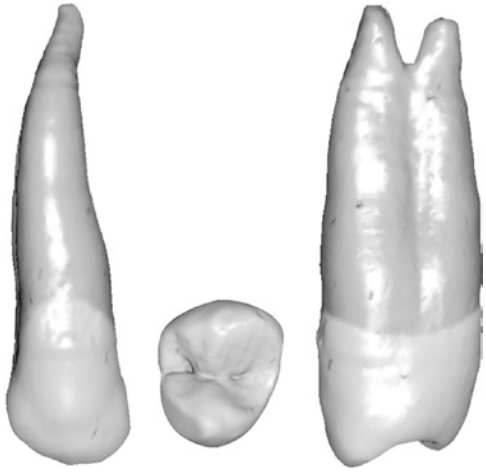

FIG. 5-91 Maxillary first premolar. Development and anatomic data: average time of eruption—10 to 11 years; average age of calcification—12 to 13 years; average length—20.6 mm. Root curvature (most common to least common): buccal root—lingual, straight, buccal; palatal root—straight, buccal, distal; single root—straight, distal, buccal.

not to overextend the preparation in that direction because this could result in perforation.

Variation

When three canals are present, the external outline form becomes triangular, with the base on the buccal aspect. The mesiobuccal and distobuccal corners of the triangle should be positioned directly over the corresponding canal orifices.

Maxillary Second Premolar

The root canal system of the maxillary second premolar is wider buccolingually than mesiodistally (Fig. 5-97). This tooth may have one, two, or three roots and canals (see Table 5-12 online at the Expert Consult site). Two or three canals can occur in a single root.[68] The scans for the maxillary second premolar can be seen in Fig. 5-98. (See Video 5-5 online at the Expert Consult site for rotational views of these teeth.) Directional positioning of small files can help identify the anatomy. The mesiodistal and buccolingual aspects of the pulp chamber are similar to those of the first premolar. A buccal and a palatal pulp horn are present; the buccal pulp horn is larger. A single root is oval and wider buccolingually than mesiodistally. The canal or canals remain oval from the pulp chamber floor and taper rapidly to the apex. The roots of the maxillary second premolar are approximately as long as those of the first premolar, and apical curvature is common, particularly with large maxillary sinus cavities.

When two canals are present in this tooth, the maxillary second premolar access preparation is nearly identical to that of the first premolar. Because this tooth usually has one root, if two canals are present, they are nearly parallel to each other, and the external outline form must have a greater buccolingual extension, to permit straight-line access to these canals, than with the first premolar with two roots and diverging canals. If only one canal is present, the buccolingual extension is less

and corresponds to the width between the buccal and palatal pulp horns (Figs. 5-99 through 5-102). If three canals are present, the external access outline form is the same triangular shape illustrated for the maxillary first premolar.

Maxillary First Molar

The maxillary first molar is the largest tooth in volume and one of the most complex in root and canal anatomy (Fig. 5-103).[50] The pulp chamber is widest in the buccolingual dimension, and four pulp horns are present (mesiobuccal, mesiopalatal, distobuccal, and distopalatal). The pulp chamber's cervical outline form has a rhomboid shape, sometimes with rounded corners. The mesiobuccal angle is an acute angle; the distobuccal angle is an obtuse angle; and the palatal angles are basically right angles. The palatal canal orifice is centered palatally; the distobuccal orifice is near the obtuse angle of the pulp chamber floor; and the main mesiobuccal canal orifice is buccal and mesial to the distobuccal orifice and is positioned within the acute angle of the pulp chamber. The mesiopalatal canal orifice (also referred to as the *MB-2*) is located palatal and mesial to the mesiobuccal orifice. A line drawn to connect the three main canal orifices—the mesiobuccal orifice, distobuccal orifice, and palatal orifice—forms a triangle, known as the *molar triangle*.

The three individual roots of the maxillary first molar (i.e., mesiobuccal root, distobuccal root, and palatal root) form a tripod. The palatal root is the longest, has the largest diameter, and generally offers the easiest access. It can contain one, two,

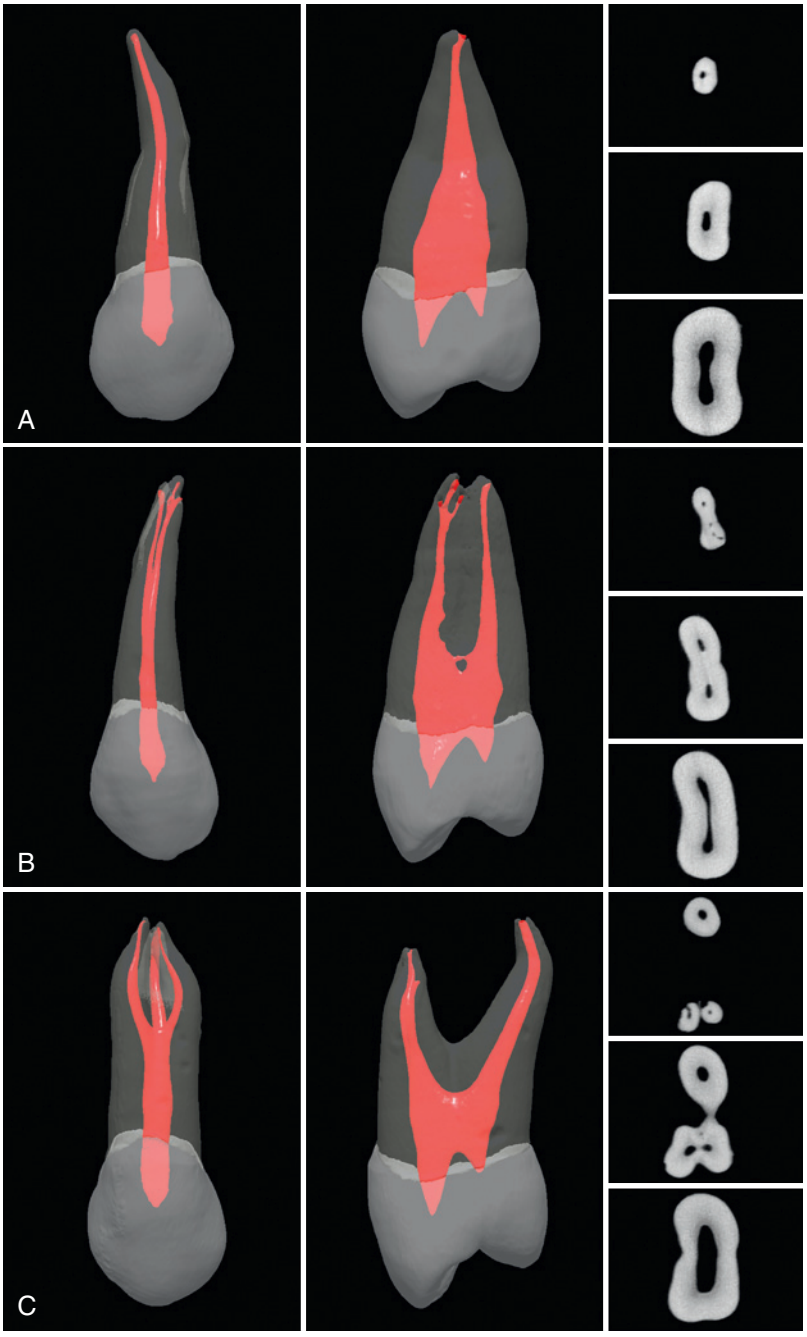

FIG. 5-98 μCT scans of maxillary second premolars. A, Common anatomic presentation showing one canal. B, Second premolar with two canals and an apical delta. FIG. 5-102 Single canal that has split into three canals.

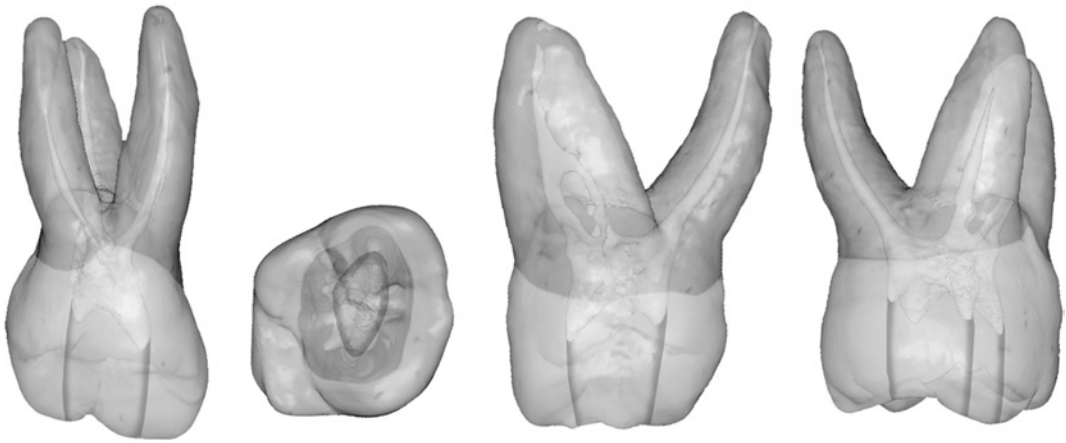

FIG. 5-103 Maxillary first molar. Average time of eruption—6 to 7 years; average age of calcification—9 to 10 years; average length—20.8 mm. Root curvature (most common to least common): mesiobuccal root—distal, straight; distobuccal root—straight, mesial, distal; palatal root—buccal, straight.

or three root canals (see Table 5-13 online at the Expert Consult site). The palatal root often curves buccally at the apical one third, which may not be obvious on a standard periapical radiograph. From its orifice the palatal canal is flat, ribbonlike, and wider in a mesiodistal direction. The distobuccal root is conical and may have one or two canals (see Table 5-14 online at the Expert Consult site). From its orifice, the canal (or canals) first is oval and then becomes round as it approaches the apical third of the root. The mesiobuccal root has generated more research and clinical investigation than any other root in the mouth.[202] It may have one, two, or three root canals (see Table 5-15 online at the Expert Consult site). A single mesiobuccal canal is oval and wider buccolingually; two or three canals are more circular. In general, a concavity exists on the distal aspect of the mesiobuccal root, which makes this wall thin. The μCT scans for the maxillary first molar can be seen in Fig. 5-104. (See Video 5-6 online at the Expert Consult site for rotational views of these teeth.) The DOM has been used to study the location and pathway of the mesiopalatal canal in maxillary first and second molars.[80] The clinician must always keep in mind that the location of this canal varies greatly; it generally is located mesial to or directly on a line between the mesiobuccal and palatal orifices, within 3.5 mm palatally and 2 mm mesially of the mesiobuccal orifice (Figs. 5-105 and 5-106). These authors[80] found that not all mesiopalatal orifices lead to a true canal. A true orifice for this canal was present in only 84% of molars in which a second orifice was identified (Fig. 5-107).[205]

Negotiation of the mesiopalatal canal often is difficult; a ledge of dentin covers its orifice, the orifice has a mesiobuccal inclination on the pulp floor, and the canal's pathway often takes one or two abrupt curves in the coronal part of the root. Most of these obstructions can be eliminated by troughing or countersinking with ultrasonic tips mesially and apically along the mesiobuccal pulpal groove (Figs. 5-108 through 5-111). This procedure may shift the canal mesially, meaning that the access wall also must be moved farther mesially. Troughing can easily be 0.5 to 3 mm deep, and care must be taken to avoid furcal wall perforation in this root. Apical to the troughing level. the canal may be straight or may curve sharply to the distobuccal, buccal, or palatal.

Because the maxillary first molar almost always has four canals, the access cavity has a rhomboid shape, with the corners corresponding to the four orifices (see Fig. 5-108). One study demonstrated that the access cavity should not extend into the mesial marginal ridge.[246] Distally, the preparation can invade the mesial portion of the oblique ridge, but it should not penetrate through the ridge. The buccal wall should be parallel to a line connecting the mesiobuccal and distobuccal orifices and not to the buccal surface of the tooth.

Maxillary Second Molar

Coronally, the maxillary second molar closely resembles the maxillary first molar (Fig. 5-112). The root and canal anatomy are similar to those of the first molar, although there are differences. The distinguishing morphologic feature of the

FIG. 5-109 Two canals in both buccal roots with a common foramen in each root.

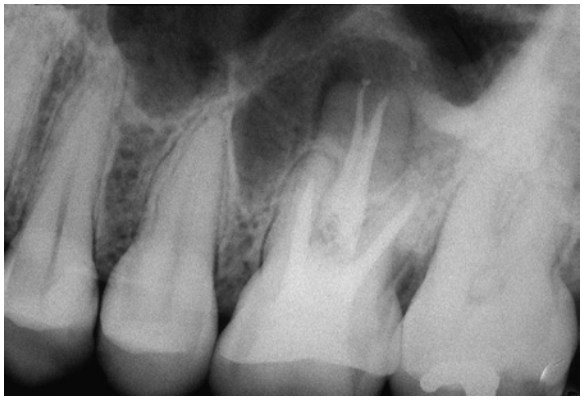

FIG. 5-110 Two separate canals in palatal root. (Courtesy Dr. Paulo Nogueira, São Paulo, Brazil.)

maxillary second molar is that its three roots are grouped closer together and are sometimes fused. Also, they generally are shorter than the roots of the first molar and not as curved. The second molar usually has one canal in each root; however, it may have two or three mesiobuccal canals, one or two distobuccal canals, or two palatal canals (see Tables 5-16 to 5-18 online at the Expert Consult site). Four canals are less likely to be present in the second molar than in the first molar. The μCT scans for the maxillary second molar can be seen in Fig. 5-113. (See Video 5-7 online at the Expert Consult site for rotational views of these teeth.) The three main orifices usually form a flat triangle and sometimes almost a straight line (Figs. 5-114 through 5-118). The mesiobuccal canal orifice is located more to the buccal and mesial than in the first molar; the distobuccal orifice approaches the midpoint between the mesiobuccal and palatal orifices[250]; and the palatal orifice usually is

(×8.4.)

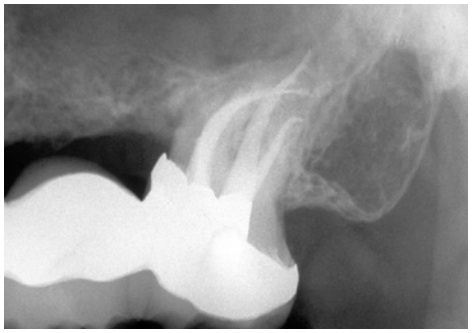

FIG. 5-116 Severely curved mesiobuccal root with a right-angle curve in the distobuccal *(DB)* root.

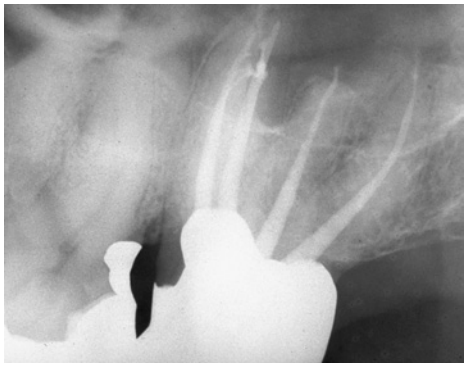

FIG. 5-117 Four canals (*MB-1, MB-2, DB,* and *P*) can be seen.

located at the most palatal aspect of the root. In general, the canal orifices in the maxillary second molar are closer mesially to each other than they are in the maxillary first molar.

The floor of the pulp chamber is markedly convex, which gives the canal orifices a slight funnel shape. On occasion the canals curve into the chamber at a more horizontal angle, requiring removal of a lip of dentin so that a canal can be entered more in a direct line with the axis. Teeth with two canals usually have a buccal and a palatal canal of equal length and diameter (see Fig. 5-114, *B*). These parallel root canals are frequently superimposed radiographically, but they can be imaged by exposing the radiograph from a distal angle. To enhance radiographic visibility, especially when interference arises from the malar process, a more perpendicular and

*Number is the percentage of cases in which one canal separates into two.

distoangular radiograph may be exposed. When two roots are present, each root may have one canal, or the buccal root may have two canals that join before reaching a single foramen. One study found that two palatal roots and two palatal canals occur in 1.47% of these teeth.[166]

When four canals are present, the access cavity preparation of the maxillary second molar has a rhomboid shape and is a smaller version of the access cavity for the maxillary first molar (see Fig. 5-115). If only three canals are present, the access cavity is a rounded triangle with the base to the buccal. As with the maxillary first molar, the mesial marginal ridge need not be invaded. Because the tendency in maxillary second molars is for the distobuccal orifice to move closer to a line connecting the mesiobuccal and palatal orifices, the triangle becomes more obtuse and the oblique ridge usually is not invaded.

If only two canals are present, the access outline form is oval and widest in the buccolingual dimension. Its width corresponds to the mesiodistal width of the pulp chamber, and the oval usually is centered between the mesial pit and the mesial edge of the oblique ridge.

Maxillary Third Molar

Loss of the maxillary first and second molars often is the reason the third molar must be considered a strategic abutment (Fig. 5-119). Careful examination of the root morphology is important before treatment is determined. The radicular anatomy of the third molar is completely unpredictable, and it may be advisable to explore the root canal morphology to evaluate the likelihood and degree of success. Even so, many third molars have adequate root formation; given reasonable accessibility, they can serve well as functioning dentition after root canal therapy.

The root anatomy of the maxillary third molar varies greatly. This tooth can have one to four roots and one to six canals, and C-shaped canals also can occur. The third molar usually has three roots and three root canals (see Table 5-19 online at the Expert Consult site). The tooth may be tipped significantly to the distal, the buccal, or both, which creates an even greater access problem than with the second molar. The μCT scans for the maxillary molar can be seen in Fig. 5-120. (See Video 5-8 online at the Expert Consult site for rotational views of these teeth.)

The access cavity form for the third molar can vary greatly. Because the tooth typically has one to three canals, the access preparation can be anything from an oval that is widest in the buccolingual dimension to a rounded triangle similar to that used for the maxillary second molar. All the canal orifices often lie nearly in a straight line as the distobuccal orifice moves even closer to the line connecting the mesiobuccal and palatal orifices. The resultant access cavity is an oval or highly obtuse triangle (Figs. 5-121 and 5-122).

FIG. 5-118 Four canals with two distinct palatal roots and canals.

Mandibular Central and Lateral Incisors

The root canal systems and access cavities for the two mandibular incisors are so similar they are discussed together (Fig. 5-123). As with the maxillary incisors, a lingual shoulder must be eliminated to allow direct-line access. The shoulder conceals the orifice to a second canal that, if present, is found immediately beneath it. Unlike the maxillary incisors, the pulp outline of the mandibular incisors is wider labiolingually. At the CEJ the pulp outline is oval and wider labiolingually than mesiodistally. At midroot the canal outline is still oval, but the canal is more constricted and narrower labiolingually. Most mandibular incisors have a single root with what radiographically appears to be a long, narrow canal. However, it is a broad canal labiolingually. Often a dentinal bridge is present in the pulp chamber that divides the root into two canals. The two canals usually join and exit through a single apical foramen, but they may persist as two separate canals. On occasion one canal branches into two canals, which subsequently rejoin into a single canal before reaching the apex (see Table 5-20 online

at the Expert Consult site). The scans of the mandibular central incisor can be seen in Fig. 5-124. The scans for the mandibular lateral incisors can be seen in Fig. 5-125. (See Videos 5-9 and 5-10 online at the Expert Consult site for rotational views of these teeth.)

One study determined that a relationship existed between crown size and the incidence of bifid root canals in these teeth.[234,235] Double root canals occur more often in teeth with a smaller index.

The mandibular incisors, because of their small size and internal anatomy, may be the most difficult access cavities to prepare. The external outline form may be triangular or oval, depending on the prominence of the mesial and distal pulp horns (Figs. 5-126 through 5-128). When the form is triangular, the incisal base is short and the mesial and distal legs are long incisogingivally, creating a long, compressed triangle. Without prominent mesial and distal pulp horns, the oval external outline form also is narrow mesiodistally and long incisogingivally. One study[152] determined that by age 40 years, the mandibular incisor pulp chamber has decreased in size sufficiently to justify an oval access cavity routinely. Complete removal of the lingual shoulder is critical because this tooth often has two canals that are buccolingually oriented, and the lingual canal most often is missed. To avoid missing this canal, the access preparation is extended well into the cingulum gingivally. Because the lingual surface of this tooth is not involved with occlusal function, restoration of the access opening with butt joint junctions between the internal walls and the lingual surface is not required.

Mandibular Canine

The root canal system of the mandibular canine is very similar to that of the maxillary canine, except that the dimensions are smaller, the root and root canal outlines are narrower in the mesiodistal dimension, and the mandibular canine occasionally has two roots and two root canals located labially and lingually (Fig. 5-129) (see Table 5-21 online at the Expert Consult site). The μCT scans of the mandibular canine can be seen in Fig. 5-130. (See Video 5-11 online at the Expert Consult site for rotational views of these teeth.) A fourth type is seen in subsequent Figs. 5-131 to 5-135.[222]

The root canal of the mandibular cuspid is narrow mesiodistally but usually very broad buccolingually. A lingual shoulder must be removed to gain access to the lingual wall of the root canal or to the entrance of a second canal. The lingual wall is almost slitlike compared with the larger buccal wall, which makes the canal a challenge to shape and clean.

The access cavity for the mandibular canine is oval or slot shaped (see Fig. 5-131). The mesiodistal width corresponds to the mesiodistal width of the pulp chamber. The incisal extension can approach the incisal edge of the tooth for straight-line access, and the gingival extension must penetrate the cingulum to allow a search for a possible lingual canal.

Mandibular First Premolar

As a group, the mandibular premolars present anatomic challenges because of the extreme variations in their root canal morphology (Fig. 5-136).[123,157,252] The root canal system of the mandibular first premolar is wider buccolingually than mesiodistally.[253] Two pulp horns are present: a large, pointed buccal horn and a small, rounded lingual horn. At the cervical line the root and canal are oval; this shape tends to become round as the canal approaches the middle of the root. If two canals are present, they tend to be round from the pulp chamber to their foramen. In another anatomic variation, a single, broad root canal may bifurcate into two separate root canals. Direct access to the buccal canal usually is possible, whereas the lingual canal may be quite difficult to find. The lingual canal tends to diverge from the main canal at a sharp angle. In addition, the lingual inclination of the crown tends to direct files

buccally, making location of a lingual canal orifice more difficult. To counter this situation, the clinician may need to extend the lingual wall of the access cavity farther lingually; this makes the lingual canal easier to locate. The mandibular first premolar sometimes may have three roots and three canals (see Table 5-22 online at the Expert Consult site). Multiple studies have reported C-shaped canal anatomy in this tooth.[13,65,67] The μCT scans for the mandibular first premolar can be seen in Fig. 5-137. (See Video 5-12 online at the Expert Consult site for rotational views of these teeth.)

The oval external outline form of the mandibular first premolar typically is wider mesiodistally than its maxillary counterpart, making it more oval and less narrow (Figs. 5-138 through 5-141). Because of the lingual inclination of the crown, buccal extension can nearly approach the tip of the buccal cusp to achieve straight-line access. Lingual extension

barely invades the poorly developed lingual cusp incline. Mesiodistally the access preparation is centered between the cusp tips. Often the preparation must be modified to allow access to the complex root canal anatomy frequently seen in the apical half of the tooth root.

Mandibular Second Premolar

The mandibular second premolar is similar to the first premolar, with the following differences: the lingual pulp horn usually is larger; the root and root canal are more often oval than round; the pulp chamber is wider buccolingually; and the separation of the pulp chamber and root canal normally is distinguishable compared with the more regular taper in the first premolar (Fig. 5-142). The canal morphology of the mandibular second premolar is similar to that of the first premolar with its many variations: two, three, and four canals and a lingually tipped crown. Fortunately, these variations are found less often in the second premolar (see Table 5-23 online at the Expert Consult site). The μCT scans for the mandibular second premolar can be seen in Fig. 5-143. (See Video 5-13 online at the Expert Consult site for rotational views of these teeth.) The access cavity form for the mandibular second premolar varies

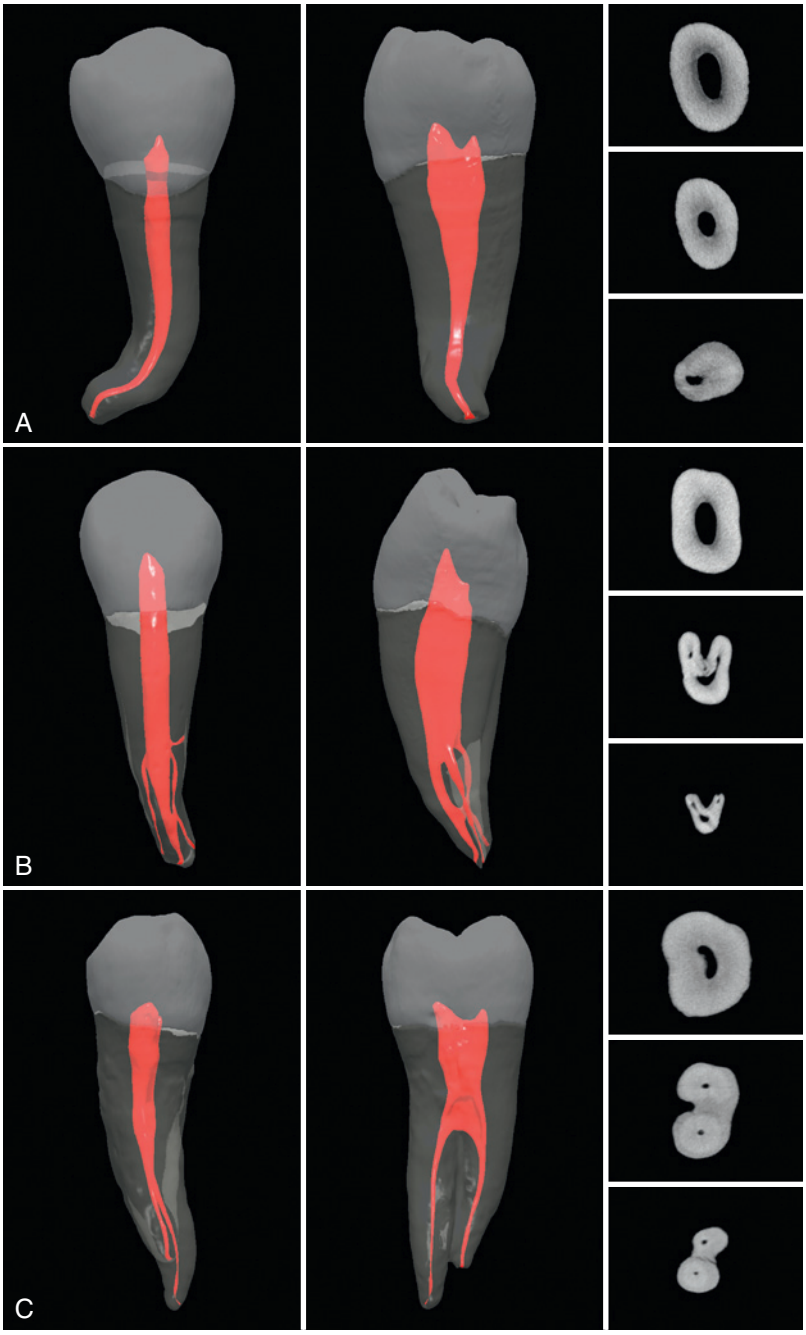

FIG. 5-143 μCT scans of mandibular second premolars. **A**, Common anatomic presentation. **B**, Second premolar with significant canal deviations in the middle to apical third. **C**, Second premolar with fused root that exhibits two distinct canals. All teeth are shown from both a buccal (vestibular) and a proximal perspective, along with the cross-sectional anatomy at the coronal, middle, and apical levels. (See Video 5-13 online at the Expert Consult site for rotational views of these teeth.)

in at least two ways in its external anatomy. First, because the crown typically has a smaller lingual inclination, less extension up the buccal cusp incline is required to achieve straight-line access. Second, the lingual half of the tooth is more fully developed; therefore, the lingual access extension typically is halfway up the lingual cusp incline.[54] The mandibular second premolar can have two lingual cusps, sometimes of equal size. When this occurs, the access preparation is centered mesiodistally on a line connecting the buccal cusp and the lingual groove between the lingual cusp tips. When the mesiolingual cusp is larger than the distolingual cusp, the lingual extension of the oval outline form is just distal to the tip of the mesiolingual cusp (Figs. 5-144 through 5-149).

Mandibular First Molar

The earliest permanent posterior tooth to erupt, the mandibular first molar seems to be the tooth that most often requires an endodontic procedure (vital pulp capping, pulpotomy, root

(From Sachdeva GS, Ballal S, Gopikrishna V, Kandaswamy D: Endodontic management of a mandibular second premolar with four roots and four root canals with the aid of spiral computed tomography: a case report, *J Endod* 34:104, 2008.)

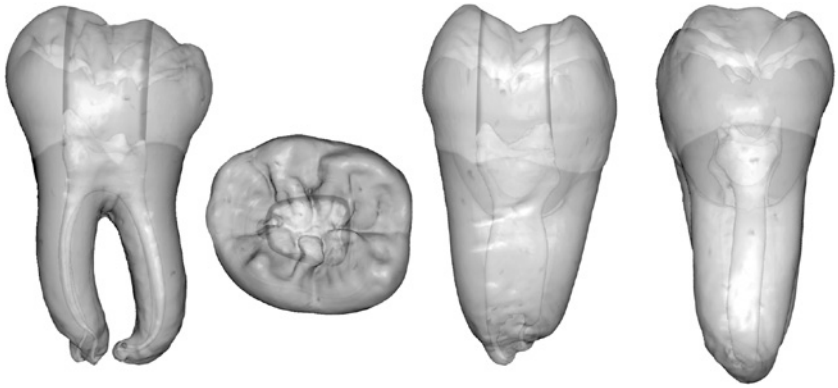

FIG. 5-150 Mandibular first molar. Average time of eruption—6 years; average age of calcification—9 to 10 years; average length—21 mm. Root curvature (most common to least common): mesial root—distal, straight; distal root—straight, distal.

canal); therefore, its morphology has received a great deal of attention (Fig. 5-150).[261] It often is extensively restored, and it is subjected to heavy occlusal stress. Consequently, the pulp chamber frequently has receded or is calcified. The tooth usually has two roots, but occasionally it has three, with two or three canals in the mesial root and one, two, or three canals in the distal root (see Tables 5-24 and 5-25 online at the Expert Consult site). The μCT scans of the mandibular first molar can be seen in Fig. 5-151. (See Video 5-14 online at the Expert Consult site for rotational views of these teeth.)

The canals in the mesial root are the mesiobuccal and mesiolingual canals. A middle mesial (MM) canal sometimes is present in the developmental groove between the other mesial canals,[148] but it may only represent a wide anastomosis between the two mesial canals.[54] The incidence of an MM canal ranges from 1%[223] to 15%.[77,209] The canals in the distal root include the distal canal (if only one canal is present) and the distobuccal and distolingual and middle distal canals (if more than one is present).[75] The orifices to these canals are connected by a developmental groove. Orifices to all canals usually are located in the mesial two thirds of the crown, and the pulp chamber floor is roughly trapezoid or rhomboid. Usually four pulp horns are present.

The presence of two separate distal roots is rare, but this does occur. In such cases the distolingual root is smaller than the distobuccal root and usually more curved. Also, the distolingual root often has a sharp apical hook toward the buccal side that is not obvious on radiographs (Fig. 5-152). The mesial root, the wider of the two roots, curves mesially from the cervical line to the middle third of the root and then angles distally to the apex. The buccal and lingual surfaces are convex throughout their length, whereas the distal surface of the mesial root and the mesial surface of the distal root have a root concavity, which makes the dentin wall very thin.

The mesial canal orifices usually are well separated in the main pulp chamber and connected by a developmental groove.[40] The mesiobuccal orifice is commonly under the mesiobuccal cusp, whereas the mesiolingual orifice generally is found just lingual to the central groove. On occasion an middle mesial canal orifice is present in the groove between the two mesial orifices (Figs. 5-152 through 5-159). The clinician must always check for such an orifice after shaping and cleaning the main root canals. A bur is used to remove any protuberance from the mesial axial wall that would prevent direct access to the developmental groove between the two mesial orifices. Magnification is a tremendous aid during the exploration of this developmental groove with the sharp tip of an endodontic explorer. If a depression or orifice is located, the groove can be troughed with ultrasonic tips, at the expense of the mesial aspect, until a small file can negotiate the space.

When only one distal canal is present, the orifice is oval buccolingually and the opening generally is located distal to the buccal groove. This orifice usually can be explored from the mesial with either an endodontic explorer or a small K-file. If the file tip takes a sharp turn in a distobuccal or distolingual direction, the clinician should search for yet another orifice; in rare cases a mesiodistal canal orifice is present.

If three main root canals are present in this tooth, each is oval in the cervical and middle thirds of the root and round in the apical third. If two canals (distobuccal and distolingual) are present in the distal root, they usually are more round than oval for their entire length. The mesial root canals usually are curved, with the greatest curvature in the mesiobuccal canal. This canal can have a significant curvature in the buccolingual plane that may not be apparent on radiographs. Such a curvature usually can be detected with precurved pathfinder instruments.

Multiple accessory foramina may be located in the furcation of the mandibular molars. These foramina usually are impossible to clean and shape directly; they are rarely seen, except occasionally on a posttreatment radiograph if they have been filled with root canal sealer or thermoplastic filling material. Because sodium hypochlorite solutions can dissolve organic debris, the pulp chamber should be thoroughly exposed to allow the solution to reach the tiny openings. Fractures occasionally occur, which are quite visible with magnification, on proximal marginal ridges and extend down the root or under the lingual cusps.

The access cavity for the mandibular first molar typically is trapezoid or rhomboid, regardless of the number of canals present.[247] When four or more canals are present, the corners of the trapezoid or rhombus should correspond to the positions of the main orifices. Mesially the access need not invade the marginal ridge, except if access to the tooth itself is compromised. Distal extension must allow straight-line access to the distal canal or canals. The buccal wall forms a straight connection between the mesiobuccal and distobuccal orifices, and the lingual wall connects the mesiolingual and distolingual orifices without bowing.

FIG. 5-159 Pretreatment radiograph. Notice position and appearance of the distolingual root. (Courtesy Dr. William J. Aippersbach, Venice, Fla.)

A variation in root morphology is the presence of an extra distolingual root.[203] Usually this root has a type 1 canal configuration. Two thirds of the first mandibular molars found in a Chinese population had this variation.[251] Similarly, this distolingual root occurred in 4% of mandibular first molars of a Kuwaiti population.[159] These results confirm the observation that East Asian populations have more three-rooted mandibular first molars than do other racial groups.[8]

Mandibular molars, mainly first molars, may also have an additional root located lingually or buccally. Although this is a rare occurrence in Caucasian populations, it is more common in Asian populations.[220] The radix entomolaris (RE) is a supernumerary root located distolingually in mandibular molars (see Fig. 5-158),[10,32] whereas the radix paramolaris (RP) is an extra root located mesiobuccally. Each root usually contains a single root canal. The orifice of the RE is located distolingually to mesiolingually from the main canal or canals of the distal root; the orifice of the RP is located mesiobuccally to distobuccally from the main mesial root canals. A dark line or groove from the main root canal on the pulp chamber floor leads to

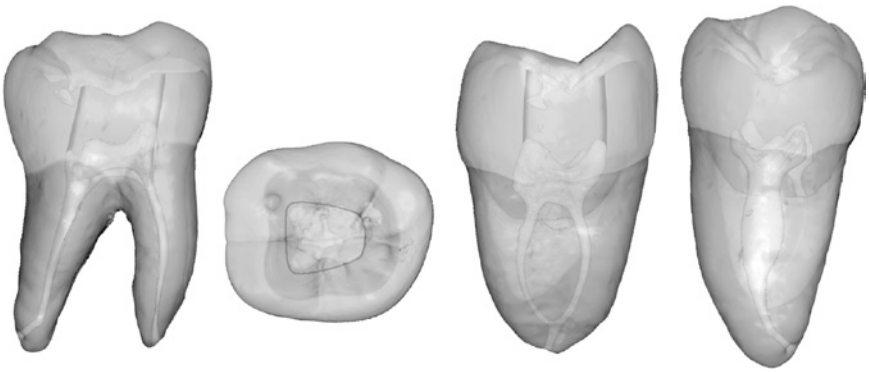

FIG. 5-160 Mandibular second molar. Average time of eruption—11 to 13 years; average age of calcification—14 to 15 years; average length—19.8 mm. Root curvature (most common to least common): mesial root—distal, straight; distal root—straight, distal, mesial, buccal; single root—straight, distal, bayonet, lingual.

these orifices.[32] These anatomic variations present definite challenges to therapy because of their orifice inclination and root canal curvature. The canal can be straight, may have a coronal curvature, or can have separate coronal and apical curvatures.[52]

Mandibular Second Molar

The mandibular second molar is somewhat smaller coronally than the first molar and tends to be more symmetric (Fig. 5-160). This tooth is identified by the proximity of its roots. The two roots often sweep distally in a gradual curve, with the apices close together. In some cases only one root is present. The degree of canal curvature and the configuration were studied in the mesial roots of 100 randomly selected mandibular first and second molars; 100% of the specimens showed curvature in both buccolingual and mesiodistal views.[45]

The pulp chamber and canal orifices of the mandibular second molar generally are not as large as those of the first molar. This tooth may have one, two, three, or four root canals (see Table 5-26 online at the Expert Consult site). The μCT scans for the mandibular second molar can be seen in Fig. 5-161. (See Video 5-15 online at the Expert Consult site for rotational views of these teeth.) Figs. 5-162 through 5-166 provide additional variations and views of this tooth.

The two mesial orifices are located closer together. In some mandibular second molars with single or fused roots, a file placed in the mesiobuccal canal may appear to be in the distal canal. This happens because the two canals sometimes are connected by a semicircular slit, a variation of the C-shaped canal[137,234,262] that often occurs in this tooth. The distal aspect of the mesial root and the mesial aspect of the distal root have concavities.

Mandibular second molars may have one to six canals, although the most prevalent configurations are two, three, and four canals (see Fig. 5-162). When three canals are present, the access cavity is similar to that for the mandibular first molar, although perhaps a bit more triangular and less rhomboid. The distal orifice is less often ribbon shaped buccolingually; therefore, the buccal and lingual walls converge more aggressively distally to form a triangle. The second molar may have only two canals, one mesial and one distal, in which case the orifices are nearly equal in size and line up in the buccolingual center of the tooth. The access cavity for a two-canal second molar is rectangular, wide mesiodistally and narrow buccolingually. The access cavity for a single-canal mandibular second molar is oval and is lined up in the center of the occlusal surface.

Mandibular Third Molar

The mandibular third molar is anatomically unpredictable and must be evaluated on the basis of its root formation (Fig. 5-167).[110] Fused short, severely curved, or malformed roots often support well-formed crowns. This tooth may have one to four roots and one to six canals (see Table 5-27 online at the Expert Consult site). The μCT scans for the mandibular third molar can be seen in Fig. 5-168. (See Video 5-16 online at the Expert Consult site for rotational views of these teeth.) Additional variations are seen in Figs. 5-169 through 5-171.

C-shaped canals also can occur (Fig. 5-172). Most of these teeth can be successfully root treated, regardless of anatomic irregularities; however, the long-term prognosis is determined by the root surface volume in contact with bone. The clinician must weigh the benefit of treatment against the prognosis.

The anatomy of the mandibular third molar is unpredictable; therefore, the access cavity can take any of several shapes. When three or more canals are present, a traditional rounded triangle or rhomboid shape is typical. When two canals are present, a rectangular shape is used. For single-canal molars, an oval shape is customary.

Teeth with C-Shaped Root Canal Systems

The main cause for C-shaped roots and canals is the failure of Hertwig's epithelial root sheath to fuse on either the buccal or lingual root surface (Fig. 5-173). The C-shaped canal system can assume many variations in its morphology (Fig. 5-174, *A*). Further cross section of types I, II, and III are seen in Fig. 5-174, *B* to *D*. The original classification[133] has been modified and has produced a more detailed description of C-shaped root and canal morphology. The C-shaped canal configuration can vary along the root depth so that the appearance of the orifices may not be good predictors of the actual canal anatomy.[62,64,137,234,262]

Category I (C1): The shape is an uninterrupted "C" with no separation or division (see Fig. 5-163, *A*).

Category II (C2): The canal shape resembles a semicolon resulting from a discontinuation of the "C" outline (see

Fig. 5-163, *B*), but either angle α or β should be no less than 60 degrees.

Category III (C3): Two or three separate canals (see Fig. 5-163, *C* and *D*) and both angles, α and β, are less than 60 degrees.

Category IV (C4): Only one round or oval canal is in the cross-section (see Fig. 5-163, *E*).

Category V (C5): No canal lumen can be observed (is usually seen near the apex only) (see Fig. 5-163, *F*).

The C-shaped root canal system was first reported in 1979 in a maxillary molar.[43] Most C-shaped canals occur in the mandibular second molar (Figs. 5-175 through 5-180),[234] but they also have been reported in the mandibular first molar,[146] the maxillary first and second molars, and the mandibular first premolar.* One study reported the incidence of C-shaped canal anatomy in maxillary first molars as 2 in 2175 (0.092%); this study also determined that the DB and palatal orifices were connected by a common groove (see Fig. 5-176, *B*).[53] Investigators who examined 309 Chinese maxillary second molars found C-shaped root canals in 4.9%.[254]

C-shaped mandibular molars are so named because of the cross-sectional morphology of their fused roots and their root

canals. Instead of having several discrete orifices, the pulp chamber of a molar with a C-shaped root canal system is a single, ribbon-shaped orifice with an arc of 180 degrees or more. It starts at the mesiolingual line angle and sweeps around either to the buccal or the lingual to end at the distal aspect of the pulp chamber (see Fig. 5-176, *A*). Below the orifice, the root structure can show a wide range of anatomic variations. These can be classified into two basic types: those with a single, ribbon-like, C-shaped canal from orifice to apex, and those with three or more distinct canals below the usual C-shaped orifice. Fortunately, molars with a single swath of canal are the exception rather than the rule. More common is the second type, with discrete canals that take unusual forms.[43] Other investigators determined that C-shaped canals in mandibular second molars can vary in shape and number along the root length.[136]

One study reported a case of a mandibular first molar with a normal mesiolingual orifice and a C-shaped groove that ran continuously from the mesiobuccal orifice along the buccal wall to the distal canal orifice.[18] The groove ran continuously down the root to the apical third, where it divided into two canals. Other researchers reported a C-shaped groove in a mandibular first molar that extended from the DL to the DB orifice and across the buccal surface to the MB orifice.[26] The ML orifice remained separate. Four separate apical foramina were noted. One investigator evaluated 811 endodontically treated mandibular second molars and found that 7.6% had C-shaped canals.[239] Several variants of the C-shaped canal

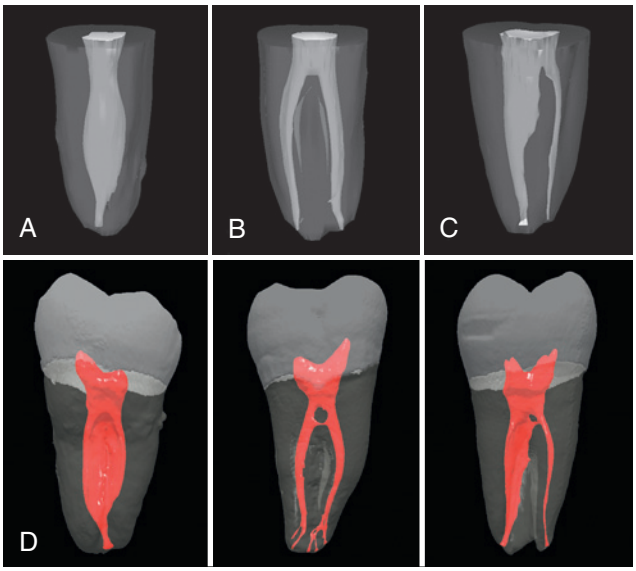

FIG. 5-175 Three-dimensional classification of C-shaped canal configuration. **A,** Merging type. **B,** Symmetrical type. **C,** Asymmetrical type. **D,** Additional C-shaped canal variations. (From Gao Y, Fan B, Cheung G, Gutmann J, Fan M: C-shaped canal system in mandibular second molars. IV. Morphological analysis and transverse measurement, *J Endod* 32:1062, 2006.)

morphology were noted, the most common being two or three canals that merged and exited as one canal.[239]

Significant ethnic variation can be seen in the incidence of C-shaped root canal systems. This anatomy is much more common in Asians than in the Caucasian population. Investigators in Japan[106] and China[254] found a 32% incidence of C-shaped canals. Others found the occurrence of C-shaped canals in a Chinese population to be 23% in mandibular first molars and 32% in mandibular second molars.[254,255,257] Another study found a 19% rate in mandibular second molars in Lebanese subjects[85] and an 11% rate in a Saudi Arabian population.[6] Mandibular molars in a Burmese population were found to have C-shaped canals in 22% of teeth.[82] Another investigation

found that 33% of Koreans had a C-shaped canal morphology in mandibular second molars.[105,189]

Four types of pulpal floors were found in mandibular second molars[137]:

Type I: A peninsula-like floor with continuous C-shaped orifice (see Fig. 5-174).

Type II: A buccal, striplike dentin connection between the peninsula-like floor and the buccal wall of the pulp chamber that separates the C-shaped groove into mesial (M) and distal (D) orifices. Sometimes the mesial orifice is separated into a mesiobuccal (MB) orifice and a mesiolingual (ML) orifice by another striplike dentin connection between the peninsula-like floor and the mesial wall of the pulp chamber (most common) (see Fig. 5-174).

Type III: Only one mesial, striplike dentin connection between the peninsula-like floor and the M wall, which separates the C-shaped groove into a small ML orifice and a large MB-D orifice. The MB-D orifice was formed by the merging of the MB orifice and the D orifice (second most common) (see Fig. 5-174).

Type IV: Non–C-shaped floors. One distal canal orifice and one oval or two round mesial canal orifices are present (least common) (see Fig. 5-174).

Not all C-shaped mandibular second molars with C-shaped canal systems have a C-shaped pulpal floor. This makes diagnosis difficult. However, radiographically a tooth with a C-shaped canal system always has a fused root with a longitudinal groove in the middle of the root.[63] Furthermore, there are three types of C-shaped canal systems in mandibular second molars (see Fig. 5-175).[73]

Type I (merging type): Canals merge to one main canal before exiting at the apical foramen

Type II (symmetric type): Separated mesial and distal canals in each root exit as separate canals

Type III (asymmetric type): Separated mesial and distal canals, with the distal canal having a long isthmus across the furcation area

The minimal wall thickness in the middle and apical parts of type III and in the apical part of type II makes these regions danger zones for canal enlargement procedures (see Fig. 5-176).[73]

Another study on mandibular molars found that there is a higher risk of root perforation at the thinner lingual walls of C-shaped canals during shaping and after canal preparation procedures. Both buccal and lingual canal walls were frequently narrower at the mesial locations.[36]

The access cavity for teeth with a C-shaped root canal system varies considerably and depends on the pulp morphology of the specific tooth. Teeth with C-shaped anatomy pose a considerable technical challenge; therefore, use of the DOM during all treatment phases is recommended.

Well-Shaped Canals
Signs of Mishaps
Sample Protocol for Contemporary Cleaning and Shaping Procedures
Summary

Clinical endodontics encompasses a number of treatments, but they have in common the goal of preventing and treating microbial contamination of pulps and root canal systems. Treatment of traumatic dental injuries and prophylactic treatment of vital pulps are fundamentally different from pulpectomies and root canal instrumentation of teeth with infected pulps (see Chapter 1 for more details on diagnosis).

Endodontic therapy is directed toward one specific set of aims: to cure or prevent periradicular periodontitis.[355,526] The ultimate aim is for patients to retain their natural teeth in function and aesthetics.

To date, many treatment modalities, including the use of nickel-titanium rotary instruments, have not consistently provided a statistically relevant impact on treatment outcomes.[375] This poses a problem in the age of evidence-based therapy, because new therapeutic techniques should deliver improved clinical results over standard procedures. However, the few pertinent clinical trials[99,375,387] and numerous in vitro studies do suggest that certain practices in canal preparation and disinfection are more appropriate than others. This chapter will summarize relevant information.

Orthograde root canal treatment is a predictable and usually highly successful procedure, both in relatively straightforward (Fig. 6-1) and more complex cases (Fig. 6-2). Studies and reviews report favorable outcome rates of up to 95% for the treatment of teeth diagnosed with irreversible pulpitis[39,103,157] and positive outcome rates of up to 85% for infected, necrotic teeth.[102,158,345,375,408]

Microorganisms can breach dental hard-tissue barriers through several avenues, the most common being dental caries (Fig. 6-3). Shaping and cleaning procedures (Box 6-1) as part of root canal treatment are directed against microbial challenges to the root canal system. However, disinfection per se does not guarantee long-term retention of root canal-treated teeth; there is good evidence that this outcome is closely related to placement of an adequate coronal restoration.[21,346,400,425] Moreover, the impact of preservation of radicular structural strength should not be underestimated.[172]

PRINCIPLES OF CLEANING AND SHAPING

Endodontists agree that a major biologic aim of root canal therapy is to address apical periodontitis by disinfection and subsequent sealing of root canal systems. However, considerable disagreement exists over how this goal should be achieved. Although the terms *cleaning* and *shaping* are often used to describe root canal treatment procedures,[417] reversing the order to *shaping* and *cleaning* more correctly reflects the fact that enlarged canals direct and facilitate the cleaning action of irrigants and the removal of infected dentin.

Planktonic microorganisms in the pulp cavity and coronal root canal may be readily killed by irrigants early in a

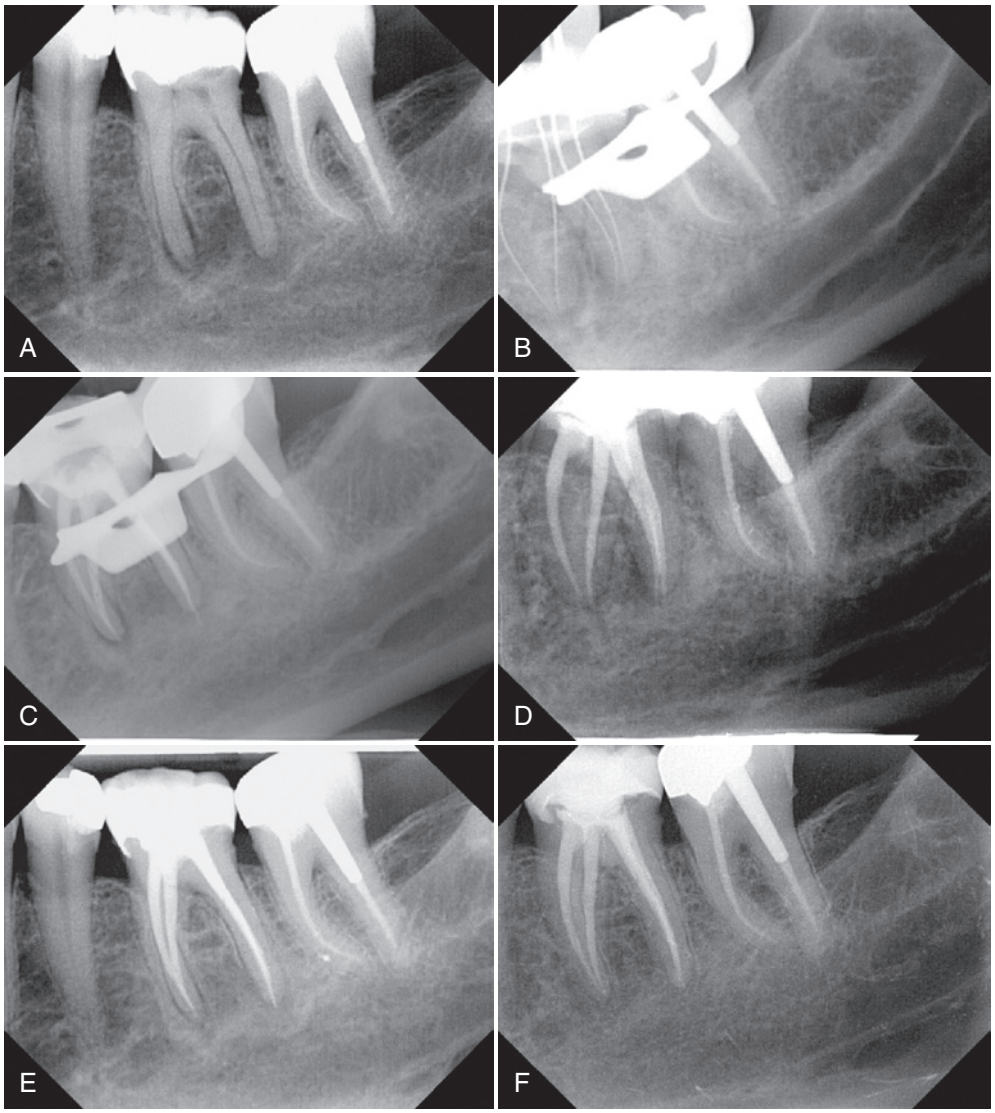

FIG. 6-1 Effect of routine root canal treatment of a mandibular molar. **A**, Pretreatment radiograph of tooth #19 shows radiolucent lesions adjacent to both mesial and distal root apices. **B**, Working length radiograph shows two separate root canals in the mesial root and two merging canals in the distal root. **C**, Posttreatment radiograph after shaping of root canal systems with nickel-titanium rotary files and obturation with thermoplasticized gutta-percha. **D**, Six-month recall radiograph after restoration of tooth #19 with an adhesively inserted full ceramic crown; some periradicular bone fill can be seen. **E**, One-year recall radiograph displays evidence of additional periradicular healing. **F**, Five-year recall radiograph; tooth not only is periapically sound but also clinically asymptomatic and fully functional.

BOX 6-1

Basic Objectives in Cleaning and Shaping

The primary objectives in cleaning and shaping the root canal system are to do the following:

- Remove infected soft and hard tissue
- Give disinfecting irrigants access to the apical canal space
- Create space for the delivery of medicaments and subsequent obturation
- Retain the integrity of radicular structures

procedure, but bacteria in less accessible canal areas or in biofilms still can elicit or maintain apical periodontitis. In everyday practice, these bacteria can be targeted only after mechanical root canal preparation.

Mechanical Objective

An ideal mechanical objective of root canal instrumentation is complete and centered incorporation of the original canals into the prepared shape, meaning that all root canal surfaces are mechanically prepared (*green areas* in Fig. 6-4, *A* and *B*). This goal is unlikely to be met with current techniques.[359,386]

Preparation errors such as deviations, zipping, and perforations should be absent. Although these negative effects of canal

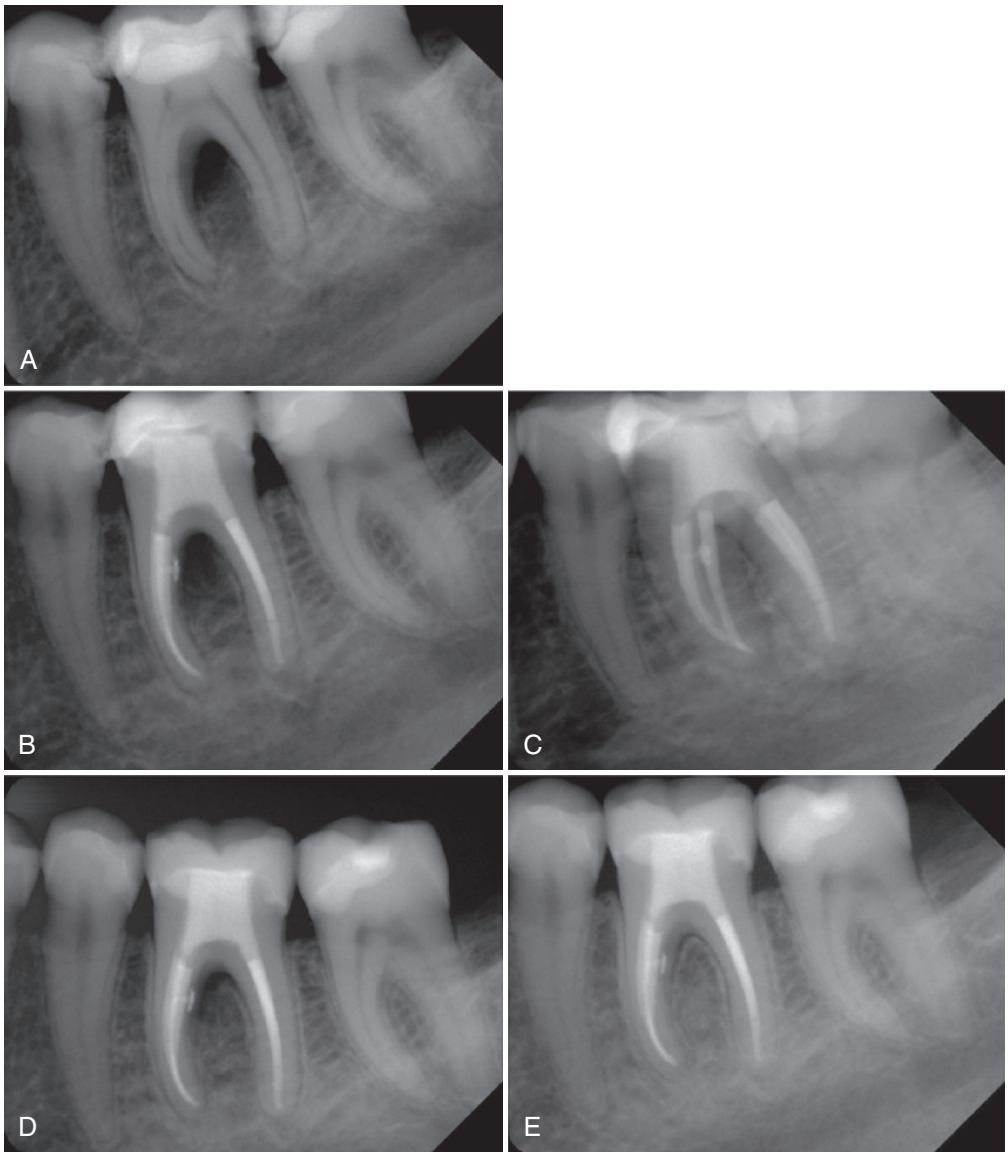

FIG. 6-2 Root canal treatment in a case of apical and interradicular pathosis. **A**, Pretreatment radiograph of tooth #19 shows an interradicular lesion. **B-C**, Posttreatment radiographs after root canal preparation and obturation. Note the lateral canal in the coronal third of the root canal. **D-E**, Two-month recall radiograph suggests rapid healing. (Courtesy Dr. H. Walsch.)

shaping and other procedural mishaps (discussed later) per se may not affect the probability of a favorable outcome,[290] they leave parts of the root canal system inaccessible for disinfection and are undesirable for that reason alone.

Another important mechanical objective is to retain as much cervical and radicular dentin as possible so as not to weaken the root structure, thereby preventing root fractures. Before root canal shaping, dentin wall thickness dimensions of 1 mm and below have been demonstrated in anatomic studies.[127,164] Straightening of canal paths can lead to thinning of curved root walls (Fig. 6-5). Although no definitive minimal radicular wall thickness has been established, 0.3 mm is considered critical by some authors.[287] To avoid overpreparation and outright perforations, adequate access cavity preparation and optimal enlargement of the coronal third of the root canal has to be ascertained (discussed later).

Biologic Objective

Schilder suggested that canals should be prepared to a uniform and continuous taper[445]; however, this guideline was aimed at facilitating obturation rather than targeting antimicrobial efficacy. For optimal disinfection, the preparation shape and antimicrobial efficacy are intimately related through the removal of infected pulp and dentin (Fig. 6-6) and creation of space for delivery of irrigants.

Traditionally, fluids have been dispensed passively into root canals by syringe and needle (Fig. 6-7). When delivered with passive needle irrigation, solutions have been shown to progress only 1 mm farther than the tip of the needle.[189,396,426] Enlarged apical canals and finer needles are likely to allow increasingly deeper needle placement, and this improves debridement and disinfection of canals.[5,12,147,532] However,

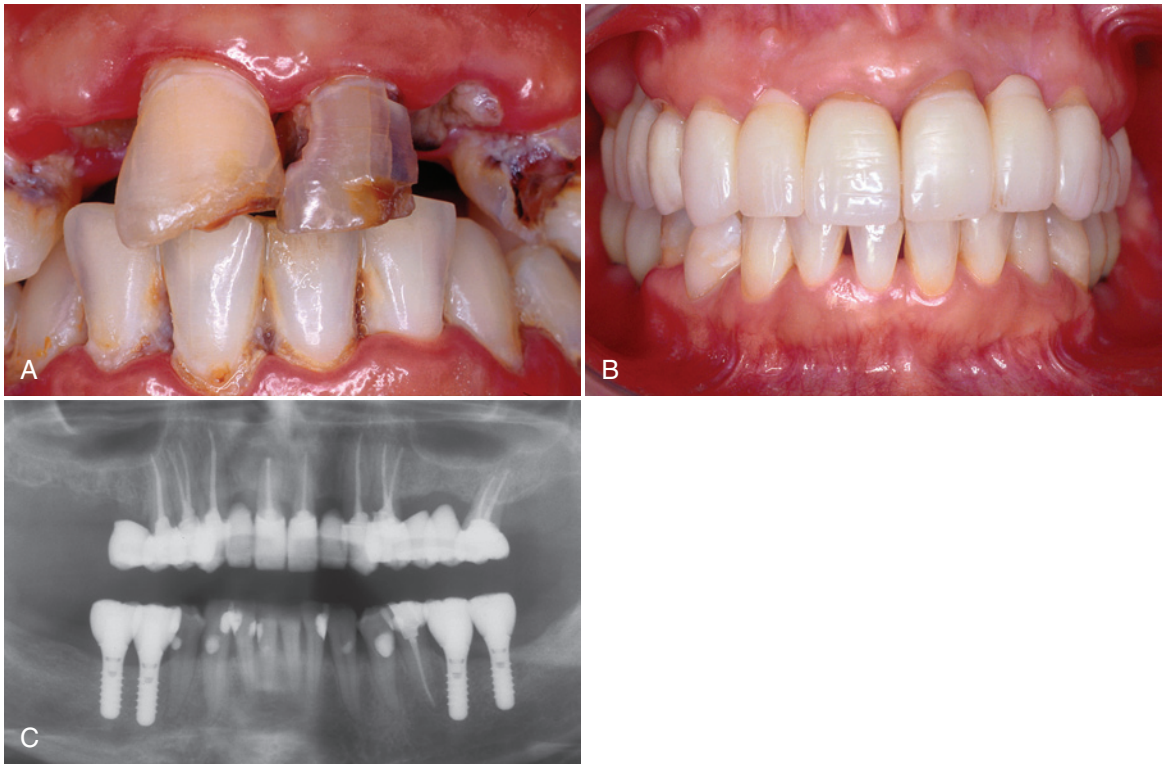

FIG. 6-3 Root canal therapy as part of a comprehensive treatment plan. The patient, who was recovering from intravenous drug addiction, requested restorative dental treatment. Because of extensive decay, several teeth had to be extracted, and nine teeth were treated endodontically. Root canal treatment was aided by nickel-titanium rotary instruments, and obturation was done with lateral compaction of gutta-percha and AH26 as the sealer. Microsurgical retrograde therapy was performed on tooth #8, and the distobuccal root of #14 had to be resected. Metal-free adhesively luted restorations were placed, and missing mandibular teeth were replaced by implants. **A,** Pretreatment intraoral status, showing oral neglect. **B,** Posttreatment intraoral status at 4-year follow-up, showing fully functional, metal-free, tooth-colored reconstructions. **C,** Panoramic radiograph at 4-year recall shows sound periradicular tissues in relation to endodontically treated teeth. (Restorations done by Dr. Till N. Göhring.)

thorough cleaning of the most apical part of any preparation remains difficult,[561] especially in narrow and curved canals.[16,211,404]

Technical Objective

Although a continuous taper that encompasses the original shape and curvature of a given root canal is an accepted goal, final apical preparation size remains a much-disputed entity in root canal therapy, as does final taper of the preparation.[47] Arguments were made for better disinfection with larger sizes (i.e., #50 or greater)[89,415] in combination with smaller tapers of .02 to .05. Others found no difference whether the selected final size was small or large.[105,570] A self-adjusting file was introduced,[327] which does not prepare canals to a specific normed size; its debridement effect is thought to result from a greater radicular wall contact, notably in buccolingually wide canals.[361]

Clinical Issues

A wide spectrum of possible strategies exists for attaining the goal of removing the canal contents and eliminating infection. Lussi and colleagues introduced an approach to removing canal contents and accomplishing disinfection that did not involve the use of a file: the noninstrumentation technique.[303,304] This system consisted of a pump, a hose, and a special valve that was cemented into the access cavity (Fig. 6-8, *A*) to provide oscillation of irrigation solutions (1% to 3% sodium hypochlorite) at a reduced pressure. Although several in vitro studies suggested that canals can be cleaned and subsequently filled using this noninvasive system (see Fig. 6-8, *B* and *C*),[304,305] preliminary clinical results have not been as convincing (see Fig. 6-8, *D*).[25]

At the opposite end of the spectrum is a treatment technique that essentially removes all intraradicular infection through extraction of the tooth in question (see Fig. 6-8, *E* and *F*). Almost invariably, periradicular lesions heal after extraction of the involved tooth.

Clinical endodontic therapy takes place somewhere along this spectrum of treatment strategies. This is reflected in some of the controversies that surround the cleaning and shaping process, such as how large the apical preparation should be and what are the correct diameter, length, and taper.[250] Once the decision has been made to initiate endodontic treatment, the clinician must integrate his or her knowledge of dental anatomy, immunology, and bioengineering science with clinical information.

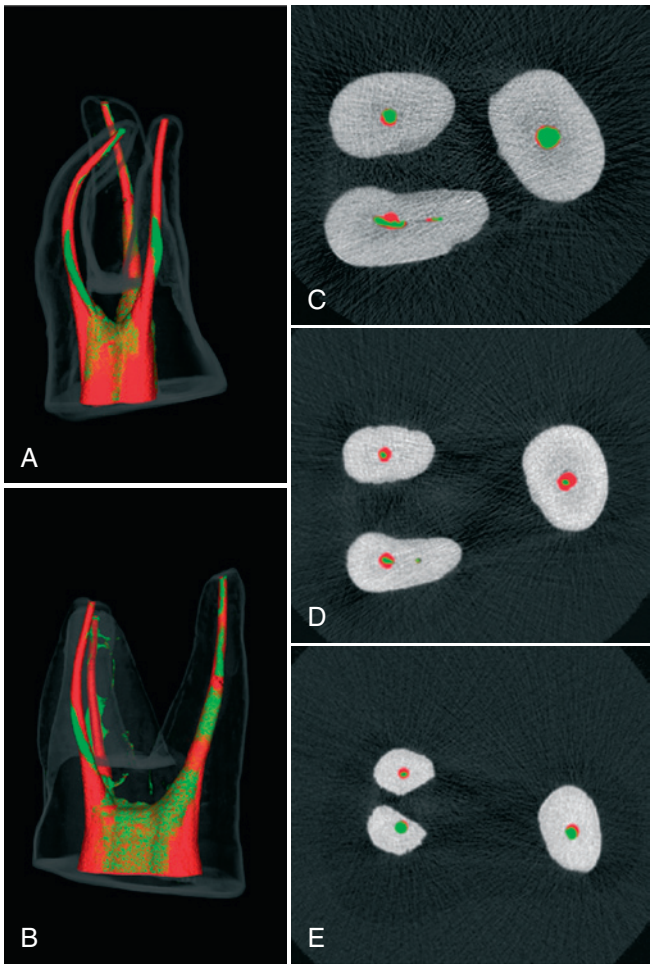

FIG. 6-4 Example of a desired shape, with the original root canal fully incorporated into the prepared outline. **A-B,** Microcomputed tomography reconstructions in clinical and mesiodistal views of a maxillary molar prepared with a NiTi rotary system. The *green area* indicates the pretreatment shape, and the *red area* indicates the posttreatment shape. Areas of *mixed red and green* indicate no change (i.e., no removal of radicular dentin). **C-E,** Cross sections of the coronal, middle, and apical thirds; the pretreatment cross sections *(green)* are encircled by the posttreatment outlines *(red)* in most areas. (*A-B,* From Hübscher W, Barbakow F, Peters OA: Root-canal preparation with FlexMaster: canal shapes analysed by micro-computed tomography, *Int Endod J* 36:740, 2003.)

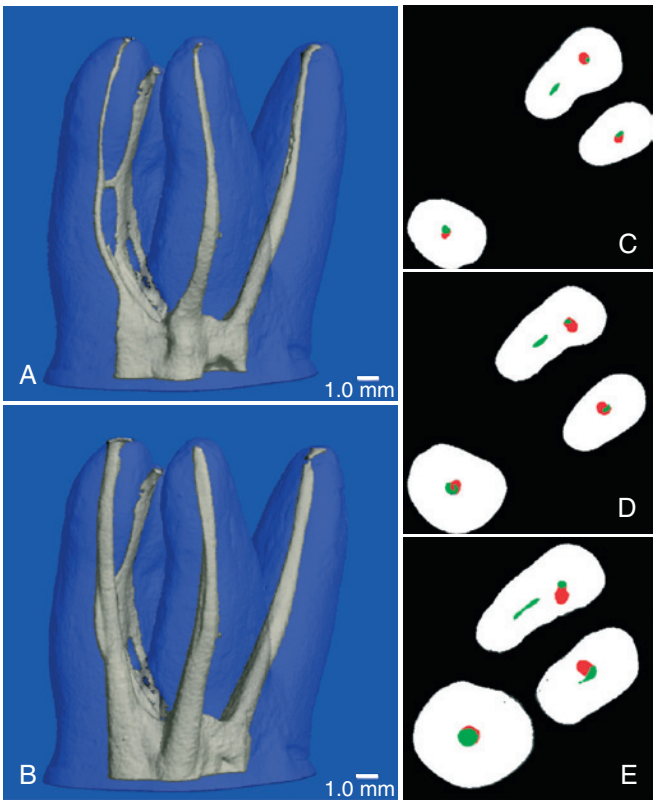

FIG. 6-5 Example of excessive thinning of dental structure during root canal treatment. **A-B,** Microcomputed tomography reconstructions show pretreatment and posttreatment root canal geometry of a maxillary molar. **C-E,** Cross sections of the coronal, middle, and apical thirds with pretreatment canal cross sections. Note the transportation and thinning, in particular, in the main mesiobuccal canal.

Endodontic therapy has been compared to a chain of events, wherein the chain is only as strong as each individual link. For the purposes of this chapter, shaping and cleaning of the root canal system is considered a decisive link, because shaping determines the efficacy of subsequent procedures. It includes mechanical debridement, the creation of space for the delivery of medicaments, and optimized canal geometries for adequate obturation.[373] These tasks are attempted within a complex anatomic framework, as recognized in the early 20th century by Walter Hess[218] (Fig. 6-9; see also Chapter 5 for a complete description of root canal anatomy).

A clinician must choose appropriate strategies, instruments, and devices to overcome challenges and accomplish precise preparation in shape, length, and width. This allows endodontic therapy to address various forms of the disease processes described previously (Fig. 6-10). Recall radiographs taken at appropriate intervals predictably demonstrate longevity and favorable outcomes (see Figs. 6-1, 6-2, and 6-11) if a systematic approach to root canal shaping is adhered to (see Box 6-1).

Endodontic files traditionally have been manufactured according to empiric designs, and most instruments still are conceived based on individual clinicians' philosophies rather than developed through an evidence-based approach. Similar to the development of composite resins in restorative dentistry, the development of new files is a fast and market-driven process. With new instruments becoming available, the clinician may find it difficult to pick the file and technique most suitable for an individual case. Clinicians must always bear in mind that all file systems have benefits and weaknesses. Ultimately, clinical experience, handling properties, usage safety, and case outcomes, rather than marketing or the inventor's name, should decide the fate of a particular design. The following section describes typical instruments used in root canal shaping.

ENDODONTIC INSTRUMENTS

General Characteristics

Design Elements

Root canal preparation instruments such as K-files and nickel-titanium rotary instruments follow certain design principles

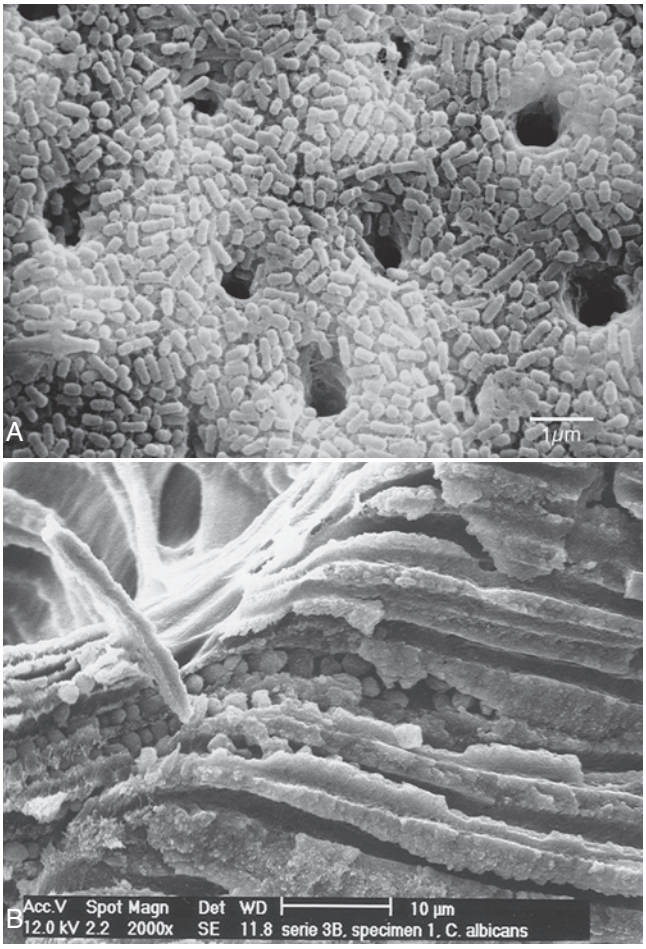

FIG. 6-6 Presence of microorganisms inside the main root canal and dentinal tubules. **A,** Scanning electron micrograph of a root canal surface shows a confluent layer of rod-shaped microbes (×3000). **B,** Scanning electron micrograph of a fractured root with a thick smear layer and fungi in the main root canal and dentinal tubules. that relate to drills and reamers used for work in wood and metal, respectively, whereas other instruments such as broaches and Hedström files do not find a direct technologic correlate. Design elements such as the tip, flutes, and cross sections are considered relevant for files and reamers used in rotary motion. These pertinent aspects are briefly described next; for a more detailed review, the reader is referred to the literature.[181,420,427,483]

Tip Design

In root canal preparation, an instrument tip has two main functions: to guide the file through the canal and to aid the file in penetrating deeper into the canal. A clinician unfamiliar with the tip design, in particular of a rotary instrument, may do either of the following: (1) transport the canal (if the tip is capable of enlarging and is used too long in one position in a curved canal) or (2) encounter excessive torsion and break the file (if a noncutting tip is forced into a canal with a smaller diameter than the tip).

The angle and radius of its leading edge and the proximity of the flute to its actual tip end determines the cutting ability of a file tip. Cutting ability and file rigidity determine the propensity to transport the canal. The clinician must keep in mind that as long as a flexible file with a noncutting tip is engaged, 360-degree canal transportation is unlikely to occur.[410]

Studies have indeed shown that tip design affects file control, efficiency, and outcome in the shaping of root canal systems.[330,331] The tip of the original K-file resembled a pyramid; instrument tips have been described as *cutting, noncutting,* and *partially cutting,* although no clear distinction exists among the three types (Fig. 6-12).

Noncutting tips, also called *Batt tips,* are created by grinding and smoothing the apical end of the instrument (see Fig. 6-12, *A*). A tip modification was introduced with the Flex-R file, which was manufactured fully by grinding so that the transitional angles were smoothed laterally between the tip and the instrument's working parts.[411] Similar techniques are required to manufacture NiTi K-files.[512]

For NiTi rotary files, typically rounded noncuttings tips are used (see Fig. 6-12, *B*), which effectively prevent preparation errors that were found with earlier so-called safe cutting tips.[236] One exception to this rule is the type of rotary

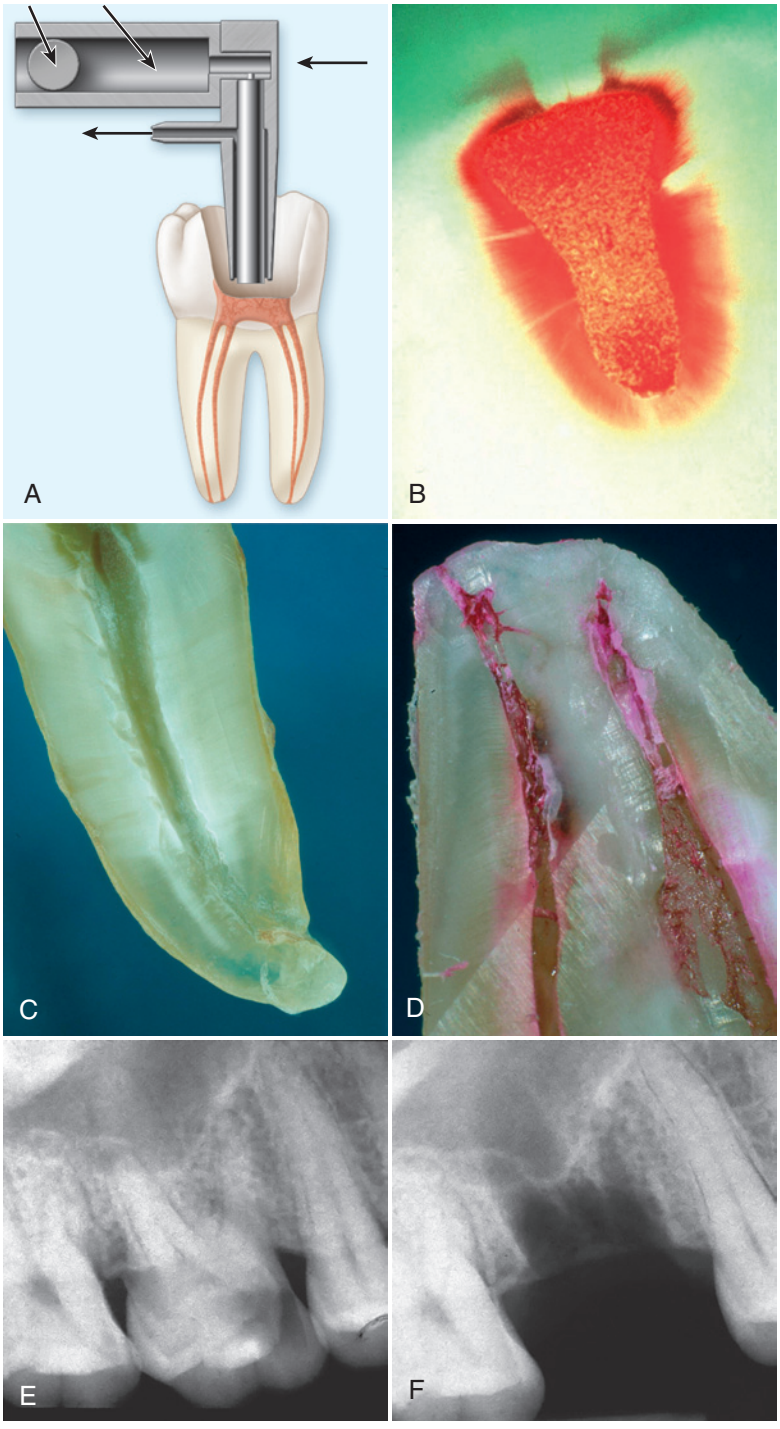

FIG. 6-8 Spectrum of strategies for accomplishing the primary aim of root canal treatment: elimination of infection. **A,** Schematic diagram of minimally invasive therapy using the noninstrumentation technique (NIT). **B,** Example of teeth cleaned in vitro using NIT. specifically designed as a retreatment instrument; cutting tips in that case facilitate removal of the existing root canal filling material and are sufficiently safe.

Longitudinal and Cross-Sectional Design

The *flute* of the file is the groove in the working surface used to collect soft tissue and dentin chips from the wall of the canal. The effectiveness of a flute depends on its depth, width, configuration, and surface finish. The surface with the greatest diameter that follows the groove (where the flute and land intersect) as it rotates forms the *leading (cutting) edge,* or the *blade* of the file. The cutting edge forms and deflects chips along the wall of the canal and severs or snags soft tissue. Its effectiveness depends on its angle of incidence and sharpness.

Some instruments have a feature between trailing and cutting edge that forms a larger contact area with the radicular wall; this surface is called a radial land (Fig. 6-13). Such a land is thought to reduce the tendency of the file to thread into the canal. It also supports the cutting edge and limits the depth of cut; its position relative to the opposing cutting edge and its width determine its effectiveness. On the other hand, landed files are typically less cutting efficient compared to triangular cross sections.[380]

To reduce frictional resistance, some of the surface area of the land that rotates against the canal wall may be reduced to form the *relief*. The angle the cutting edge forms with the long axis of the file is called the *helical angle* (see Fig. 6-13).

If a file is sectioned perpendicular to its long axis, the *rake angle* is the angle formed by the leading edge and the radius of the file through the point of contact with the radicular wall. If the angle formed by the leading edge and the surface to be cut is 90 degrees, the rake angle is said to be neutral. The rake angle may be *negative* or *scraping* (Fig. 6-14, *A*) or *positive* or *cutting* (Fig. 6-14, *C*).

The *cutting angle* is considered a better indication of a file's cutting ability and is determined by measuring the angle formed by the leading edge of the file and a tangent to the radicular wall in the point of contact. The clearance angle corresponds to the cutting angle at the trailing edge of the file and, in case of reciprocating action, becomes the cutting angle. The sum of cutting angle and rake angle is 90 degrees.

The *pitch* of the file is the distance between a point on the leading edge and the corresponding point on the adjacent leading edge (the distance from one "spiral twist" to the next) (see Fig. 6-13). The smaller the pitch or the shorter the distance between corresponding points, the more spirals the file has and the greater the helix angle. Although K-files have a constant pitch typically in the range of 1 mm, many NiTi rotaries have a variable pitch, one that changes along the working surface. When variable pitch is used, usually tighter spirals are located close to the tip of the file and more space between the flutes is located toward the coronal part of the file. A longitudinal section through an instrument reveals the *core* (see Fig. 6-13). The outer diameter of a tapered instrument increases from the file tip toward the handle; depending

on core dimensions, the flute may become proportionately deeper, resulting in a *core taper* that may be different from the *external taper*.

The cutting angles, helix angles, and external and core tapers may vary along the working surface of the file, and the ratios of these quantities can vary among instruments of the same series. A change in any of these features may influence the file's effectiveness or its propensity for breakage as it progresses into the canal space.

Taper

The taper usually is expressed as the amount the file diameter increases each millimeter along its working surface from the tip toward the file handle. For example, a size #25 file with a .02 taper would have a 0.27-mm diameter 1 mm from the tip, a 0.29-mm diameter 2 mm from the tip, a 0.31 mm diameter 3 mm from the tip, and so forth. Instruments can have constant or variable taper: Some manufacturers express the taper in terms of percentage (e.g., a .02 instrument has been said to have a 2% taper; Fig. 6-15). Current instrument developments include variations in helical angle, pitch, and taper along the cutting portion, which along with variations in alloy and rotational speed (rpm) all affect cutting behavior.[380] The ability to determine cross-sectional diameter at a given point on a file can help the clinician determine the file size in the point of curvature and the relative stress being placed on the instrument. Instruments with greater tapers are designed so that the tip of the instrument functions as a guide and the middle and coronal part of the instrument's working part is the one engaging the canals walls.

ISO Norms

Standardized specifications have been established to improve endodontic instrument quality.[238] For example, the International Standards Organization (ISO) has worked with the Fédération Dentaire Internationale (FDI) to define specifications. These standards are designated with an ISO number. The American Dental Association (ADA) also has been involved in this effort, as has the American National Standards Institute (ANSI); these standards are designated with an ANSI number. However, new instrument designs have resulted in a need for reconsideration of the standards.

Two ISO standards pertain to endodontic instruments. ISO No. 3630-1 deals with K-type files as does ANSI No. 28), Hedström files (ANSI No. 58), and barbed broaches and rasps (ANSI No. 63). ISO No. 3630-3 deals with condensers,

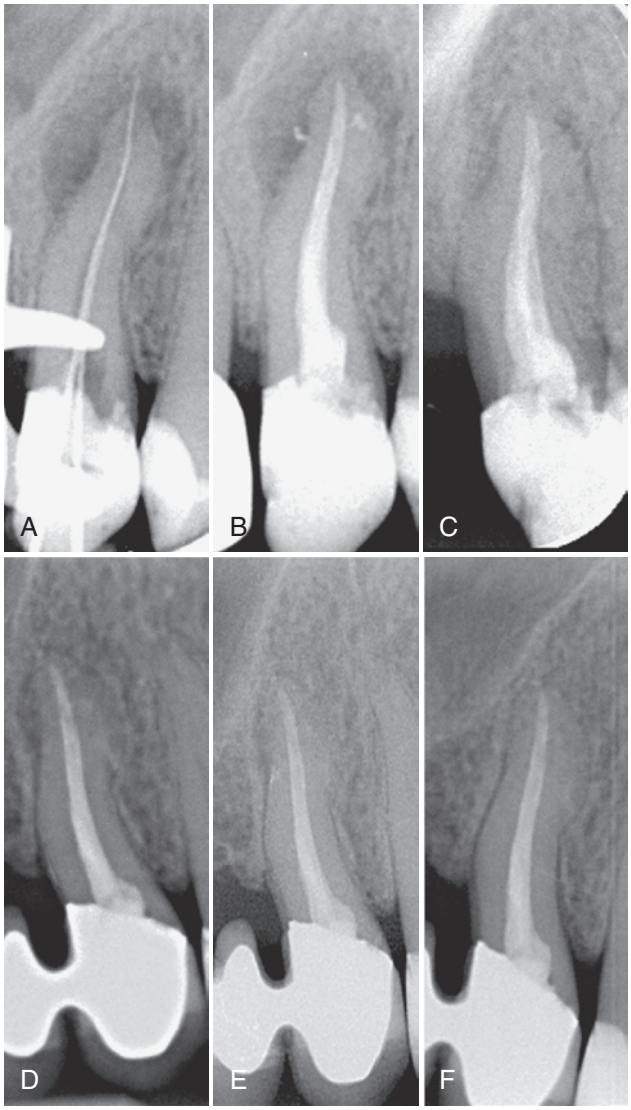

FIG. 6-11 Relationship of radicular anatomy and endodontic disease as shown by filled accessory canals. **A,** Working length radiograph of tooth #13 shows lesions mesially and distally but not apically. **B,** Posttreatment radiograph shows the accessory anatomy. **C,** Six-month recall radiograph before placement of the restoration. **D,** Two-year recall radiograph after resection of the mesiobuccal root of tooth #14 and placement of a fixed partial denture. Excess sealer appears to have been resorbed, forming a distal residual lesion. **E,** Four-year recall radiograph shows almost complete bone fill. **F,** Seven-year recall radiograph; tooth #14 is radiologically sound and clinically within normal limits.

pluggers, and spreaders (ANSI No. 71); however, the term *ISO-normed instruments* is often used as a synonym for K-files (see Fig. 6-15).

One important feature of ISO-normed hand instruments is a defined increase in tip diameter of 0.05 or 0.1 mm, depending on the instrument size (Fig. 6-16). ISO-normed K- and Hedström files (Fig. 6-17) are available in different lengths (21, 25, and 31 mm), but all have a 16-mm-long section of cutting flutes (see Figs. 6-12 and 6-15). The cross-sectional diameter at the first rake angle of any file is labeled D0. The point 1 mm coronal to D0 is D1, the point 2 mm coronal to D0 is D2, and so on up to D16. The D16 point is the largest diameter of an ISO-normed instrument. Each file derives its numeric name from the diameter at D0 and is assigned a specific color code (see Fig. 6-15).

Another aspect of ISO files is the standard taper of 0.32 mm over 16 mm of cutting blades, or 0.02 mm increase in diameter per millimeter of flute length (.02 taper). Thus, a size #10 instrument has a diameter of 0.1 mm at D0 and a corresponding diameter of 0.42 mm at D16 [0.1 mm + (16 * 0.02 mm)]. For a size #50 instrument, the diameters are 0.5 mm at D0 and 0.82 mm at D16.

The ISO-normed design is a simplification that has specific disadvantages, and it may explain the clinical observation that enlarging a root canal from size #10 to #15 is more difficult than the step from size #55 to #60. The introduction of K-type files with tip sizes between the ISO-stipulated diameters seemed to solve the problem. However, the use of such files is not universally recommended, perhaps because the approved machining tolerance of ±0.02 mm could negate any intended advantages. Moreover, although ±0.02 mm tolerance is stipulated by the ISO norm, most manufacturers do not adhere to it.[253,449,499,581]

Another suggested modification relates to tips with a constant 29% percentage of diameter increments. This sizing pattern creates smaller instruments that carry less of a workload. However, the intended advantage is offset by larger diameters, because the 29% increase between successive files is

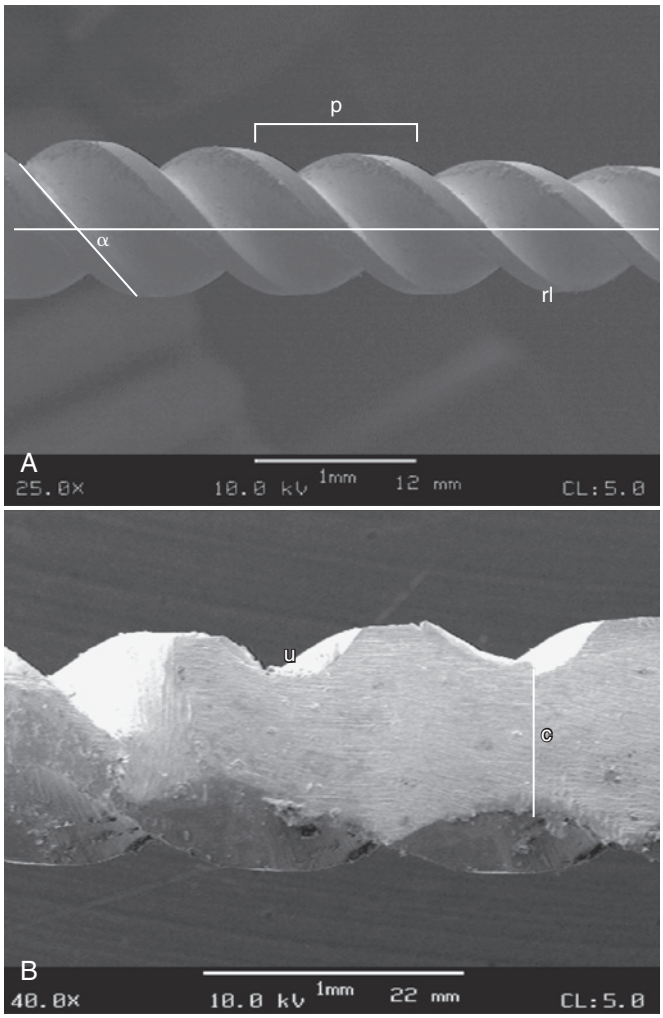

FIG. 6-13 Design characteristics of nickel-titanium rotary instruments. **A**, Lateral view showing the details of the helical angle, pitch *(p)*, and the presence of guiding areas, or radial lands *(rl)* (scanning electron micrograph [SEM], ×25). **B**, Ground working part of the instrument in **A**, showing U-shaped excavations and the dimension of the instrument core *(c)*.

actually greater than the percentage change found in the ISO file series.

Further changes to the numbering system for files with different sizes have been implemented by several manufacturers. One system has introduced "half" sizes in the range of #15 through #60, resulting in instruments in sizes #15, #17.5, #20, #22.5, and so on.

Alloys

There are currently two principally different types of alloys used for endodontic instruments, stainless steel and nickel-titanium. Most manually operated endodontic instruments are fabricated from stainless steel and have considerable resistance to fracture. A clinician who is careful in applying force and adheres to a strict program of discarding instruments after use should have few instrument fractures. Stainless steel files are comparably inexpensive so that adequate cleaning and sterilization for reuse of files in sizes up to #60 may not be cost effective. If this is the case, files in the range up to #60 may be considered disposable instruments.[490]

Several burs and instruments designed for slow-speed handpiece operation such as Gates Glidden drills, Peeso burs, and pilot drills for intraradicular posts are also manufactured from stainless steel. Instruments designed for rotary root canal instrumentation, however, are typically made of nickel-titanium.[454] This alloy offers unique properties, specifically flexibility and corrosion resistance.

Physical and Chemical Properties of Steel and Nickel Titanium Alloys

Basic engineering terms relate to metals and their behavior when used to manufacture endodontic instruments. Stress-strain diagrams describe the response of metal wires under loading depending on their crystal configuration (Fig. 6-18).

During the development of the equiatomic *nitinol* [this acronym is derived from *ni*ckel-*ti*tanium investigated at the *N*aval *O*rdinance *L*aboratory] alloy (55% [by weight] nickel and 45% [by weight] titanium), several effects were noted that relate to its specific crystal arrangement with two stable main phases, *austenite* and *martensite* (Fig. 6-19): a shape memory effect as temperature- and strain-dependent pseudoelasticity, all attributable to specific thermodynamic properties of the new alloy.[77,133,356,517]

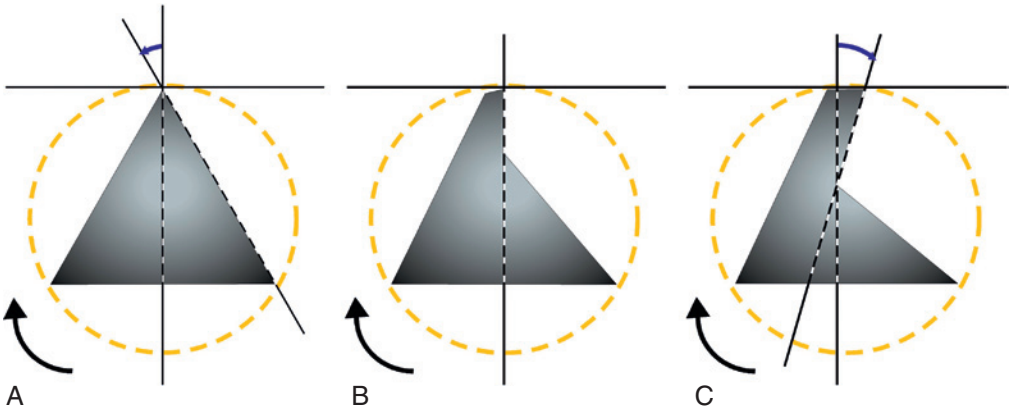

FIG. 6-14 The rake angle of an endodontic file can be negative (**A**), neutral (**B**) or positive (**C**).

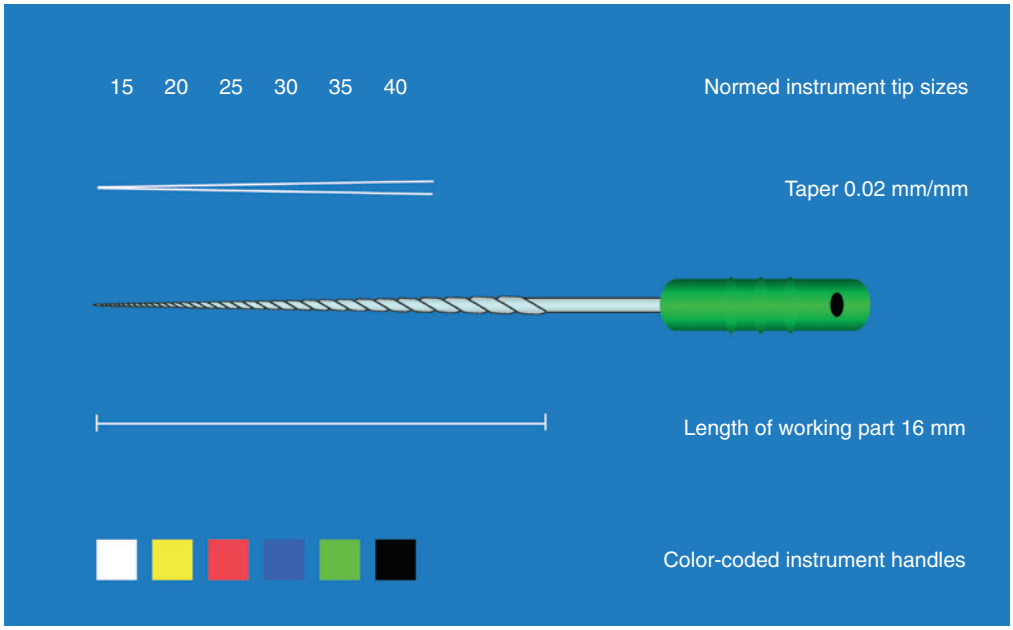

FIG. 6-15 Schematic drawing of an ISO-normed hand instrument size #35. Instrument tip sizing, taper, and handle colors are regulated by the ISO/ANSI/ADA norm.

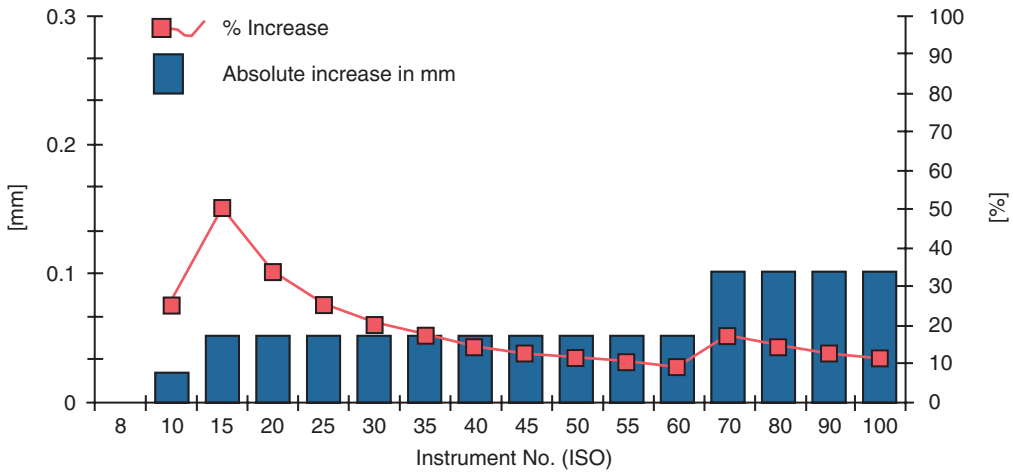

FIG. 6-16 Increase in tip diameter in absolute figures and in relation to the smaller file size. Note the particularly large increase from size #10 to size #15.

Walia and colleagues thought that the pseudoelastic properties of 55-nitinol might prove advantageous in endodontics and initially tested hand instruments.[542] They found that size #15 NiTi instruments were two to three times more flexible than stainless steel instruments; moreover, the instruments showed superior resistance to angular deflection.[542]

Furthermore, hardly any plastic deformation of cutting flutes was recorded when an instrument was bent up to 90 degrees, and forces required to bend endodontic files to 45 degrees were reduced by 50% with NiTi.[454,542] Serene and colleagues speculated that heat, probably during sterilization cycles, could even restore the molecular structure of used NiTi files, resulting in an increased resistance to fracture.[454] Such a behavior is claimed to occur for current martensitic instruments.[377]

These unusual properties are the result of a molecular crystalline phase transformation in specific crystal structures of the austenitic and martensitic phases of the alloy.[517] External stresses transform the austenitic crystalline form of NiTi into a martensitic crystalline structure that can accommodate greater stress without increasing the strain. As a result, a NiTi file has transformational elasticity, also known as *pseudoelasticity,* or the ability to return to its original shape after being deformed (see Fig. 6-19, *B*). This property dictates that typically NiTi instruments are manufactured by milling rather than twisted; twisting incorporates plastic deformation and is used, for example, to produce stainless steel K-files.

Similar to the application of deforming forces, heat can also result in phase transformation (see Fig. 6-19, *A*) from austenite to martensite and vice versa.[209,329] Moreover, thermal conditions during the production of the raw wire can be used to modify its properties, most important of which is its flexibility.[192,461] For austenitic endodontic instruments, a recoverable

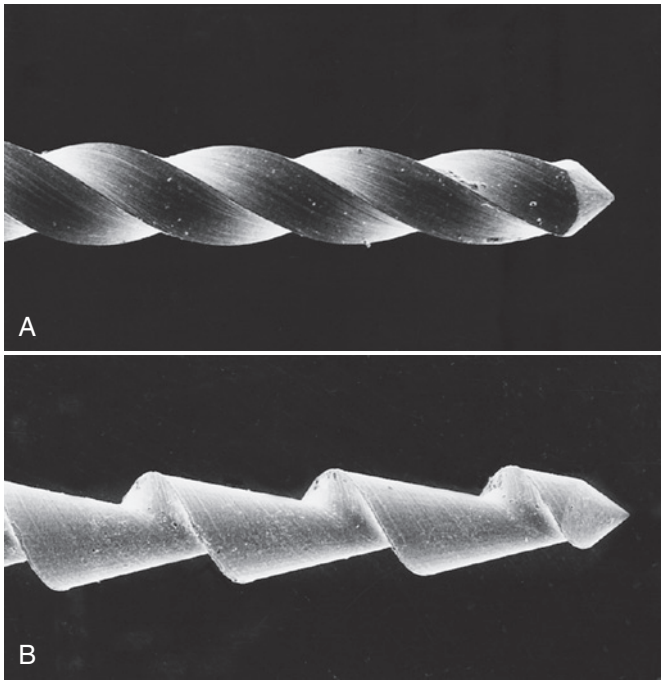

FIG. 6-17 Scanning electron micrographs of endodontic hand files fabricated by twisting (K-file size #40, **A**) and grinding (Hedström file #50, **B**). (Both images courtesy Dentsply Maillefer, Ballaigues, Switzerland).

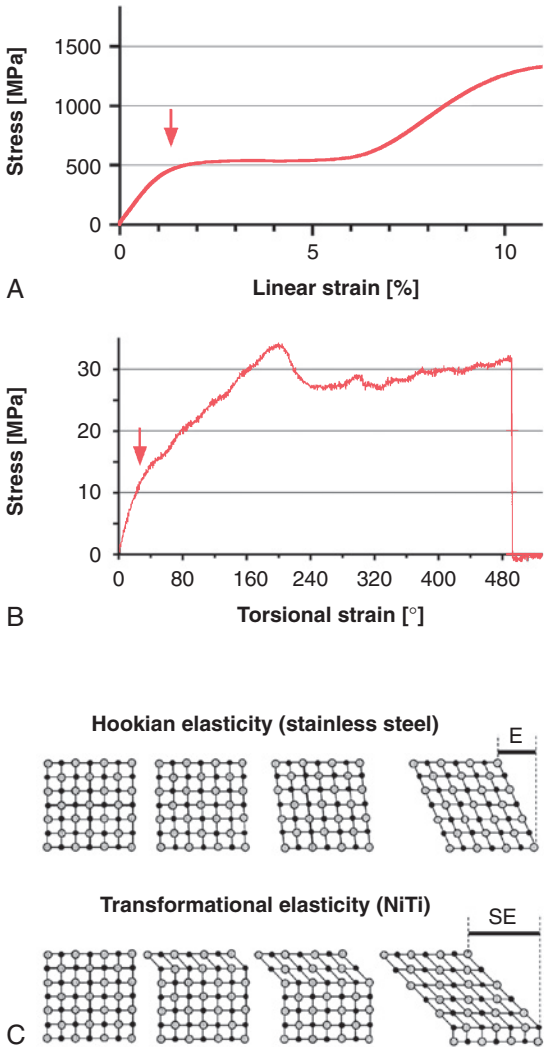

FIG. 6-18 Stress-strain behavior of nickel-titanium alloy. **A,** Schematic diagram of linear extension of a NiTi wire. **B,** Torque to failure test of a size #60, #.04 taper ProFile NiTi instrument. Note the biphasic deformation, indicated by arrows in **A-B. C,** Comparison of stainless steel and nickel-titanium crystal lattices under load. Hookian elasticity accounts for the elastic behavior *(E)* of steel, whereas transformation from martensite to austenite and back occurs during the pseudoelastic *(PE)* behavior of NiTi alloy. (*C,* Modified from Thompson SA: An overview of nickel-titanium alloys used in dentistry, *Int Endod J* 33:297, 2000.)

elastic response of up to 7% is expected (Fig. 6-20). However, more martensitic instruments will have less of an elastic range and are more likely to plastically deform during use.[377,461]

Experiments designed to test fracture resistance demonstrate physical properties of endodontic instruments; following the pertinent ISO norm, 3630-1 graphs such as those shown in Fig. 6-20 are generated and compared among different designs.

Attempts to improve the NiTi alloy continue, and reports indicate that new NiTi alloys may be five times more flexible than currently used alloys.[225,461] NiTi instruments may have imperfections such as milling marks, metal flash, or rollover.[135,454,524,542] Some researchers have speculated that fractures in NiTi instruments originate at such surface imperfections.[11]

Surface irregularities may provide reservoirs of corrosive substances, most notably sodium hypochlorite (NaOCl). Chloride corrosion may lead to micropitting[428] and possibly subsequent fracture in NiTi instruments.[202] Immersion in various disinfecting solutions for extended periods (e.g., overnight soaking) produced corrosion of NiTi instruments and subsequent decreased torsional resistance.[350,486] For ProTaper,[52] RaCe, and ProFile385 instruments, 2-hour immersion damaged the integrity of the alloy. Other authors did not find a corrosion-related effect on K3-files[36] or ProFile instruments.[120]

Regular reprocessing procedures do not seem to significantly affect NiTi rotary instruments.[293,330,503] In one study, only limited material loss occurred when NiTi LightSpeed instruments were immersed in 1% and 5% NaOCl for 30 to 60 minutes.[84] Corrosion of NiTi instruments used in the clinical setting, therefore, might not significantly contribute to fracture except when the instruments are immersed in warmed NaOCl for longer than 60 minutes. In the majority of studies, sterilization procedures do not appear to negatively impact torsional strength[221,464] or fatigue resistance[79,220] of most NiTi instruments: austenitic[538] and martensitic[92] alloy behaved grossly similarly in this aspect.

There is an ongoing discussion over the impact of other aspects of clinical usage on the mechanical properties of NiTi rotaries. Most likely, clinical usage leads to some changes in the alloy, potentially through work hardening.[10,254]

Another strategy to improve surface characteristics is electropolishing; also surface coatings and ion implantation have been tried. Electropolishing is a process that removes surface irregularities such as flash and bur marks. It is thought to improve material properties, specifically fatigue and corrosion resistance; however, the evidence for both these claims is

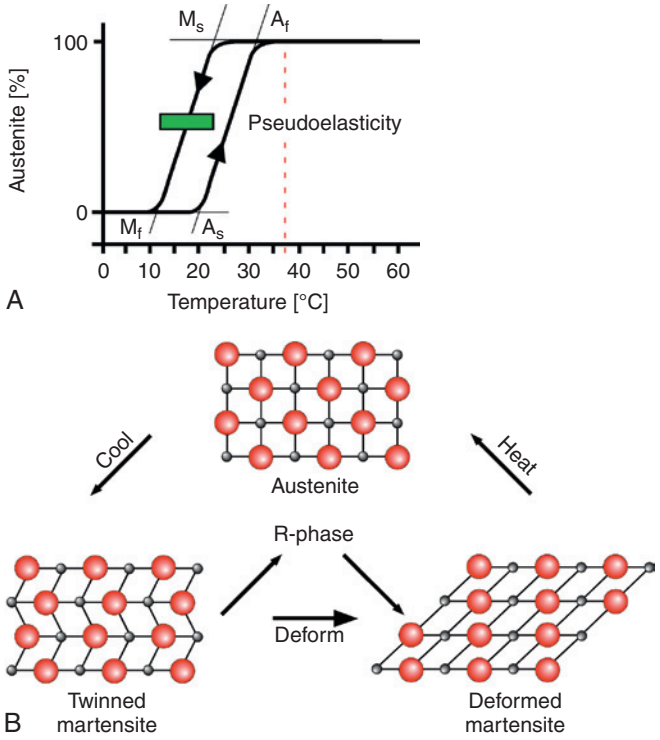

FIG. 6-19 Pseudoelastic behavior of Nickel titanium is based on the two main crystal configurations, martensite and austenite, which depend on temperature (**A**) and applied strain (**B**). Formation of the respective configuration initiates at the start temperatures, M_s and A_s.

mixed. One study found an extension of fatigue life for electropolished instruments,[20] whereas others found no improvement of fatigue resistance of electropolished instruments.[78,100,217] Boessler and colleagues suggested a change in cutting behavior with an increase of torsional load after electropolishing.[59]

Corrosion resistance of electropolished NiTi rotaries is also controversial. One study found superior corrosion resistance for electropolished RaCe instruments,[63] whereas another study demonstrated similar corrosion susceptibility for RaCe and nonelectropolished ProFile instruments.[385] Attempts have been made to improve surface quality by coating it with titanium nitride.[398,438] The latter process also seems to have a beneficial effect on cutting efficiency.[438]

Perhaps more relevant than surface treatment are modification of the base alloy that significantly alter material properties within the atomic ratio.[369] The first commercialized alloy was M-Wire (SportsWire, Langley, OK), which was shown to have higher fatigue resistance with similar torsional strength.[249] More recently, instrument are produced through production process that include annealing and cooling steps to create instruments that, after cold working during the production process, are more martensitic during dental treatment, as defined by their M_s temperature (see Fig. 6-19, *A*). Under clinical conditions these alloys are more flexible[510] and present higher fatigue resistance.[377] Examples are the newly introduced gold and blue alloys types (Dentsply Tulsa Dental Specialties, Tulsa, OK) or so-called controlled memory alloy used in Hyflex instruments (Coltene Endo, Cuyahoga Falls, OH).

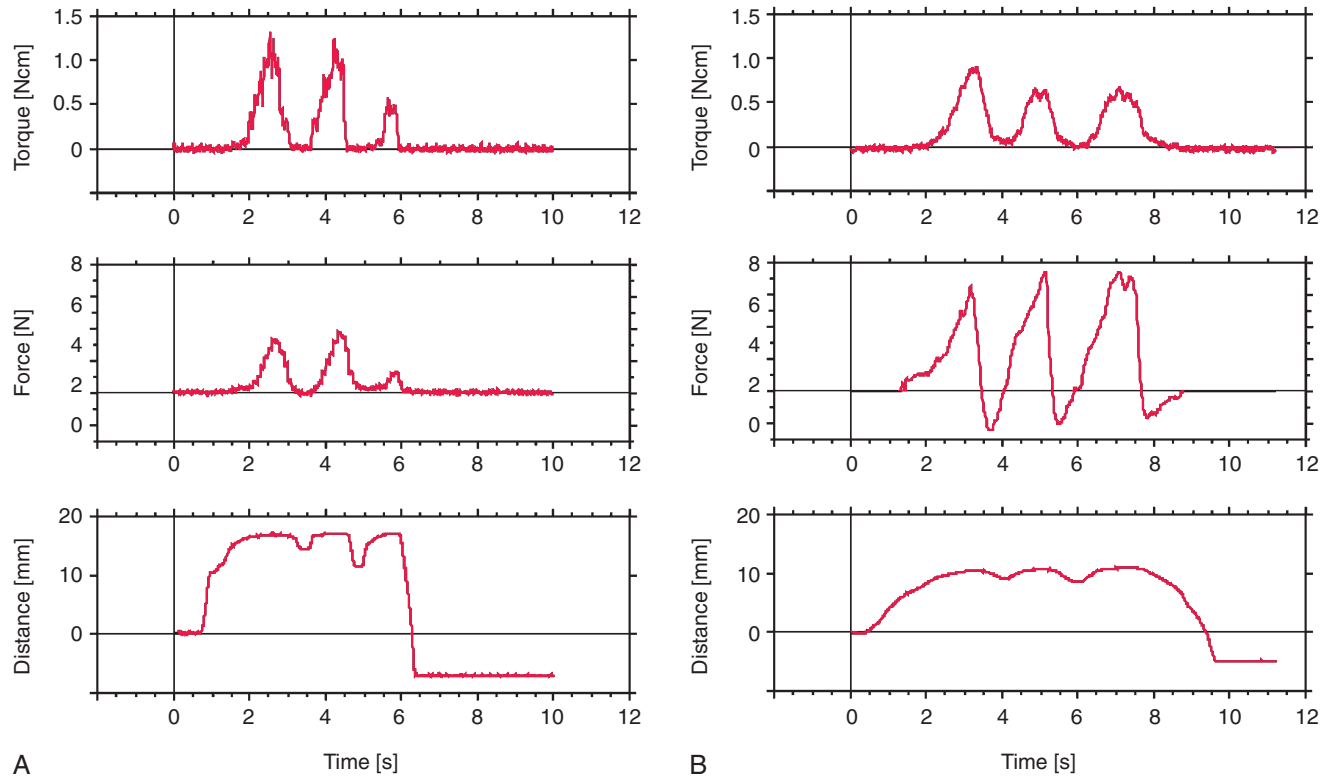

FIG. 6-20 Physical factors (torque, axial force, and insertion depth) that affect root canal instrumentation documented with a torque-testing platform. **A**, ProFile size #45, #.04 taper used in a mildly curved canal of a single-rooted tooth, step-back after apical preparation to size #40. **B**, FlexMaster size #35, #.06 taper used in a curved distobuccal canal of a maxillary first molar, crown-down during the initial phase of canal preparation.

Manually Operated Instruments

Endodontic trays contain many items familiar from general dentistry but certain hand instruments are designed specifically for endodontic procedures. This includes instruments employed for procedures inside the pulp space, for example hand and engine-driven instruments for root canal preparation, and energized instruments for root canal shaping. Special instruments and devices for root canal obturation are selected for filling prepared canal spaces.

K-Type Instruments

Manually operated instruments are generically called *files*. Defined by function, files are instruments that enlarge canals with apico-coronal insertion and withdrawal motions.

Historically, root canal instruments were manufactured from carbon steel. Subsequently, the use of stainless steel greatly improved the quality of instruments. More recently, K-type files manufactured from NiTi were introduced (NiTi-Flex, Dentsply Maillefer, Ballaigues, Switzerland).

Files were first mass produced by the Kerr Manufacturing Co. of Romulus, Michigan, in the early 1900s, hence the name "K-type" file (or K-file) and K-type reamer (K-reamer). K-files and K-reamers were manufactured by the same process—that is, by twisting square or triangular metal blanks along their long axis, producing partly horizontal cutting blades (see Fig. 6-17, *A*). Three or four equilateral, flat surfaces were ground at increasing depths on the sides of a piece of wire, producing a tapered pyramidal shape. The wire then was stabilized on one end, and the distal end was rotated to form the spiral instrument. The number of sides and the number of spirals determine whether the instrument is best suited for filing or reaming. Generally, a three-sided configuration with fewer spirals (e.g., 16 per 16-mm working portion) is used for reaming (i.e., cutting and enlarging canals with rotational motions). A file has more flutes per length unit (e.g., 20) than a reamer, whereas a three- sided or triangular configuration is generally more flexible than a four-sided one.[437]

K-type instruments are useful for penetrating and enlarging root canals. Generally, a reaming motion (i.e., constant file rotation) causes less transportation than a filing motion (translational or "in and out" motion).[171,482] (*Transportation* is defined here as the excessive loss of dentin from the outer wall of a curved canal in the apical segment, as described in more detail later.)

Stainless steel K-files may be precurved by overbending. This procedure subjects the file to substantial strain and should therefore be done carefully. Permanent deformation occurs when the flutes become wound more tightly or opened more widely (Fig. 6-21). When such deformation occurs, the instrument should no longer be used; file fracture is likely to occur during clockwise motion after plastic deformation.[456]

Interestingly, although the force required for failure is the same in both directions of rotation,[271,278] failure occurs in the counterclockwise direction at half the number of rotations required for failure in the clockwise direction. Therefore, K-type instruments should be operated more carefully when pressure is applied in a counterclockwise direction.

Cross-sectional analysis of a K-file reveals why this design allows careful application of clockwise and counterclockwise rotational and translational working strokes: the cross section is symmetrical with negative rake angles, allowing dentin to be adequately cut in both clockwise and counter-clockwise direction.

Reamers are instruments that are similar to K-files in overall design, but they have fewer cutting flutes per mm of the working surface. They are more appropriate for twisting motion and are less frequently used today.[437]

H-Type Instruments

H-type instruments, also known as Hedström files (see Fig. 6-17, *B*), are milled from round, stainless steel blanks. These files are very efficient for translational strokes,[437] because of a positive rake angle and a blade with a cutting rather than a scraping angle. Rotational working movements are strongly discouraged because of the possibility of fracture. Hedström

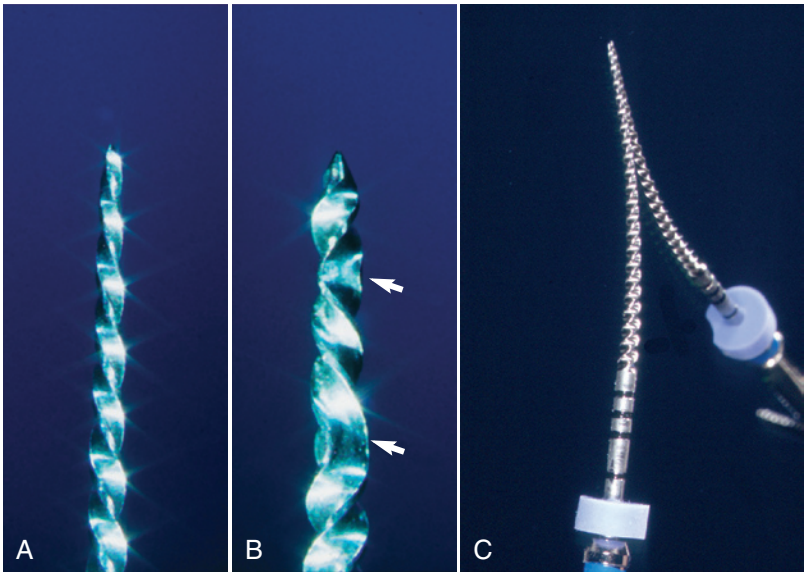

FIG. 6-21 Deformation of endodontic instruments manufactured from nickel-titanium alloy. **A** and **B**, Intact and plastically deformed ProFile instruments (*arrow* indicates areas of permanent deformation). **C**, ProFile instrument placed on a mirror to illustrate elastic behavior.

files up to size #25 can be efficiently used to relocate canal orifices and, with adequate filing strokes, to remove overhangs. Similarly, wide oval canals can be instrumented with Hedström files as well as with rotary instruments. On the other hand, overzealous filing can lead to considerable thinning of the radicular wall and strip perforations (Fig. 6-22). As with stainless steel K-files, Hedström files have been described as disposable instruments.[490]

Bending Hedström files results in points of greater stress concentration than in K-type instruments. These prestressed areas may lead to the propagation of cracks and ultimately fatigue failure.[200] Note that clinically, fatigue fractures may occur without visible signs of deformation.

Hedström files are produced by grinding a single continuous flute into a tapered blank. Computer-assisted machining technology has allowed the development of H-type instruments with complex forms. This process, called *multiaxis grinding,* allows adjustment of the rake angle, helix angle, multiple flutes, and tapers and is also used to fabricate the majority of NiTi instruments. Because the H-file generally has sharper edges than the K-file, it has a tendency to thread into the canal during rotation, particularly if the instrument's blades are nearly parallel. Awareness of threading-in forces is important to avoid instrument failure.

Effectiveness and Wear of Instruments

The ability of an endodontic hand instrument to cut and machine dentin is essential; however, no standards exist for either the cutting or the machining effectiveness of endodontic files, nor have clear requirements been established for resistance to wear. In any study of the effectiveness of an instrument, two factors must be investigated: (1) effectiveness in cutting or breaking loose dentin and (2) effectiveness in machining dentin.

Attempts have been made to evaluate the effectiveness of an instrument when used with a linear movement.[437,442] Collectively, these studies showed that instruments might differ significantly, not only when comparing brands and types but also within one brand and type. For K-files, effectiveness varies 2 to 12 times between files of the same brand. This variation for Hedström files is greater, ranging from 2.5 to more than 50 times.[498] The greater variation among Hedström files is easy to understand because the H-file is the result of more individual grinding during manufacture than the conventional K-file, which is difficult to alter much during the manufacturing process. For example, during the grinding of a Hedström file, the rake angle can be modified to neutral or even slightly positive; this is impossible to achieve with a K-file.

During canal preparation, a file's rake edge shaves off dentin that accumulates in the grooves between the rake edges. The deeper and larger this space, the longer the stroke can be before the instrument is riding on its own debris, making it ineffective.

These design variations and the rake angle of the edges determine the effectiveness of a Hedström file. Of the hybrid files, the K-Flex (SybronEndo, Orange, CA) file has properties similar to those of K-files. The Flex-R file (Integra Miltex, York, PA), which is a ground instrument with a triangular cross section similar to a K-file, more closely resembles a Hedström file in its variations in cutting behavior. It also is more effective at substrate removal than the K-files but cannot measure up to the H-files' ability to machine radicular dentin.[498]

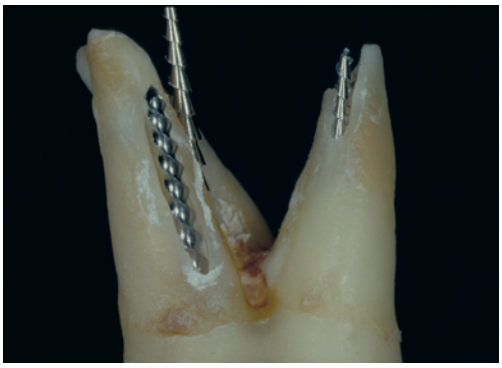

FIG. 6-22 Result of an overenthusiastic attempt at root canal treatment of a maxillary second molar with large stainless steel files. Multiple strip perforations occurred; consequently, the tooth had to be extracted.

Barbed Broaches

Barbed broaches (Fig. 6-23) are produced in a variety of sizes and color codes. They are manufactured by cutting sharp, coronally angulated barbs into metal wire blanks. Broaches are intended to remove vital pulp from root canals, and in cases of mild inflammation, they work well for severing pulp at the constriction level *in toto*. The use of broaches has declined since the advent of NiTi rotary instruments, but broaching occasionally may be useful for expediting emergency procedures (see Chapter 18) and removing materials (e.g., cotton pellets or absorbent points) from root canals.

Low-Speed Engine-Driven Instruments

Burs

Specialized burs are available for endodontic access cavities. These burs are used in both high-speed and slow-speed handpieces and are manufactured from stainless steel. Access cavity preparation and used materials are described in detail in Chapter 5).

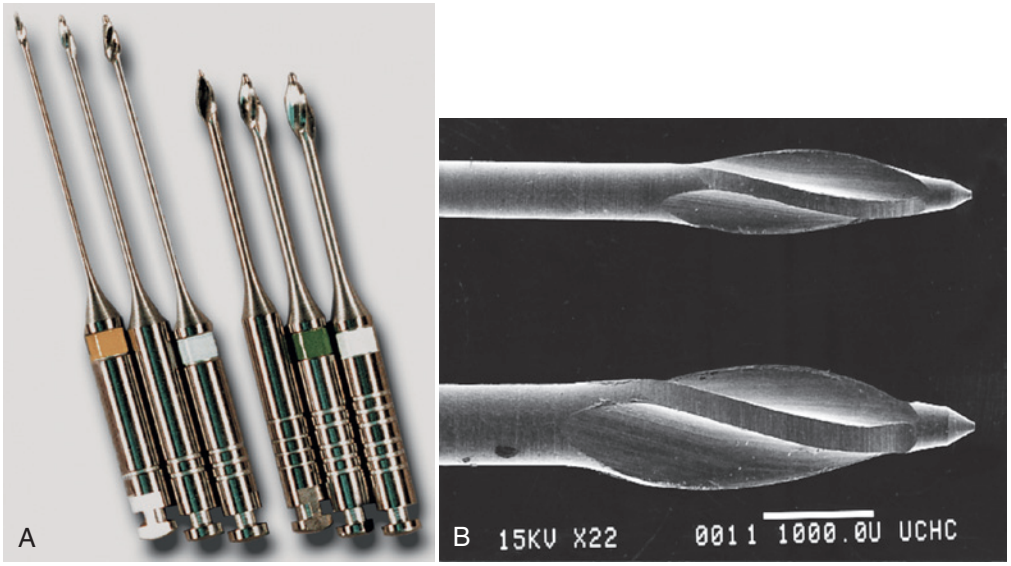

FIG. 6-24 A, Various Gates-Glidden (GG) burs made of stainless steel and scanning electron micrograph (B, working tip). (*A*, From Johnson WT: *Color atlas of endodontics,* St Louis, 2002, Saunders.)

Gates-Glidden Drills

Gates-Glidden (GG) drills (Fig. 6-24) have been used for more than 100 years without noteworthy design changes. Gates Glidden drills are typically used to enlarge coronal canal areas.[119] When misused, GG drills can dramatically reduce radicular wall thickness.[173,242]

GG drills are sized from 1 to 6 (with corresponding diameters of 0.5 to 1.5 mm); the number of rings or color-coding on the shank identifies the specific drill size. GG instruments are available in various lengths and by several manufacturers. Each instrument has a long, thin shaft with parallel walls and a short, oval cutting head with safety tips (Fig. 6-24, *B*); these drills are produced in stainless steel and NiTi varieties. Because of their design and physical properties,[68] GG drills are side-cutting instruments; they can be used to cut dentin as they are withdrawn from the canal (i.e., on the outstroke).[417] Used this way, their cutting action can deliberately be directed away from external root concavities in single-rooted and furcated teeth. GG drills should be used only in the straight portions of a canal.[522]

Two procedural sequences have been proposed: with the step-down technique, the clinician starts with a large drill and progresses to smaller ones; conversely, with the step-back technique, the clinician starts with a small drill and progresses to larger ones. With the step-down approach, the clinician must select a GG instrument with a diameter that allows introduction into the respective orifice and progression for about 1 mm. The subsequent smaller instruments progress deeper into the canal until the coronal third has been preenlarged. This technique efficiently opens root canal orifices and works best when canals exit the access cavity without severe angulations. Opened orifices simplify subsequent cleaning and shaping procedures and help establish a smooth glide path from the access cavity into the root canal system.

With the step-back approach, a small GG instrument is introduced into the canal, and dentin is removed on the outstroke. This process is repeated with the next larger GG instrument, which is again worked shorter than the preceding smaller one. In this way, the coronal third of the root canal is enlarged and dentin overhangs are removed.

When used adequately, GG instruments are inexpensive, safe, and clinically beneficial tools. Gates-Glidden drills may be used safely and to their fullest potential at 750 to 1500 rpm. High revolutions per minute (rpm), excessive pressure, an incorrect angle of insertion, and the use of GG instruments to aggressively drill into canals have resulted in mishaps such as strip perforation. The preferred mode of action for GG drills is against the outer canal wall, away from the canal curvature. Also, cyclic fatigue may cause GG instruments to fracture when used in curved canal areas, and the short cutting heads may fracture with high torsional loads. As with nickel-titanium rotary instruments, GG drills work best when used in electric gear reduction handpieces rather than with air motors.

Peeso Drills (Reamers)

Peeso drills are typically used in root canal preparation either for coronal flaring or during post preparation. These drill are at this point manufactured mostly from stainless steel by milling similar to the Gates Gliddens. Peeso drills are also used in the electric slow-speed handpiece; the rotational speed is the range of 800 to 1200 rpm; the cutting flutes are more parallel and longer compared to GG drills but shorter than the 16 mm prescribed for ISO-normed hand files. Peeso drills are classified as type P and type B-l, as defined by ISO norm 3630-2.[299] The sizing for these drills is also numbers 1 to 6, similar to GGs. Peeso drills are available with cutting and noncutting tips and should be used with caution to avoid excessive preparation and thinning of radicular dentin walls.[4]

Engine-Driven Instruments for Canal Preparation

Instrument Types

Engine-driven instruments for root canal preparation made of stainless steel have been in use for more than half a century—for the first decades, mainly in handpieces that permitted reciprocation (alternating clockwise-counterclockwise motion). The major two problems with this type of instrument were canal transportation (discussed later) and file fracture. This

Group II instruments have a triangular cross section and cutting action. Group III is made up of instruments with unusual geometry, movement, or sequence.

changed with the advent of NiTi rotaries from about the early 1990s; the much more flexible alloy allowed continuous rotation and reduced both canal preparation errors and instrument fracture compared to earlier engine driven techniques.

Currently, more than 50 types of rotary instrument systems have been described and more continue to be developed. The instruments vary greatly in terms of design, alloy used, and recommended cutting movement (Table 6-1). Various built-in features may help prevent procedural errors, increase efficiency, and improve the quality of canal shaping.

For example, a longer pilot tip may guide the instrument and help to stay centered in the canal long axis. Alternatively, a file can be given an asymmetric cross section to help maintain the central axis of the canal.

Another direction of instrument development is the prevention of instrument fractures (Fig. 6-25). There are several ways to modify an instrument to make it less likely to fracture; for example, increasing the core diameter will increase torsional resistance. Another approach is to use a torque-limiting motor (discussed later). Alternatively, a zero taper or nearly parallel and fluted working portion of the file can be provided for curved canals so that the apical portion of the canal can be enlarged without undue file stress and compression of debris. More recently a reciprocation motion was reapplied to NiTi rotary instruments to prevent threading-in and instrument fractures in general.

Yet another, more recent, direction of instrument development is to improve shaping as it relates to circumferential root canal wall contact. One example for this strategy is a file manufactured from an expandable and flexible hollow NiTi tube, the so-called Self-adjusting File (ReDent-Nova, Ra'anana, Israel, Israel) (Fig. 6-26). More recently, a substantial S-shape was superimposed onto a flexible NiTi rotary that provides a larger envelope of motion while maintaining a limited maximum flute diameter (TRUShape, Dentsply Tulsa Dental Specialties).

Marketed files vary greatly in terms of their specific design characteristics, such as tip sizing, taper, cross section, helix angle, and pitch (see Fig. 6-13). Some of the early systems have been removed from the market or relegated to minor roles; others, such as ProFile (Dentsply Tulsa Dental Specialties), are still successfully used. More recently added instruments vary in cross-sectional and longitudinal design (Fig. 6-27). However, the extent to which clinical outcome changes (if any) will depend on design characteristics is difficult to forecast.[375,381]

Most instruments described in the following section are manufactured by a grinding process, although some are produced by laser etching and yet others by plastic deformation under specific heating and cooling processes. Surface quality has been considered an important detail because cracks that arise from superficial defects may play a role in instrument fracture.[11] Moreover, surface defects such as metal flash and rollover are common in unused NiTi instruments.[135,314]

Many variables and physical properties influence the clinical performance of NiTi rotaries.[272,374,454,512] Clinical practice has generated much of what is known about NiTi instruments, including reasons for instrument fracture[33] and instrument sequences. These instruments have substantially reduced the incidence of relevant canal shaping errors,[387] but they are also thought to fracture somewhat more easily than hand instruments.

Table 6-1 and the following sections describe the instrument groups most widely used for root canal preparation at this point in time. Most basic strategies apply to all NiTi rotary instruments, regardless of the specific design or brand. However, three design groups need to be analyzed separately: group I, instruments designed for passive preparation; group II, rotary instruments designed for active cutting; and group III, unique designs that do not fit in either group I or group II.

Group I: Passive Preparation; Presence of Radial Lands

The first commercially successful rotary instruments were ProFile (Dentsply Tulsa Dental Specialties), LightSpeed (marketed in its current form by SybronEndo), and GT rotaries (Dentsply Tulsa Dental Specialties) and have in common a cross section with so-called radial lands. These are created by three round excavations, also known as the U-shape. The

A full crown was placed immediately after obturation. **E**, Recall radiograph 5 years after obturation shows sound periradicular tissues. **F**, Removed fragment and separated file (gradation of ruler is 0.5 mm).

design of the instrument tip and also the lateral file surface (radial land) guide the file as it progresses apically. This makes rotaries listed in group I fairly safe regarding preparation errors. On the other hand, it results in a reaming action rather than cutting of dentin and this makes them inefficient. Moreover, the smear layer produced with radial-landed rotaries is different in consistency and amount compared to the debris and smear created by cutting files.[366,573]

LightSpeed

The LightSpeed file, developed by Drs. Steve Senia and William Wildey in the early 1990s and now also known as LS1, was introduced as an instrument different from all others because of its long, thin, noncutting shaft and short anterior cutting head. The same design principles apply to the currently available LSX instrument (SybronEndo) that is manufactured not by milling but by a stamping process. A full set consists of 25 LightSpeed LS1 instruments in sizes #20 to #100, including half sizes (e.g., 22.5, 27.5); LSX does not have half sizes, and a set includes sizes #20 to #80.

The original LightSpeed is a widely researched NiTi rotary instrument,[50,392,394,459,513,514] and most reports have found that the system has a low incidence of overall and specific preparation errors. One report found similar shaping abilities for LSX and LightSpeed LS1 assessed with a double-exposure technique.[240]

FIG. 6-26 The SAF instrument. The instrument is made as a hollow, thin NiTi lattice cylinder that is compressed when inserted into the root canal and adapts to the canal's cross section. It is attached to a vibrating handpiece. Continuous irrigation is applied through a special hub on the side of its shank. Inset shows the abrasive surface of the instrument. (Courtesy ReDent-Nova, Ra'anana, Israel.)

ProFile

The ProFile system (Dentsply Tulsa Dental Specialties) was introduced by Dr. Ben Johnson in 1994. ProFile instruments have increased tapers compared with conventional hand instruments. The ProFile system was first sold as the "Series 29" hand instruments in .02 taper, but it soon became available in .04 and .06 tapers. The tips of the ProFile Series 29 rotary instruments had a constant proportion of diameter increments (29%). Later, a ProFile series with ISO-sized tips (Dentsply Maillefer) was developed and marketed in Europe.

Cross sections of a ProFile instrument show a U-shape design with radial lands (Fig. 6-28) and a parallel central core. Lateral views show a 20-degree helix angle, a constant pitch, and bullet-shaped noncutting tips (see Fig. 6-12). Together with a slightly negative rake angle, this configuration facilitates a reaming action on dentin rather than cutting. Also, debris is transported coronally and is effectively removed from the root canals.

ProFile instruments shaped canals without major preparation errors in a number of in vitro investigations.[74,75,515,516] A slight improvement in canal shape was noted when .04 and .06 tapered instruments were used in an alternating fashion.[73] Loss

of working length did not exceed 0.5 mm[73-75,515,516] and was not affected by the use of .06 tapered instruments.[73] Comparative assessments in vitro suggested that ProFile prepared mesial canals in mandibular molars with less transportation than K3 and RaCe.[9]

A more recent addition to the ProFile family of instruments was Vortex (Dentsply Tulsa Dental Specialties). The major change lies in the nonlanded cross section, whereas tip sizes and tapers are similar to existing ProFiles, hence these files are placed in group 2 (discussed later).

GT and GTX Files

The Greater Taper, or GT file, was introduced by Dr. Steve Buchanan in 1994. This instrument incorporates a radial landed cross-sectional design and was marketed as ProFile GT (Dentsply Tulsa Dental Specialties). The system was first produced as a set of four hand-operated files and later as engine-driven files. The instruments came in four tapers (.06, .08, .10, and .12), and the maximum diameter of the working part was 1 mm. The design limited the maximum shank diameter and decreased the length of the cutting flutes with increasing taper. The instruments had a variable pitch and a growing number of flutes in progression to the tip; the apical instrument diameter was 0.2 mm. Instrument tips were noncutting and rounded; these design principles are mostly still present in the current incarnation, the GTX instrument. The main differences are the M-Wire alloy type used and minor design and handling changes.

Studies on GT files found that the prepared shape stayed centered and was achieved with few procedural errors.[173,208] A shaping assessment using micro-computed tomography [μCT; see Fig. 6-4 as an example)] showed that GT files machined statistically similar canal wall areas compared with ProFile and LightSpeed preparations.[386] These walls were homogeneously planed and smooth.[366,573] The more recently introduced GTX variant is manufactured from M-Wire and does not appear to have significantly improved physical properties[254] or shaping capacity.[241] GT instruments were available for small (tip size #20), medium (tip size #30), and large canal diameters (tip size #40).

K3

In a sequence of design developments by their inventor, Dr. McSpadden, the Quantec 2000 files were followed by the Quantec SC, the Quantec LX, and the current K3 system (all by SybronEndo). The overall design of the K3 is similar to that of the ProFile in that it includes instruments with .02, .04, and .06 tapers. The most obvious difference between the Quantec and K3 models is the K3's unique cross-sectional design: a slightly positive rake angle for greater cutting efficiency, wide radial lands, and a peripheral blade relief for reduced friction. Unlike the Quantec, a two-flute file, the K3 features a third radial land to help prevent threading-in.

In the lateral aspect, the K3 has a variable pitch and variable core diameter, which provide apical strength. This intricate

design is relatively difficult to manufacture, resulting in some metal flash.

Like most other current instruments, the K3 features a round safety tip, but the file is about 4 mm shorter than other files (although it has the same length of cutting flutes) because of the so-called Axxess handle. The instruments are coded by ring color and number.

Tested in vitro, K3's shaping ability seems to be similar to that of the ProTaper[51] and superior to that achieved with hand instruments.[440] More recently, when curved canals in lower molars were shaped to a size #30 .06,[14] K3 files had less canal transportation in a modified Bramante model than RaCe but more than ProFile.

Summary

Radial landed rotary instruments are considered very safe, even when accidentally taken beyond the confines of the root canal. Fracture resistance to torsional loading and cyclic varies depending on specific instrument design. The limited cutting efficacy of these files was perceived as a downside and is a reason that the market share has diminished.[55] However, their excellent track record in clinical applications and research continues to support the use of rotaries listed in group I.

Group II: Active Cutting; Triangular Cross Section

Rotaries in group II all have a more active cutting flute design in common. Radial lands are absent (see Fig. 6-13), and this fact results in a higher cutting efficacy. This translates to a higher potential for preparation errors, in particular when the instrument is taken through the apical foramen, thus eliminating the guide derived from the noncutting tip.

ProTaper Universal

The ProTaper system originally comprised six instruments: three shaping files and three finishing files. This set is now complemented by two larger finishing files and a separate set of three rotaries tailored to retreatment procedures. The instruments were designed by Drs. Cliff Ruddle, John West, and Pierre Machtou. In cross sections, ProTaper shows a convex triangle with sharp cutting edges and no radial lands. The cross section of finishing files F3, F4, and F5 is slightly relieved for increased flexibility. The three shaping files have tapers that increase coronally, and the reverse pattern is seen in the five finishing files.

Shaping files nos. 1 and 2 have tip diameters of 0.185 mm and 0.2 mm, respectively, 14-mm-long cutting blades, and partially active tips. The finishing files (F1-F5) have tip diameters of 0.2, 0.25, 0.3, 0.4, and 0.5 mm, respectively, between D0 and D3, and the apical tapers are .07, .08, .09, .05, and .04, respectively. The finishing files have rounded noncutting tips.

Two aspects of handling have been emphasized for ProTaper. The first is the preparation of a glide path, either manually[368] or with special rotary instruments.[53] An enlargement to a size approaching the subsequent rotaries' tips, at least larger than the file's core diameter, prevents breakage and allows assessment of the canal size.[368] This means that the glide path should correspond to a size #15 or #20. The second specific recommendation is the use of a more laterally directed "brushing" working stroke. Such a stroke allows the clinician to coronally direct larger files away from danger zones and counteract any "threading-in" effect.[58] Both usage elements should be considered good practice for other instruments, particularly for more actively cutting ones.[391]

In a study using plastic blocks, ProTaper created acceptable shapes more quickly than GT rotary, ProFile, and Quantec instruments,[573] but it also created somewhat more aberrations. This was recently corroborated comparing preparations of mesial root canals in mandibular molars ex vivo with ProTaper Universal to Alpha (Gebr. Brasseler GmbH & Co. KG-Komet, Lemgo, Germany).[536] In a comparison of ProTaper and K3 instruments (SybronEndo), Bergmans and colleagues found few differences, with the exception of some transportation by the ProTaper into the furcation region.[51] A study using μCT showed that the ProTaper created consistent shapes in constricted canals, without obvious preparation errors, although wide canals may be insufficiently prepared with this system.[384] It has been recommended that ProTaper be combined with less tapered, more flexible rotaries to reduce apical transportation.[244]

A newer version of this system, called ProTaper Next was introduced in 2013. Current research suggests that mechanical properties of these instruments, manufactured from M-Wire, are better than ProTaper Universal.[23,138,370]

No data are currently available on shaping outcomes or clinical results.

HERO 642, HERO Shaper

Several systems in group II (see Table 6-1) were designed with positive rake angles, which provide greater cutting efficiency. HERO instruments (MicroMega, Besançon, France) are an example. The original version was known as *HERO 642* (the acronym *HERO* stands for *h*igh *e*lasticity in *ro*tation), and the name has now changed into HERO Shaper, with little apparent differences in the instrument design.

Cross sections of HERO instruments show geometries similar to those of an H-file without radial lands. Tapers of .02, .04, and .06 are available in sizes ranging from #20 to #45. The instruments are relatively flexible but maintain an even distribution of force into the cutting areas.[528,529] HERO instruments have a progressive flute pitch and a noncutting passive tip, similar to other NiTi rotary systems. The instruments are coded by handle color.

Research with HERO files indicates a shaping potential similar to that of the FlexMaster[230] (VDW, Munich, Germany) and ProFile,[164] although in one study HERO files induced more changes in cross-sectional anatomy.[179] HERO instruments also caused some aberrations when used in simulated canals with acute curves,[517] but they were safer than Quantec SC instruments (SybronEndo).[236] More recently, HERO Shapers had a better centering ability compared to RaCe instruments in resin blocks.[28] Using a modified Bramante technique in vitro, earlier HERO 642 and current HERO Shaper rotaries showed no differences in canal cross sections before and after shaping.[28]

FlexMaster

The FlexMaster file system is currently unavailable in the United States but popular in Europe. It features .02, .04, and .06 tapers. The cross sections have a triangular shape, with sharp cutting edges and no radial lands. This makes for a relatively solid instrument core and active cutting ability. The overall manufacturing quality seems high, with minimal metal flash and rollover.

FlexMaster files have rounded, passive tips; the tip diameters range from 0.15 to 0.7 mm for .02 instruments and 0.15

to 0.4 mm for.04 and .06-tapered files. In addition to the standard set, the Intro file is available, which has a .11 taper and a 9-mm cutting part. The instruments are marked with milled rings on the instrument shaft, and the manufacturer provides a system box that indicates sequences for narrow, medium-size, and wide canals.

Several studies indicate that the FlexMaster allows centered preparations in both constricted and wider canals[227] and that it performed on par with other systems.[230,550] Clinical studies confirmed that the FlexMaster showed superior shaping characteristics compared with K-files.[441] Also, novice dental students were able to shape plastic blocks successfully with the FlexMaster after a short training period.[484,485] Tested in a well-described model of simulated canals, FlexMaster instruments led to few aberrations but took longer than preparations with RaCe files.[325] Moreover, FlexMaster appeared to be less effective than RaCe in removing dye from the walls of simulated canals prepared to size #30 but were more effective than ProFile.[446]

RaCe, BioRaCe, BT Race

The RaCe file has been manufactured since 1999 by FKG and was later distributed in the United States by Brasseler (Savannah, GA). The name, which stands for *r*eamer with *a*lternating *c*utting *e*dges, describes just one design feature of this instrument. Light microscopic imaging of the file shows flutes and reverse flutes alternating with straight areas; this design is aimed at reducing the tendency of files to thread into a root canal. Cross sections are triangular or square for .02 instruments with size #15 and #20 tips. The lengths of cutting parts vary from 9 to 16 mm.

The surface quality of RaCe instruments has been modified by electropolishing, and the two largest files (size #35, .08 taper and size #40, .10 taper) are also available in stainless steel. The tips are round and noncutting, and the instruments handles are color-coded and marked by and milled rings. RaCe instruments have been marketed in various packages to address small and large canals; recently they are sold as BioRaCe, purportedly to allow larger preparation sizes, with an emphasis on the use of .02 tapered instruments.

Few results of in vitro experiments comparing RaCe to other contemporary rotary systems are available,[443,444] Canals in plastic blocks and in extracted teeth were prepared by the RaCe system with less transportation than with ProTaper files.[443] In another study, ProTaper and RaCe performed similarly when canals were prepared to an apical size #30.[360] When preparing to a size #40, RaCe files prepared canals rapidly and with few aberrations or instrument deformities.[397] The newer BioRaCe instrument sequence utilizes .02 tapered instruments to promote larger apical sizes. As with any rotary system, this is also possible in a hybrid hand-rotary technique. BioRace instruments prepared S-shaped canals in plastic blocks (to size #40) similarly to ProTaper and MTwo but were superior when combined with S-Apex.[62] In a clinical study, Rocas and colleagues found no significant differences between NiTi hand file preparation and BioRace regarding the reduction of bacterial load.[413] A new variant, BT RaCe, has been introduced and incorporates different tip designs, as well as different sequences.

EndoSequence

The EndoSequence rotary instrument is produced by FKG in Switzerland and marketed in the United States by Brasseler. This instrument adheres to the conventional length of the cutting flutes, 16 mm, and to larger tapers, .04 and .06, to be used in a crown-down approach. The overall design, including the available tapers and cross sections, is thus similar to many other files; however, the manufacturer claims that a unique longitudinal design (called alternating wall contact points [ACP]) reduces torque requirements and keeps the file centered in the canal. It also has varying, comparatively small helical angles. Another feature of the EndoSequence design is an electrochemical treatment after manufacturing, similar to that of RaCe files, resulting in a smooth, polished surface. This is thought to promote better fatigue resistance, hence a rotational speed of 600 rpm is recommended for EndoSequence.[264] Most in vitro results, however, suggest that EndoSequence is not superior to other files in cyclic fatigue resistance.[217,277,401]

Twisted File

In 2008, SybronEndo presented the first fluted NiTi file manufactured by plastic deformation, a process similar to the twisting process that is used to produce stainless steel K-files: the Twisted File (TF). According to the manufacturer, a thermal process allows twisting during a phase transformation into the so-called R-phase of nickel-titanium. The instrument is currently available with a size tip from #25 to #50 and in tapers from .04 to .12.

The unique production process is thought to result in superior physical properties; indeed, early studies suggested significantly better fatigue resistance when size #25 .06 taper Twisted Files were compared to K3 instruments of the same size GTX instrument.[163] Moreover, as determined by bending tests according to the ISO norm for hand instruments, 3630-1, Twisted Files size #25 .06 taper were more flexible than ProFiles of the same size.[162] Others found similar levels for fatigue resistance for TF and Profile of similar size.[277]

A more recent development for TF is the use of an electric motor that allows different file movement, both continuous rotation and reciprocation, depending on the clinical situation (TF Adaptive, SybronEndo).

ProFile Vortex

Profile Vortex files are manufactured from NiTi. Two versions are on the market, one made from M-Wire and another from so-called blue wire (Vortex Blue, which showed greater resistance to cyclic fatigue and increased torque resistance), and they have varying helical angles to counteract the tendency of nonlanded files to thread into the root canal. Vortex instruments are recommended to be used at 500 rpm; higher rotational speed results in less torque generated.[37] Canal preparation with ProFile Vortex in vitro was similar to other rotary instruments.[83,563] Vortex instruments are available in sizes #15 to #50 and in .04 and .06 tapers.

MTwo

This instrument, originally sold in Italy by Sweden e Martina, was put onto the European market in 2004. The instrument has a two-fluted S-shaped cross section. The original strategy allowed for three distinct shaping approaches after the use of a basic sequence with tip sizes from #10 to #25 and tapers ranging from .04 to .06. Subsequent enlargement was meant to create apical sizes up to #40 .04 or, alternatively, to #25 .07 or to larger apical sizes with so-called apical files. MTwo is a well-researched and cutting-efficient instrument; clinically it is an example for the so-called single length technique. Canal shapes with MTwo were similar to other

contemporary root canal instruments, either in rotation or reciprocation.[80]

Summary

The market share for rotary files without radial lands continues to expand because of perceived higher efficacy. The overall incidence of clinically relevant preparation errors (details are discussed later) appears to be low, in spite of more aggressive cutting by files without radial lands. Instrument fractures remain a concern, as does the tendency of continuously rotating instruments to thread or pull into the canal, specifically as working length is approached.

Group III, Special Cases

WaveOne, Reciproc

A way to mitigate problems with continuous rotation (e.g., taper lock, fatigue fracture, threading-in) is to return to reciprocation, which had been used decades ago (e.g., in the Giromatic handpiece).[233] A case report[566] described this approach using ProTaper F2 in reciprocation. Based on experiments evaluating the maximal rotational angle before plastic deformation for the selected instrument, a forward angle of 144 degrees followed by a reverse rotation of 72 degrees was recommended.[566] This cycle continues at 400 rpm until working length is reached.

Subsequently two instruments specifically designed for reciprocation were brought to the market: WaveOne (Tulsa Dentsply Dental Specialties) and Reciproc (VDW, currently not available in the United States). WaveOne instruments are available in three tip sizes, #21, #25, and #40, with tapers of .06 and .08, respectively. Corresponding sizes for Reciproc are tips of #25, #40, and #50 with tapers of .08, .06, and .05, respectively. Both instruments feature variable tapers that are largest toward the tips. The main WaveOne cross section is triangular, similar to ProTaper, whereas Reciproc is a two-fluted file with a design similar to MTwo.

Special motors are used for both systems to provide reciprocation action with alternating counterclockwise and clockwise rotations of about 150 to 170 and 30 to 50 degrees, respectively.[151]

Both files are machined with left-leaning flutes; therefore, the cutting direction for both is clockwise. One problem that may occur with this design is the transportation of dentin debris into the apical area, rather than moving debris coronally. There is mixed evidence for this phenomenon[81,124] in vitro. Clinically, frequent careful cleaning of the cutting blades with a moist gauze is recommended.

The shaping ability of these systems, according to current in vitro data, seems similar to that of established systems with continuous rotation.[80,324,537]

Self-Adjusting File

The self-adjusting file (SAF; ReDent-Nova) represents a different approach, both in file design and mode of operation.[327] The file is really a cylindrical, hollow device, designed as a thin-walled NiTi lattice with a lightly abrasive surface (see Fig. 6-26). An initial glide path is established up to a #20 K-file to allow the insertion of the SAF file. The file is proposed to be compressed from its 1.5 mm diameter into dimensions equivalent to those of a #25 K-file. It is operated with a handpiece that generates in-and-out vibrations (4000 per minute) and 0.4 mm amplitudes. As noted, the file is hollow, which allows for continuous irrigation through the file while operated in the root canal.

In vitro data for this system suggest that indeed more wall contact is made compared to rotary files,[361,382] resulting in better debridement and antimicrobial efficacy.[289,472] Shaping quality is also on par with rotary instruments.[382,537]

Endo-Eze

The Giromatic handpiece (MicroMega), a rotary instrument system in use since 1969, delivers 3000 quarter-turn reciprocating movements per minute. Special rasps and barbed broaches made from stainless steel were most often used in Giromatic handpieces, but K-type and H-type instruments may also be used. The preparation quality with this system was insufficient in curved canals, and the technique fell into disregard.[233]

The Endo-Eze file system (Ultradent, South Jordan, UT) is a more recently introduced addition using a similar motion, provided by special equipment or an original Giromatic handpiece. The set has four engine-driven instruments that are designed to clean the middle third of the canal. The sizes and tapers are #10 and #13, with tapers ranging from 0.02 to 0.04. In this system, the use of stainless steel hand instruments is suggested for the apical third of the canal.

Preparation quality in curved canals appeared to be inferior to NiTi rotaries.[349,358] In straight canals, Endo-EZE performed similar to FlexMaster.[419]

Sonic and Ultrasonic Instruments

An alternative way of instrumenting root canals was introduced when clinicians became able to activate files by electromagnetic ultrasonic energy. Piezoelectric ultrasonic units are also available for this purpose. These units activate an oscillating sinusoidal wave in the file with a frequency of about 30 kHz.

Two types of units, ultrasonic and sonic, are marketed. Ultrasonic devices, which operate at 25 to 30 kHz, include the magnetostrictive Cavi-Endo (Dentsply Caulk, Milford, DE), the piezoelectric ENAC (Osada, Tokyo), the EMS Piezon Master 400 (Electro Medical Systems, Vallée de Joux, Switzerland), and the P5 Neutron (Acteon Satelec, Merignac Cedex, France) (Fig. 6-29). Sonic devices, which operate at 2 to 3 kHz, include the Sonic Air MM 1500 (MicroMega), the Megasonic 1400 (Megasonic Corp, House Springs, MO), and the Endostar (Syntex Dental Products, Valley Forge, PA).

FIG. 6-29 Example of an ultrasonic unit. (Neutron P5 piezoelectric, courtesy Acteon Satelec, Merignac Cedex, France).

Ultrasonic device holders can fit regular types of instrument blanks (e.g., K-files), whereas sonic devices use special inserts known as Rispi-Sonic, Shaper-Sonic, Trio-Sonic, or Heli-Sonic files.

Although similar in function, piezoelectric units have some advantages over the magnetostrictive systems. For example, piezoelectric devices generate little heat, so no cooling is needed for the handpiece. Magnetostrictive systems, however, generate considerable heat, and a special cooling system is needed in addition to the cooling effect provided by root canal irrigation. Working without water-cooling becomes essential when using an operating microscope, because the water spray may obstruct visualization.

The piezoelectric transducer transfers more energy to the file than does the magnetostrictive system, making it more cutting efficient. The file in an ultrasonic device vibrates in a sinus wave–like fashion. A standing wave has areas with maximal displacement (i.e., antinodes) and areas with no displacement (i.e., nodes). The tip of the instrument exhibits an antinode. If powered too high, especially with no contact with the canal wall, the instrument may break because of the intense vibration. Therefore, files must be used only for a short time, must remain passive within the canal, and the power must be controlled carefully. The frequency of breakage in files used for longer than 10 minutes may be as high as 10%, and the breakage normally occurs at the nodes of vibrations.[7] Ultrasonic devices have been linked to a higher incidence of preparation errors and to reduced radicular wall thickness.[298,321,582]

Summary

An abundance of NiTi systems is currently on the market. Table 6-1 lists these instruments systematically and illustrates some of the most relevant properties. Most systems included in Table 6-1 have files with tapers greater than the .02 stipulated by the ISO norm. Differences exist in tip designs, cross sections, and manufacturing processes. In vitro tests have continued to identify the effect of specific designs on shaping capabilities and fracture resistance. A desirable goal is the instrumentation of more canal surface, in an effort to make biofilm more susceptible to subsequent chemical disinfection. At the same time, instrumentation paradigms that conserve more dentin appear desirable to promote long-term function.[172] Meaningful differences in clinical outcomes in regard to various specific design variations have yet to be ascertained.[187,375,443]

Motors

Motors for rotary instruments have become more sophisticated since the simple electric motors of the first generation in the early 1990s (Fig. 6-30, *A*). Electric motors with gear reduction are most suitable for rotary NiTi systems, because they ensure a constant rpm level and constant torque. They can also be programmed to provide alternative rotation patterns, for example, reciprocation with freely selectable angles of rotation.[151] Electric motors often have presets for rpm and torque and are capable of delivering torques much higher than those required to break tips. Some authors think that torque-controlled motors (see Fig. 6-30, *B* to *D*) increase operational safety.[160] Others have suggested that such motors may mainly benefit inexperienced clinicians.[569] These motors probably do not reduce the risk of fracture caused by cyclic fatigue, and even if the torque is below the fracture load at D3, a fracture at a smaller diameter (D2) is still possible.

To complicate matters further, a differential exists between torque at failure at D3 and the working torque needed to operate an instrument effectively (Fig. 6-31 and Box 6-2).[57,374,383,432] In many cases the working torque is greater than the torque required to fracture the instrument's tip.

This differential between working torque and tip fracture load is especially large, with files having a taper equal to or greater than .06; therefore, these files are rather ineffective in

FIG. 6-30 Examples of motors used with rotary nickel-titanium endodontic instruments. **A**, First-generation motor without torque control. **B**, Fully electronically controlled second-generation motor with sensitive torque limiter. **C**, Frequently used simple torque-controlled motor. **D**, Newer-generation motor with built-in apex locator and torque control.

BOX 6-2

Instrument Breakage with Torsional Load (MacSpadden Factor)

For rotary instrument tips, susceptibility to breakage is governed by the quotient of torque needed to fracture divided by working torque. Simply put, the larger the value, the safer the file.

most torque-controlled motors. Future motors will likely offer more microprocessor controlled features—for example, information about the specific instrument being used, such as the presets and the usage history.

Certain motors have built-in apex locators (see Fig. 6-30, *D*). This type of motor may be programmed to stop a rotary instrument when working length is reached or go into reverse gear. Similar changes in movement can occur in an adaptive fashion, depending on the torsional load that the instrument experiences in the root canal. The TF Adaptive motor (SybronEndo) is an example for this technology.

Some of the factors, besides the motor itself, that may influence the incidence of fracture in engine-driven NiTi rotary instruments are lubrication, specific instrument motion, and speed of rotation. It cannot be overemphasized that NiTi rotary instruments should be used only in canals that have been flooded with irrigant. Although lubricants such as RC-Prep (Premier Dental Products Co., Plymouth Meeting, PA) and Glyde (Dentsply Maillefer) have been recommended in the past, their benefit may be restricted to plastic blocks[19] and less relevant when rotary instruments engage dentin surfaces. Moreover, experimental data for dentin suggest that the use of lubricants fails to reduce torque values during simulated canal preparation.[61,376] Finally, because of chemical interactions between NaOCl and ethylenediamine tetra-acetic acid (EDTA),[183] alternating irrigants and using lubricants that contain EDTA may even be counterproductive. Details in irrigation solution interactions are described later in this chapter.

For instrument motion, some manufacturers recommend a pecking, up-and-down motion. This not only prevents threading in of the file, it is also thought to distribute stresses away from the instrument's point of maximum flexure, where fatigue failure would likely occur.[285,394] However, such in-and-out movements did not significantly enhance the life span of ProFile .04 taper or GT rotary instruments rotated around a 5-mm radius cylinder with a 90-degree curve.[374,379] Furthermore, large variations were noted in the lengths of the fractured segments.[226,530] This suggests that ductile fractures may originate at points of surface imperfections. Files made of more martensitic alloy tend to work better with longer sweeping or brushing strokes. The notion of "brushing" is not directly related to a paintbrush motion, as this would predispose a file to bending and subsequent fatigue.[391] It rather refers to stroking against the wall away from the danger zone, the inner curvature of a curved root.

Rotational speed may influence instrument deformation and fracture. Some studies indicated that ProFile instruments with ISO-norm tip diameters failed more often at higher rotational speed,[131,159] whereas other studies did not find speed to be a factor.[116,252] For Vortex, 300 rpm reduced the generated torque and force; this higher rpm preset did not result in an increase of instrument fractures in vitro.[37]

Clinicians must fully understand the factors that control the forces exerted on continuously rotating NiTi instruments (Box 6-3). To minimize the risk of fracture and prevent taper lock, motor-driven rotary instruments should not be forced in an apical direction. Similarly, acute apical curves limit the use of instruments with higher tapers because of the risk of cyclic fatigue. The incidence of instrument fracture can be reduced to an absolute minimum if clinicians use data from well-designed torque and stress studies. Adequate procedural strategies, such as an adequate glide path, a detailed knowledge of anatomic structures, with avoidance of extreme canal

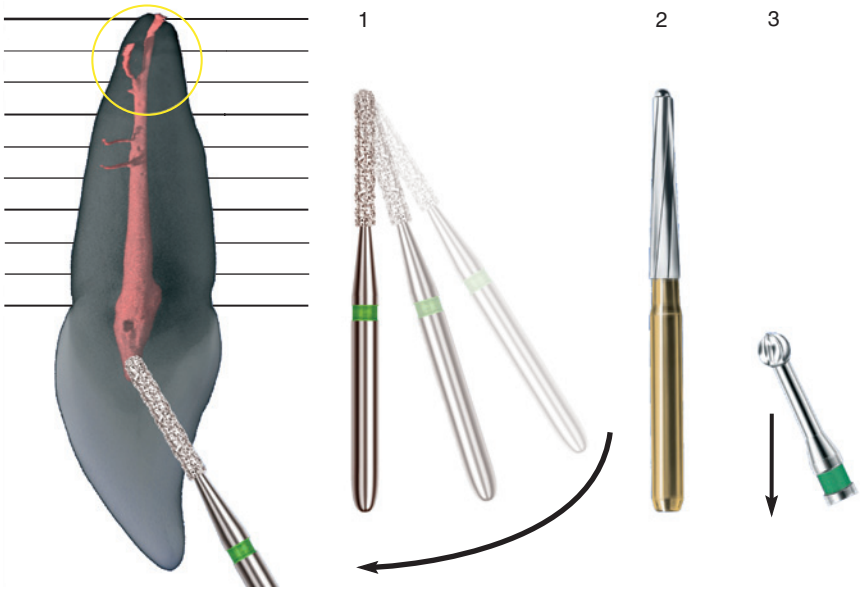

FIG. 6-32 Sequence of instruments used for optimal preparation of an access cavity (e.g., in an incisor). A parallel-sided diamond or steel bur is used to remove overlying enamel in a 90-degree angle toward the enamel surface *(1).* The bur is then tilted vertically to allow straight-line access to the root canal *(arrow).* A bur with a noncutting tip (e.g., Endo-Z bur or ball-tipped diamond bur) is then used to refine access *(2).* Overhangs or pulp horns filled with soft tissue are finally cleared with a round bur used in a brushing or pulling motion *(3).*

Factors Governing the Potential for Nickel-Titanium Rotary Instrument Fractures

- Clinician's handling (most important)
- Combination of torsional load, bending, and axial fatigue
- Root canal anatomy
- Manufacturing process and quality

configurations, and specific instrumentation sequences may also improve shaping results.

Certain procedures have evolved for removing fractured instruments from root canals (see Fig. 6-25); these are discussed in detail elsewhere in this book (see Chapters 8 and 19). Most of those methods require the use of additional equipment, such as a dental operating microscope and ultrasonic units. However, the best way to deal with instrument fracture is prevention. An understanding of the anatomy of the root canal system, together with a clear plan for selecting, sequencing, and using shaping instruments, can certainly help prevent procedural mishaps.

STEPS OF CLEANING AND SHAPING

Access: Principles

Access cavity preparation is essential for root canal treatment and is described in detail elsewhere in this book (Chapter 5). It should be emphasized at this point that mishaps during access (e.g., perforation) significantly affect the long-term outcome of a root canal treated tooth. Overenlargement or gouging during access significantly reduces structural strength[402] and may lead to root fracture and nonrestorable conditions.

Rationally, the use of a cylindrical diamond bur, followed by a tapered fluted bur with noncutting tip and perhaps a small round bur, is recommended (Fig. 6-32). One experiment suggested that more conservative access cavities, in particular in premolars, may increase fracture resistance and permit similar shaping outcomes.[270] The use of ultrasonically powered tips under magnification is aimed at achieving ideal access cavities (Fig. 6-33), including discovery and perhaps relocation of the canal orifices.

Coronal Preflaring

The extension of an access cavity into the coronal-most portion of the root canal is called *coronal flaring.* If a canal is constricted, mineralized, or difficult to access, flaring the coronal portion prior to any deep entry into the root canal is beneficial. This canal modification should be preceded by a scouting step, in which a small (e.g., size #10) K-file is passively placed several millimeters into the root canal. Tools for preflaring include Gates Gliddens (Fig. 6-34) and dedicated NiTi instruments (Fig. 6-35). Both step-back and step-down sequences have been recommended for Gates Gliddens, whereas NiTi rotaries are typically used in a crown-down sequence. More recently, specific orifice shaping rotaries have been developed that are used as a single instrument, rather than a sequence.

The use of laterally cutting NiTi rotaries allows the clinician to modify the root canal orifice to form a receptacle for subsequent instrumentation. This is related to removal of coronal mineralization and to relocation of the canal pathway by removal of dentin overhangs. For example, a second mesiobuccal canal typically exits the pulp chamber toward the mesial under a dentin shelf and then curves toward the distal. It is this curve in a small canal that often leads to formation of a ledge, which in turn prevents shaping to length.

Preenlargement of the coronal half to two thirds of a root canal allows files unimpeded access to the apical one third and

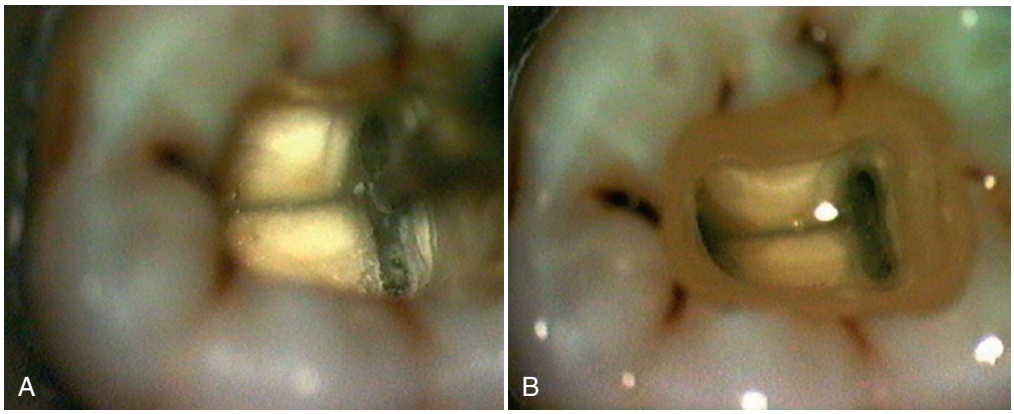

FIG. 6-33 Clinical views of an access cavity in a mandibular molar. **A,** As seen through an operating microscope (×20). **B,** Modification with an ultrasonically activated tip.

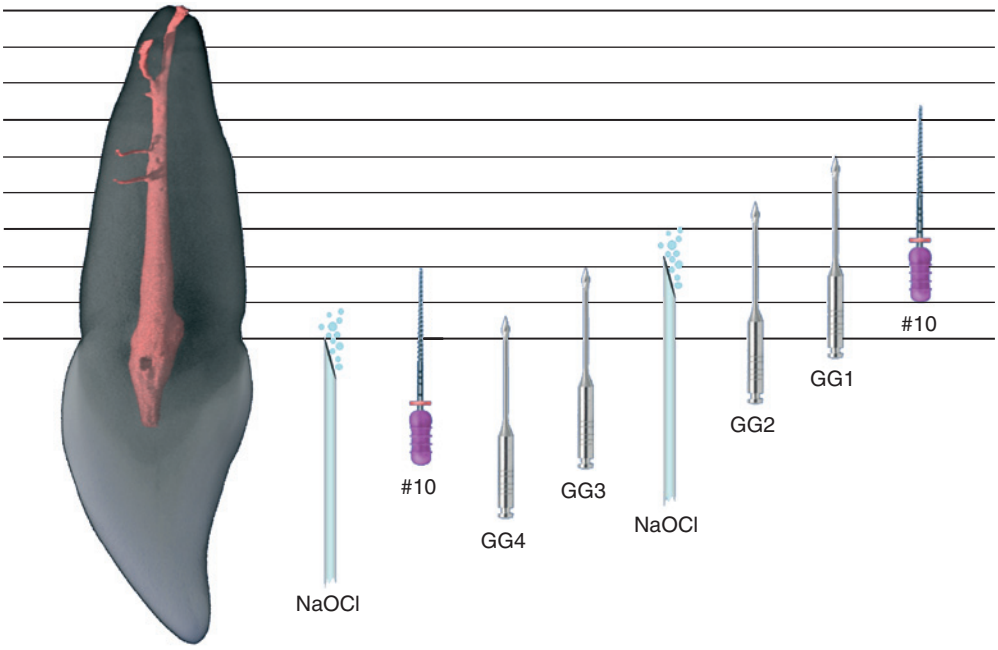

FIG. 6-34 Diagram of coronal enlargement in a maxillary anterior tooth. After preparation of the access cavity (see Fig. 6-32) and copious irrigation, Gates-Glidden burs are used in a step-down manner to enlarge the orifice and provide straight-line access into the middle third of the canal. Precurved size #10 K-files are used to explore the canal path and dimension.

gives the clinician better tactile control in directing small, adequately precurved negotiating files (Fig. 6-36).

One of the purported benefits of early coronal flaring is access of disinfecting irrigation solutions, but this has not been confirmed in experiments. On the other hand, a documented benefit of coronal flaring is mitigation of working length changes during canal preparation.[496]

Comparatively little is known about the efficacy of individual flaring instruments. One study compared the cutting efficacy of radial-landed and triangular cross sections.[338,380] The latter were shown to be more cutting efficient compared to radial-landed design; somewhat surprisingly, flexible martensitic alloy was cutting more rapidly compared to conventional NiTi alloys.

Patency File

A *patency file* is a small K-file (usually a size #10 or #15) that is passively extended slightly beyond the apical foramen. The use of a patency file has been suggested for most rotary techniques. This step is thought to remove accumulated debris, to help maintain working length, and to translate into greater clinical success.[345] One concern with the patency file was that instead of having a cleaning effect, the file would push contaminated debris through the foramen. However, an in vitro study suggested that the risk of inoculation was minimal when canals were filled with NaOCl.[243] Maintaining patency throughout an endodontic procedure does not lead to an increase in posttreatment symptoms.[22] Only initial clinical evidence exists favoring the use of a patency file; however, experience suggests

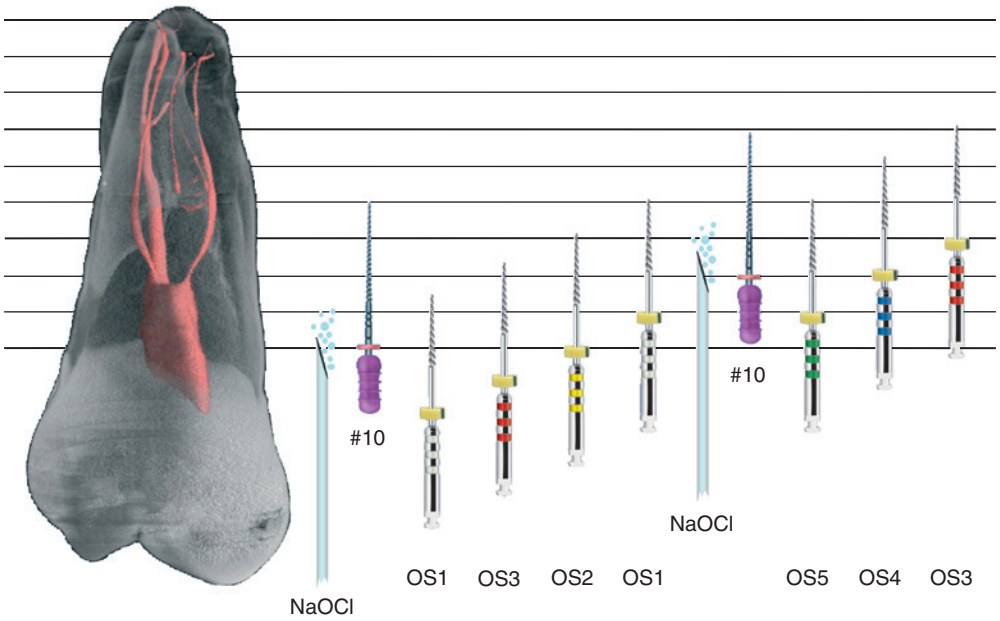

FIG. 6-35 Diagram of coronal enlargement in a more complicated maxillary posterior tooth. This maxillary molar presents several difficulties, including a narrow mesiobuccal canal that exits the pulp cavity at an angle. A possible approach in a case involving difficult entry into the root canal system is to use a small orifice shaper (OS1) after ensuring a coronal glide path with a K-file. Use of a sequence of orifice shapers (OS3 to OS1) then allows penetration into the middle third of the root canal. Wider canals can accept a second sequence of orifice shapers. Copious irrigation and securing a glide path with a size #10 K-file are prerequisites for use of NiTi rotary instruments.

that this technique involves relatively little risk and provides some benefit as long as small files are used carefully.

Working Length Determination

Devices

Radiographs, tactile sensation, the presence of moisture on paper points, and knowledge of root morphology have been used to determine the length of root canal systems. Following earlier experiments by Custer,[110] Sunada developed the first commercialized electronic apex locator,[501] suggesting that the apical foramen could be localized using a direct electric current. Currently, the electronic apex locator is considered an accurate tool for determining working length.[153] One study reported that the use of electronic apex locators in a dental student clinic resulted in a higher quality of obturation length control and an overall reduction in the number of radiographs taken.[152] However, these devices must not be considered flawless, because several variables are known to affect their accuracy. For example, immature roots can present problems.[234] Once roots mature (i.e., form a narrow apical foramen) and instruments are able to contact the canal walls, an electronic apex locator's accuracy greatly improves. Some investigators have found no statistical difference between roots with vital and necrotic tissue.[175,319] Because apical root resorption is prevalent in necrotic cases with longstanding apical lesions,[541] it may be concluded that apical resorption does not have a significant effect on the accuracy of electronic apex locators.

Some clinicians have advocated the use of the electronically determined working length in lieu of working length estimations using the placement of a file in the canal and a radiograph. However, combined use of both of these techniques has been shown to result in greater accuracy.[136] Furthermore, radiographs may add essential anatomic information that could be missed if electronic apex locators are used exclusively.

The first two generations of electronic apex locators were sensitive to the contents of the canal and irrigants used during treatment. The development of an algorithm called the *ratio measurement method* distinguished the third generation of apex locators.[263] To arrive at this method, the impedance of the canal was measured with two current sources of different frequencies, and a quotient was determined using the electrical potentials proportional to each impedance.[263] This study found that

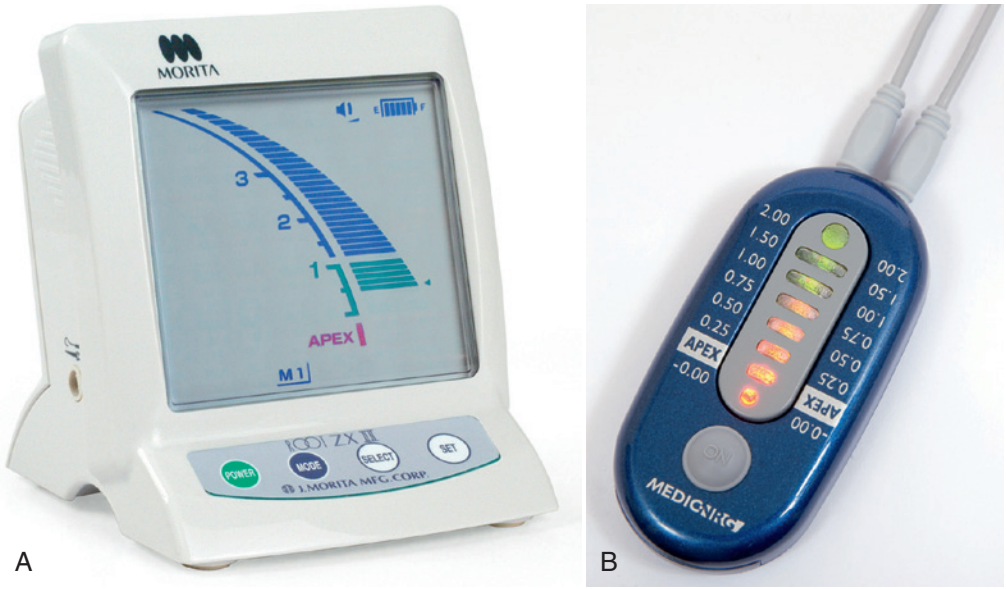

FIG. 6-37 A, Root ZX apex locator with lip clip and file holder. B, NRG miniature electronic apex locator. (*A*, Courtesy J Morita, Irvine, CA. *B*, Courtesy MedicNRG, Kibutz Afikim, Israel.)

electrolytes did not have a significant effect on the accuracy of the unit. This means that clinically canal contents need not be dried, but fluids in contact with crowns or coronal metallic restoration materials could conduct currents and lead to false results.

Some third-generation apex locators are the Endex Plus, or Apit (Osada, Los Angeles, CA), the Root ZX (J. Morita, Kyoto, Japan),[153,276] and the Neosono Ultima EZ (Acteon Satelec). The Endex Plus device uses 1 and 5 kHz and provides apex location based on subtraction. The Root ZX emits currents at frequencies of 8 and 0.4 kHz and provides apex location based on the resulting quotient. In addition to latest model apex locators, manufacturers have developed smaller models (Fig. 6-37, *B*).

Apex locators are generally safe to use; however, manufacturers' instructions state that they should not be used on patients with pacemakers without consulting the patient's cardiologist. However, when connected directly to cardiac pacemakers in vitro, electronic apex locators did not interfere with the function of the pacemaker,[165] and they did not interfere with the functioning of any of the cardiac devices tested in a clinical study under electrocardiogram monitoring.[556]

Strategies

Anatomic studies and clinical experience suggest that typically teeth are 19 to 25 mm long. Most clinical crowns are approximately 10 mm long, and most roots range from 9 to 15 mm in length. Roots, therefore, can be divided into thirds that are 3 to 5 mm long. An important issue in root canal treatment is the apical end point of the prepared shape in relation to the apical anatomy. Traditional treatment has held that canal preparation and subsequent obturation should terminate at the *apical constriction*, the narrowest diameter of the canal (Fig. 6-38). This point is thought to coincide with the cementodentinal junction (CDJ) (see Chapter 12) and is based on histologic sections and ground specimens. However, the position and anatomy of the CDJ vary considerably from tooth to tooth, from root to root, and from wall to wall in each canal. Moreover, the CDJ cannot be located precisely on radiographs. For this reason, some have advocated terminating the preparation in necrotic cases at 0.5 to 1 mm short of the radiographic apex and 1 to 2 mm short[206,407,562] in cases involving irreversible pulpitis. Although there is no definitive validation for this strategy at present,[435] well-controlled follow-up studies seem to support it.[476,478]

Working to shorter lengths may lead to the accumulation and retention of debris, which in turn may result in apical blockage (Fig. 6-39). If the path to the apex is blocked, working to short lengths may contribute to procedural errors such as apical perforations and fractured instruments. Such obstacles (which consist of collagen fibers, dentin mud, and, most important, residual microbes) in apical canal areas are a major cause of persistent or recurrent apical periodontitis,[196,342,466] or *post-treatment disease*[156,559] (also see Chapters 14 and 15).

Using an electronic apex locator has helped clinicians identify the position of apical foramina more accurately and allow safe canal shaping as close as 0.5 mm to the canal terminus.

Canal Enlargement/Preparation

Rationale

Like the position of the apical constriction, apical diameters are difficult to assess clinically.[274] Some have recommended gauging canal diameters by passing a series of fine files apically until one fits snugly. However, such an approach is likely to result in underestimation of the diameter.[555] This is a crucial point because the initial canal size is a major determinant for the desired final apical diameter.

An ongoing debate exists between those who prefer smaller apical preparations combined with tapered shapes and those who favor larger apical preparations for better removal of infected dentin and to allow irrigation fluids access to the apical areas (Table 6-2). Both sides stress the importance of maintaining the original path of the canal during preparation; otherwise, bacteria in the apical one-third of the root canal may not be reached by sufficient amounts of an antimicrobial agent.[335] Investigators demonstrated a higher percentage of

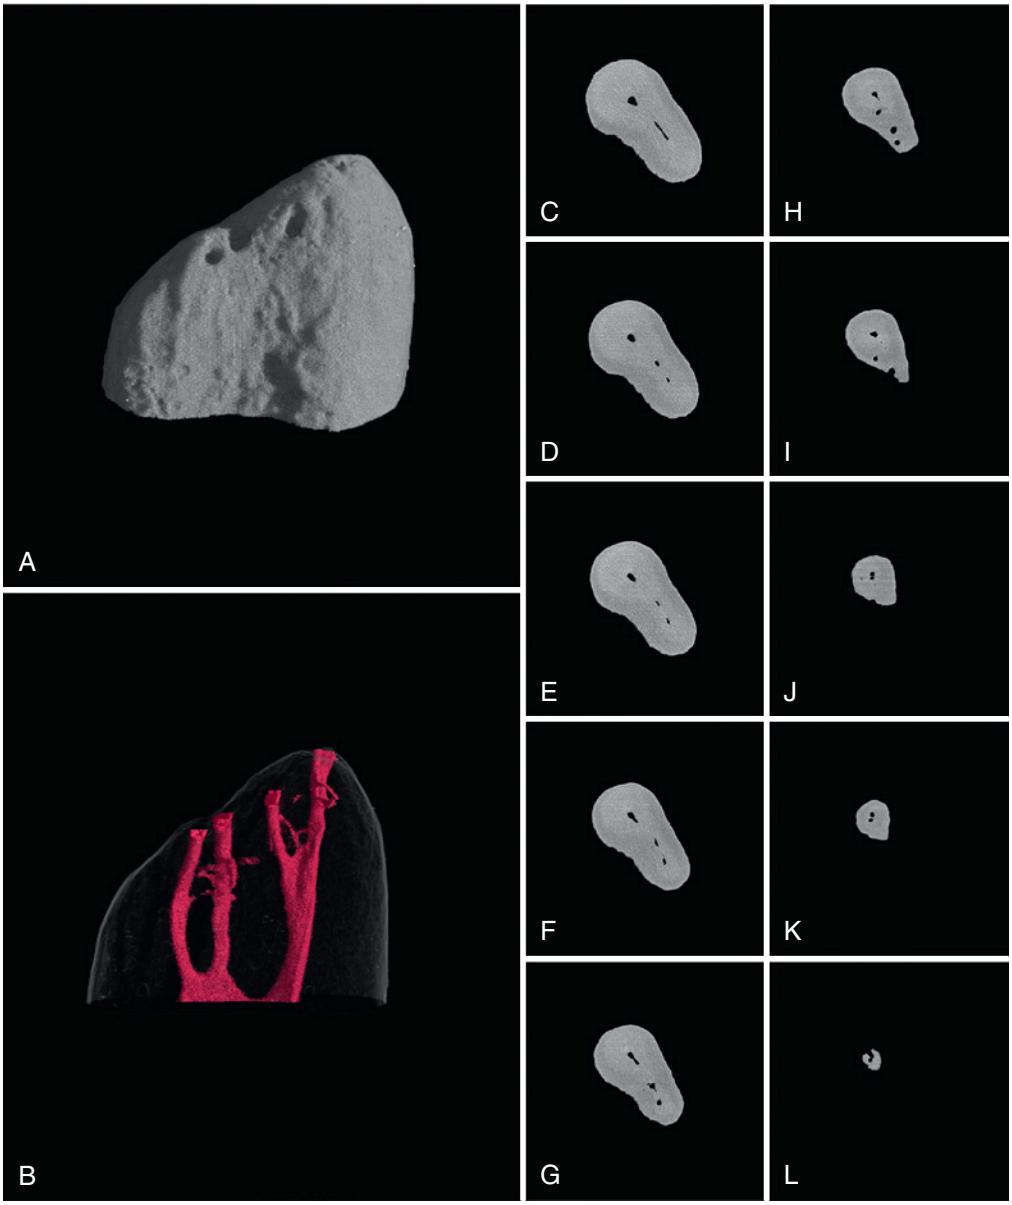

FIG. 6-38 Microcomputed tomographic scan of anatomy of the apical 5 mm of a mesiobuccal root (8 μm resolution). **A-B,** Three-dimensional reconstruction of outer contour and root canal systems. **C-L,** Cross sections of root at 0.5 mm apart.

TABLE 6-2

Characteristics of Wide and Narrow Apical Preparations

Root Canal Preparation	Benefits	Drawbacks
Narrow apical size	Minimal risk of canal transportation and extrusion of irrigants or filling material Can be combined with tapered preparation to counteract some drawbacks Less compaction of hard tissue debris in canal spaces	Little removal of infected dentin Questionable rinsing effect in apical areas during irrigation Possibly compromised disinfection during interappointment medication Not ideal for lateral compaction
Wide apical size	Removal of infected dentin Access of irrigants and medications to apical third of root canal	Risk of preparation errors and extrusion of irrigants and filling material Not ideal for thermoplastic obturation

FIG. 6-39 Presence of dentin dust as a possible source of microbial irritation. Tooth #18 underwent root canal therapy. The clinician noted an apical blockage but was unable to bypass it. Unfortunately, intense pain persisted and at the patient's request, the tooth was extracted a week later. **A**, Mesial root of tooth #18; mesial dentin has been removed. **B**, Magnified view (×125) of rectangle in **A** shows an apical block (gradation of ruler is 0.5 mm).

bacterial elimination in single-root canal systems by using a combination of significant enlargement of the apical third and NaOCl irrigation.[89] Preparation errors (e.g., zips, canal transportation) may occur in larger preparations, with both stainless steel and NiTi instruments (Fig. 6-40).

Thorough disinfection of the apical part of a root canal is essential, because this area is most likely to harbor residual intraradicular bacteria.[343] Wider apical preparations remove potentially infected dentin, allowing the delivering needle and subsequently the antimicrobial irrigant to penetrate the root canal more deeply.[101,147]

A study investigating rotary NiTi files of three tapers (.06, .08, and .10) with file tips in sizes #20, #30, and #40 showed that size #20 instruments left significantly more debris in the apical third compared with size #40 instruments.[532] On the other hand, a study in which half the samples were prepared to a size #25 file and the other half to a size #40 file found no statistically significant difference in bacterial growth after instrumentation, with no growth observed after 1 week of treatment with a $Ca(OH)_2$ dressing.[570] Step-down sequences with additional apical enlargement to ISO size #35 and a serial step-back technique with no apical enlargement were compared, using NaOCl and EDTA as irrigants. Here, no significant difference was detected in colony-forming units with or without apical enlargement.[105] These researchers concluded that dentin removal in the apical third might be unnecessary if a suitable coronal taper is achieved.

Despite the disagreement over the appropriate width of a preparation (see Table 6-2), these studies suggest that root canal preparations should be confined to the canal space, should be sufficiently wide, and should incorporate the original root canal cross sections (see Fig. 6-4).

Traditional cleaning and shaping strategies (e.g., the step-back technique) focused immediate preparation of the apical third of the root canal system, followed by various flaring techniques to facilitate obturation.[180,436,518] In an attempt to reach the canal terminus, the clinician first selected a small file, placed an appropriate curve on the instrument, and then tried to work the file to full length. If the terminus could not be reached, the file was removed and, after irrigation, either the same file or a smaller one was inserted. However, not infrequently, full length was not obtained, either because of blockage or because of coronal binding.

Coronal binding is caused by overhangs at the orifice level and when the canal is less tapered than an instrument, making it bind coronally. Moreover, a straight root often contains a curved canal, such as buccal and lingual curvatures that cannot be seen on radiographs.[109,389] In addition, passing a precurved negotiating file through a coronally tight canal will straighten the instrument.[487]

Various instrumentation sequences have been developed for hand and rotary instruments; these are discussed later in this chapter. However, the shape of the access cavity is *the* prerequisite that must be optimized before any canal preparation can take place (see Chapter 5).

As stated previously, preparation of an adequate access cavity (see Fig. 6-32) may involve the use of a cylindrical diamond or fissure bur, a safety-ended drill for additional enlargement, and round burs to remove overhangs on outward strokes. The access cavity shape must allow instruments unimpeded access to the middle third of the root canal system. Ultrasonically powered instruments used under an operating microscope greatly facilitate removal of mesial dentin shelves in mandibular molars (see Fig. 6-33, *A* and *B*) and other teeth. Preexisting restorations allow for ideal access cavities that serve as reservoirs of irrigants (see Fig. 6-33, *C*).

Basic cleaning and shaping strategies for root canal preparation can be categorized as crown-down, step-back, apical widening, and hybrid techniques. In a crown-down approach, the clinician passively inserts a large instrument into the canal up to a depth that allows easy progress. The next smaller instrument is then used to progress deeper into the canal; the third instrument follows deeper again, and this process continues until the terminus is reached. Both hand and rotary instruments may be used in a crown-down manner. However, instrument sets with various tip diameters and tapers allow the use of either decreasing tapers or decreasing diameters for apical progress. Debate continues as to which of those strategies is superior for avoiding taper lock; currently, no compelling evidence favors either of them.

In the step-back approach, working lengths decrease in a stepwise manner with increasing instrument size. This prevents less flexible instruments from creating ledges in apical curves while producing a taper for ease of obturation.

As discussed previously, the aim of apical widening is to fully prepare apical canal areas for optimal irrigation efficacy and overall antimicrobial activity. Apical enlargement has been broken down into three phases: preenlargement, apical enlargement, and apical finishing.[545]

Most rotary techniques require a crown-down approach to minimize torsional loads,[57] and they reduce the risk of instrument fracture. Used sequentially, the crown-down technique can help enlarge canals further. All basic techniques described so far may be combined into a hybrid technique to eliminate or reduce the shortcomings of individual instruments.

Root canal preparation can be broken down into a series of steps that parallel the insertion depths of individual instruments. Anatomic studies and clinical experience suggest that most teeth are 19 to 25 mm long. Most clinical crowns are approximately 10 mm long, and most roots range from 9 to 15 mm in length. Roots, therefore, can be divided into thirds that are 3 to 5 mm long.

Provided adequate tools are used and the access cavity design is appropriate, excessive thinning of radicular structures can be avoided (see Fig. 6-5). Vertical root fractures and perforations are possible outcomes of excessive removal of radicular dentin in zones that have been termed *danger zones*.[15] Overenthusiastic filing, for example, may lead to more procedural errors (see Figs. 6-22 and 6-40). On the other hand, ideal preparation forms without any preparation errors and with circular incorporation of the original canal cross sections may be achieved with suitable techniques (see Fig. 6-4).

Dedicated NiTi instruments have been introduced or suggested for coronal preenlargement, such as the ProFile orifice shapers, GT accessory files, the ProTaper SX, the FlexMaster Intro file, and the size #40, .10 taper or size #35, .08 taper RaCe files. These instruments are better suited than GGs and safer for more difficult cases (see Figs. 6-34 and 6-35).

Techniques

Standardized Technique

The standardized technique adopts the same working length definition for all instruments introduced into a root canal. It therefore relies on the inherent shape of the instruments to impart the final shape to the canal. Negotiation of fine canals is initiated with lubricated fine files in a so-called watch-winding movement. These files are advanced to working length and worked either in the same hand movement or with "quarter-turn-and-pull" until a next larger instrument may be used. Conceptually, the final shape should be predicted by the last instrument used (Fig. 6-41). A single matching gutta-percha point may then be used for root canal filling. In reality, this concept is often violated: curved canals shaped with the standardized technique will be wider than the last used instrument,[14] exacerbated by the pulling portion of the hand movement. Moreover, adequate compaction of gutta-percha in such small a taper (~.02) is difficult or impossible[13] (see Chapter 7).

The standardized technique was hampered by the very standardization of the instruments used to perform the technique. Specifically, the similar size increment by 0.05 mm up to size 55 was clinically more difficult to achieve moving from size #10 to size #15, compared to the step from size #40 to #45. In very small files (sizes #6 to #10), the problem is partly resolved by several key points: (1) apical dimensions are such that a size #6 file does not significantly remove dentin other than in severely calcified cases; (2) a size #8 file taken 0.5 to 1 mm long to establish patency (discussed later in the chapter) contacts the desired end point of the preparation with a diameter approaching the tip size of a #10 file; (3) similarly, placing a size #10 file just minutely through the foramen eases the way for passive insertion of the subsequent #15 file to full length.[417]

Step-Back Technique

Realizing the importance of a shape larger than that produced with the standardized approach, one investigator suggested the step-back technique,[552] incorporating a stepwise reduction of the working length for larger files, typically in 1-mm or 0.5-mm steps, resulting in flared shapes with 0.05 and 0.10 taper, respectively (Fig. 6-42). Incrementally reducing the working length when using larger and stiffer instruments also reduced the incidence of preparation errors, in particular in curved canals. This concept appeared to be clinically very effective.[339]

Although the step-back technique was primarily designed to avoid preparation errors in curved canals, it applies to the preparation of apparently[109,439] straight canals as well. Several modifications of the step-back technique have been described over the years. Another investigator advocated the insertion of progressively larger hand instruments as deep as they would passively go in order to explore and provide some enlargement prior to reaching the working length.[518]

Step-Down Technique

Other investigators described a different approach.[174] They advocated shaping the coronal aspect of a root canal first, before apical instrumentation commenced. This technique is intended to minimize or eliminate the amount of necrotic debris that could be extruded through the apical foramen during instrumentation.[146] Moreover, by first flaring the coronal two thirds of the canal, apical instruments are unimpeded through most of their length. This in turn may facilitate greater control and less chance of zipping near the apical constriction.[280]

Crown-Down Technique

Numerous modifications of the original step-down technique have been introduced, including the description of the crown-down technique.[150,317,433] The more typical step-down technique includes the use of a stainless steel K-file exploring the apical constriction and establishing working length. In

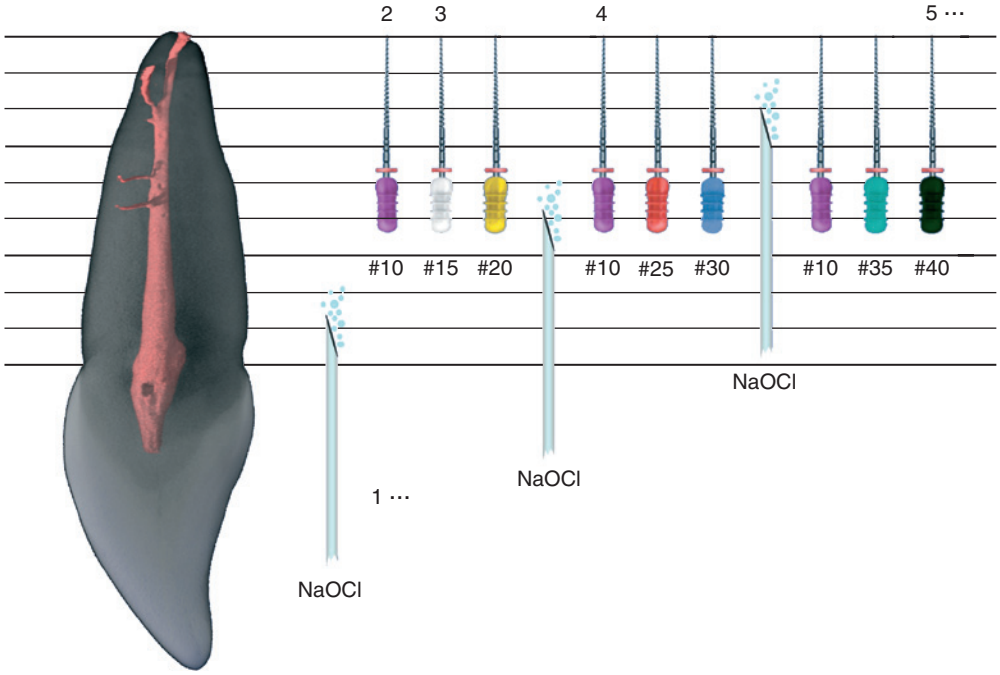

FIG. 6-41 Root canal instrumentation with hand files: Part I. After the orifice has been accessed and copious irrigation performed *(1),* the working length (WL) is determined. A size #10 or #15 K-file is advanced to the desired apical preparation end point, aided by an electronic apex locator *(2).* The apical canal areas are then enlarged with K-files *(3)* used in the balanced force technique (see Fig. 9-43). Frequent, copious irrigation with sodium hypochlorite is mandatory to support antimicrobial therapy. Frequent recapitulation with fine K-files is recommended to prevent blockage *(4).* Apical enlargement is complete to the desired master apical file (MAF) size *(5),* which depends on pretreatment canal sizes and individual strategy. Typically, size #40 or larger may be reached in anterior teeth, as in this example. File sizes larger than #20 may be used with NiTi instruments (e.g., NiTiFlex).

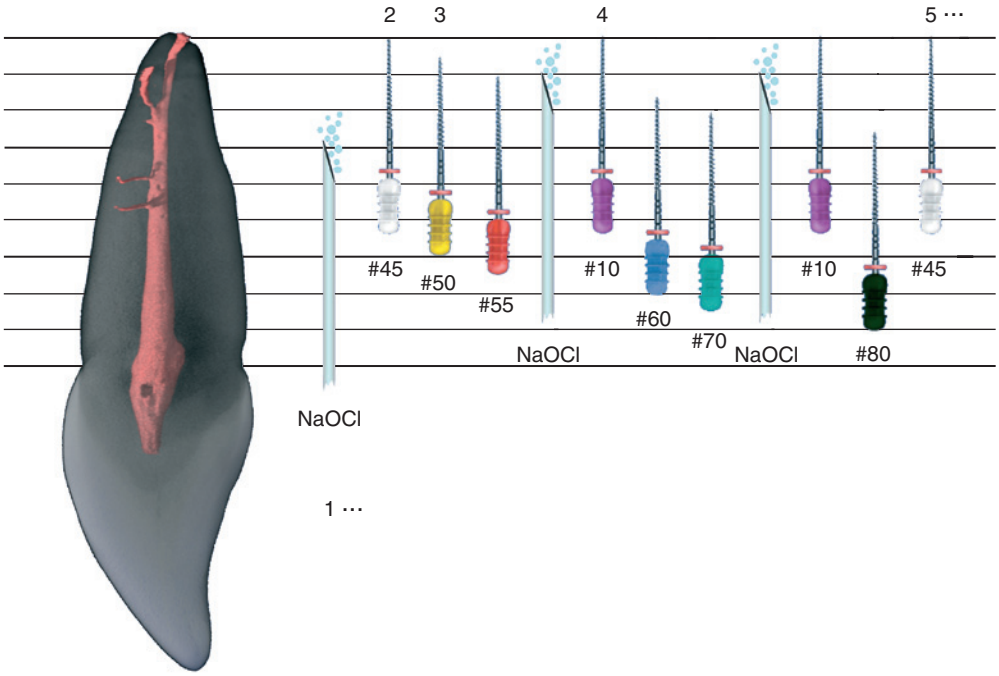

FIG. 6-42 Root canal instrumentation with hand files: Part II. Frequent irrigation with sodium hypochlorite *(1)* is more efficient after the working length (WL) is reached, because irrigation needles may penetrate deeper into the canal. Canal taper is increased to further improve antimicrobial efficiency and to simplify subsequent obturation. Hand instruments are set to decreasing working length in 0.5 mm increments (step-back) from the master apical file (MAF) (*2 and 3*). A fine K-file is used to recapitulate to WL during the procedure *(4),* and the MAF is used as a final recapitulation *(5)* to ensure that remaining dentin chips have been removed.

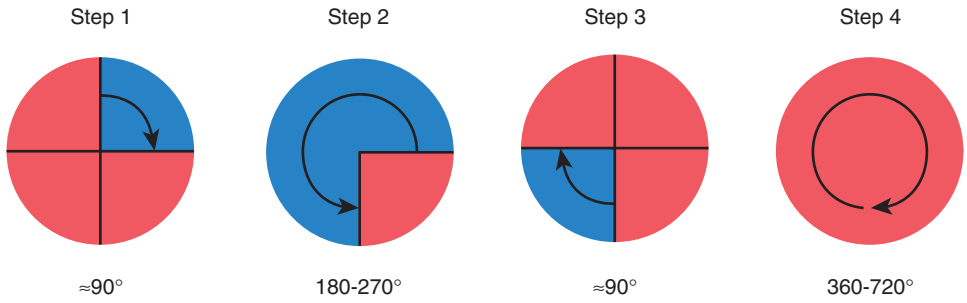

FIG. 6-43 Diagram of handle movements during balanced force hand preparation. **Step 1:** After pressureless insertion of a Flex-R or NiTiFlex K-file, the instrument is rotated clockwise 90 degrees, using only light apical pressure. **Step 2:** The instrument is rotated counterclockwise 180 to 270 degrees; sufficient apical pressure is used to keep the file at the same insertion depth during this step. Dentin shavings are removed with a characteristic clicking sound. **Step 3:** This step is similar to step 1 and advances the instrument more apically. **Step 4:** After two or three cycles, the file is loaded with dentin shavings and is removed from the canal with a prolonged clockwise rotation.

contrast, a crown-down technique relies more on coronal flaring and then determination of the working length later in the procedure.

To ensure penetration during step-down, one may have to enlarge the coronal third of the canal with progressively smaller GG drills or with other rotary instruments. Irrigation should follow the use of each instrument and recapitulation after every other instrument. To properly enlarge the apical third and to round out ovoid shape and lateral canal orifices, a reverse order of instruments may be used starting with a size #20 (for example) and enlarging this region to a size #40 or #50 (for example). The tapered shape can be improved by stepping back up the canal with larger instruments, bearing in mind all the time the importance of irrigation and recapitulation.

The more typical crown-down, or double-flare, technique[150] consisted of an exploratory action with a small file, a crown-down portion with K-files of descending sizes, and an apical enlargement to size #40 or similar. The original technique included stepping back in 1-mm increments with ascending file sizes and frequent recapitulations with a small K-file and copious irrigation. It is further emphasized that significant wall contact should be avoided in the crown-down phase to reduce hydrostatic pressure and the possibility of blockage. Several studies demonstrated more centered preparations in teeth with curved root canals shaped with a modified double-flare technique and Flex-R files compared to shapes prepared with K-files and step-back technique.[434,433] A double-flare technique was also suggested for ProFile rotary instruments.[447]

Balanced Force Technique

Regarding hand movements, a general agreement exists that the so-called balanced force technique creates the least canal aberrations with K-files. This technique has been described as a series of rotational movements for Flex-R files,[412] but it can also be used for K-files and other hand instruments such as GT hand files. Many explanations have been offered for the obvious and undisputed efficacy of the balanced force approach,[94,275,439] but general agreement exists that it provides excellent canal-centering ability, superior to other techniques with hand instruments.[30,71,283]

The balanced force technique involves three principle steps.[412] The first step (after passive insertion of an instrument into the canal) is a clockwise rotation of about 90 degrees to engage dentin (Fig. 6-43). In the second step, the instrument is held in the canal with adequate axial force and rotated counterclockwise to break loose the engaged dentin chips from the canal wall; this produces a characteristic clicking sound. Classically, in the third step, the file is removed with a clockwise rotation to be cleaned; however, because files used with the balanced force technique are not precurved, every linear outward stroke essentially is a filing stroke and may lead to some straightening of the canal path. Therefore, in many cases, the clinician may advance farther apically rather than withdrawing the file, depending on the grade of difficulty.

Rotary Instrumentation

NiTi rotary instruments are an invaluable adjunct in the preparation of root canals, although hand instruments may be able to enlarge some canals just as efficiently when used in appropriate sequences. Hand instruments should be used only after coronal preenlargement (e.g., with GG drills). After preenlargement, the access cavity and canals are flooded with irrigant, and a precurved scouting file is advanced into the canal. A lubricant when using hand instruments can help prevent apical blockage in this early stage. Once the working length has been established (aided by an electronic apex locator and radiographically verified), apical preparation to begins to facilitate a glide path for subsequent rotary instrumentation (Fig. 6-44).

The term *glide path* has been used in endodontics since the early 2000s[384] and relates to securing an open pathway to the canal terminus that subsequent engine-driven instruments can follow. The typical minimum glide path is a size #15 to #20 K-file and should be confirmed with a straight, not precurved file. Various small engine-driven instruments were introduced to simplify this process, such as Pathfiles (Dentsply Maillefer),[53] Scout RaCe (FKG Dentaire SA, La Chaux-de-Fonds Switzerland),[344] and G-file (MicroMega).[112] Copious irrigation and frequent recapitulations with a smaller file to working length may be required, and in some instances, clinicians must devise creative strategies using small crown-down or step-back sequences.

Fig. 6-45 illustrates the development of two different shapes in the mesial root canals of a mandibular molar, clearly showing that substantial areas of the root canal surface in either case are not instrumented, even when apical size #50 or 0.09 taper are reached (see the red areas in Fig. 6-45, *G* and *I*).

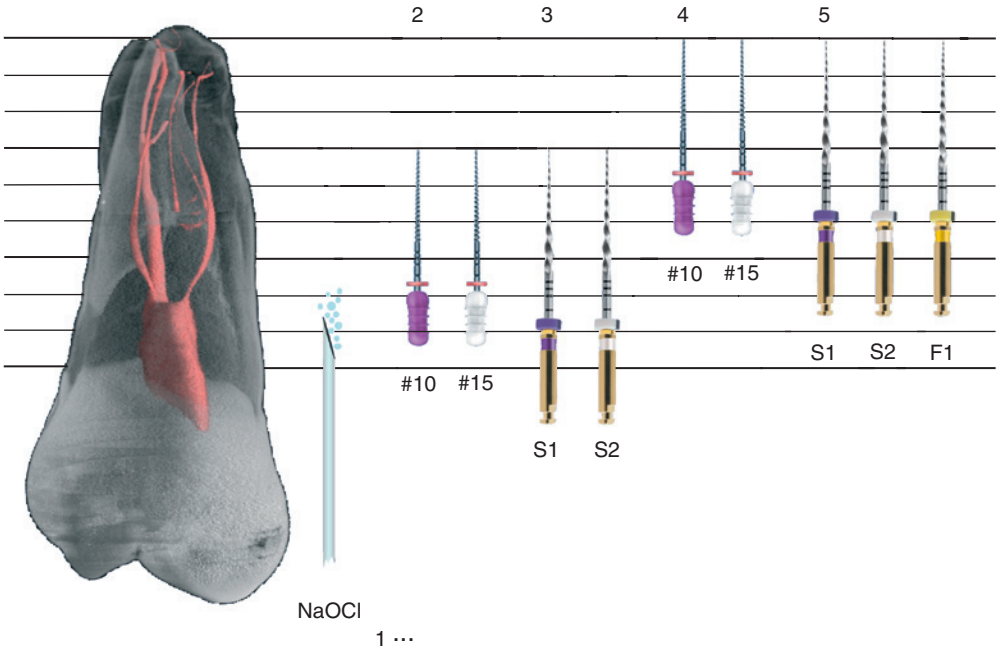

FIG. 6-44 Instrumentation of root canals with ProTaper instruments. After irrigation and scouting (*1* and *2*), the coronal thirds are enlarged with shaping files S1 and S2. Hand files then are used to determine the WL and to secure a glide path. Apical preparation is completed with S1 and S2. Finishing files are used to the desired apical width.

Specific NiTi Instrumentation Techniques

Crown Down

This was the dominant approach for many years and is still being used, for example, for ProFile and several others (ProFile Vortex, HERO 642, K3, and FlexMaster). It must be noted that the manufacturers' instructions for these systems vary somewhat, and the instructions for GT rotary, RaCe, and the Twisted File vary even more. Clinicians should always read the manufacturers' instructions for details on working with those instruments.

Working length is determined after any coronal preenlargement , and an open glide path is secured with K-files up to size #15 or #20, depending on the canal anatomy. If canal size permits, canal preparation begins with .06 taper instruments in descending tip diameters.[57] In more difficult small canals, .06 tapers are followed by .04-tapered instruments, also with descending tip diameters. Apical preparation is performed either with multiple shaping waves, as suggested for GT rotary files,[76] or in a step-back manner.[445] Recapitulation with a small hand file is recommended throughout the preparation.

Single Length

The approach for ProTaper Universal and ProTaper Next instruments differs from that for many other NiTi rotary files (except MTwo, WaveOne and Reciproc) in that no traditional crown-down procedure is performed (see Fig. 6-44).

Size #10 and #15 hand files are passively inserted into the coronal two thirds of a root canal as path-finding files, which confirm the presence of a smooth, reproducible glide path. This step is essential for ProTaper shaping instruments, because they are mostly side cutters and have fine, fragile tips.

Shaping files S1 and S2 are then passively inserted into the scouted canal spaces, which have been filled with irrigant (preferably NaOCl). If necessary, the SX file can be used at this stage to relocate orifices or remove obstructing dentin. After each shaping file is used, the canals are reirrigated, and a size #10 file is used to recapitulate to break up debris and move it into solution. This process is repeated until the depth of the path-finding #10 or #15 file is reached.

After irrigation, the apical third is fully negotiated and enlarged to at least a size #15 K-file, and the working length is confirmed (see Fig. 6-44). Depending on the canal anatomy, the rest of the apical preparation can be done with engine-driven ProTaper shaping and finishing hand files. As an alternative, handles can be placed on these instruments so that they can be used for the balanced force technique.

ProTapers S1 and S2 are then carried to the full working length, still in a floating, brushing motion. The working length should be confirmed after irrigation and recapitulation with a K-file, aided by an electronic apex locator or radiographs. Because of the progressive taper and more actively cutting flutes higher up in the ProTaper design, interferences in the middle and coronal thirds are removed at this stage.

The preparation is finished with one or more of the ProTaper finishing files, used in a nonbrushing manner; because of their decreasing taper, these files will reach the working length passively. Recapitulation and irrigation conclude the procedures (see Fig. 6-44).

LightSpeed Technique

Since the introduction of LightSpeed instruments, the manufacturer's guidelines have changed. This section presents a version used for the original LightSpeed rather than the LS variant (Fig. 6-46).

After access and coronal preenlargement with the instrument of choice, working lengths are obtained, and apical enlargement is done with at least a loose-fitting size #15 K-file. LSX instruments are then slowly advanced to working length

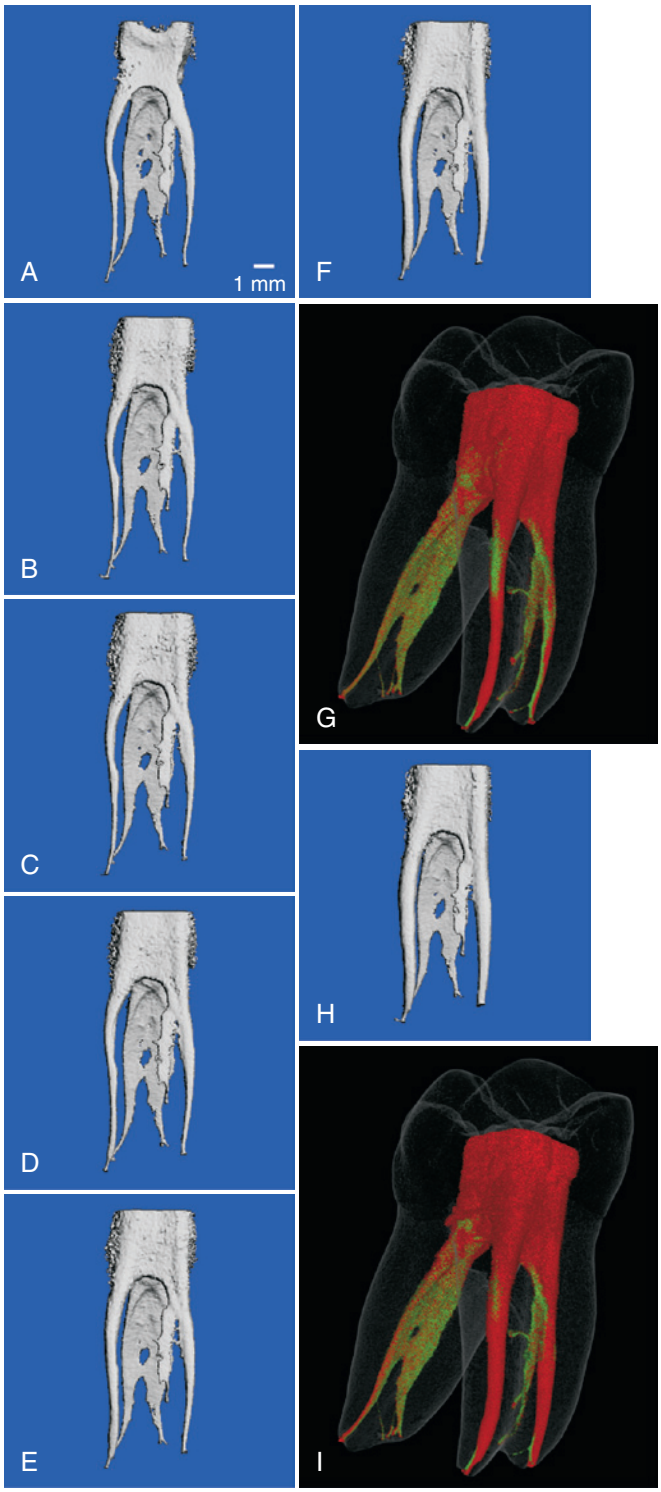

FIG. 6-45 Stepwise enlargement of mesial root canal systems in an extracted mandibular molar demonstrated with microcomputed tomography (μCT) reconstructions. The buccal canal *(left)* was prepared with a LightSpeed (LS) instrument, and the lingual canal *(right)* was shaped with a ProTaper (PT) instrument. **A**, Pretreatment view from the mesial aspect. Note the additional middle canal branching from the lingual canal into the coronal third. **B**, Initial preparation and opening of the orifices, aided by ultrasonically powered instruments. **C**, First step of root canal preparation, up to LightSpeed size #20 and ProTaper shaping file S1. **D**, Further enlargement to LS size #30 and PT shaping file S2. **E**, Apical preparation to LS size #40 and PT finishing file F1. **F**, Additional enlargement to LS size #50 and PT finishing file F2. **G**, Superimposed μCT reconstructions comparing the initial canal geometry *(in green)* with the shape reached after use of the instruments shown in **F**. **H**, Final shape after step-back with LS instruments and PT finishing file F3. **I**, Superimposed μCT reconstructions comparing initial geometry and final shape. Note the slight ledge in the buccal canal after LS preparation and some straightening in the lingual canal after PT preparation.

while registering tactile feedback. The first instrument that experiences resistance 4 mm short of working length is the final apical size; it is then advanced to working length like the smaller instruments before. The next larger instrument is placed to 4 mm short of working length. This prepares the apical 5 mm for a matching SimpliFill obturator (SybronEndo). Midroot shaping is then accomplished with sequentially larger LSX instruments. Finally, the so-called master apical rotary, or MAR, is used to recapitulate to the working length.

All LightSpeed instruments are used in the following way: a slow, continuous apical movement is used until the blade binds; after a momentary pause, the blade is advanced further with intermittent ("pecking") motions.

Technique with the Self-Adjusting File

For this unusual file, a coronal flaring step—for example, with a G—precedes exploration with small K-files, including verification of patency and determining of working length. A glide path to a size #20 is considered appropriate; then the selected self-adjusting file is introduced into the canal with continuous irrigation through the center of the hollow file at a rate of approximately 5 ml/min. This maintains a continuous flow of active irrigant that carries with its outflow tissue debris and the dentin mud generated by the file. One file is used throughout the procedure. It is initially compressed into the root canal and gradually enlarges while cleaning and shaping the canal.

The file can rotate passively around its long axis and is guided by the operator to working length. The file is initially compressed into the root canal and gradually enlarges while cleaning and shaping the canal. The suggested time frame of instrumentation per canal dictates the final size and is approximately 3 to 4 minutes.[60] Obturation may commence with various techniques that allow plastifying gutta-percha (see Chapter 7).

Hybrid Techniques

For some time, combining various NiTi preparation systems have been suggested[89,545] to address certain shortcomings of current instruments (Box 6-4). Although many combinations are possible, the most popular and useful ones involve coronal preenlargement followed by different additional apical preparation sequences. However, clinicians must keep in mind that anatomic variations in each canal must be addressed individually with specific instrument sequences. Most important, oval canals extend deep into the apical area,[505,551,560] and apical foramina may in fact be oval in most cases.[70] Naturally, a rotating file can produce a round canal at best (Fig. 6-47); therefore, a strategy must be devised for adequately shaping oval canals without overly weakening radicular structure (compare Figs. 6-4 and 6-5). One hybrid approach completely prepared 95%

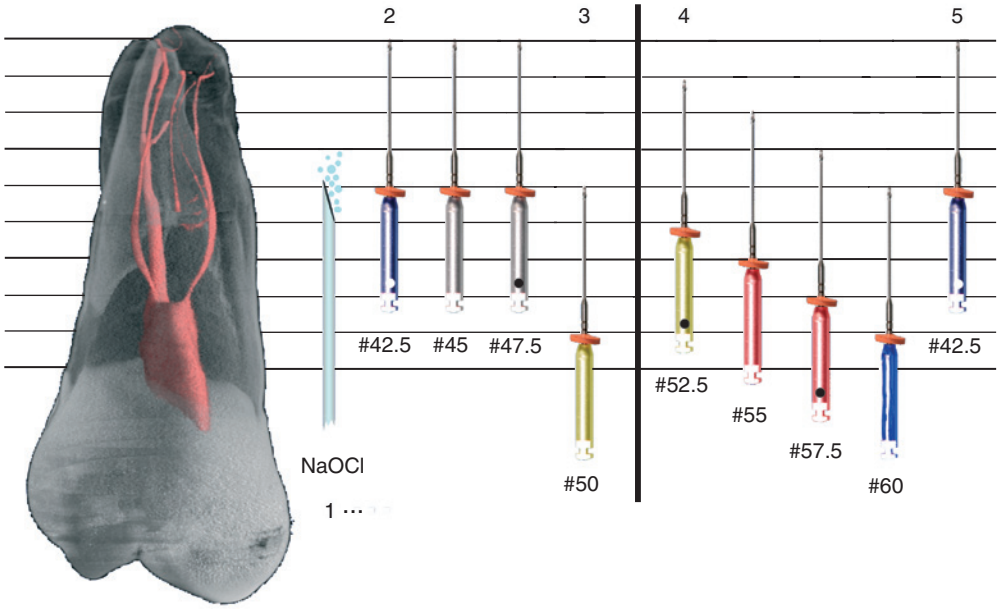

FIG. 6-46 Finishing of LightSpeed preparations to allow obturation. With the canal system flooded *(1)*, apical preparation *(2)* is continued until an LS instrument requires 12 pecks to reach the working length (WL). The next LS instrument *(3)* then is used to a point 4 mm short of the WL to prepare for LightSpeed's SimpliFill obturation system. Alternatively, canals may be flared for other root canal filling techniques by preparing with each subsequent instrument 1 mm shorter *(5)*.

BOX 6-4

Benefits of Using a Combination of Instruments for Endodontic Therapy

- Instruments can be used in a manner that promotes their individual strengths and avoids their weaknesses (most important).
- Hand instruments secure a patent glide path.
- Tapered rotary instruments efficiently enlarge coronal canal areas.
- Less tapered instruments allow additional apical enlargement.

or more of all such canals and resulted in extremely wide apical sizes that may be difficult to achieve with most instrument systems.[255,257,256]

Histologic slides (see Fig. 6-47) and µCT reconstructions show critical areas that were not mechanically prepared despite the use of various individual rotary techniques. The aim of hybridizing NiTi rotary techniques, therefore, is to increase apical size using a fast and safe clinical procedure.

Various clinicians have used this type of hybrid procedure in their practices (see Figs. 6-2 and 6-10). The principle involves the use of a variety of instruments: for example, GG drills and K-files for establishing straight-line access; ProTaper instruments for body shaping and apical preenlargement; NiTi K-files or LightSpeed instruments for apical widening; and various instruments for final smoothing.[545]

After a stainless steel file has confirmed a smooth glide path into the coronal two thirds, irrigation and mechanical preparation with a sequence of ProTaper shaping files opens and preenlarges the apical third (Fig. 6-48). Once the working length has been established, the apical third is flooded with

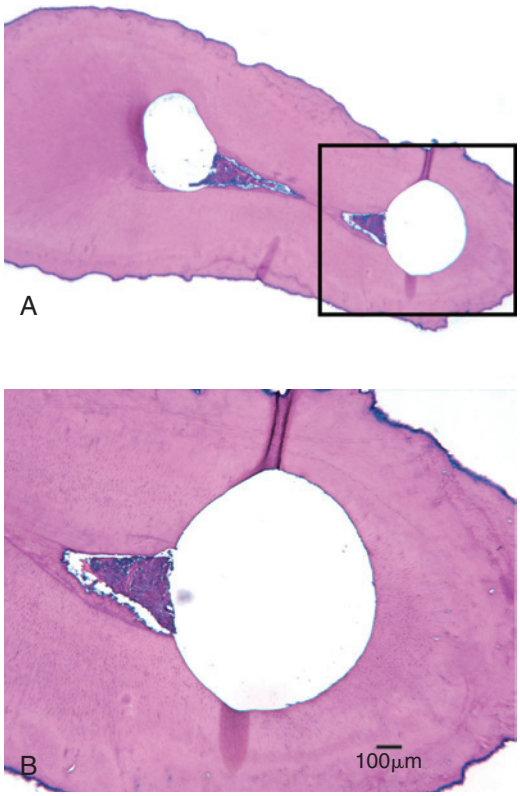

FIG. 6-47 Remaining potentially infected tissue in fins and isthmus configuration after preparation with rotary instruments. **A**, Cross section through a mesial root of a mandibular molar, middle to coronal third of the root. Both canals have been shaped; the left one is transported mesially (×10). **B**, Magnified view of rectangle in **A**. Note the presence of soft tissue in the isthmus area (×63). (Courtesy Professor H. Messer.)

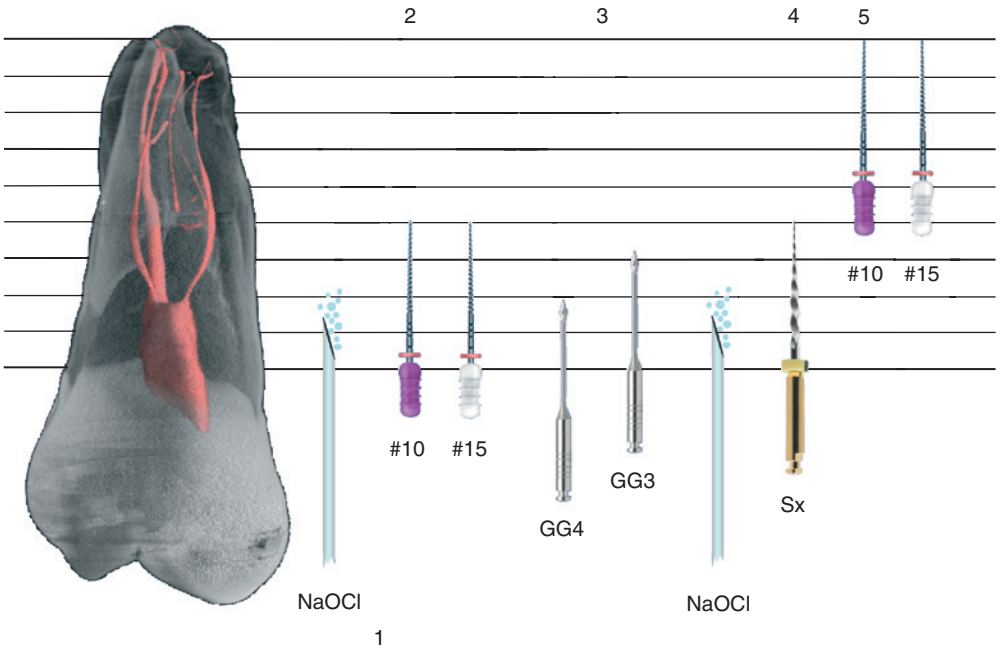

FIG. 6-48 Hybrid technique: Part I. After irrigation *(1)* and scouting *(2)*, GG drills *(3)* or ProTaper SX files *(4)* are used for coronal preenlargement and to secure straight-line access to the middle third. Precurved K-files are then used to explore and determine the working length *(5)*.

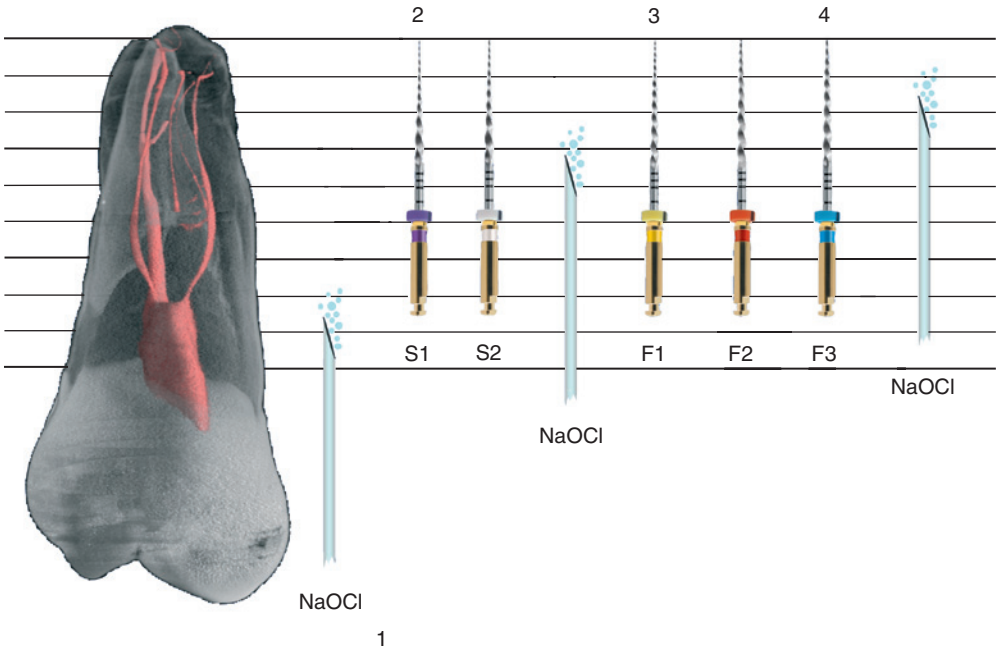

FIG. 6-49 Hybrid technique: Part II. In canal systems flooded with irrigant *(1)*, ProTaper shaping instruments S1 and S2 *(2)* and then finishing instruments F1 and F2 *(3)* are used to preenlarge the apical third, allowing irrigants access to the canals. Finishing instrument F3 may be used if feasible *(4)*.

NaOCl and further enlarged with ProTaper finishing files F1 and F2. The F3 ProTaper finishing file is relatively inflexible, and because of its side-cutting action, it should be used with caution in curved canals (Fig. 6-49). Further enlargement is possible with the F4 and F5 instruments, but these files may not be used in more acutely curved canals. The effectiveness of techniques combining different rotary instruments in enlarging canals recently was documented using superimposed root canal cross sections (Fig. 6-50). This method can help identify insufficiently prepared areas and weakening of the radicular structure.

A different approach, using, for example, NiTi K-files, .02 tapered rotaries (e.g., RaCe), or LightSpeed LSX (Fig. 6-51), may be also advantageous if larger sizes are desired. Finally, the overall shape may be smoothed with either engine-driven or handheld instruments. Handheld ProTaper or GT instruments may aid removal of acute apical curvatures or ledges and provide access to apical canal areas for irrigants.

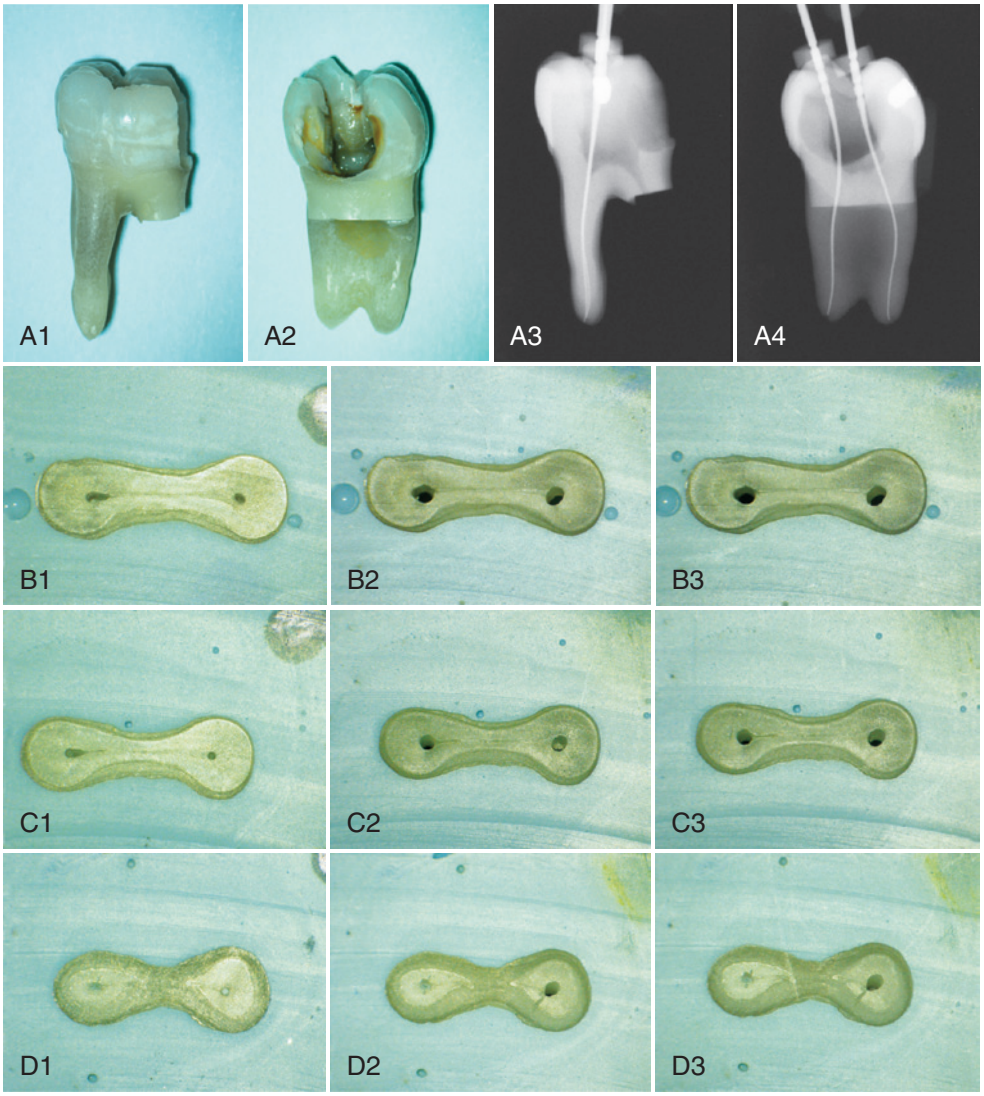

FIG. 6-50 Effect of a hybrid technique on root canal anatomy studied in a Bramante model. **A1-A4**, Both mesial canals of an extracted mandibular molar have been instrumented. Canal cross sections are shown before instrumentation (**B1-D1**). **B2-D2**, Cross sections after preenlargement with a ProTaper F3 file (*left canal*) and a size #45, #.02 taper instrument *(right canal)*. The final apical sizes were LightSpeed (LS) #50 and size #50, #.02 taper in the left and the right canal, respectively. (Courtesy Drs. S. Kuttler, M. Gerala, and R. Perez.)

Some hybrid systems seem to work better than others, but the deciding factors are likely the root canal anatomy and an adequate preparation goal.

Most cases requiring root canal therapy lend themselves to canal preparation with many different systems. Depending on the individual anatomy and the clinician's strategy, various sequences may be used. Mesiobuccal roots of the maxillary molar can show substantial curvature; rotary instrumentation or hybrid techniques allow preservation of the curvature and optimal enlargement. Occasionally hand instruments other than ISO-normed files are used in these cases to ensure a smooth, tapered shape or to eliminate ledges.

Final Apical Enlargement

Conceptually, file sizes during canal preparation were termed *initial apical file, master apical file,* and *final file* (or IAF, MAF, and FF, respectively). The first file to bind, the IAF, is supposed to give clinicians a guide in determining the final size of their canal preparation. On the other hand, many current instrumentation techniques have, due to their design, predefined final sizes—for example, WaveOne shaping aims at final sizes #25 .08 taper and #40, .08 taper.

Whichever apical size was conceptually aimed for, after shaping the overall canal to a tapered form, the apical size at that point should be assessed during apical gauging. K-files or K-Flexofiles are often recommended for this step; the files should be gently moved toward the working length (WL), and the binding point should be noted. The presence of an apical narrowing would translate into the fact that the WL may be reached without shaping effort with the desired size during gauging; however, the next larger size will stay back by a small distance. Finally, it should be verified that patency is maintained.

If apical gauging suggests that the canal is undershaped, additional enlargement is done with any technique appropriate to the specific anatomy of the root canal, often necessitating a hybrid technique.

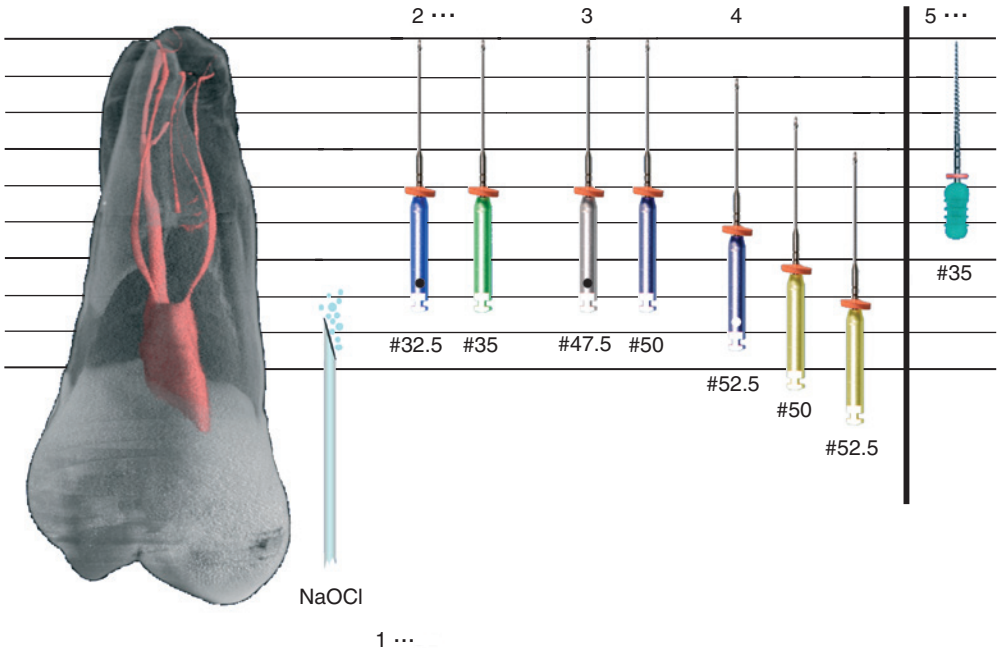

FIG. 6-51 Hybrid technique: Part III. Under irrigation *(1)*, LightSpeed instruments may be used to enlarge substantially (*2* and *3*) and to flare the apical section *(4)*. NiTi hand instruments *(5)* may be used similarly (see text for a more detailed explanation).

DISINFECTION OF THE ROOT CANAL SYSTEM

Hydrodynamics of Irrigation

Irrigation dynamics refers to how irrigants flow, penetrate, and readily exchange within the root canal system as well as the forces they produce. A better understanding of the fluid dynamics of different modes of irrigation will contribute to achieving predictable disinfection of the root canal system. Hence, in endodontic disinfection, the process of delivery is as important as the antibacterial characteristics of the irrigants.[65]

Irrigation is defined as "to wash out a body cavity or wound with water or a medicated fluid" and aspiration as "the process of removing fluids or gases from the body with a suction device." Disinfectant, meanwhile, is defined as "an agent that destroys or inhibits the activity of microorganisms that cause disease."[106]

The objectives of irrigation in endodontics are mechanical, chemical, and biologic. The mechanical and chemical objectives are as follows: (1) flush out debris, (2) lubricate the canal, (3) dissolve organic and inorganic tissue, and (4) prevent the formation of a smear layer during instrumentation or dissolve it once it has formed.[42] The mechanical effectiveness will depend on the ability of irrigation to generate optimum streaming forces within the entire root-canal system. The chemical effectiveness will depend on the concentration of the antimicrobial irrigant, the area of contact, and the duration of interaction between irrigant and infected material.[65] The final efficiency of endodontic disinfection will depend on its chemical and mechanical effectiveness.[190]

The biologic function of irrigants is related to their antimicrobial effects. In principle, irrigants should (1) have a high efficacy against anaerobic and facultative microorganisms in their planktonic state and in biofilms, (2) inactivate endotoxin, and (3) be nontoxic when they come in contact with vital tissues, and (4)b not cause an anaphylactic reaction.[42]

Efficiency of root canal irrigation in terms of debris removal and eradication of bacteria depends on several factors: penetration depth of the needle, diameter of the root canal, inner and outer diameter of the needle, irrigation pressure, viscosity of the irrigant, velocity of the irrigant at the needle tip, and type and orientation of the needle bevel (Fig. 6-52).

Penetration Depth of the Needle

The size and length of the irrigation needle—in relation to root canal dimensions—is of utmost importance for the effectiveness of irrigation.

Diameter of the Root Canal

The apical diameter of the canal has an impact on needle penetration depth (see earlier in this chapter for details regarding apical preparation size (see Fig. 6-7, Table 6-2).[72,578]

Inner and Outer Diameter of the Needle (Fig. 6-53, *A* and *B*)

The external needle diameter is of relevance for the depth of introduction into the root canal and for rigidity of the tip, an important consideration for irrigation of curved canals. Common 27 gauge injection needles have an external diameter of 0.42 mm, but smaller irrigation tips with external diameters of 0.32 mm (30 gauge) are available.[235] The Stropko Flexi-Tip (30 gauge) needle is fabricated from nickel-titanium to improve penetration into curved root canals.[205]

Irrigation Pressure

The internal diameter determines the pressure necessary for moving the syringe plunger. The speed of the plunger

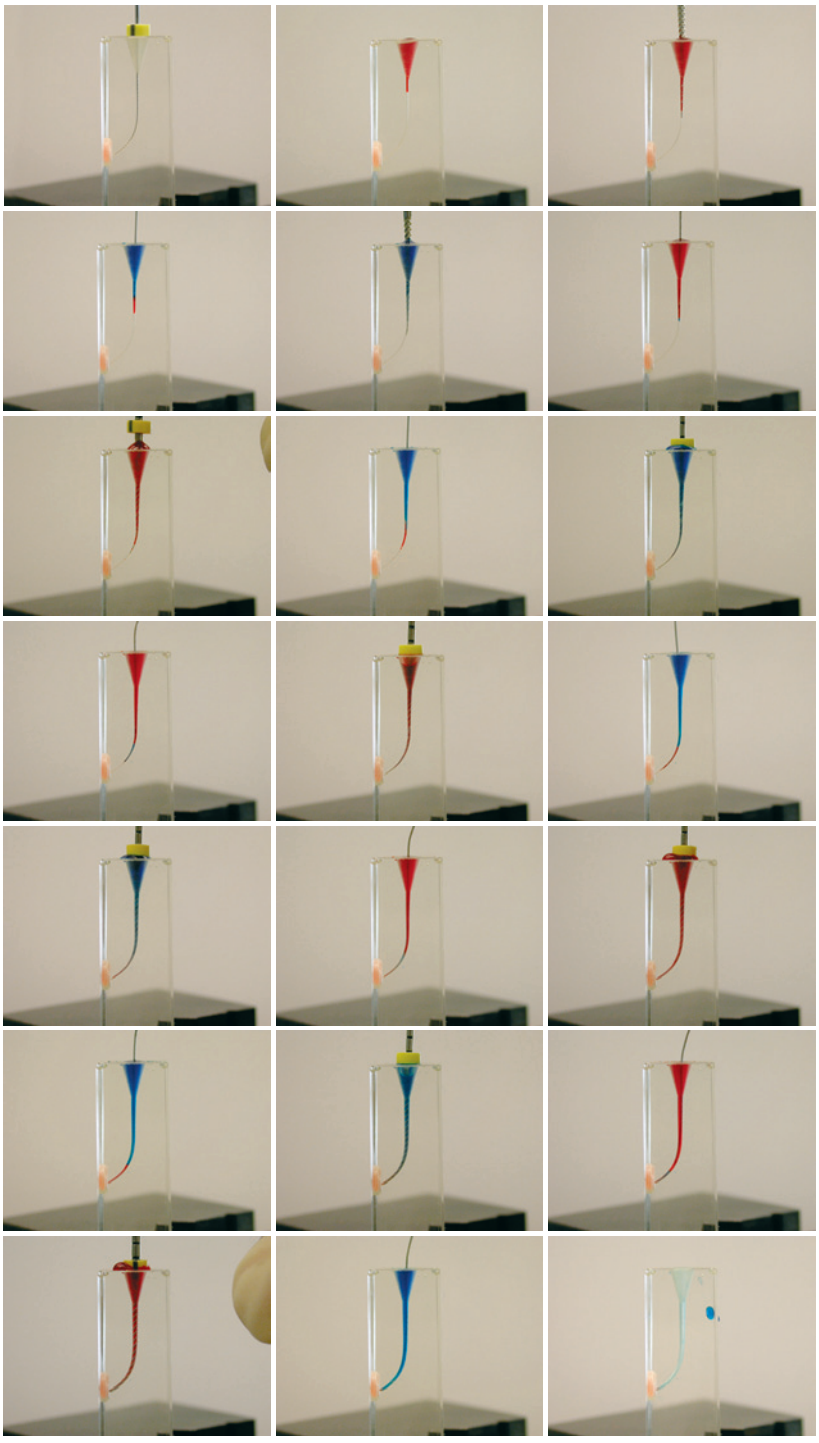

FIG. 6-52 Irrigation and movement of irrigants depends on canal shape. Sequential enlargement of a canal in clear plastic block was performed with a sequence of ProFile instruments in accordance with the manufacturer's recommendations. Alternating irrigation with blue and red fluid was done after each preparation step. Note the apical presence of irrigant after sufficient shape has been provided. Note the distribution of fluid immediately after irrigation with a 30-gauge needle.

determines the velocity with which the irrigant is extruded. Narrow needles require more pressure onto the plunger and extrude the irrigant with higher velocity than large needle sizes, which extrude greater amounts of irrigants but cannot be introduced as deep.

Type and Orientation of the Bevel of the Needle

To improve safety of irrigation and prevent extrusion of the irrigant through the apical foramen, some needles release the solution via lateral openings and have a closed, safe-ended tip. The orientation of the bevel is crucial to produce a turbulence effect on the dentinal wall of the canal. Side-vented and double side-vented needles lead to maximum shear stress concentrated on the wall facing the outlet (the proximal outlet for the double side-vented).[67]

Irrigants

An optimal irrigant would have all of the characteristics considered beneficial in endodontics but none of the negative or harmful properties. Presently, no solution can be regarded

BOX 6-5

Benefits of Using Irrigants in Root Canal Treatment

- Removal of particulate debris and wetting of the canal walls
- Destruction of microorganisms
- Dissolution of organic debris
- Opening of dentinal tubules by removal of the smear layer
- Disinfection and cleaning of areas inaccessible to endodontic instruments

BOX 6-6

Properties of an Ideal Irrigant for Root Canal Treatment

An ideal irrigant should do the following:

- Be an effective germicide and fungicide
- Be nonirritating to the periapical tissues
- Remain stable in solution
- Have a prolonged antimicrobial effect
- Be active in the presence of blood, serum, and protein derivatives of tissue
- Have low surface tension
- Not interfere with repair of periapical tissues
- Not stain tooth structure
- Be capable of inactivation in a culture medium
- Not induce a cell-mediated immune response
- Be able to completely remove the smear layer, and be able to disinfect the underlying dentin and its tubules
- Be nonantigenic, nontoxic, and noncarcinogenic to tissue cells surrounding the tooth
- Have no adverse effects on the physical properties of exposed dentin
- Have no adverse effects on the sealing ability of filling materials
- Have a convenient application
- Be relatively inexpensive

as optimal. However, combined use of selected irrigation products greatly contribute to successful outcome of treatment (Box 6-5 and Box 6-6).

Sodium Hypochlorite

NaOCl is the most commonly used irrigating solution[332] because of its an antibacterial capacity and the ability to dissolve necrotic tissue, vital pulp tissue, and the organic components of dentin and biofilms in a fast manner.[453]

NaOCl solution is frequently used as a disinfectant or a bleaching agent. It is the irrigant of choice in endodontics, owing to its efficacy against pathogenic organisms and pulp digestion, and satisfies most of the preferred characteristics stated earlier.[332]

History

Hypochlorite was first produced in 1789 in France. Hypochlorite solution was used as a hospital antiseptic that was sold under the trade names Eusol and Dakin's solution. Dakin recommended NaOCl as a buffered 0.5% solution for the irrigation of wounds during World War I.[114] Coolidge[108] later introduced NaOCl to endodontics an intracanal irrigation solution.[575]

Mode of Action

When sodium hypochlorite contacts tissue proteins, nitrogen, formaldehyde, and acetaldehyde are formed. Peptide links are fragmented and proteins disintegrate, permitting hydrogen in the amino groups (-NH-) to be replaced by chlorine (-NCl-) forming chloramines; this plays an important role for the antimicrobial effectiveness. Necrotic tissue and pus are dissolved and the antimicrobial agent can better reach and clean the infected areas.

In 2002 Estrela reported that sodium hypochlorite exhibits a dynamic balance (Fig. 6-54)[142]:

1. Saponification reaction: Sodium hypochlorite acts as an organic and fat solvent that degrades fatty acids and transforms them into fatty acid salts (soap) and glycerol (alcohol), reducing the surface tension of the remaining solution.
2. Neutralization reaction: Sodium hypochlorite neutralizes amino acids by forming water and salt. With the exit of hydroxyl ions, the pH is reduced.
3. Hypochlorous acid formation: When chlorine dissolves in water and it is in contact with organic matter, it forms

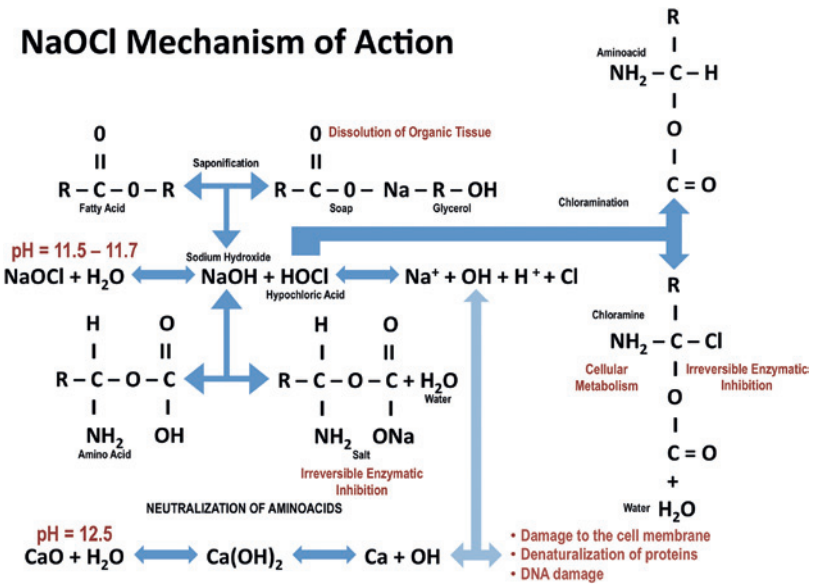

FIG. 6-54 Schematic diagram of the mechanism of action of NaOCl with the main interactions and properties highlighted. (Courtesy Dr. A. Manzur.)

hypochlorous acid. It is a weak acid with the chemical formula HClO that acts as an oxidizer. Hypochlorous acid ($HOCl^-$) and hypochlorite ions (OCl^-) lead to amino acid degradation and hydrolysis.

4. Solvent action: Sodium hypochlorite also acts as a solvent, releasing chlorine that combines with protein amino groups (NH) to form chloramines (chloramination reaction). Chloramines impede cell metabolism; chlorine is a strong oxidant and inhibits essential bacterial enzymes by irreversible oxidation of SH groups (sulfydryl group).[142]
5. High pH: Sodium hypochlorite is a strong base (pH > 11). The antimicrobial effectiveness of sodium hypochlorite, based on its high pH (hydroxyl ions action), is similar to the mechanism of action of calcium hydroxide. The high pH interferes in cytoplasmic membrane integrity due to irreversible enzymatic inhibition, biosynthetic alterations in cellular metabolism, and phospholipid degradation observed in lipidic peroxidation.[142]

Allergic Reactions to Sodium Hypochlorite

Although few reports have been published on allergic reactions to NaOCl,[144,198] real allergies to NaOCl are unlikely to occur, as both Na and Cl are essential elements in the physiology of the human body. It must be remembered that the hypochlorous acid (active component of the sodium hypochlorite) is a chemical substance that is elaborated by neutrophils in the process of phagocytosis; it may create local tissue damage when it is produced in excess (liquefaction necrosis: purulent exudate) but does not cause allergic responses. Nevertheless, hypersensitivity and contact dermatitis may occur in rare situations. A case report describes a serious chemical burn in an endodontist's eye caused by accidental contact with 3.5% NaOCl used as an irrigant during root canal.[403]

When hypersensitivity to NaOCl is suspected or confirmed, chlorhexidine should not be used either because of its chlorine content. For individuals who genetically have more possibilities than the normal population to generate allergies to multiple elements (allergies to food or to latex), a skin test

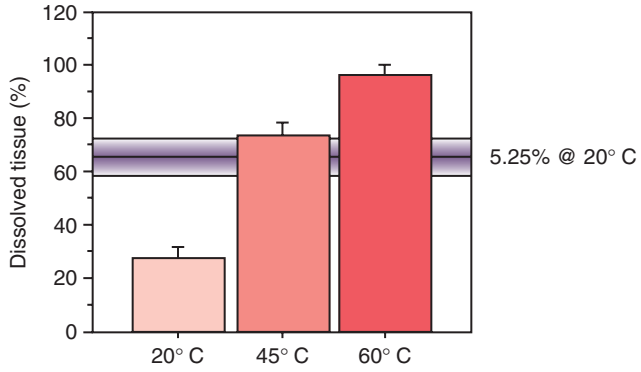

FIG. 6-55 Effect of heating on the ability of 0.5% sodium hypochlorite (NaOCl) to dissolve pulp tissue: NaOCl heated to 113° F (45° C) dissolved pulp tissue as well as the positive control (5.25% NaOCl) did. When the NaOCl was heated to 140° F (60° C), almost complete dissolution of tissue resulted. (Modified from Sirtes G, Waltimo T, Schaetzle M, Zehnder M: The effects of temperature on sodium hypochlorite short-term stability, pulp dissolution capacity, and antimicrobial efficacy, *J Endod* 31:669, 2005.)

for both NaOCl and CHX may be indicated. The use of an alternative irrigant with high antimicrobial efficacy, such as iodine potassium iodide, should be considered, assuming there is no known allergy to that irrigant. Solutions such as alcohol or tap water are less effective against microorganisms and do not dissolve vital or necrotic tissue; however, $Ca(OH)_2$ could be used as a temporary medicament because it dissolves both vital and necrotic tissue.[18,207]

Temperature

Increasing the temperature of low-concentration NaOCl solutions improves their immediate tissue-dissolution capacity (Fig. 6-55).[575] Furthermore, heated hypochlorite solutions remove organic debris from dentin shavings more efficiently. Bactericidal rates for NaOCl solutions, the capacity of human pulp dissolution, and increased efficacy were detailed in several

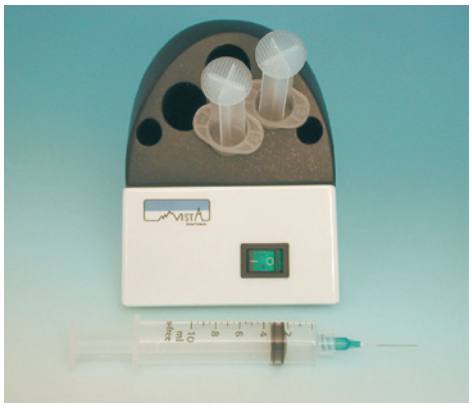

FIG. 6-56 Device for heating syringes filled with irrigation solution (e.g., sodium hypochlorite) before use. (Courtesy Vista Dental Products, Racine, WI.)

studies.[475] There are various devices to preheat NaOCl syringes (Fig. 6-56); however, it was demonstrated that as soon as the irrigant touches the root canal system, the temperature reaches the body temperature.[579] Therefore, some authors recommend in situ heating of NaOCl. This can be done by activating ultrasonic or sonic tips to the NaOCl inside the root canal for a couple of minutes (see irrigation timings, discussed later). Macedo and colleagues stated that the efficacy of NaOCl on dentin is improved by refreshment, ultrasonic activation, and exposure time.[307] In this investigation, a 10° C temperature rise during ultrasonic activation was insufficient to increase the reaction rate. However, no clinical studies are available at this point to support the use of heated NaOCl.[42,104]

Concentrations

NaOCl is used in concentrations between 0.5% and 6% for root canal irrigation. Controversy exists over recommended concentrations of sodium hypochlorite during root canal treatment. Some in vitro studies have shown that NaOCl in higher concentrations is more effective against *Enterococcus faecalis* and *Candida albicans*.[177,395,547] In contrast, clinical studies have indicated both low and high concentrations to be equally effective in reducing bacteria from the root canal system.[87,111] NaOCl in higher concentrations has a better tissue-dissolving ability.[204] However, in lower concentrations when used in high volumes it can be equally effective.[336,470] Higher concentrations of NaOCl are more toxic than lower concentrations.[491] However, due to the confined anatomy of the root canal system, higher concentrations have successfully been used during root canal treatment, with a low incidence of mishaps.

In summary, if lower concentrations are to be used for intracanal irrigation, it is recommended that the solution be used in higher volume and in more frequent intervals to compensate for the limitations in effectiveness.[470]

Instrumentation coupled with an antimicrobial irrigant, such as NaOCl, has been shown to yield more negative cultures than instrumentation alone.[86,323,364,372,463] However, even with the use of NaOCl, removal of bacteria from the root canal systems following instrumentation remains an elusive goal.

Grossman observed pulp tissue dissolution capacity and reported that 5% sodium hypochlorite dissolved this tissue in between 20 minutes and 2 hours.[185] The dissolution of bovine pulp tissue by sodium hypochlorite (0.5, 1.0, 2.5, and 5.0%) was studied in vitro under different conditions.[142] The study yielded the following conclusions:

1. The velocity of dissolution of the bovine pulp fragments was directly proportional to the concentration of the sodium hypochlorite solution and was greater without the surfactant;
2. variations in surface tension, from beginning to end of pulp dissolution, were directly proportional to the concentration of the sodium hypochlorite solution and greater in the solutions without surfactant. Solutions without surfactant presented a decrease in surface tension and those with surfactant an increase;
3. in heated sodium hypochlorite solutions, dissolution of the bovine pulp tissue was more rapid;
4. the greater the initial concentration of the sodium hypochlorite solutions, the smaller was the reduction of its pH.[142]

Time

There is conflicting evidence regarding the time course of the antibacterial effect of NaOCl.[42,195] In some articles hypochlorite is reported to kill the target microorganism in seconds, even at low concentrations, whereas other reports have published considerably longer times for the killing of the same species.[185] Such differences are likely a result of several factors: the presence of organic matter during experiments has a detrimental effect on the antibacterial activity of NaOCl. Haapasalo and colleagues showed that the presence of dentin caused marked delays in the killing of *Enterococus faecalis* by 1% NaOCl.[193] Morgental and colleagues reported similar findings.[337]

Many of the earlier studies were performed in the presence of an unknown amount of organic matter. When such confounding factors are eliminated, it has been shown that NaOCl kills the target microorganisms rapidly even at low concentrations of less than 0.1%.[195,539] However, in vivo the presence of organic matter (inflammatory exudate, tissue remnants, and microbial biomass) consumes NaOCl and weakens its effect. Therefore, continuous replenishing of irrigation solution and allowing sufficient contact time are important factors for the effectiveness of NaOCl.[195]

The chlorine ion, which is responsible for the dissolving and antibacterial capacity of NaOCl, is unstable and consumed rapidly during the first phase of tissue dissolution, probably within 2 minutes,[336] which provides another reason for continuous replenishment. This should especially be considered in view of the fact that rotary root canal preparation techniques have expedited the shaping process. The optimal time that a hypochlorite irrigant at a given concentration needs to remain in the canal system is an issue yet to be resolved.[575]

Toxicity

If inadvertently NaOCl is extruded through the apex, severe accidents may occur (Fig. 6-57, A-C). It is important to recognize the symptoms and act accordingly. After an accident with NaOCl, the following can be expected: severe pain, edema of neighboring soft tissues, possible extension of edema over the injured half of face and upper lip, profuse bleeding from root canal, profuse interstitial bleeding with hemorrhage of skin and mucosa (ecchymosis), chlorine taste and irritation of throat after injection into maxillary sinus, secondary infection possible, and reversible anesthesia or paresthesia is possible. To manage these lesions, the clinician should inform the patient and control pain with local anesthesia and analgesics.

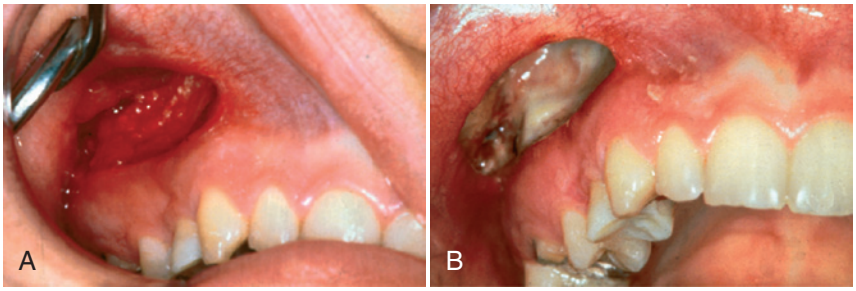

FIG. 6-57 Toxic effect of sodium hypochlorite on periradicular tissues. After root canal treatment of tooth #3, the patient reported pain. A, On a return visit, an abscess was diagnosed and incised. B, Osteonecrosis was evident after 3 weeks.

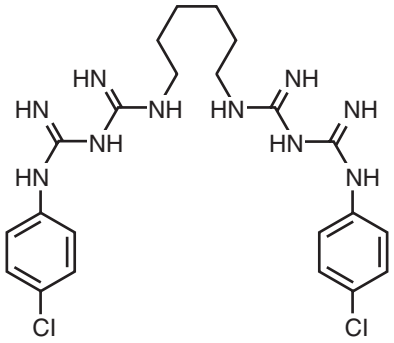

FIG. 6-58 Schematic drawing of the chlorhexidine molecule.

The application of extraoral cold compresses to reduce swelling is also effective. After 1 day, warm compresses and frequent warm mouth rinses for stimulation of local systemic circulation should be used. Patients should be recalled daily to monitor recovery. The use of antibiotics is not obligatory and is recommended only in cases of high risk or evidence of secondary infection. The administration of antihistamine is also not obligatory, and the use of corticosteroids is controversial. Further endodontic therapy with sterile saline or chlorhexidine as root canal irrigants and referral to a hospital in case of worsening symptoms were suggested.[260]

Chlorhexidine

History

Chlorhexidine (CHX) was developed in the UK and first marketed as an antiseptic cream.[148] It has been used for general disinfection purposes and the treatment of skin, eye, and throat infections in both humans and animals.[148,294] It has been used as an irrigant and medicament in endodontics for more than a decade.[309,333,363]

Molecular Structure

CHX is a strongly basic molecule with a pH between 5.5 and 7 that belongs to the polybiguanide group and consists of two symmetric four-chlorophenyl rings and two bisbiguanide groups connected by a central hexamethylene chain. CHX digluconate salt is easily soluble in water and very stable[184] (Fig. 6-58).

Mode of Action

Chlorhexidine, because of its cationic charges, is capable of electrostatically binding to the negatively charged surfaces of bacteria,[117] damaging the outer layers of the cell wall and rendering it permeable.[214,229,228] CHX is a wide-spectrum antimicrobial agent, active against gram-positive, gram-negative bacteria and yeasts.[129]

Depending on its concentration, CHX can have both bacteriostatic and bactericidal effects. At high concentrations, CHX acts as a detergent; and exerts its bactericidal effect by damaging the cell membrane and causes precipitation of the cytoplasm. At low concentrations, CHX is bacteriostatic, causing low molecular-weight substances (i.e., potassium and phosphorus) to leak out without the cell being permanently damaged.[43]

Substantivity

Because of the cationic nature of the CHX molecule, it can be absorbed by anionic substrates such as the oral mucosa and tooth structure.[308,312,414,527] CHX is readily adsorbed onto hydroxyapatite and teeth. Studies have shown that the uptake of CHX onto teeth is reversible.[222] This reversible reaction of uptake and release of CHX leads to substantive antimicrobial activity and is referred to as *substantivity*. This effect depends on the concentration of CHX. At low concentrations of 0.005% to 0.01%, only a constant monolayer of CHX is adsorbed on the tooth surface, but at higher concentrations (>0.02%), a multilayer of CHX is formed on the surface, providing a reservoir of CHX that can rapidly release the excess into the environment as the concentration of CHX in the surrounding environment decreases.[139] Time and concentration of CHX can influence the antibacterial substantivity, and the conclusions are inconsistent. Some studies demonstrated that 4% CHX has greater antibacterial substantivity than 0.2% after a 5-minute application.[333] Other studies stated that CHX should be left for more than 1 hour in the canal to be adsorbed by the dentin.[291] Komorowski and colleagues suggested that a 5-minute application of CHX did not induce substantivity, so dentin should be treated with CHX for 7 days.[265] However, when Paquette and Malkhassian,[364] in their in vivo study, medicated the canals with either liquid or gel forms of CHX for 1 week, neither of them could achieve total disinfection. Therefore, residual antimicrobial efficacy of CHX in vivo still remains to be demonstrated.

Cytotoxicity

CHX is normally used at concentrations between 0.12% and 2%. Löe and colleagues[294] demonstrated that at these concentrations, CHX has a low level of tissue toxicity, both locally and systemically. When 2% CHX was used as a subgingival irrigant, no apparent toxicity was noted on gingival tissues.[295,488] Additionally, CHX rinses have been suggested to promote healing

of periodontal wounds after surgery.[24] These reports were the basis of many studies that assumed that CHX will be tolerated on periapical tissues with a similar response than in the gingival tissues.[245] When compared CHX and NaOCl into subcutaneous tissues of guinea pigs and rats, an inflammatory reaction developed; however, the toxic reaction from CHX was less than that of NaOCl.[352,571] Moreover, a reduced incidence of alveolar osteitis was found when CHX was applied as a rinse in the extraction sites of the third molars on the day of surgery and several days after.[91] Allergic and anaphylactic reactions to CHX were reported in only a few articles.[166,351] It is important to mention that patients that are allergic to NaOCl may be also allergic to CHX.

On the other hand, some controversial results were found. Some studies demonstrated that CHX is cytotoxic to some lines of cultured human skin fibroblasts.[219] It has been reported that CHX has a higher cytotoxicity profile than povidone iodine when studied in osteoblastic human alveolar bone.[88] Also, when CHX was injected in the hind paw of mice, it could induce severe toxic reactions.[149]

Finally, when CHX is mixed with NaOCl, parachloroaniline (PCA) is formed.[46] The toxicity level of CHX on periapical tissues when applied in the root canals, especially with other irrigants, merits further investigation.

Chlorhexidine as an Endodontic Irrigant

CHX has been extensively studied as an endodontic irrigant and intracanal medication, both in vivo[35,292,311,364,564] and in vitro.[41,44,45,141,245,265,273,281,282,469,471,506,540,574]

The antibacterial efficacy of CHX as an irrigant is concentration dependent. It has been demonstrated that 2% CHX has a better antibacterial efficacy than 0.12% CHX in vitro.[45] When comparing with the effectiveness with NaOCl, controversial results can be found. NaOCl has an obvious advantage over CHX with the dissolution capacity of organic matter that CHX lacks; therefore, even though in vitro studies suggest some advantages with the use of CHX, as soon as organic and dental tissue is added, NaOCl is clearly preferable.

The antibacterial effectiveness of CHX in infected root canals has been investigated in several in vivo studies. Investigators reported that 2.5% NaOCl was significantly more effective than 0.2% CHX when the infected root canals were irrigated for 30 minutes with either of the solutions.[409]

In a controlled and randomized clinical trial, the efficacy of 2% CHX liquid was tested against saline using culture technique. All the teeth were initially instrumented and irrigated using 1% NaOCl. Then either 2% CHX liquid or saline was applied as a final rinse. The authors reported a further reduction in the proportion of positive cultures in the CHX group. Their results showed a better disinfection of the root canals using CHX compared to saline as a final rinse.[574]

The antibacterial efficacy of 2% CHX gel was tested against 2.5% NaOCl in teeth with apical periodontitis, with the bacterial load assessed using a real-time quantitative polymerase chain reaction (RTQ-PCR) and colony forming units (CFUs). The bacterial reduction in the NaOCl group was significantly greater than that for the CHX group when measured by RTQ-PCR. Based on culture technique, bacterial growth was detected in 50% of the CHX group cases compared to 25% in the NaOCl group.[540] On the other hand, another study based on this culture technique revealed no significant difference between the antibacterial efficacy of 2.5% NaOCl and 0.12% CHX liquid when used as irrigants during the treatment of infected canals.[469,471]

In a systematic review, Ng and colleagues demonstrated that abstaining from using 2% CHX as an adjunct irrigant to NaOCl was associated with superior periapical healing.[345] Unlike NaOCl, CHX lacks a tissue-dissolving property. Therefore, NaOCl is still considered the primary irrigating solution in endodontics.

Chlorhexidine as an Intracanal Medication

CHX as intracanal medication has been the focus of many in vitro[38,128,265,281,468] CHX used as intracanal medicament has at least as good or even better antimicrobial efficacy than $Ca(OH)_2$.[468] and it was shown to be very effective in eliminating a biofilm of *E. faecalis*.[288]

When in vivo studies are analyzed,[35,115,123,140,292,311,364,580] some controversial results were found. On one hand, CHX, inhibits experimentally induced inflammatory external root resorption when applied for 4 weeks.[292] In infected root canals, it was shown to reduce bacteria as effectively as $Ca(OH)_2$ when applied for 1 week.[34] Because of its substantivity, CHX has the potential to prevent bacterial colonization of root canal walls for prolonged periods of time.[245,265] It was demonstrated that its effect depended on the concentration of CHX but not on its mode of application, which may be as a liquid or gel.[44]

In vivo, results can be different; one of the reasons for this is that researchers[193] developed an experimental model using dentin powder particles to investigate the possible inactivation of some antibacterial medicaments when they come in contact with dentin. They showed that dentin powder had inhibitory effects on all medicaments tested. The effect was dependent on the concentration of the medicament and the duration of contact. The effect of $Ca(OH)_2$ was totally abolished by the presence of dentin powder. The effect of 0.05% CHX and 1% NaOCl was reduced but not totally eliminated by the presence of dentin. No inhibition could be measured when full-strength solutions of CHX and IKI were used.

An in vivo investigation assessed the antibacterial efficacy of three different intracanal medications: camphorated paramonochlorophenol, $Ca(OH)_2$, and 0.12% CHX liquid by applying them for 1 week in single-rooted teeth of patients with apical periodontitis. The proportions of positive cultures were not significantly different among the tested medications, but they were slightly lower in teeth medicated with CHX (0.12%) liquid than those medicated with camphorated paramonochlorophenol or $Ca(OH)_2$.[35] Another in vivo study evaluated antibacterial effectiveness of 2% CHX liquid as an intracanal medication in teeth with apical periodontitis. The authors concluded that a moderate increase in bacterial counts during a medication period of 7 to 14 days that was similar to outcomes seen and reported for $Ca(OH)_2$ by Peters and colleagues.[364, 372] On the other hand, an alternative investigation[311] demonstrated no significant differences among the medication groups. Intracanal medication with $Ca(OH)_2$, 2% CHX gel, or a mixture of $Ca(OH)_2$/CHX applied for 7 days did not reduce the bacterial concentration beyond what was achieved after chemomechanical preparation using 1% NaOCl. Other research showed that a final rinse with MTAD and medication with 2%CHX gel, did not reduce bacterial counts beyond levels achieved by a chemomechanical preparation using NaOCl.[310]

Chlorhexidine Mixed with Calcium Hydroxide

To enhance the properties of both CHX and $Ca(OH)_2$, their combination was analyzed in several in vitro and in vivo studies. The high pH of $Ca(OH)_2$ was unaffected when combined with CHX.[46] However, the results have not been conclusive. Some in vitro studies have reported an improved antibacterial action when both agents were combined,[45,145,575] whereas other studies reported contradictory results.[199]

The combination of CHX and $Ca(OH)_2$ showed good antimicrobial properties when tested in animal studies.[480] When studied in vivo in patients with apical periodontitis, the results showed similar antibacterial efficacy of each medicament alone or in combination.[311] In another clinical study, when 0.12% CHX was used during cleaning and shaping and an intracanal medication with $Ca(OH)_2$/0.12% CHX was left in the canals for 7 days, it was found that using 0.12% CHX solution as an irrigant significantly reduced the number of intracanal bacteria, but it failed to render the canals bacteria free.[465] Therefore, it seems that the usefulness of mixing $Ca(OH)_2$ with CHX remains controversial.

Chlorhexidine and Coronal Penetration of Bacteria

Several studies analyzed the property of antibacterial substantivity and bacterial penetration.[178] It was demonstrated that placement of intracanal medication delays bacterial penetration because of the physical barrier alongside the antibacterial action of the medicament. Gomes and colleagues,[178] in a laboratory study, investigated the time required for recontamination of the root canal system of teeth with coronal restorations medicated with $Ca(OH)_2$, 2% CHX gel, or a combination of both and concluded that if medication is present, retardation of microorganism invasion was seen. Overall, because of its substantivity, CHX as an intracanal medicament/irrigant may delay the coronal recontamination of the root canal system, but more in vivo studies are needed to corroborate these results.

Interaction between CHX, NaOCl, and EDTA

NaOCl and CHX when in contact produce a change of color and a precipitate (Fig. 6-59, *A* and *B*). The reaction is dependent of the concentration of NaOCl. The higher the concentration of NaOCl, the more precipitate is generated in the presence of 2% CHX.[46] Furthermore, concerns have been raised that the color change may have some clinical relevance because of staining, and the resulting precipitate might interfere with the seal of the root obturation. Basrani and colleagues evaluated the chemical nature of this precipitate and reported the formation of 4-chloroaniline (PCA).[46] Furthermore, a study using time-of-flight secondary ion mass spectrometry (TOF-SIMS) analysis shows the penetration of PCA inside dentinal tubules. PCA has been shown to be toxic in humans with short-term exposure, resulting in cyanosis, which is a manifestation of methemoglobin formation. The combination of NaOCl and CHX causes color changes and formation of a possibly toxic insoluble precipitate that may interfere with the seal of the root obturation. Alternatively, the canal can be dried using paper points before the final CHX rinse.[575]

The combination of CHX and EDTA produces a white precipitate, so a group of investigators [399] did a study to determine whether the precipitate involves the chemical degradation of CHX. The precipitate was produced and redissolved in a known amount of dilute trifluoroacetic acid. Based on the results, CHX was found to form a salt with EDTA rather than undergoing a chemical reaction.

Chlorhexidine and Dentin Bonding

Researchers evaluated the effect of CHX on resin-dentin bond stability ex vivo.[90] They concluded that autodegradation of collagen matrices can occur in resin-infiltrated dentin, but this may be prevented by the application of a synthetic protease inhibitor such as CHX.[90] Because of its broad-spectrum matrix metalloproteinase (MMP)-inhibitory effect, CHX may significantly improve resin-dentin bond stability.[90]

Allergic Reactions to Chlorhexidine

Allergic responses to CHX are rare, and there are no reports of reactions following root canal irrigation with CHX.[27,235] Several studies have reported the sensitization rate to be approximately 2%.[268] However, some allergic reactions such as anaphylaxis, contact dermatitis, and urticaria have been reported following direct contact to mucosal tissue or open wounds.[134,388,451,479]

Decalcifying Agents

Debris is defined as dentin chips or residual vital or necrotic pulp tissue attached to the root canal wall. Smear layer was defined by the American Association of Endodontists in 2003 as a surface film of debris retained on dentin or another surface after instrumentation with either rotary instruments or endodontic files; it consists of dentin particles, remnants of vital or necrotic pulp tissue, bacterial components, and retained irrigants. Although it has been viewed as an impediment to irrigant penetration into dentinal tubules (Fig. 6-60), there is

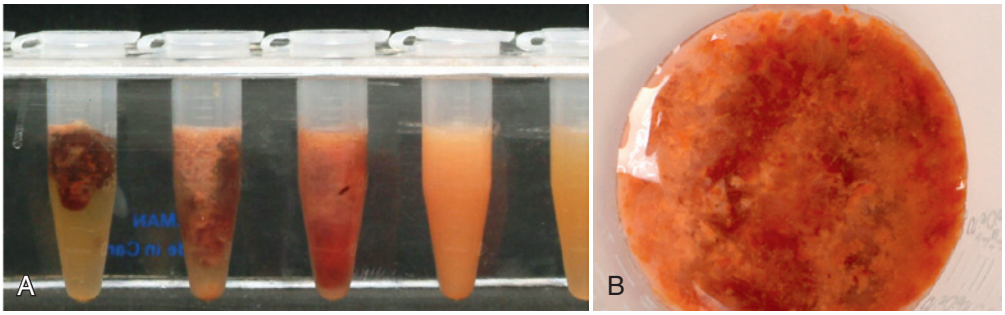

FIG. 6-59 Red precipitate forming after contact between NaOCl and chlorhexidine. **A**, When 2% CHX is mixed with different concentration of NaOCl, a change of color and precipitate occurs. The higher the concentration of NaOCl, the larger is the precipitate formation. **B**, Detail of the interaction between 2% CHX and 5%NaOCl.

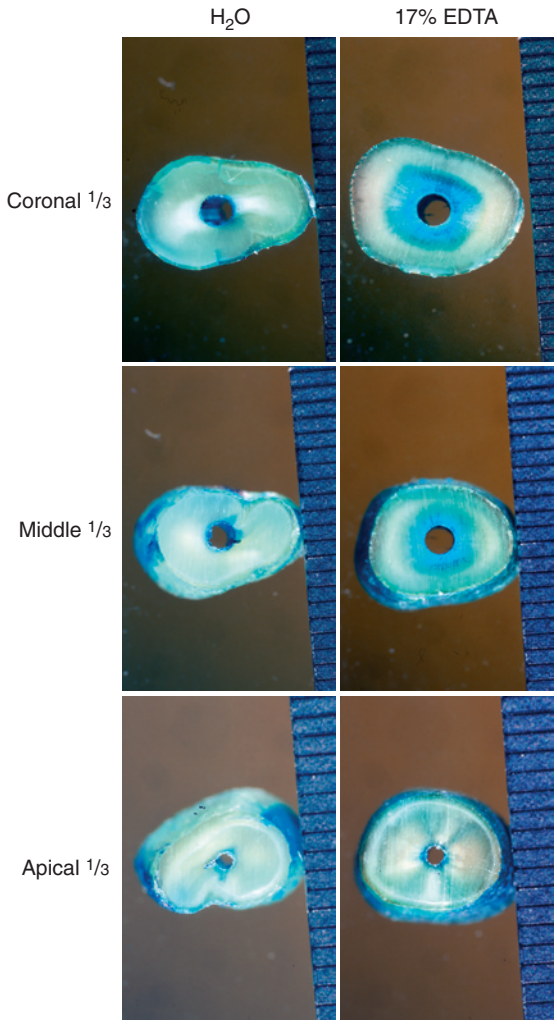

FIG. 6-60 Penetration of irrigants into dentinal tubules after root canal preparation with different dentin pretreatments. *Left column,* Irrigation with tap water and then with blue dye. *Right column,* Smear layer is removed with 17% EDTA, applied in high volume and with a 30-gauge needle, followed by irrigation with blue dye. Note the comparable diffusion of dye in the apical sections, whereas dye penetrated deeper into the dentin in the two coronal sections.

still a controversy about the influence of smear layer on the outcome of endodontic treatment. Some researchers emphasize the importance on removing the smear layer to allow irrigants, medications, and sealers to penetrate dentinal tubules and improve disinfection. On the other hand, other researchers focused on keeping the smear layer as a protection for bacterial invasion, apical and coronal micro leakage, bacterial penetration of the tubules, and the adaptation of root canal materials. The majority of the conclusions on smear layer are based on in vitro studies. A clinical study by Ng and colleagues[345] found that the use of EDTA significantly increased the odds of success of retreatment cases twofold.

Ethylenediamine Tetra-Acetic Acid

Ethylenediamine tetra-acetic acid, widely abbreviated as EDTA, is an aminopolycarboxylic acid and a colorless, water-soluble solid EDTA is often suggested as an irrigation solution because it can chelate and remove the mineralized portion of the smear layer (Fig. 6-61). It is a polyaminocarboxylic acid with the formula $[CH_2N(CH_2CO_2H)_2]_2$. Its prominence as a chelating agent arises from its ability to sequester di- and tricationic metal ions such as Ca^{2+} and Fe^{3+}. After being bound by EDTA, metal ions remain in solution but exhibit diminished reactivity.[494]

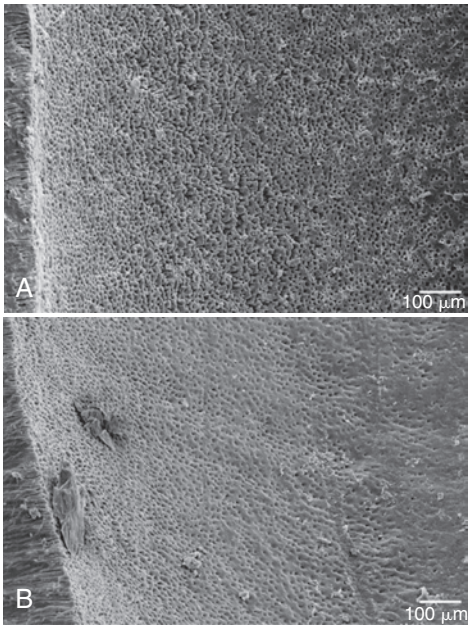

FIG. 6-61 Example of canals with minimal smear layer. **A**, Middle third after irrigation with 17% ethylenediaminetetraacetic acid (EDTA) and 2.5% sodium hypochlorite (NaOCl). **B**, Apical third with some particulate debris.

History

The compound was first described in 1935 by Ferdinand Munz, who prepared the compound from ethylenediamine and chloroacetic acid. Chelating agents were introduced into endodontics as an aid for the preparation of narrow and calcified root canals in 1957 by Nygaard-Østby.[232] Today, EDTA is mainly synthesized from ethylenediamine (1,2-diaminoethane), formaldehyde (methanal), and sodium cyanide.[232,494]

Mode of Action

On direct exposure for extended time, EDTA extracts bacterial surface proteins by combining with metal ions from the cell envelope, which can eventually lead to bacterial death.[232] Chelators such as EDTA form a stable complex with calcium. When all available ions have been bound, equilibrium is formed and no further dissolution takes place; therefore, EDTA is self-limiting.[232]

Applications in Endodontics

EDTA alone normally cannot remove the smear layer effectively; a proteolytic component, such as NaOCl, must be added to remove the organic components of the smear layer.[176] For root canal preparation, EDTA has limited value alone as an irrigation fluid.[176] EDTA is normally used in a concentration of 17% and can remove the smear layers when in direct contact with the root canal wall for less than 1 minute. Even though EDTA has self-limited action, if it is left in the canal for longer or NaOCl is used after EDTA, erosion of dentin has been demonstrated (Fig. 6-62).

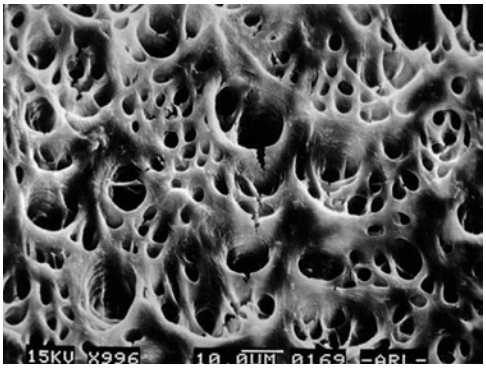

FIG. 6-62 Scanning electron microscope (SEM) image of root canal dentin exposed to 2 minutes of EDTA.

FIG 6-63 Container with BioPure MTAD. (Courtesy Dentsply Tulsa Dental Specialties, Tulsa, OK.)

Although citric acid appears to be slightly more potent at similar concentration than EDTA, both agents show high efficiency in removing the smear layer. In addition to their cleaning ability, chelators may detach biofilms adhering to root canal walls.[188] This may explain why an EDTA irrigant proved to be highly superior to saline in reducing intracanal microbiota despite the fact that its antiseptic capacity is relatively limited.[188] Antiseptics such as quaternary ammonium compounds (EDTAC) or tetracycline antibiotics (MTAD) (see the discussion on the combination of irrigants, presented later) have been added to EDTA and citric acid irrigants, respectively, to increase their antimicrobial capacity. The clinical value of this, however, is questionable. EDTAC shows similar smear-removing efficacy as EDTA, but it is more caustic.

The effect of chelators in negotiating narrow, tortuous, calcified canals to establish patency depends on both canal width and the amount of active substance available, since the demineralization process continues until all chelators have formed complexes with calcium.[232,452,577] Therefore, studies should be read with cautious because one study can show demineralization up to a depth of 50 μ m into dentin,236 but other reports demonstrated significant erosion after irrigation with EDTA.[519]

A comparison of bacterial growth inhibition showed that the antibacterial effects of EDTA were stronger than citric acid and 0.5% NaOCl but weaker than 2.5% NaOCl and 0.2% CHX.[467] EDTA had a significantly better antimicrobial effect than saline solution. It exerts it strongest effect when used synergistically with NaOCl, although no disinfecting effect on colonized dentin could be demonstrated.[212]

Interaction of EDTA and NaOCl

Investigators studied the interactions of EDTA with NaOCl.[183] They concluded that EDTA retained its calcium-complex ability when mixed with NaOCl, but EDTA caused NaOCl to lose its tissue-dissolving capacity, with virtually no free chlorine detected in the combinations. Clinically, this suggests that EDTA and NaOCl should be used separately. In an alternating irrigating regimen, copious amounts of NaOCl should be administered to wash out remnants of the EDTA. In modern endodontics, EDTA is used once the cleaning and shaping is completed for around 1 minute. It can be activated with ultrasonic activation for better penetration in dentinal tubules. It should be taken into consideration that an increase in the temperature of EDTA is not desirable. Chelators have a temperature range within which they work best. When EDTA is heated from 20° to 90°, the calcium binding capacity decreases.[576]

HBPT

HEBP (1-hydroxyethylidene-1, 1-bisphosphonate; also called etidronic acid) is a weak chelator.[575] It is a potential alternative to EDTA because it has no short-term reactivity with NaOCl. It can be used in combination with NaOCl without affecting its proteolytic or antimicrobial properties.[575] It is nontoxic,[26,125] and it is used in medicine to treat bone diseases.[362]

Combination of Irrigants and Added Detergent

Surface Tension

Irrigants with low surface tension have better wettabilty, and it is assumed that they may penetrate better in dentinal tubules and anatomic irregularities. Detergents (e.g., Tween 80) are added to irrigants to lower their surface tension. However, Boutsioukis and Kishen did not find support for this rationale,[65] perhaps because the effect of surface tension is important only at the interface between two immiscible fluids (e.g., between irrigant and an air bubble, but not between irrigant and dentinal fluid). Studies have also confirmed that surfactants do not enhance the ability of NaOCl to dissolve pulp tissue[251] or the efficacy of common chelators to remove calcium or smear layer.[65,125,300,577]

BioPure MTAD and Tetraclean

Two new irrigants based on a mixture of antibiotics, citric acid, and a detergent have been developed. These irrigants are capable of removing both the smear layer and organic tissue from the infected the root canal system.[520] MTAD (Fig. 6-63), introduced by Torabinejad and Johnson at Loma Linda University in 2003,[520] is an aqueous solution of 3% doxycycline, a broad-spectrum antibiotic; 4.25% citric acid, a demineralizing agent; and 0.5% polysorbate 80 detergent (Tween 80).[520] It is mixed as a liquid and powder prior to use. MTAD has been recommended in clinical practice as a final rinse after completion of conventional chemomechanical preparation.[48,248,457,458,520,521]

Tetraclean (Ogna Laboratori Farmaceutici, Muggio, Italy) is a combination product similar to MTAD. The two irrigants differ in the concentration of antibiotics (doxycycline 150 mg/5 ml for MTAD and 50 mg/5 ml for Tetraclean) and the kind of detergent (Tween 80 for MTAD, polypropylene glycol for Tetraclean).

Mode of Action

All tetracyclines are derivatives of four ringed nuclei that differ structurally in regard to the chemical groups at the 2, 5, 6, and

7 positions. These derivatives exhibit different characteristics such as absorption, protein binding, metabolism, excretion, and degree of activity against susceptible organism.[210] Tetracyclines inhibit protein synthesis by reversibly binding to the 30S subunit of bacterial ribosome in susceptible bacteria. It is effective against *Aa. capnocytophaga*, *P. gingivalis*, and *P. intermedia* and affects both gram-positive and gram-negative (more gram-negative effect) types. Tetracycline is a bacteriostatic antibiotic, but in high concentrations, tetracycline may also have a bactericidal effect. Doxycycline, citric acid, and Tween 80 together may have a synergistic effect on the disruption of the bacterial cell wall and on the cytoplasmic membrane.

Smear Layer Removal

In two studies, the efficacy of MTAD or EDTA in the removal of the smear layer was confirmed, but no significant difference between these two solutions was reported.[507,508]

Antibacterial Efficacy

Earlier in vitro research on MTAD showed its antimicrobial efficacy over conventional irrigants.[118,267,507,508,521] Torabinejad and colleagues found that MTAD was effective in killing *E. faecalis* up to 200× dilution.[117] Shabahang and Torabinejad showed that the combination of 1.3% NaOCl as a root canal irrigant and MTAD as a final rinse was significantly more effective against *E. faecalis* than the other regimens.[458]A study using extracted human teeth contaminated with saliva showed that MTAD was more effective than 5.25% NaOCl in disinfection of the teeth. In contrast to the previously mentioned studies, later research suggested less than optimal antimicrobial activity of MTAD.[170,248,258] Krause and colleagues,[267] using bovine tooth sections, showed that 5.25% NaOCl was more effective than MTAD in disinfection of dentin disks inoculated with *E. faecalis*.[458,468]

Clinical Trials

Malkhassain and colleagues, in a clinical controlled trial of 30 patients, reported that the final rinse with MTAD did not reduce the bacterial counts in infected canals beyond levels achieved by a chemomechanical preparation using NaOCl alone.[310]

Protocol for Use

MTAD was developed as a final rinse to disinfect the root canal system and remove the smear layer. The effectiveness of MTAD to completely remove the smear layer is enhanced when a low concentration of NaOCl (1.3%) is used as an intracanal irrigant before placing 1 ml of MTAD in a canal for 5 minutes and rinsing it with an additional 4 ml of MTAD as the final rinse.[457]

QMiX

QMiX was introduced in 2011; it is one of the new combination products introduced for root canal irrigation (Fig. 6-64). It is recommended to be used at the end of instrumentation, after NaOCl irrigation. According to the patent[194] QMix contains a CHX-analog, Triclosan (N-cetyl-N,N,N-trimethylammonium bromide), and EDTA as a decalcifying agent; it is intended as antimicrobial irrigant as well as an agent to remove canal wall smear layers and debris.

Protocol

QMiX is suggested as a final rinse. If sodium hypochlorite was used throughout the cleaning and shaping, saline can rinse out NaOCl to prevent the formation of PCA.

FIG 6-64 QMiX 2in1. Combination of C, EDTA and detergent. QMiX irrigating solution is a single solution used as a final rinse after bleach for one-step smear layer removal and disinfection. (Courtesy Dentsply Tulsa Dental Specialties, Tulsa, OK.)

Smear Layer Removal

Stojic and colleagues investigated the effectiveness of smear layer removal by QMiX using scanning electron microscopy.[500] QMiX removed smear layer equally well as EDTA. Dai and colleagues examined the ability of two pH versions of QMiX to remove canal wall smear layers and debris using an open canal design.[113] Within the limitations of an open-canal design, the two experimental QMiX versions are as effective as 17% EDTA in removing canal wall smear layers after the use of 5.25% NaOCl as the initial rinse.

Antibacterial Efficacy and Effect on Biofilms

Stojic and colleagues assessed,[500] in a laboratory experimental model, the efficacy of QMiX against *Enterococcus faecalis* and mixed plaque bacteria in planktonic phase and biofilms. QMiX and 1% NaOCl killed all planktonic *E. faecalis* and plaque bacteria in 5 seconds. QMiX and 2% NaOCl killed up to 12 times more biofilm bacteria than 1% NaOCl ($P < .01$) or 2% CHX ($P < .05$; $P < .001$). Wang and colleagues compared the antibacterial effects of different disinfecting solutions on young and old *E. faecalis* biofilms in dentin canals using a novel dentin infection model and confocal laser scanning microscopy.[548] Six percent NaOCl and QMiX were the most effective disinfecting solutions against the young biofilm, whereas against the 3-week-old biofilm, 6% NaOCl was the most effective followed by QMiX. Both were more effective than 2% NaOCl and 2% CHX. Morgental and colleagues showed that QMiX was less effective than 6% NaOCl and similar to 1%NaOCl in bactericidal action.[337] According to their in vitro study, it appears that the presence of dentin slurry has the potential to inhibit most current antimicrobials in the root canals system,

Moreover, Ordinola and colleagues found that several endodontic irrigants containing antimicrobial compounds such as chlorhexidine (QMiX), cetrimide, maleic acid, iodine compounds, or antibiotics (MTAD) lacked an effective antibiofilm activity when the dentin was infected intraorally.[353] The irrigant solutions 4% peracetic acid and 2.5% to 5.25% sodium hypochlorite decreased significantly the number of live bacteria in biofilms, providing also cleaner dentin surfaces ($P < .05$). They concluded that several chelating agents containing antimicrobials could not remove or kill significantly biofilms developed on intraorally infected dentin, with the exception of

sodium hypochlorite and 4% peracetic acid. Dissolution ability is mandatory for an appropriate eradication of biofilms attached to dentin.

Clinical Trials

The efficacy and biocompatibility of QMiX was demonstrated via nonclinical in vitro and ex vivo studies. Further clinical research from independent investigators is needed to corroborate the findings.

Iodine Potassium Iodide

Iodine potassium iodide (IKI) is a root canal disinfectant that is used in concentrations ranging from 2% to 5%. IKI kills a wide spectrum of microorganisms found in root canals but shows relatively low toxicity in experiments using tissue cultures.[491] Iodine acts as an oxidizing agent by reacting with free sulfhydryl groups of bacterial enzymes, cleaving disulfide bonds. *E. faecalis* often is associated with therapy-resistant periapical infections (see Chapter 15), and combinations of IKI and CHX may be able to kill $Ca(OH)_2$-resistant bacteria more efficiently. One study evaluated the antibacterial activity of a combination of $Ca(OH)_2$ with IKI or CHX in infected bovine dentin blocks.[473] Although $Ca(OH)_2$ alone was unable to destroy *E. faecalis* inside dentinal tubules, $Ca(OH)_2$ mixed with either IKI or CHX effectively disinfected dentin. Others demonstrated that IKI was able to eliminate *E. faecalis* from bovine root dentin when used with a 15-minute contact time.[32] An obvious disadvantage of iodine is a possible allergic reaction in some patients. Although iodine is not generally considered an allergen, some patients are hypersensitive to this compound and may be considered to have an iodine "allergy."

Intracanal Medication

When treatment cannot be completed in one appointment (see Chapters 3 and 14), the surviving intracanal bacteria proliferate between appointments.[85,546] Therefore, an intracanal medication that will restrict bacterial regrowth, supply continued disinfection, and create a physical barrier can be advantageous.

Calcium Hydroxide

Calcium hydroxide is the most popular intracanal medication in use. Hermann introduced it in 1920.[215,216] Although its use was well documented for its time, evidence of its efficacy in clinical endodontics is controversial. A series of articles promoted the antibacterial efficacy of $Ca(OH)_2$ in human root canals.[85,87] Subsequent studies substantiated these reports,[354,477] and the routine use of $Ca(OH)_2$ as an interappointment intracanal medicament became widespread.[429]

However, newer clinical studies and systematic reviews failed to show a clear benefit of $Ca(OH)_2$ to further eliminate bacterial from the root canal.[372,429] $Ca(OH)_2$ mostly is used as slurry of $Ca(OH)_2$ in a water base; at body temperature, less than 0.2% of the $Ca(OH)_2$ is dissolved into Ca^{++} and OH^- ions. Because $Ca(OH)_2$ needs water to dissolve, water should be used as the vehicle for the $Ca(OH)_2$ paste. In contact with air, $Ca(OH)_2$ forms calcium carbonate ($CaCO_3$). However, this is an extremely slow process and of little clinical significance. $Ca(OH)_2$ paste, with a significant amount of calcium carbonate, feels granular because the carbonate has a very low solubility.[422,477]

$Ca(OH)_2$ is a slow-acting antiseptic; direct-contact experiments in vitro show that a 24-hour contact period is required for complete killing of enterococci.[422,477] Another study of 42 patients found that NaOCl canal irrigation reduced the bacteria level by only 61.9%, but use of $Ca(OH)_2$ in the canals for 1 week resulted in a 92.5% reduction.[463] These researchers concluded that $Ca(OH)_2$ should be used in infected cases to more predictably obtain disinfection.

In addition to killing bacteria, $Ca(OH)_2$ has the beneficial ability to hydrolyze the lipid moiety of bacterial lipopolysaccharides (LPS), thereby inactivating the biologic activity of the lipopolysaccharide and reducing its effect.[424,423] This is a desirable effect because dead cell wall material remains after the bacteria have been killed and can continue to stimulate inflammatory responses in the periradicular tissue.

The main characteristics of $Ca(OH)_2$ include limited solubility, high pH, use as a broad-spectrum antimicrobial agent, and the ability to sustain antimicrobial action for long periods.

Other Uses of $Ca(OH)_2$

Long-term calcium hydroxide treatment can be used to induce apexification of the immature tooth with pulpal necrosis before placing an obturation material such as gutta-percha in the root canal system.[155] Also, in cases where revascularization is desired, $Ca(OH)_2$ can be used instead of antibiotic pastes (for more details, see the discussion presented later in the chapter and Chapter 10).

Clinical Protocol

Calcium hydroxide should be in contact with the tissue to act. $Ca(OH)_2$ powder may be mixed with sterile water or saline and placed into the canal with using a lentulo paste filler.[371] Alternatively, the mix may be applied from sterile, single-dose packages (e.g., Calasept [J.S. Dental, Ridgefield, CT], Calcijet [Centrix, Shelton, CT], and DT Temporary Dressing [Global Dental Products, North Bellmore, NY]) (Fig. 6-65). The mixture should be thick to carry as many $Ca(OH)_2$ particles as possible; however, it should not be overdried to retain enough moisture and to promote continued dissociation with a resulting high pH. For maximum effectiveness, the root canal should be filled homogeneously to the working length.

Limitations of Calcium Hydroxide

There are some concerns regarding the use of $Ca(OH)_2$. The handling and proper placement of $Ca(OH)_2$ present a challenge to the average clinician.[296,474] Moreover, the removal of $Ca(OH)_2$ is frequently incomplete,[306] resulting in a residue covering 20% to 45% of the canal wall surfaces, even after copious irrigation with saline, NaOCl, or EDTA.[276] Residual $Ca(OH)_2$ can shorten the setting time of zinc oxide eugenol–based endodontic sealers.[315] Most notably, it may interfere with the seal of the root filling and compromise the quality of treatment. An additional concern is that $Ca(OH)_2$ is not totally effective against several endodontic pathogens, including *E. faecalis* and *Candida albicans*.[547] The ability of $Ca(OH)_2$ to completely eradicate bacteria from the root canal has been questioned. For example, in vitro studies have shown that dentin can inactivate the antibacterial activity of $Ca(OH)_2$,[193,393] and one clinical study has shown that the number of bacteria-positive canals actually increased after $Ca(OH)_2$ medication.[372] Other studies have also indicated that $Ca(OH)_2$ could not predictably eliminate bacteria or that cultures changed from negative to positive after $Ca(OH)_2$ placement.[372,546]

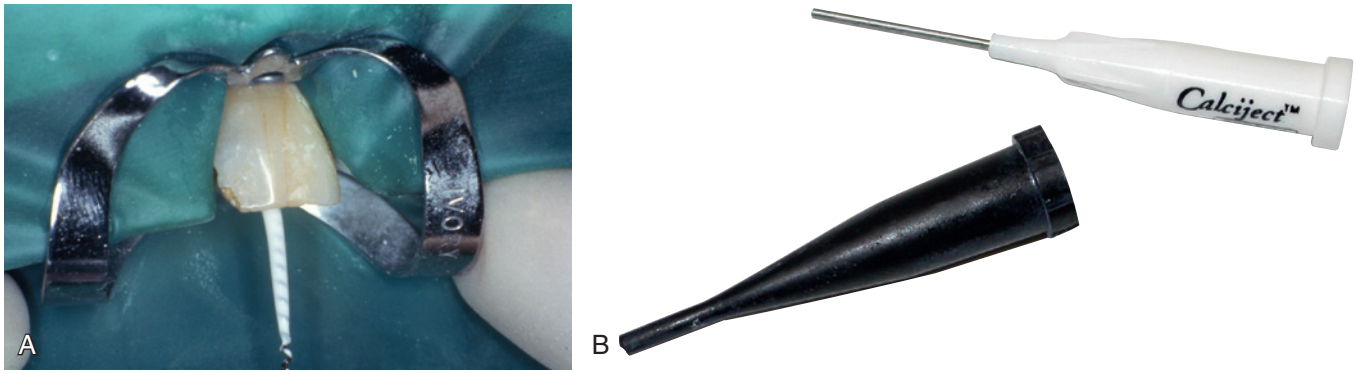

FIG. 6-65 A, Application of calcium hydroxide paste in the canal with a lentulo spiral. B, Calciject is a calcium hydroxide prefilled, easy-to-use, single-dose syringe system. Centrix NeedleTube cartridges can be used for direct syringe injection into the root canal. (*A,* Courtesy Dr. S. Friedman. *B,* Courtesy Centrix, Shelton, CT.)

When different studies report inconsistent results, a systematic review and meta-analysis technique can clarify conflicting research data and the current state of knowledge regarding specific issues. Therefore, based on the current best available evidence, $Ca(OH)_2$ has limited effectiveness in eliminating bacteria from human root canals when assessed by culture techniques. The quest for better antibacterial protocols and sampling techniques must continue to ensure that bacteria can be been reliably eradicated prior to obturation.

Phenolic Preparations

Phenol (C_6H_5OH) and phenolic preparation used to be commonly used intracanal medicament in endodontics. It was thought that because of their volatile properties, they could penetrate dentinal tubules and anatomic irregularities. However, later it was demonstrated that these compounds have a short life span, and their volatility can diffuse through the temporary fillings and also through the periapical tissue causing toxicity. Despite the severe toxicity of phenolic preparations, derivatives of phenol, such as paramonochlorophenol (C_6H_4OHCl), thymol ($C_6H_3OHCH_3C_3H_7$), and cresol ($C_6H_4OHCH_3$), remain available. Currently, $Ca(OH)_2$ or no medication is preferred.[167] Phenol is a nonspecific protoplasm poison that has an optimal antibacterial effect at 1% to 2%. Many dental preparations use much too high a concentration of phenol (e.g., in the range of 30%).[167] At such a concentration, the antimicrobial effect in vivo is lower than optimal and of very short duration.[326] Derivatives of phenol are stronger antiseptics and more toxic than phenol. Phenolic compounds are available as camphorated solutions.[491,492] Camphorated solutions result in a less toxic phenolic compound because they slow the release of toxins to the surrounding tissues. Studies in vitro have shown that phenol and phenol derivatives are highly toxic to mammalian cells, and their antimicrobial effectiveness does not sufficiently balance their toxicity.[491,492] Phenols are ineffective antiseptics under clinical conditions.[85,137]

Formaldehyde

Formaldehyde, used as formocresol, is highly toxic, mutagenic, and carcinogenic; however, it has been used extensively in endodontic therapy.[284] These formulations are still being recommended for use in pediatric dentistry when treating deciduous teeth. The formaldehyde component of formocresol may vary substantially between 19% and 37%. Tricresol formalin, another formaldehyde preparation, contains 10% tricresol and 90% formaldehyde.[284] All of these preparations have a formaldehyde content well above the 10% normally used for fixation of pathologic specimens. Formaldehyde is volatile and releases antimicrobial vapors when applied to a cotton pellet for pulp chamber disinfection. All formaldehyde preparations are potent toxins with an antimicrobial effectiveness much lower than their toxicity.[492,493] There is no clinical reason to use formocresol as an antimicrobial agent for endodontic treatment, based on what is known at this time. The alternatives are better antiseptics with significantly lower toxicity.[492,493]

Halogens

Chlorinated solutions have been used for many years to irrigate root canals. They are also used as intracanal dressings in the form of chloramine-T, an *N*-chloro-tosylamide sodium salt. Iodine, in the form of IKI, is a very effective antiseptic solution with low tissue toxicity. IKI is an effective disinfectant for infected dentin and can kill bacteria in infected dentin in 5 minutes in vitro.[422] IKI releases vapors with a strong antimicrobial effect. The solution can be prepared by mixing 2 g of iodine in 4 g of potassium iodide; this mixture then is dissolved in 94 ml of distilled water. Tincture of iodine (5%) has proved to be one of the few reliable agents for disinfecting rubber dam and tooth surfaces during the preparation of an aseptic endodontic workfield.[334]

Chlorhexidine

CHX is also used as an intracanal medication and was discussed extensively earlier in this chapter.

Steroids

Steroids have been used locally, within the root canal system, to reduce pain and inflammation. Ledermix (Riemser Arzneimittel AG, Insel Riems, Germany) is a commercially available product that was developed about 1960 by Prof. André Schroeder.[450] The active ingredients are the potent anti-inflammatory corticoid triamcinolone acetonide in combination with the broad-spectrum antibiotic demeclocycline. It is an intracanal medicament paste popularly used in some countries. Ledermix paste has been advocated as an initial dressing, particularly if the patient presents with endodontic symptoms.[450] Ledermix paste contains triamcinolone acetonide as an anti-inflammatory agent, at a concentration of 1%.[261] The

clinical effect is a rapid relief of pain associated with acute inflammatory conditions of the pulp and periodontium.

Ledermix paste is a nonsetting, water-soluble paste material for use as root canal medicament or as a direct or indirect pulp-capping agent. The mechanism of action of this substance is based on inhibition of the ribosomal protein synthesis in the bacteria. The release and dentin diffusion characteristics of triamcinolone from Ledermix paste when used as a root canal medicament have been investigated under different conditions.[1-3] Collectively, these studies show that triamcinolone is released from Ledermix paste in the root canal and can reach the systemic circulation via diffusion through dentinal tubules, lateral canals, and the apical foramen. Also, because of its root resorption inhibition property, it was tested for replanted teeth in dogs. The results showed that the groups treated with Ledermix, triamcinolone, and demeclocycline had significantly more favorable healing and more remaining root structure than the group filled with gutta-percha and sealer (positive control).[95]

Triple-Antibiotic Paste

The triple-antibiotics regimen, composed of metronidazole, ciprofloxacin, and minocycline, was first tested[430] for its effectiveness against *Escherichia coli*–infected dentin in vitro. The same research group also tested its bactericidal efficacy against microbes from carious dentin and infected pulp. They found that the mixture of antibiotics is sufficiently potent to eradicate the bacteria.[511] The clinical effectiveness of the triple-antibiotic paste in the disinfection of immature teeth with apical periodontitis has been reported.[557] One potential concern of using an intracanal antibiotic paste is that it may cause bacterial resistance. Additionally, intracanal use of minocycline can cause tooth discoloration, creating potential cosmetic complications. For this reason, a dual paste (metronidazole, ciprofloxacin) and, alternatively, abandonment of this protocol in favor of $Ca(OH)_2$ have been considered.[279] Another reason for such a change could be the reported high toxicity to stem cells of paste prepared from antibiotic powder.[418]

Bioactive Glass

Research is under way in the use of bioactive glass as an intracanal medicament. In one study,[578] the glass used was composed of 53% SiO_2 (w/w), 23% Na_2O, 20% CaO, and 4% P_2O_5 and was prepared from reagent-grade Na_2CO_3, $CaHPO_4$, $2H_2O$, $CaCO_3$, and Belgian sand. When used in root canals, bioactive glass was found to kill bacteria, but the mechanism of action was not pH related, and dentin did not seem to alter its effect.[578] Some newer obturating materials (e.g., Resilon; Pentron Clinical Technologies, Wallingford, CT) contain bioactive glass.

Lubricants

In root canal treatment, lubricants are mostly used to emulsify and keep in suspension debris produced by mechanical instrumentation. Although irrigation solutions serve as lubricants for hand instrumentation, special gel-type substances are also marketed. Two of these are wax-based RC-Prep, which contains EDTA and urea peroxide, and glycol-based Glyde. Another purported function of lubricants is to facilitate the mechanical action of endodontic hand or rotary files. A study evaluating the effects of lubrication on cutting efficiency found that tap water and 2.5% NaOCl solutions increased cutting efficiency compared with dry conditions.[572] The authors of this study cited the ability of an irrigant to remove debris as the factor for the increased efficiency. Similarly, a reduction of torque scores was found when canals in normed dentin disks were prepared with ProFile and ProTaper instruments under irrigation, but the use of a gel-type lubricant resulted in similar torques as in dry, nonlubricated canals.[61,376]

In summary, irrigation is an indispensable step in root canal treatment to ensure disinfection. NaOCl is the irrigant of choice because of its tissue-dissolving and disinfecting properties. EDTA or other chelators should be used at the end of a procedure to remove the smear layer, followed by a final flush with NaOCl for 1 minute for maximum cleaning efficiency and to minimize dentin erosion. This strategy also minimizes inactivation of NaOCl by chemical interactions.

Disinfection Devices and Techniques

Syringe Delivery

Application of an irrigant into a canal by means of a syringe and needle allows exact placement, replenishing of existing fluid, rinsing out of larger debris particles, as well as allowing direct contact to microorganisms in areas close to the needle tip. In passive syringe irrigation, the actual exchange of irrigant is restricted to 1 to 1.5 mm apical to the needle tip, with fluid dynamics taking place near the needle outlet.[66,575] Volume and speed of fluid flow are proportional to the cleansing efficiency inside a root canal.[66] Therefore, both the diameter and position of the needle outlet determine successful chemomechanical debridement; placement close to working length is required to guarantee fluid exchange at the apical portion of the canal, but close control is required to avoid extrusion.[66,224,322] Therefore, the choice of an appropriate irrigating needle is important. Although larger-gauge needles allows a quicker and larger amount of fluid exchange, the wider diameter does not allow cleaning of the apical and narrower areas of the root canal system (see irrigation dynamics earlier in this chapter) (see Fig. 6-7). Excess pressure or binding of needles into canals during irrigation with no possibility of backflow of the irrigant should be avoided under all circumstances[231] to prevent extrusion into periapical spaces. In immature teeth with wide apical foramina or when the apical constriction no longer exists, special care must be taken to prevent irrigation extrusion and potential accidents.[111]

There are different sizes and types of irrigation needles. The size of the irrigation needle[101] should be chosen depending on the canal size and taper.[89,328,347] Most root canals that have not been instrumented are too narrow to be reached effectively by disinfectants, even when fine irrigation needles are used (see Figs. 6-7 and 6-52). Therefore, effective cleaning of the root canal must include intermittent agitation of the canal content with a small instrument[320,535] to prevent debris from accumulating at the apical portion of the root canal (see Fig 6-47).

Preparation size[328] and taper[105] ultimately determine how close a needle can be placed to the final apical millimeters of a root canal. Open-ended needles are recommended over the end open needles to prevent extrusion of the irrigant. Some needles and suction tips may be attached to the air/water syringe to increase both the speed of irrigant flow and the volume of irrigant. Examples include the Stropko Irrigator (Vista Dental Products), which is an adapter that connects to the air/water syringe and accepts standard Luer-lock needle tips for irrigant removal and application as well as air-drying.

Manually Activated Irrigation

Liquid placed inside the root canal more effectively reaches crevices and mechanically untouched areas if it is agitated inside the root canal. Corono-apical movements of the irrigation needle,[231] stirring movements with small endodontic instruments,[320,535] and manual push-pull movements using a fitted master gutta-percha cone have been recommended.[225]

Other than conventional irrigation, additional techniques for endodontic disinfection have been proposed and tested, including laser systems and gaseous ozone. Several new devices for endodontic irrigation or disinfection have been introduced, among which are the EndoActivator System (Dentsply Tulsa Dental Specialties), passive ultrasonic irrigation, EndoVac (Discus Dental Inc., Culver City, CA), the Safety-Irrigator (Vista Dental Products, Racine, WI), the Self-adjusting File (discussed earlier), photoactivation disinfection, and ozone. These new devices use pressure, vacuum, oscillation, or a combination with suction.

Sonically Activated Irrigation

The EndoActivator System uses safe, noncutting polymer tips in an easy-to-use subsonic hand piece to quickly and vigorously agitate irrigant solutions during endodontic therapy (Fig. 6-66).

In one study,[130] the safety of various intracanal irrigation systems was analyzed by measuring the apical extrusion of irrigant. The authors concluded that EndoActivator had a minimal statistically insignificant amount of irrigant extruded out of the apex in comparison with manual, ultrasonic, and Rinsendo (Dürr Dental, Bietigheim-Bissingen, Germany) groups.[130]

When cleanliness of the root canal walls was analyzed, [421] investigators suggested that both passive sonic or ultrasonic irrigation rendered root canals significantly cleaner than manual preparation in comparison with manual syringe irrigation.[82,533] When comparing sonic with ultrasonic irrigation, the results can be controversial. The majority of the studies benefit ultrasonic irrigation.[246,421] The difference lies in the oscillating movements: sonic devices range between 1500 Hz and 6000 Hz, and ultrasonic equipment requires vibrations greater than 20,000 Hz.[246,302,497] If sonic devices are left in the canal for longer periods of time, better cleaning effects can be found. Sonic or ultrasonic irrigation may be carried out with activated smooth wires or plastic inserts, endodontic instruments, or activated irrigation needles. Examples include EndoSonor (Dentsply Maillefer) and EndoSoft ESI (EMS Electro Medical Systems, Nyon, Switzerland) inserts, IrriSafe (Acteon Satelec), the EndoActivator System (Dentsply Tulsa Dental Specialties), and the Vibringe sonic syringe (Vibringe B.V., Amsterdam, Netherlands). Inadvertent cavitation of root canal walls has not been observed with sonic activation of instruments.[320]

Passive Ultrasonic Irrigation

Richman was the first to introduce ultrasonic devices in endodontics.[405] The files are driven to oscillate at ultrasonic frequencies of 25 to 30 kHz to mechanically prepare the root canal walls.[543,544] (See the discussion presented earlier in this chapter for more details.) It has been shown that ultrasonically driven files are effective to activate the irrigation liquids inside the root canal system by inducing acoustic streaming and cavitation.

Two types of ultrasonic irrigation have been described in the literature: one where irrigation is combined with simultaneous ultrasonic instrumentation (UI) and another without simultaneous instrumentation, called *passive ultrasonic irrigation* (PUI).[8,554] During UI, the file is intentionally brought into contact with the root canal wall. But because of the complex canal anatomy, the UI will never contact the entire wall and it may result in uncontrolled cutting of the root canal walls without effective disinfection.[8,373,560] In a study by Macedo,[307] instrument oscillation frequency, ultrasonic power, and file taper determined the occurrence and extent of cavitation. Some degree of cavitation occurred between the file and canal surface and reached lateral canals and isthmuses.

Passive ultrasonic irrigation (PUI) was first described by Weller and colleagues[554] The term *passive* is related to the noncutting action of the ultrasonically activated file.[8] PUI relies on the transmission of acoustic energy from an oscillating file or smooth wire to an irrigant in the root canal.

PUI should be introduced in the canal once that the root canal system has a final apical size and taper. A fresh solution of irrigant should be introduced and a small file or smooth wire (for example, size #15) is ultrasonically activated. Because the root canal has already been shaped, the file or wire can move more freely,[416,534,535] and the irrigant can penetrate into the apical part of the root canal system,[269] with the cleaning effect being more significant.[301] Using this noncutting methodology, the potential to create aberrant shapes within the root canal are reduced to a minimum. Obviously, a file larger than a #15 or #20 will require a wide root canal to reduce oscillation dampening by wall contact.

Ultrasonic activation of the irrigant seems to improve debridement of the root canal system in vitro, and the results in vivo present some controversy. Therefore, objective guidelines regarding their risks and benefits have not been ascertained.[286,575] Ultrasonic activation of the irrigant can be intermittent or continue. The ProUltra PiezoFlow (Dentsply Tulsa Dental Specialties) has been introduced to irrigate and activate the liquids at the same time. The device consists mainly of an ultrasonically energized needle connected to a reservoir of sodium hypochlorite (NaOCl). This continuous ultrasonic irrigation (CUI) system allows simultaneous continuous irrigant delivery and ultrasonic activation; unlike PUI,

it does not require the intermittent replenishment of irrigant between ultrasonic file activations. Research shows better elimination of debris and better penetration of irrigant into dentinal tubules.[6,93,247]

Negative Apical Pressure

Another approach to afford better access of irrigation solution to the apical portion of the canal is so-called negative-pressure irrigation (Fig. 6-67). Here, irrigant is delivered into the access chamber, and a very fine needle connected to the dental unit's suction device is placed into the root canal. Excess irrigant from the access cavity is then transported apically and ultimately removed via suction. First, a macrocannula, equivalent to an ISO size #55, .02 taper instrument, removes coronal debris. Subsequently, a microcannula, equivalent to a size #32, .02 taper, removes particles lodged close to working length. Such a system is commercially available (EndoVac, Discus Dental) and may prove a valuable adjunct in canal disinfection.[348] One of the main characteristics of the system is the safety. Many studies proved that EndoVac will not extrude irrigation solution through the apex. On the other hand, because the irrigation is deposited in the coronal area, the irrigant flow in the apical last millimeters of the canal is very passive, and some concerns were expressed that flow is laminar and passive in the apical region. In one study, the apical negative pressure mode of irrigation generated the lowest wall shear stress.[96]

Another device that makes use of pressure-suction technology is the RinsEndo system (Dürr Dental, Bietigheim-Bissingen, Germany). It aspirates the delivered rinsing solution into an irrigation needle that is placed close to working length and at the same time activates the needle with oscillations of 1.6 Hz amplitude.[69,322]

FIG. 6-69 The GentleWave system. The system uses multisonic energy to develop a broad section of waves within the irrigation solution to clean inside the roots canal system. It has two main components: a handpiece and a console (shown in figure). (Courtesy Sonendo, Inc, Laguna Hills, CA.)

Safety-Irrigator

The Safety-Irrigator (Vista Dental Products) is an irrigation/evacuation system that apically delivers the irrigant under positive pressure through a thin needle containing a lateral opening and evacuates the solution through a large needle at the root canal orifice (Fig. 6-68). The Safety-Irrigator features a large coronal evacuation tube, enabling the user to safely irrigate and evacuate simultaneously. It fits any standard Luer-lock syringe. Designed to limit risk of NaOCl accidents, this "negative-pressure" irrigation device comes fully assembled and fitted with a side-vented irrigating needle for added safety. This system was tested in vitro to evaluate the removal of dentin debris from artificially made grooves in standardized root canals and showed that there was no significant difference among the manual dynamic activation (MDA) with a nontapered gutta-percha cone, the Safety Irrigator, and the apical negative pressure irrigation. These techniques produced better cleaning efficacy than syringe irrigation ($P < .005$) but significantly worse than MDA with a tapered cone ($P < .05$). Continuous ultrasonic irrigation was significantly better than all the other techniques tested in this study ($P < .001$).[247]

Gentle Wave System

Sonendo Inc. develops a so-called multisonic cleaning technology (Gentle Wave, Fig. 6-69) that only requires pulp chamber access. This system is noninstrumentational and being tested

clinically with, according to the company, promising results. It appears to have the potential to reach inaccessible canal areas with significantly more cleaned surface than other systems. A first in vitro study shows the potential of the system to debride better than conventional needle irrigation or ultrasonically activated irrigation.[197]

Laser-Activated Irrigation

Lasers are widely used in dentistry and include diode, Nd:YAG, erbium, and CO_2, which produces radiation in both the near- and far-infrared electromagnetic spectrum.[186] Laser devices have been proposed to improve the efficacy of irrigants.[186] Lasers have been studied for their ability to clean and effectively disinfect root canals. The Er:YAG laser wavelength (2940 nm) has the highest absorption in water and a high affinity to hydroxyapatite, which makes it suitable for use in root canal treatment.[107]

Laser energy may be used to activate irrigant solutions in different ways—for example, at a molecular level, as in photoactivated disinfection (PAD), or at a bulk flow level, as in laser-activated irrigation (LAI). Several studies in vivo and ex vivo have indicated that laser activated irrigation is promising for removing smear layer[168] and dentin debris[121,122] in less time than PUI. The mechanism of action[56] is based on the generation of a secondary cavitation effect with expansion and successive implosion of fluids.[56]

These results are in agreement with data related to a new erbium laser technique that used a photon-induced photoacoustic streaming (PIPS) of irrigants. In that technique, the laser tip is placed into the coronal access opening of the pulp chamber only and is kept stationary without advancing into the orifice of the canal.[132] The use of a newly designed tapered and stripped tip with specific minimally ablative laser settings is required, resulting in low energy (20 mJ), a pulse repetition rate of 15 Hz, and a very short pulse duration (50 µs). The difference in laser penetration and bacterial killing is attributed to the difference in the degree of absorption of different wavelengths of light within the dentin. Bergmans and colleagues concluded in their in vivo study that the Nd:YAG laser irradiation is not an alternative but a possible supplement to existing protocols for canal disinfection, as the properties of laser light may allow a bactericidal effect beyond 1 mm of dentine.[49] Endodontic pathogens that grow as biofilms, however, are difficult to eradicate even upon direct laser exposure.[65]

Photoactivation Disinfection

Photodynamic therapy (PDT) or light-activated therapy (LAT) may have endodontic applications because of its antimicrobial effectiveness.[203] In principle, antimicrobial photodynamic therapy (APDT) is a two-step procedure that involves the introduction of a photosensitizer (step 1: photosensitization of the infected tissue) followed by light illumination (step 2: irradiation of the photosensitized tissue) of the sensitized tissue, which would generate a toxic photochemistry on the target cell, leading to cell lysis. Each of these elements used independently will not have any action, but together they have a synergism effect to produce antibacterial action. Indeed, in vitro experiments showed promising results when used as an adjunct disinfected device. Shresta and Kishen concluded that the tissue inhibitors existing within the root canal affected the antibacterial activity of PDT at varying degrees,[462] and further research is required to enhance their antimicrobial efficacy in an endodontic environment.

Antibacterial Nanoparticles

Nanoparticles are microscopic particles with one or more dimensions in the range of 1 to 100 nm. Nanoparticles are recognized to have properties that are unique from their bulk or powder counterparts. Antibacterial nanoparticles have been found to have a broad spectrum of antimicrobial activity and a far lower propensity to induce microbial resistance than antibiotics. Such nanoparticles in endodontics are being studied in different ways, such as mixed with irrigants, photosensitizer, and sealers.[259] Currently, the consensus is that the successful application of nanoparticles in endodontics will depend on both the effectiveness of antimicrobial nanoparticles and the delivery method used to disperse these particles into the anatomic complexities of the root canal system.

Superoxidized Water

Superoxidized water,[191] also called electrochemically activated water[313,481] or oxidative potential water,[208,455] is effectively saline that has been electrolyzed to form superoxidized water, hypochlorous acid, and free chlorine radicals. It is commercially available as Sterilox (Sterilox Technologies, Radnor, PA). This solution is nontoxic to biologic tissues yet able to kill microorganisms. The solution is generated by electrolyzing saline solution, a process no different than that used in the commercial production of NaOCl.[154] The difference, however, is that the solution accumulating at the anode is harvested as the anolyte and that at the cathode as the catholyte. These solutions display properties that are dependent on the strength of the initial saline solution, the applied potential difference, and the rate of generation. The technology that allows harvesting of the respective solutions resides in the design of the anode and the cathode and originates either in Russia (electrochemically activated water) or in Japan (oxidative potential water).[312,313] Although the solutions bear different names, the principles in the manufacturing process appear to be similar.

The use of superoxidized water is sparsely described in the endodontic literature but shows early promise. The solutions from both technologies have been tested for their ability to debride root canals,[208,313] remove smear layer,[455,481] and kill bacteria[223] and bacterial spores.[297] Results are favorable and show biocompatibility with vital systems.[237]

Anolyte and catholyte solutions generated from one such technology (Radical Waters Halfway House 1685, South Africa) have shown promise as antibacterial agents against laboratory-grown, single-species biofilm models.[169] Such solutions have been recommended as suitable for removing biofilms in dental unit water lines[312] and have even been marketed for this purpose. Cautious clinicians may prefer to wait for more studies to demonstrate safety and efficacy under ordinary clinical setting conditions before adopting newer, less tested irrigating solutions.

CRITERIA TO EVALUATE CLEANING AND SHAPING

Well-Shaped Canals

The main aims of canal shaping are to directly remove tissues and microbial irritants and to provide sufficient

geometrical space for subsequent obturation (see Table 6-2). To achieve these goals, the prepared canal should include the original canal (see the red areas in Fig. 6-4); there should be an apical narrowing and the canal should be tapered. These concepts were popularized by Schilder[445] and are still maintained today.[17,258]

Therefore, a well-shaped canal is defined more specifically by the absence of procedural errors (discussed later) and the achievement of disinfection; more recently another element was added to this equation, the retention of as much tooth structure as feasible.[172]

A clinician can often determine whether a canal is adequately shaped by examining radiographs and relying on clinical experience—for example, when fitting a cone. At this time the feel would be of tug-back, a slight resistance to pull; a radiograph should show a symmetrical canal-shape lateral of the cone, the presence of an intact apical narrowing, and no thinned-out radicular wall sections.

Using magnification, clinicians should inspect the canal orifice and the coronal third of each shaped canal for clean canal walls.[367] Immediately after irrigation with sodium hypochlorite, an absence of visible turbidity and effervescence should be noted. If present, these phenomena, along with visible deposits on the canal walls, are indicative of organic matter still in suspension or adherent to the radicular walls.

Signs of Mishaps

Instrument Fracture

Most reports suggest that manual endodontic file fracture or rotary instrument fracture occur at a rate of approximately 1% to 6% and 0.4% to 5%, respectively.[365,495,531] Such fractures are untoward events and perceived as such by clinicians.[55] Evidently, retained instrument fragments limit access of disinfecting irrigants to the root canal system, possibly impeding sufficient elimination of microorganisms.[196] However, the current clinical evidence does not suggest that the presence of a retained instrument must result in a significantly higher rate of failing root canal treatments when done by specialists.[495]

In general, instruments used in rotary motion break into two distinct modes: torsional and flexural.[374,431,530] Torsional fracture occurs when an instrument tip is locked in a canal while the shank continues to rotate, thereby exerting enough torque to fracture the tip. This also may occur when instrument rotation is sufficiently slowed in relation to the cross-sectional diameter. In contrast, flexural fracture occurs when the cyclic loading leads to metal fatigue. This problem precludes the manufacture of continuously rotating stainless steel endodontic instruments, because steel develops fatal fatigue after only a few cycles.[454] NiTi instruments can withstand several hundred flexural cycles before they fracture,[201,285,394,530,567] but they still can fracture in the endodontic setting after a low (i.e., below 10,000) number of cycles.[97]

Repeated loading and cyclic fatigue tests for endodontic instruments are not described in pertinent norms. Initially, rotary instruments such as Gates-Glidden burs and Peeso reamers were tested with a superimposed bending deflection.[68] In GG burs, a 2-mm deflection of the instrument tip resulted in fatigue life spans ranging from 21,000 revolutions (size #1 burs) to 400 revolutions (size #6 burs).[68] In another study, stainless steel and NiTi hand files were rotated to failure in steel tubes with an acute 90-degree bend and an unspecified radius.[454] Under these conditions, size #40 stainless steel instruments fractured after fewer than 20 rotations, whereas various NiTi files of the same size withstood up to 450 rotations.

Cyclic fatigue was also evaluated for ProFile .06 taper instruments using a similar device.[567,568] The number of rotations to failure for unused control instruments ranged from 1260 (size #15 files) to 900 (size #40 files). These scores did not change when the instruments were tested under simulated clinical conditions such as repeated sterilization and contact with 2.5% NaOCl. Subsequently, control instruments were compared with a group of instruments used in the clinical setting in five molar cases[568]; again, no significant differences were found in resistance to cyclic fatigue.

One study used a different testing method involving tempered metal cylinders with radii of 5 mm and 10 mm that produced a 90-degree curve.[201] The researchers reported fatigue fractures for size #15, .04 taper ProFile instruments after about 2800 cycles with the 10 mm cylinders. In size #40, .04 taper ProFile instruments, fractures occurred after about 500 cycles with the 5-mm cylinders. In comparison, size #15, .06 taper ProFile instruments also failed after about 2800 revolutions with the 10-mm cylinders, but failure occurred in size #40, .06 taper ProFile specimens after only 223 cycles with the 5-mm cylinders.

Rotary NiTi instruments with larger tapers and sizes consistently fractured after fewer rotations,[390] and although the radius of the curves was halved, fatigue life was reduced by 400%. Another investigation reported similar results for selected HERO instruments,[201] and the findings were confirmed by other tests on GT rotary instruments. Size #20, .06 taper GT files failed after 530 rotations in a 90-degree curve with a 5-mm radius; size #20, .12 taper GT files failed after 56 rotations under the same conditions.[378]

Reuse of rotary instruments depends on safety, specifically on assessment of fatigue and also the potential to properly clean NiTi surfaces.[36,63,350,357,460,486,489,525] Specific instruments perform differently in this regard, as fatigue depends more on the amount of metal in cross section at the point of stress concentration[182,523] than on the specifics of instrument design.[98]

On the other hand, manufacturers constantly claim that their instrument has been equipped with design elements that render it more fatigue resistant. For example, LightSpeed LSX is manufactured without a milling process. However, no data have been published regarding its fatigue resistance. GTX is manufactured from a novel NiTi alloy, M-Wire, to increase its fatigue resistance.[249] However, investigators could not confirm these findings.[266] Similarly, another study did not find the Twisted File,[277] which is not milled and hence thought to be fatigue resistant,[163] to perform better than conventionally manufactured ProFile rotaries. Another feature, electropolishing (discussed earlier), does not appear to confer a significantly increased fatigue resistance to EndoSequence[277,401] and RaCe.[523,525,565] One possible reason for these variable outcomes is the different testing environments used in vitro[100]; clinically, even greater variability is to be expected.

Attempts have been made to use tests according to norms and specifications described for stainless steel hand instruments such as K-files and Hedström files,[239] as no comparable norms exist for instruments used in continuous rotary motion. Consequently, a number of models have been devised to assess specific properties of NiTi rotary instruments, including torque at failure, resistance against cyclic fatigue, and others

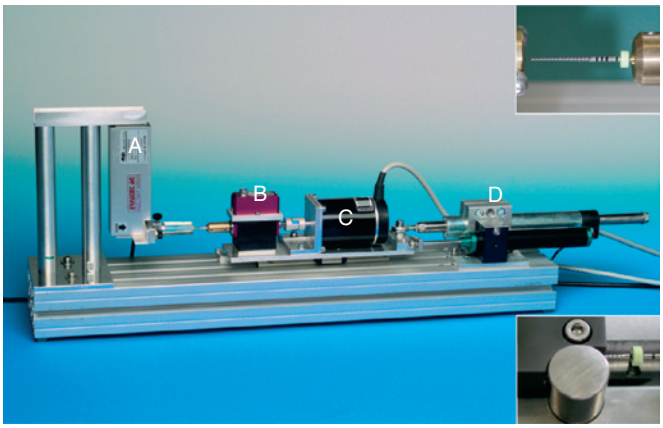

FIG. 6-70 Testing platform for analysis of various factors during simulated canal preparation with rotary endodontic instruments. Labeled components are a force transducer **(A)**, a torque sensor **(B)**, a direct-drive motor **(C)**, and an automated feed device **(D)**. For specific tests, a cyclic fatigue phantom or a brass mount compliant with ISO No. 3630-1 *(insets)* may be attached.

(Fig. 6-70). These systems may simultaneously assess torque at failure, working torque axial force, and cyclic fatigue.

According to the norms mentioned previously, torque at failure is recorded with the apical 3 mm of the instrument firmly held in the testing device while the instrument's handle is rotated. A wide variety of rotary NiTi endodontic instruments have been tested in this way—for example, ProFile NiTi rotary files in ISO sizes #25, #30, and #35 (.04 taper) fractured at 0.78, 1.06, and 1.47 Ncm, respectively.[503]

Investigators reported similar scores when instruments were forced to fracture in plastic blocks with simulated curved canals.[504] In a different setup, GT rotary instruments (size #20, .06 taper to size #20, .12 taper) fractured at 0.51 and 1.2 Ncm, respectively.[378] These values are somewhat lower than data obtained from the same but slightly modified torque bench,[254] pointing to the importance of experimental conditions for torque and fatigue measurements.

Compared with NiTi instruments with tapered flutes, LightSpeed instruments had lower torque to fracture (0.23 to 2 Ncm).[318] No such data are currently available for LightSpeed LSX.

When analyzing clinical factors involved in instrument fracture, one must consider both torsional load and cyclic fatigue.[431] However, these are not separate entities, especially in curved canals.[64] Working an instrument with high torque may lower resistance to cyclic fatigue.[161] Conversely, cyclic prestressing has been shown to reduce the torsional resistance of ProTaper finishing files,[530] as well as K3[31] and MTwo.[390] Also, cyclic fatigue occurs not only in the lateral aspect when an instrument rotates in a curved canal but also axially when an instrument is bound and released by canal irregularities.[54]

The torque generated during canal preparation depends on a variety of factors, and an important one is the contact area.[57] The size of the surface area contacted by an endodontic instrument is influenced by the instrumentation sequence or by the use of instruments with different tapers.[448] A crown-down approach is recommended to reduce torsional loads (and thus the risk of fracture) by preventing a large portion of the tapered rotating instrument from engaging root dentin (known as *taper lock*).[57,569]

The clinician can further modify torque by varying axial pressure, because these two factors are related448 (see Fig. 6-20). In fact, a light touch is recommended for all current NiTi instruments to avoid forcing the instrument into taper lock. The same effect might occur in certain anatomic situations, such as when canals merge, dilacerate, and divide.

The torsional behavior of NiTi rotary endodontic instruments cannot be described properly without advanced measurement systems and a new set of norms. However, the clinician must be able to interpret correctly the stress-strain curves for all rotary NiTi instruments used in the clinical setting to be able to choose an appropriate working torque and axial force.

Therefore, a careful evaluation should be performed before the attempt is made to remove any retained fragment (see Fig. 6-25). In fact, Ward and colleagues suggested that any attempt of fragment removal be made only when the fragment is located coronal of a significant root canal curve and thus visible with the aid of magnification.[549]

There are sophisticated means and strategies to remove retained fragments, which are described in detail in Chapter 19.

Of note, assessment of physical parameters governing rotary root canal preparation was considered crucial because NiTi rotary in vitro had increased risk of fracture compared with K-files. Some clinicians also describe instrument fracture as a main issue for concern.[55]

In a study using plastic blocks, as many as 52 ProFile Series 29 instruments became permanently deformed.[515] Three fractures were reported in a subsequent study on ISO-norm ProFile taper .04 instruments, and three other instruments were distorted.[75] An even higher fracture incidence was shown in a study on rotary instruments used in plastic blocks in a specially designed testing machine.[509] These findings were supported by two studies in which high fracture incidences were reported for LightSpeed and Quantec rotary instruments used in a clinical setting.[33,431]

On the other hand, as stated previously, a retrospective clinical study suggested similar outcomes with and without retained instrument fragments[495]; moreover, others' experience suggests that the number of rotary instrument fractures is lower than previously estimated.[126,262,558] Removal of such fragments is possible in many situations, but there is also the potential for further damage (e.g., perforation) rather than successful removal.[502,558] Consequently, a benefit-versus-risk analysis should be carried out prior to attempts to remove NiTi instrument fragments to address the reasons and the clinical consequences of instrument fracture.

Canal Transportation

Perhaps the most frequent adverse outcomes during canal shaping are aberrations from the original canal path. Much has been written on the appearance of such aberrations using labels as zip and elbow formation, ledging, perforation, stripping, and others.[553]

Canal transportation is at the root of all these clinical problems and may be defined as "the removal of canal wall structure on the outside curve in the apical half of the canal due to the tendency of files to restore themselves to their original linear shape during canal preparation."[17]

As files tend to straighten in the canal, transportation typically occurs toward the inner (or convex) radicular wall at

midroot. Such a shift of the canal axis during shaping results in excessive loss of dentin and may ultimately result in perforation, whereas apical transportation may lead to zipping or apical perforation (see Fig. 6-40).

Conceptually, any canal preparation will shift the canal axis, which is often determined as the center of gravity in cross sections. It has been held that a transportation of about 100 to 150 µm may be clinically acceptable.[233]

If canal transportation has led to ledge formation, subsequent instruments will bypass the area of the ledge only when adequately precurved. In case of rotary instrumentation, hand-operated instruments of comparable size are then recommended (Fig. 6-71).

Perforation

As indicated earlier, perforation may be the ultimate result of canal transportation when it occurs within the root canal system. Other perforations are those in the access cavity; a discussion of access cavity preparation may be found in Chapter 5. Obviously, the preparation of mineralized canals requires advanced operator skills and is facilitated by magnification (Fig. 6-72).

Three types of perforations can be defined: strip perforations that occur toward the furcation in multirooted teeth (also known as *"danger zones"*[15]), perforations associated with canal curvatures, and perforations though the apical foramen.

Blockage

A canal may become impassable during the process of cleaning and shaping due to two distinct, but often connected, occurrences. A ledge is a dentinal shelf that is created by shaping instruments that straighten and dig into the convex side of the canal wall. In less severe cases, ledges can be corrected and smoothed out with precurved instruments. This condition may lead to false paths and impede optimal obturation when working length cannot be reached with master cones.

A blockage refers mainly to a root canal area that is filled with densely compacted debris or collagenous pulp remnants (see Fig. 6-39). It may also be caused by other obstacles such as a fractured files or remnants of a preexisting coronal or radicular filling materials. Clinically the presence of ledge or block is signaled by the inability of a straight flexible instrument to penetrate deeper into the root canal; however, this needs to be differentiated from a small or mineralized canal, which causes longer portions of the instrument's cutting flutes to bind.

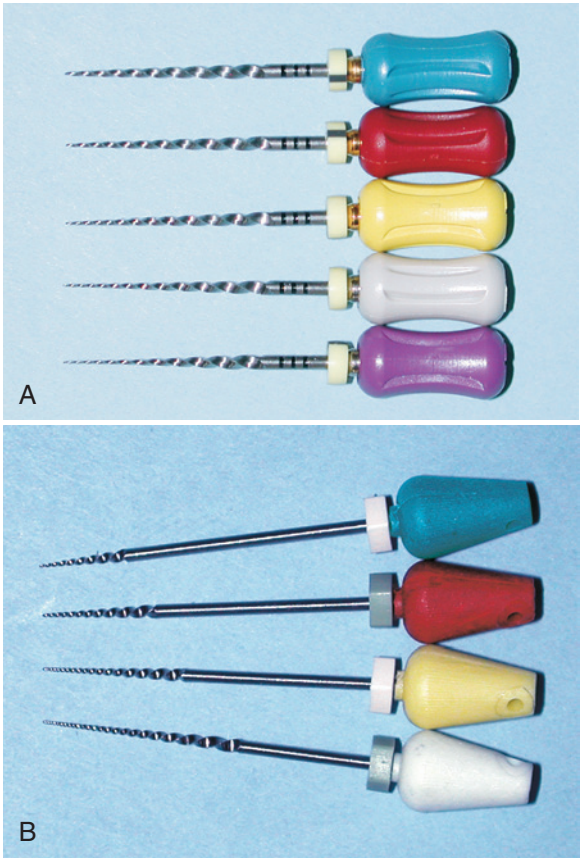

FIG. 6-71 Instruments with increased taper that can be used by hand. **A**, ProTaper instruments with special handles attached to rotary instrument shanks. **B**, GT hand instruments.

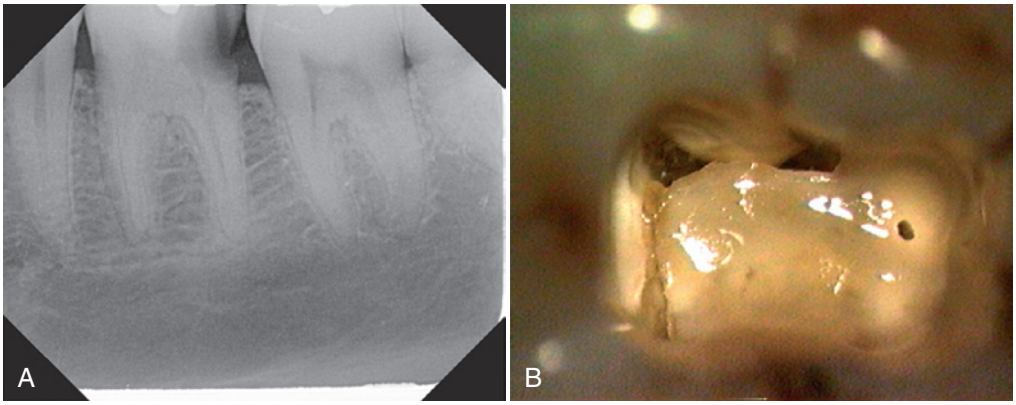

FIG. 6-72 Evidence of coronal hard-tissue deposition. **A**, Periapical radiograph of tooth #19 shows evidence of reduced coronal and radicular pulp space. **B**, Intraoral photograph, taken through an operating microscope (×25), of access cavity of the tooth shown in **A**; note the calcific metamorphosis.

Obviously, such a blockage prevents the apical canal portion from being disinfected. For details of strategies to deal with ledge and blockage, please refer to Chapter 19.

Another reason for a perceived blockage may be an abrupt canal curvature.

SAMPLE PROTOCOL FOR CONTEMPORARY CLEANING AND SHAPING PROCEDURES

- Using well-angulated preoperative radiographs, analyze case difficulty under well-established parameters.
- Place rubber dam and estimate working length.
- Prepare a conservative access cavity sufficient to reveal all root canal orifices.
- Scout canals with a #10 K-file in the presence of a lubricant.
- If the selected series of rotary instruments advances easily to the estimated working length (WL), confirm patency and determine WL using an electronic apex locator.
- If the instruments meet resistance and the file does not progress gently to WL, use a dedicated NiTi instrument; it is prudent to modify the orifice to create a coronal receptacle for the subsequent rotaries. Negotiate, confirm patency, and determine WL.
- Create a reproducible glide path to WL with appropriate instruments.
- Irrigate with sodium hypochlorite throughout the shaping procedure.
- Advance the selected series of rotary instruments (based on canal anatomy) passively in the presence of sodium hypochlorite to shape the middle third. When shaping canals that have a larger buccal-lingual dimension, consider shaping as two canals.
- Clean cutting flutes routinely upon removal, and remove debris with an alcohol-moistened gauze. If the selected rotary does not progress easily, remove irrigant, recapitulate with a #10 K-file, and choose a different, often smaller, instrument.
- Use copious irrigation, and reverify canal patency and working length throughout and upon completion of shaping. Gauge the size of the foramen with an appropriate hand file.
- Protocol for irrigation:
  - Irrigate using copious amounts of sodium hypochlorite.
  - Activate the irrigant.
  - Select irrigation solution for smear layer management.
  - Perform the final irrigation.
- Dry the canal thoroughly and obturate with a technique that promotes a three-dimensional fill.
- Restore the endodontically treated tooth in a timely manner.

SUMMARY

Cleaning and shaping are important, interdependent steps in root canal treatment. Cleaning, as demonstrated by an intracanal surface free of smear layer, can be done only after root canals have been sufficiently enlarged to accommodate adequate irrigation needles. Canal preparation is optimized when mechanical aims are fulfilled and enlargement is acceptable; such aims include avoiding both significant preparation errors and weakening of the radicular structure, which can result in fractures.

Taken together and performed to a high standard, the procedures described in this chapter lay the foundation for biologic success in both straightforward (Fig. 6-73) and more

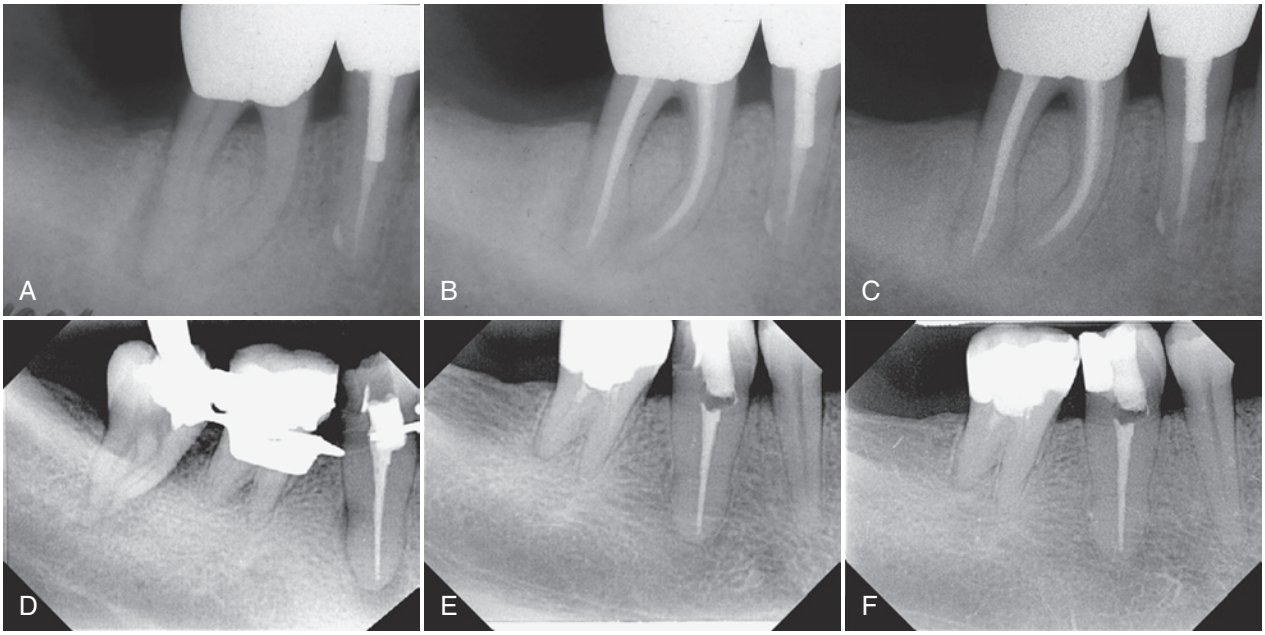

FIG. 6-73 Clinical cases treated according to the principles detailed in this chapter. **A**, Pretreatment radiograph of tooth #30 with a periradicular lesion. **B**, Postobturation radiograph. **C**, Two-year follow-up radiograph shows osseous healing. **D**, Immediate postobturation radiograph of tooth #29 shows both a periapical and a lateral osseous lesion. **E-F**, One-year and three-year follow-up radiographs show progressing osseous healing. Note the imperfect obturation of tooth #30.

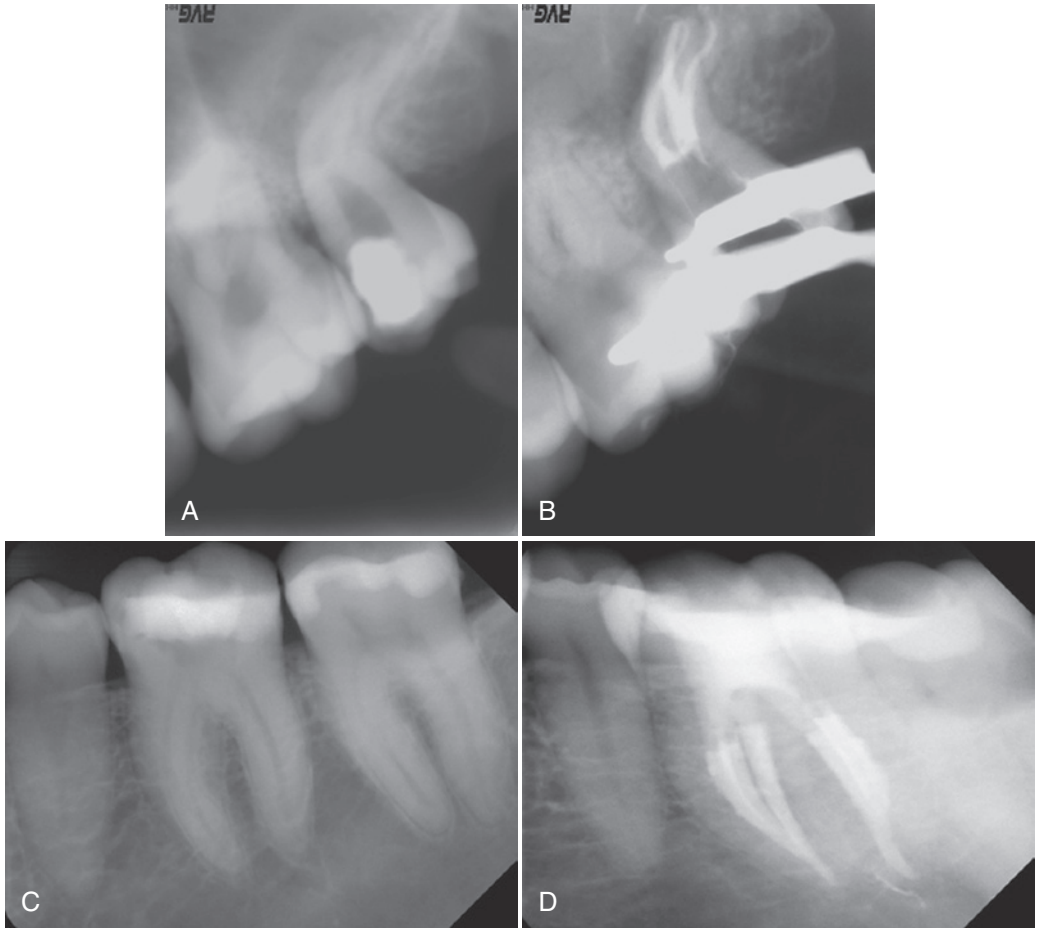

FIG. 6-74 Complicated clinical cases treated with hybrid techniques. **A,** Pretreatment radiograph of tooth #16 indicates laceration and significant curvature of all roots. **B**, Posttreatment radiograph shows multiple planes of curvature. **C,** Pretreatment radiograph of tooth #19, which was diagnosed with irreversible pulpitis. **D,** Angulated posttreatment radiograph shows three canals in the mesiobuccal root canal system, all of which were prepared to apical size #50. complicated (Fig. 6-74) clinical cases. Recall radiographs confirm favorable outcomes or biologic success (i.e., prevention or healing of periradicular periodontitis) over the years. Similarly, adherence to the principles discussed leads to predictable outcomes for root canal treatments.

CHAPTER 7

Obturation of the Cleaned and Shaped Root Canal System

WILLIAM JOHNSON | JAMES C. KULILD | FRANKLIN TAY

CHAPTER OUTLINE

Importance of Effectively Sealing the Root Canal System
Historical Perspectives
Timing of Obturation
Vital Pulp Tissue
Necrotic Pulp Tissue
Length of Obturation
Preparation for Obturation
The Ideal Root Canal Filling
Types of Sealers
Zinc Oxide and Eugenol
Calcium Hydroxide Sealers
Noneugenol Sealers
Glass Ionomer Sealers
Resin Sealers
Silicone Sealers
Calcium Silicate Sealers
Medicated Sealers
Sealer Placement
Core Materials
Silver Cones
Gutta-Percha
Activ GP
Resilon
Custom Cones
Methods of Obturation
Lateral Compaction
Warm Vertical Compaction
Continuous Wave Compaction Technique
Warm Lateral Compaction
Thermoplastic Injection Techniques
Carrier-Based Gutta-Percha
Thermomechanical Compaction
Solvent Techniques
Pastes
Immediate Obturation
Coronal Orifice Seal

IMPORTANCE OF EFFECTIVELY SEALING THE ROOT CANAL SYSTEM

Success in endodontic treatment was originally based on the triad of debridement, thorough disinfection, and obturation, with all aspects equally important. At present, successful root canal treatment is based on broader principles. These include diagnosis and treatment planning; knowledge of anatomy and morphology; the traditional concepts of debridement, thorough disinfection, and obturation; the coronal restoration, and three-dimensional imaging of the healing of teeth with preexisting periapical pathosis. A meta-analysis of factors influencing the efficacy of primary root canal treatment found that the following four factors influenced success: the absence of a pretreatment periapical lesion, root canal fillings with no voids, obturation to within 2.0 mm of the apex, and an adequate coronal restoration.[265]

In an early radiographic study of success and failure, Ingle and colleagues[179] indicated that 58% of treatment failures were due to incomplete obturation. Unfortunately, teeth that are poorly obturated are often poorly prepared. Procedural errors such as loss of length, canal transportation, perforations, loss of coronal seal, and vertical root fracture may have occurred. These procedural errors have been shown to adversely affect the apical seal.[420]

Since the classic study by Ingle and colleagues, great emphasis has been placed on developing materials and techniques for obturating the radicular space. Various experimental methods have been used to assess microleakage after obturation, including radioisotopes,[102] dyes,[188] bacteria,[68] proteins,[248] endotoxins,[68] glucose penetration,[276] and computerized fluid filtration.[385] These methodologies have employed a variety of in vitro conditions, experimental periods that often produce conflicting results with unclear clinical implications.[113,426] There is general consensus that treatment outcomes cannot be predicted from the results of in vitro dye leakage models.[268,296,373] Even the results of microbial leakage studies have recently been challenged, due to flaws in experimental designs.[306,307] Fortunately, tooth retention rates after root canal treatment are high despite the varied conditions, materials, and techniques employed.[74,218,322] Circumstantial evidence indicates that the cleaning and shaping procedures provide an aseptic environment. With this elimination of the etiology for pathosis, the method of obturation becomes less critical.

A primate study of infected teeth with apical periodontitis demonstrated non-healing in 28% of the teeth with no bacteria after cleaning and shaping, whereas the presence of bacteria after cleaning and shaping resulted in 79% being classified as not healed.[119] When no bacteria were present, healing occurred regardless of the quality of the obturation. When bacteria were present at the time of obturation, there was a correlation between the quality of obturation and nonhealing. These results emphasized the role of bacteria in apical pathosis and the importance of cleaning and shaping procedures.

In a controlled animal study,[318] periapical lesions were created by removing the pulp and leaving the teeth open to the oral cavity. In the control group, the canals were cleaned and shaped before obturation with gutta-percha and a resin sealer. The teeth of the experimental group were cleaned and shaped as in the control group but left unobturated. At 190 days, the animals were killed and histological evaluations were performed. There was no difference in the healing between the instrumented and obturated teeth and the instrumented and unobturated teeth. The results emphasized the importance of cleaning and shaping in eliminating bacteria. Although obturation may not influence the short-term success rates, results may be different in long-term studies if coronal leakage were to occur.[314]

To date, there is no effective method for determining whether cleaning and shaping procedures have been effective. The criteria of clean dentinal filings and/or enlargement beyond the first file to bind at working length proved to be unreliable.[402] Although the length of preparation has been emphasized, the irregular canal diameter (the forgotten dimension) may be a more significant factor in success and failure.[181] Evidence indicates canals are often underprepared in the apical one-third.[67] Historically, culturing has been employed and obturation delayed until a "negative" culture was obtained. In contemporary endodontic treatment, culturing has been abandoned during routine care.[329] With vital pulp tissues, bacteria are not a major concern. In necrotic cases, the organisms involved in the disease process are primarily facultative or obligate anaerobes that may not grow in culture. Molecular microbiologic techniques (polymerase chain reaction) have demonstrated that a variety of organisms are present that do not grow in culture.[10,315,362] The role these organisms play in the disease process is not well understood.[257] The reader is referred to Chapters 14 and 15 for a fuller discussion.

The process of cleaning and shaping determines both the degree of disinfection and the ability to obturate the radicular space. Obturation is therefore a reflection of the cleaning and shaping and is evaluated on the basis of length, taper, density, level of gutta-percha removal, and the coronal seal (i.e., an adequate provisional restoration) (Fig. 7-1). It is not possible to assess the quality of the seal established during obturation with a radiograph, and it is important to remember that no material or technique prevents leakage.[2,153] Indeed, obtaining an impervious seal may not be feasible because of the porous tubular structure of dentin[2] and canal irregularities.

The primary etiology of pulpal and periradicular pathosis is, as discussed in Chapter 15, bacterial.[191,253] Pulpal remnants, necrotic tissue, bacteria, and bacterial by-products remaining in the inaccessible areas of a cleaned and shaped canal system could initiate and/or perpetuate a lesion because the host defense mechanisms are unable to remove them. Studies indicate that root canal systems cannot be completely cleaned and disinfected.[165,359,425] Obturation of the radicular space is necessary to eliminate leakage. Obturation reduces coronal leakage and bacterial contamination, seals the apex from the periapical tissue fluids, and entombs the remaining irritants in the canal.[412]

Coronal leakage has also been proposed to contribute to treatment failure based on in vitro leakage studies.[389,392] The clinical implication is that retreatment has to be performed in those teeth that are not restored permanently after 3 months of root canal treatment. This controversial issue has been recently challenged.[33,310,311] Although a coronal seal may be produced by a well-filled root filling, a coronal restoration with margins that prevent bacteria penetration, or both, data derived from a retrospective clinical study[305] suggest that a favorable treatment outcome may be achieved even in poorly filled root canals when the quality of the coronal restoration is adequate. Data produced by this retrospective study overtly challenged the rationale of endodontics. The data stimulated intense research and discussions for almost two decades on whether the quality of the coronal restoration is more significant than the quality of root canal treatment in eliminating apical periodontitis. A recent systematic review and meta-analysis of the results derived from nine similar studies indicate that poor quality root canal treatment and poor quality coronal restorations have similar odds (i.e., likelihood in non-statistical terms) in adversely affecting the healing of apical periodontitis.[137] Based on the best available evidence currently available, the odds for healing of apical periodontitis increase with both adequate root canal treatment and adequate restorative treatment.[137] It must be emphasized that these two factors were examined in isolation in those studies. While these postoperative prognostic factors are certainly important, as exemplified by the data derived from a prospective clinical study,[262,263] other preoperative and intraoperative prognostic factors also contributed significantly to periapical healing in primary and secondary root canal treatment. Nevertheless, maintaining an effective coronal seal through optimal filling of the instrumented radicular space and placing an appropriate restoration, as discussed in Chapter 22, should be considered essential components of successful root canal treatment.[168,180]

Clinicians are concerned with whether it is more appropriate to place a permanent restorative material instead of a temporary material to prevent leakage.[234,393] This is a controversial issue, as previous studies failed to provide definitive evidence to demonstrate that the presence of a permanent restoration will contribute to the long-term success of root canal treatment when those canals are optimally filled.[76,321] These results were supported by a more recent prospective clinical study that examined the factors affecting the outcomes of nonsurgical root canal treatment.[262] In this study, the authors found that the type of coronal restoration had no significant influence on periapical healing, as long as those restorations are of good quality. Paradoxically, the same group of authors reported in a separate study that cast restorations, when compared with temporary restorations, significantly improved the survival of teeth that had undergone primary or secondary root canal treatment.[263] This may be due to protection of remaining, weakened tooth structure by full-coverage cast restorations that enabled those teeth to function longer. Regarding the necessity for retreatment of root-filled teeth without permanent restorations, there is no clear evidence to justify that retreatment has to be performed in teeth in which a temporary

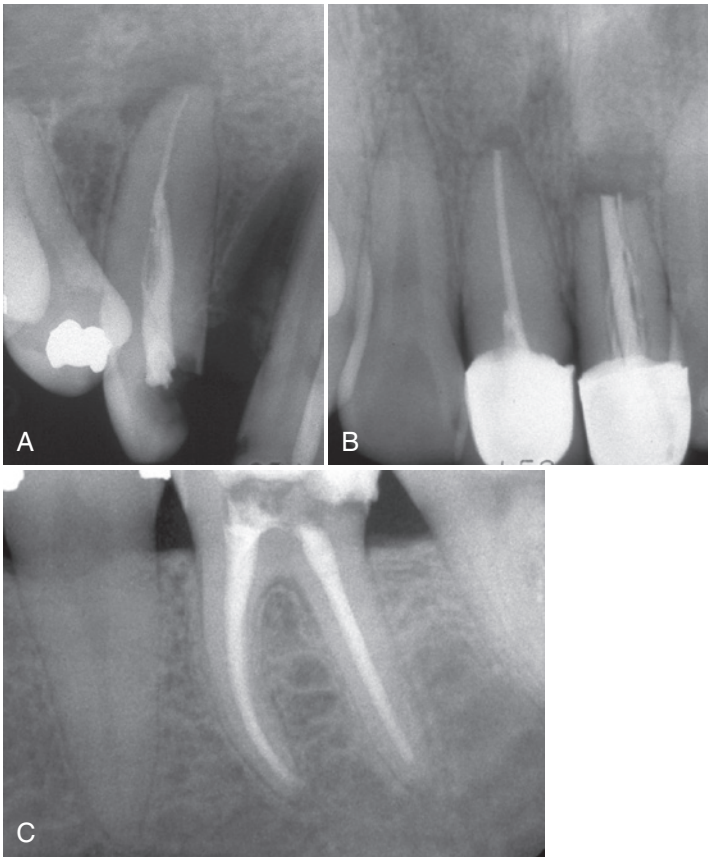

FIG. 7-1 Examples of inadequate obturation. **A,** Maxillary right canine with adequate length but lacking density and no coronal seal. Central incisor is filled to adequate length, but obturation exhibits voids. **B,** Maxillary central incisors. Maxillary right central incisor exhibits a lack of density and taper. Maxillary left central incisor has voids and unfilled canal space. **C,** Mandibular left first molar with adequate obturation; provisional restoration shows poor adaptation on the distal because of the failure to remove caries.

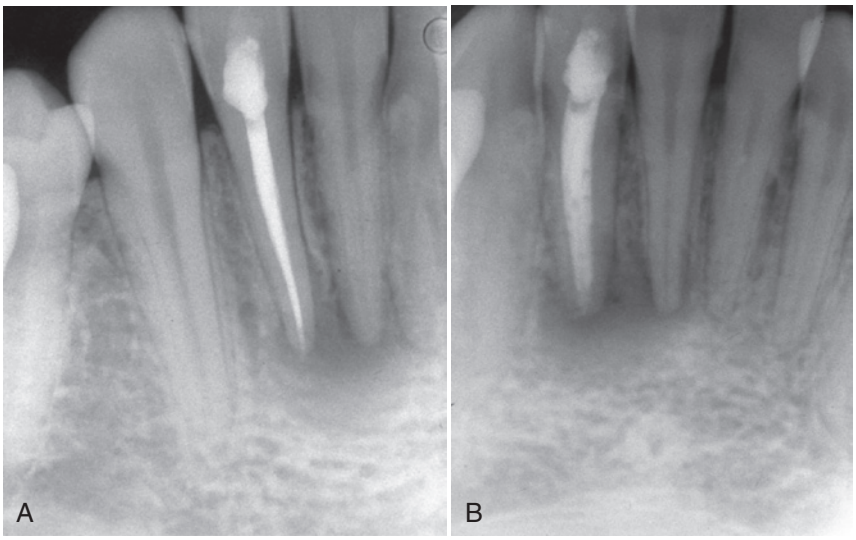

FIG. 7-2 **A,** Posttreatment radiograph of a mandibular left lateral incisor with ostensibly adequate obturation. **B,** Angled view reveals voids.

restoration has been inserted for more than three months, solely because of the suspicion of microleakage.[195] One may consider replacing the temporary restoration with a new coronal restoration immediately and to observe the tooth for at least three months before placing a permanent crown.[195]

Three-dimensional obturation of the radicular space is essential to long-term success. The canal system should be sealed apically, coronally, and laterally. Various methods have been advocated for obturation. Unfortunately, all materials and techniques result in some degree of leakage.[426] Although a poorly obturated canal and leakage are correlated, radiographic evaluation of obturation does not correlate well with leakage.[154,199] An adequate two-dimensional radiographic appearance of the obturation may not correlate with an adequate seal (Fig. 7-2).[110] Variation in radiographic interpretation by the clinician, the overlying osseous structures, and the lack of uniformity in the obturation materials are significant variables.[36,106,107,199,388]

The diagnostic outcome of root canal treatment is based on clinical and radiographic findings. In a series of prospective

studies, the Toronto group evaluated success and failure of root canal treatment at 4 to 6 years after completion of treatment. For primary root canal treatment,[91,121,127,241] teeth with pre-existing apical periodontitis were found to have a lower healing rate (82%) compared with teeth without periapical radiolucency (93%). Better outcomes were associated with teeth without periapical radiolucency, with single roots, and without mid-treatment complications such as root perforation. Teeth were treated by using flared preparation and vertical compaction of warm gutta-percha or step-back preparation and lateral compaction. Differences were noted with the adequacy of the fill and the treatment technique. Adequate length had a higher success rate (87%) when compared with inadequate length (77%). The flared preparation and vertical compaction had a higher success rate (90%) when compared with step-back preparation and lateral compaction (80%). For secondary non-surgical root canal treatment,[92,120] teeth with pre-existing apical periodontitis were also found to have a lower healing rate (80%) compared with teeth without periapical radiolucency (93%). Better outcomes were achieved in teeth with inadequate previous root filling, without perforation and radiolucency. Similar results were reported in a more recent prospective clinical study that examined the effects of primary or secondary root canal treatment on periapical healing.[262] The percentage of roots with complete periapical healing after primary (83%) or secondary (80%) root canal treatment was similar. Absence of preoperative apical periodontitis was identified as one of the prognostic factors affecting primary or secondary root canal treatment. In the presence of apical periodontitis, treatment prognosis was significantly improved by the presence of a smaller lesion. These studies are in agreement with earlier work[364,374] indicating preexisting apical pathosis as a major factor reducing a favorable prognosis and highlighted obturation technique as a factor influencing success and failure.[364]

Although periapical radiographs have been used to examine healing of post-treatment apical periodontitis since 1922,[264] their suitability for evaluating the outcomes of root canal treatment has recently been challenged, in that previously reported outcomes based on this assessment modality may have overestimated the healing rates of apical periodontitis.[97,118,423] Imaging with periapical radiographs produces a two-dimensional superimposition of a three-dimensional structure; partially healed periapical lesions that are confined within the cancellous bone alone are not usually detected using periapical radiographs.[32] With the advent of cone-beam computed tomography (CBCT), a better diagnosis of periapical lesions within the cancellous bone can be made. This is because CBCT softwares create reconstructed images from slices of data in any plane and location of the volume of interest, thus eliminating the lack of three-dimensional assessment and anatomical noise which hampers the accuracy of periapical radiography. This results in a higher signal-to-noise ratio and image contrast, and improves the detection of periapical radiolucencies.[283,335] Although the use of CBCT may not be practical for every clinical case, the significance in adopting this novel imaging technology for assessing the healing of apical periodontitis after primary root canal treatment can be demonstrated in a recent one-year follow-up study.[284] Diagnosis using CBCT revealed a lower healed and healing rate for primary root canal treatment compared with the use of digital radiography. Complete resolution of periapical radiolucency was found to be 93% using periapical radiography and 74% for CBCT. For those teeth with preexisting periapical radiolucency, reconstructed CBCT images also showed more failures (14%) when compared with the use of periapical radiographs (10%). In another follow-up study, the technical quality of root canal fillings and the associated treatment outcome were evaluated two years post-treatment, using both periapical radiography and CBCT.[226] Complete absence of post-treatment periapical radiolucency was observed in CBCT scans in 81% and 49% of adequate and inadequate root fillings, respectively, as compared to 87% and 61% revealed by periapical radiographs. Preoperative apical periodontitis and the quality of root filling were identified by both periapical radiographs and CBCT as significant prognosis predictors. The combined use of periapical radiography and CBCT imaging confirmed that satisfactory root fillings were associated with a favorable outcome. The results of this work emphasized that developing good technical skills for obturating root canals should not be underscored, and that suitable canal obturation methods should be developed to achieve more compacted, void-free filling materials and at the correct length.

HISTORICAL PERSPECTIVES

The achievement of a "hermetic seal" is often cited as a major goal of root canal treatment. According to accepted dictionary definitions, the word *hermetic* means sealed against the escape or entry of *air*—or made airtight by fusion or sealing. However, root canal seals are commonly evaluated for *fluid* leakage—a parameter used to praise or condemn obturation materials and techniques. This occurs both apically and coronally. Somehow, the term *hermetic* has crept into endodontic nomenclature in a manner probably quite similar to the invention of an airtight seal. A god of wisdom, learning, and magic in ancient Egypt, Thoth, better known as Hermes Trismegistus (Hermes thrice greatest), is credited with this invention.[343] His significant contribution to civilization allowed the preservation of oils, spices, aromatics, grains, and other necessities in previously porous, earthenware vessels. A simple wax seal of the vessel walls helped to create the "hermetic seal." Endodontically speaking, the term *hermetic* is inappropriate; instead, terms such as *fluid-tight, fluid-impervious,* or *bacteria-tight* seals are more contemporary.

In 1924, Hatton indicated: "Perhaps there is no technical operation in dentistry or surgery where so much depends on the conscientious adherence to high ideals as that of pulp canal filling."[162] The essence of this statement had been significantly influenced by years of trial and error in both the techniques and materials used to obturate the prepared root canal system. Much of the frustration and challenge that emanated from this concern, however, was due to the lack of development in root canal preparation techniques coupled with indictments of the "focal infection" craze of that era.[178]

Before 1800, root canal filling, when done, was limited to gold. Subsequent obturations with various metals, oxychloride of zinc, paraffin, and amalgam resulted in various degrees of success and satisfaction.[203] In 1847, Hill developed the first gutta-percha root canal filling material known as "Hill's stopping."[203] The preparation, which consisted principally of bleached gutta-percha and carbonate of lime and quartz, was patented in 1848 and introduced to the dental profession. In 1867, Bowman made claim (before the St. Louis Dental Society) of the first use of gutta-percha for canal filling in an extracted first molar.[12]

References to the use of gutta-percha for root canal obturation before the turn of the twentieth century were few and vague. In 1883, Perry claimed that he had been using a pointed gold wire wrapped with some soft gutta-percha (the origin of the present-day core carrier technique?).[289] He also began using gutta-percha rolled into points and packed into the canal. The points were prepared by cutting base plate gutta-percha into slender strips, warming them with a lamp, laying them on his operating case, and rolling them with another flat surface (a contemporary technique still used by a few to custom roll a large cone?). Perry then used shellac warmed over a lamp and rolled the cones into a point of desired size, based on canal shape and length. Before placing the final gutta-percha point, he saturated the tooth cavity with alcohol; capillary attraction let the alcohol run into the canal, softening the shellac so that the gutta-percha could be packed (the forerunner of a chemical-softening technique?).

In 1887, the S.S. White Company began to manufacture gutta-percha points.[193] In 1893, Rollins introduced a new type of gutta-percha to which he added vermilion.[405] Because vermilion is pure oxide of mercury and therefore dangerous in quantity, many people justifiably criticized this technique.

With the introduction of radiographs for the assessment of root canal obturations, it became painfully obvious that the canal was not cylindrical, as earlier imagined, and that additional filling material was necessary to fill the observed voids. At first, hard-setting dental cements were used, but these proved unsatisfactory. It was also thought that the cement used should possess strong antiseptic action, hence the development of many phenolic or formalin-type paste cements. The softening and dissolution of the gutta-percha to serve as the cementing agent, through the use of resins was introduced by Callahan in 1914.[60] Subsequently a multitude of various pastes, sealers, and cements were created in an attempt to discover the best possible sealing agent for use with gutta-percha.

Over the past 70 to 80 years, the dental community has seen attempts to improve on the nature of root canal obturation with these cements and with variations in the delivery of gutta-percha to the prepared canal system. During this era, the impetus for these developments was based heavily on the continued belief in the concept of focal infection, elective localization, the hollow-tube theory, and the concept that the primary cause for failure of root canal treatment was the apical percolation of fluids, and microorganisms, into a poorly obturated root canal system.[102,317] From this chronological perspective of technical and scientific thought, this chapter clarifies and codifies contemporary concepts in the obturation of the cleaned and shaped root canal system.

TIMING OF OBTURATION

Factors influencing the appropriate time to obturate a tooth include the patient's signs and symptoms, status of the pulp and periradicular tissue, the degree of difficulty, and patient management.

Vital Pulp Tissue

At present, the consensus is that one-step treatment procedures are acceptable when the patient exhibits a completely or partially vital pulp.[123,328,372] Removal of the normal or inflamed pulp tissue and performance of the procedure under aseptic conditions should result in a successful outcome because of the relative absence of bacterial contamination. Obturation at the initial visit also precludes contamination as a result of leakage during the period between patient visits.

Elective root canal treatment for restorative reasons can be completed in one visit provided the pulp is vital, to some degree, and time permits. Obturation of root canals in patients whose condition is urgent depends on the pretreatment diagnosis. When pain occurs as the result of irreversible pulpitis, obturation can occur at the initial visit because removal of the vital tissue will generally resolve the patient's pain.

Necrotic Pulp Tissue

Patients who present with pulp necrosis with or without asymptomatic periradicular pathosis (asymptomatic apical periodontitis, chronic apical abscess, condensing osteitis) may be treated in one visit, based on the best available information. When patients present with acute symptoms caused by pulp necrosis and acute periradicular abscess, obturation is generally delayed until the patient is asymptomatic. However, more than 20 years ago, investigators demonstrated that cases with soft-tissue swelling could be completed in one visit with appropriate endodontic treatment, incision for drainage, and a regimen of antibiotics.[366] Management of these patients, however, may be more difficult should problems persist or become worse after the completion of treatment.

During the 1970s, there was concern about the timing of obturation. Performing endodontic treatment in one visit was controversial. Conventional wisdom suggested that patients would have a higher incidence of posttreatment pain. However, recent clinical studies[252,285,292] and systematic reviews[123,328,372] indicate that there is no significant difference in the healing rates of apical periodontitis between single-visit and multiple-visit root canal treatment. Patients experience less frequency of short-term post-obturation pain after single-visit than those having multiple-visit root canal treatment.[372]

In contrast to teeth with vital pulp tissue, teeth exhibiting pulp necrosis frequently exhibit bacterial contamination and may require a different approach to treatment. Sjögren and colleagues raised questions regarding the long-term prognosis of teeth exhibiting necrotic pulp tissue and apical periodontitis treated in a single-visit.[363] In their clinical study, the authors thoroughly instrumented 55 infected teeth with apical pathosis, using only 0.5% sodium hypochlorite (NaOCl) [*Editor's note:* Today, stronger concentrations of NaOCl are more commonly used. The reader is referred to Chapter 14 for a fuller discussion of this issue]. Before obturation, cultures were obtained, using anaerobic bacteriologic techniques. After cleaning and shaping, bacteria could be detected in 22 teeth. Complete healing occurred in 94% of cases that yielded a negative culture, whereas the rate of successful treatment of teeth with positive cultures before obturation was 68%, a statistically significant difference.

With the introduction of the concept of biofilms, other investigators examined the intracanal microbial status of sixteen mesial roots of human mandibular first molars with primary apical periodontitis immediately after one-visit root canal treatment.[258] In that study, the instrumented canals were irrigated with 5.25% NaOCl and 17% ethylenediaminetetraacetic acid (EDTA), and obturated with gutta-percha and zinc oxide–eugenol cement. The apical portion of the root of each tooth was removed by flap-surgery and prepared for correlative light and transmission electron microscopy

examination. Fourteen of the 16 root-treated teeth revealed residual intracanal infection after instrumentation, antimicrobial irrigation, and obturation. The microbes existed mostly as biofilms in inaccessible recesses of instrumented main canals, the intercanal isthmus, and accessory canals.

In a more recent histobacteriological study, the in vivo microbiological status of the mesial roots of mandibular molars with primary apical periodontitis was examined after single-visit or two-visit root canal treatment.[397] Those roots were instrumented and irrigated with 5% NaOCl, 17% EDTA, and 2% chlorhexidine. In the single-visit group, the canals were immediately obturated, whereas in the two-visit group, calcium hydroxide dressing was placed in the canals for one week prior to obturation. In the single-visit group, no canal, out of the six canals examined, was completely free of bacteria. Residual biofilms were identified in the main canal, isthmus, apical ramifications, and dentinal tubules. In the two-visit group, two out of seven roots were rendered bacteria-free. Residual biofilms were found predominantly in the isthmus and ramifications, intermixed with necrotic tissues and debris. Taken together, these 3 studies illustrate that microbes are extremely difficult to eliminate within the complex root canal system, and that the use of an inter-appointment antimicrobial dressing resulted in improved microbiological status of the root canal system when compared with the single-visit protocol.

Calcium hydroxide has been advocated as an antimicrobial and temporary dressing in necrotic cases that cannot be treated in one visit[363] because investigators noted that bacteria in instrumented, unfilled canals can multiply and reach their pretreatment numbers in 2 to 4 days.[57] Nevertheless, the ability of calcium hydroxide to completely eradicate microbial species from the root canal system has recently been questioned. In vitro studies demonstrated that the antibacterial activity of calcium hydroxide can be inactivated by dentin.[156,297] Other clinical studies showed that the number of bacteria-positive canals did not decrease after the use of calcium hydroxide as an inter-appointment dressing.[291,401] A systematic review and meta-analysis of 8 clinical studies concluded that calcium hydroxide is useful but has limited effectiveness in completely eliminating bacteria from human root canals when assessed by culture techniques.[330] Although calcium hydroxide has a wide range of antimicrobial activity against common endodontic pathogens and is an effective anti-endotoxin agent, it is less effective against *Entercoccus faecalis* and *Candida albicans*.[251] Alternative inter-appointment dressings such as the use of chlorhexidine gel, calcium hydroxide in chlorhexidine gel, or triantibiotic paste (metronidazole, minocycline, and ciprofloxacin) has been proposed, with dichotomous results.[95,271,361,403] While there are clinical trials to support the use of calcium hydroxide or alternative inter-appointment dressings, they do not reduce bacteria load beyond levels already achieved by canal preparation with NaOCl.[238,240,360] It is fair to say inter-appointment antimicrobial dressings are fairly well accepted by clinicians in cases that cannot be treated in a single visit.

In general, obturation can be performed after cleaning and shaping procedures when the canal can be dried and the patient is not experiencing swelling. An exception is the presence or persistence of exudation from the canal. Obturation of a canal that cannot be dried is contraindicated. Procedural concerns also dictate the time of obturation. Difficult cases may require more time for preparation and can be managed more uneventfully in multiple appointments. Patients may require multiple short appointments because of medical conditions, their psychological state of mind, and fatigue.

LENGTH OF OBTURATION

One of the controversies in endodontics that remains unresolved is the apical limit of root canal treatment and obturation.[33,309] Early studies identified the dentinocemental junction as the apical limit for obturation. However, this histologic landmark cannot be determined clinically, and it has been found to be irregular within the canal. The dentinocemental junction may be several millimeters higher on the mesial canal wall when compared with the distal wall. In addition, the dentinocemental junction does not coincide with the narrowest portion of the canal or apical constriction. The reader is referred to Chapter 5 for more information about this anatomy.

Traditionally, the apical point of termination has been approximately 1 mm from the radiographic apices as determined by radiographs. Kuttler noted that the apical anatomy consists of the major diameter of the foramen and the minor diameter of the constriction (Fig. 7-3),[212] with the apical constriction identified as the narrowest portion of the canal. The average distance from the foramen to the constriction was found to be 0.5 mm, with the foramen varying in distance from the apex up to 2.5 mm. Kuttler also noted that the foramen-to-constriction distance increases with age because of cementum deposition. Supporting this finding, other investigators found that the location of the foramen was not at the apex. Deviations occurred in 92% of the roots and averaged 0.6 mm.[56] Another study noted the average apex-to-constriction distance was 0.9 mm and that 95% of the constrictions were between 0.5 and 1 mm in diameter[108]; this study also noted that the classic apical anatomy described by Kuttler was present in only 46% of the teeth. Other variations identified were the tapering constriction, the multiconstriction, and the parallel constriction. Other investigators examined 230 roots of permanent teeth stereomicroscopically and with radiographs.[37] Results of this study indicated a deviation of the foramen from the apex in 76% of the roots with microscopy and 57% with radiography; the mean distance was 1 mm.

A later study found that no foramina coincided with the longitudinal axis of the root, with the distance ranging from 0.2 to 3.8 mm (Fig. 7-4).[152] Root resorption is an additional factor in length determination. Resorption is more common

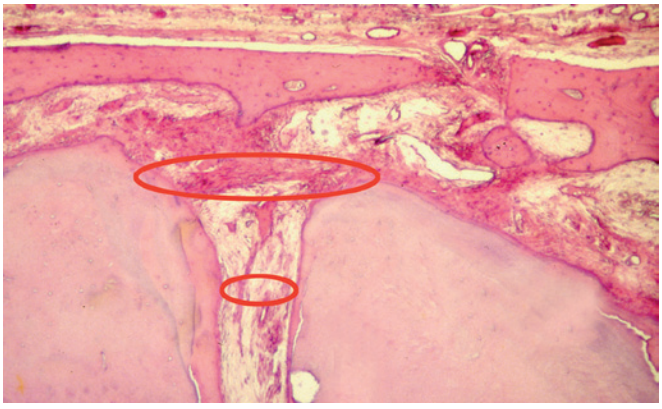

FIG. 7-3 Histologic section of a root apex, demonstrating anatomy of the classic foramen and constriction.

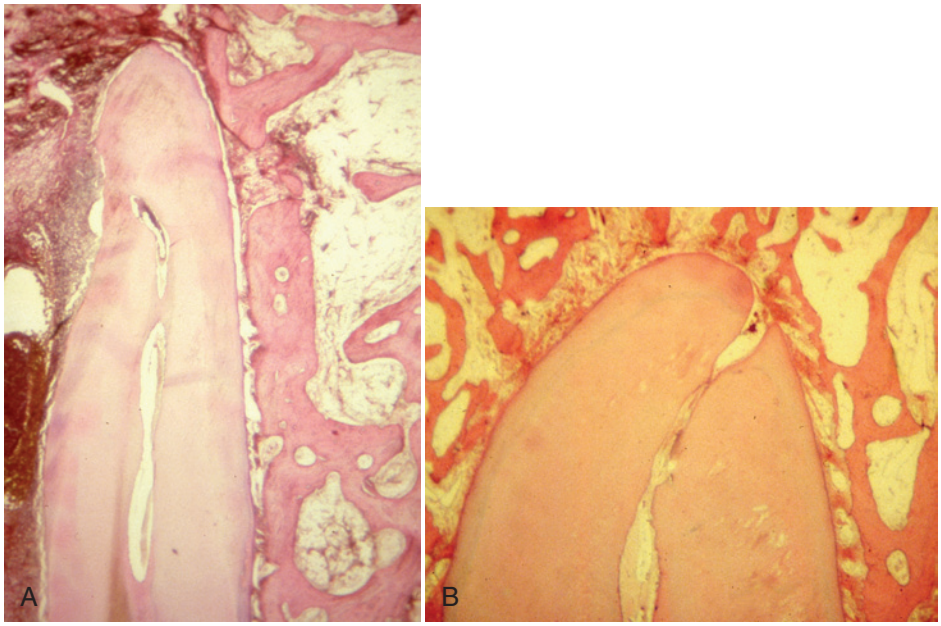

FIG. 7-4 Histologic sections demonstrating the foramen exiting short of the root apex.

with necrosis and apical bone resorption, and this can result in loss of the constriction (Fig. 7-5).[122,239] On the basis of these findings it appears that canals filled to the radiographic apex reflect an overextension of the obturating material. If overextension occurs that cannot be retrieved, and there appears to be resultant nerve damage, the practitioner is obligated to refer the patient to a qualified practitioner skilled in cases of this type.[139]

A study by the Toronto group on the prognosis of retreatment identified perforation,[92] pretreatment periradicular disease, and adequate length of the root canal filling as factors significantly influencing success and failure. The authors speculated that canals filled more than 2 mm short harbored necrotic tissue, bacteria, and irritants that when re-treated could be cleaned and sealed. The success rate for negotiating the apical unfilled canal was 74%.

Controversy also exists regarding the role accessory canals play in success and failure (Fig. 7-6). A scanning electron microscopy (SEM) study of the apical anatomy of each tooth group except the third molars noted no pattern for foraminal openings[151]; the number of accessory canals ranged from 1 to 16. Although lateral canals can be associated with pathosis, one study that examined root-treated teeth from human cadavers reported no relationship between unfilled lateral canals and periradicular pathosis.[20]Accessory/lateral canals are often obturated by chance and only serendipitously identified on the posttreatment radiograph (Fig. 7-7).

A later histobacteriological study also found no evidence to support that lateral canals must be filled to achieve a successful long-term treatment outcome (Fig. 7-8).[313] In cases with vital pulps, forcing obturation materials into lateral canals resulted in unnecessary damage to the periradicular tissues with consequential inflammation. In cases with nonvital, infected pulps in which lateral canals appeared radiographically filled, they were actually not sealed or disinfected, and the remaining tissue in the ramification was inflamed and enmeshed with the filling material. This, however, does not mean that lateral canals should not be optimally debrided and disinfected by

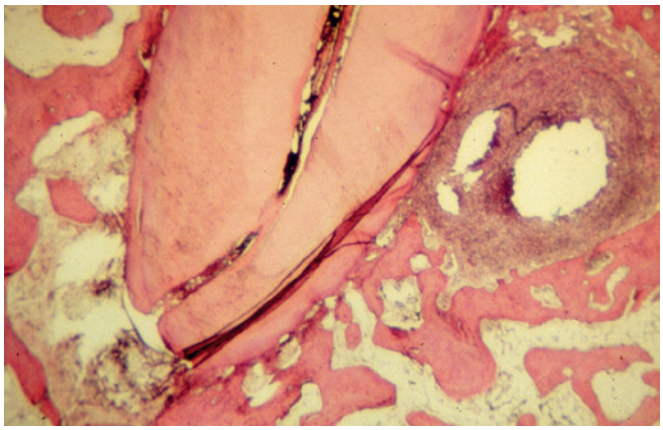

FIG. 7-7 Histologic section of a mesial root of a mandibular molar with a lateral canal present and associated lesion. Will the lesion resolve after the removal of the main canal contents, or will the lesion persist because of necrotic pulpal remnants in the lateral canal? The question remains unanswered.

FIG. 7-8 Posttreatment radiograph of a mandibular right first molar with a lateral canal associated with the distal root.

contemporary irrigant delivery and agitation techniques to reduce microbes and/or biofilms that reside within those spaces, prior to obturation of the canal space with root-filling materials and sealers.

The importance of length control in obturation relates to extrusion of root-filling materials. In a quantitative systematic review of the literature,[338] the authors critically analyzed 12 outcome studies that fulfilled the following criteria: i) a minimum follow-up period of two years; ii) data available on termination of obturation/instrumentation; iii) adequate definition of treatment failure; iv) data available on success/failure of root canal therapy in relation to the obturation/instrumentation length; and v) presence or absence of periapical radiolucency. The 12 studies were classified into three categories based on the obturation length from the radiographic apex: A) 0-1 mm; B) >1 mm but <3 mm; and C) obturated past the radiographic apex, including sealer. From the 12 studies, only four studies that included data that could be placed into the three length categories were further subjected to meta-analysis. Results of the meta-analysis indicated that the success rate in group A (obturated 0-1 mm from apex) was marginally better than group C (obturated past apex) by 29%. Although group A had better success than group B (obturated >1 mm short), the difference was not statistically significant. The authors concluded that a better success rate was achieved when treatment involved obturation short of the apex.

The aforementioned results derived from the sophisticated meta-analysis of multiple publications highlighted the data presented in the classic work performed by Sjögren and coworkers on healing of root-treated teeth with necrotic pulps and periapical lesions 8 to 10 years after treatment.[364] When those teeth were filled within 2 mm of the apex, 94% revealed normal periapical conditions with the use of periapical radiography at the follow-up examination. Conversely, roots with excess root fillings and those with fillings more than 2 mm short of the apex had significantly lower success rates of 76% and 68%, respectively.

Similar results were also reported in a prospective clinical study on the healing[262] and survival[263] of teeth that had undergone primary or secondary root canal treatment for 2 to 4 years. Absence of root-filling extrusion was found to be a highly significant postoperative prognostic factor affecting the success of both primary and secondary root canal treatment.[262] With respective to tooth survival, extrusion of gutta-percha root filling did not have any effect on tooth survival within the first 22 months, but significantly increased the risk of tooth loss beyond 22 months.[263] This prognostic factor was common to both primary and secondary root canal treatment. The authors attributed the delayed effect of extrusion of gutta-percha root filling on tooth survival to the possibility of subcritical cracks created by excessive forces during compaction of gutta-percha, which eventually propagated during function and ultimately resulted in catastrophic failure.

On the basis of biologic and clinical principles, the conclusions derived from studies performed for more than two decades apart are all agreeable, in that instrumentation and obturation should not extend beyond the apical foramen.[259] This was also demonstrated in a histologic study which evaluated 41 human root-filled teeth from 36 patients.[312] In six cases exhibiting overfills, histologic examination revealed severe inflammation.

Whereas the guideline of 1 mm from the radiographic apex remains rational when using radiographs, the point of apical termination of the preparation and obturation remains empirical. The use of an apex locator in conjunction with radiographs and sound clinical judgment makes this decision more logical. The need to compact the gutta-percha and sealer against the apical dentin matrix (constriction of the canal) is necessary to prevent extrusion of materials into the periapical tissues. Deciding where the apical constriction of the canal lies is based on the clinician's basic knowledge of apical anatomy, tactile sensation, radiographic interpretation, apex locators, apical bleeding, and (if not anesthetized) the patient's response.

PREPARATION FOR OBTURATION

During the cleaning and shaping process, organic pulpal materials and inorganic dentinal debris accumulate on the canal wall, producing an amorphous irregular smear layer (Fig. 7-9).[25,244,281] As shown in one of these studies, the smear layer is superficial with a thickness of 1 to 5 μm.[244] This superficial debris can be packed into the dentinal tubules to various distances.[1]

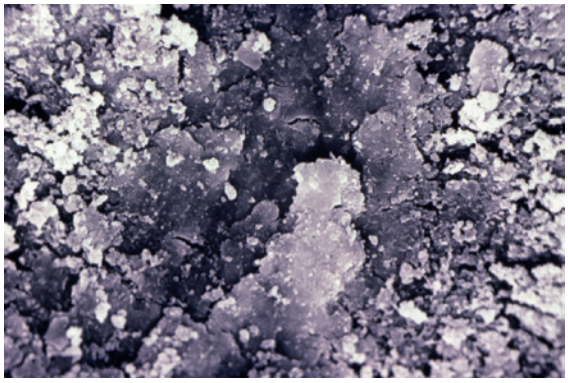

FIG. 7-9 Scanning electron microscopy of a prepared canal wall. The tubules are covered with a smear layer of organic and inorganic material.

In cases of necrosis this layer may also be contaminated with bacteria and their by-products. For example, one study found that bacteria can extend 10 to 150 μm into the dentinal tubules of necrotic teeth.[346] Another study noted that capillary action and fluid dynamics play a role in packing debris into the tubules.[3] Another investigation noted a mean penetration of 479 μm after a 28-day incubation period.[287]

The smear layer is not a complete barrier to bacteria but may act as a physical barrier, decreasing bacterial penetration into tubules. This was illustrated by a study demonstrating that removal of the smear layer permitted colonization of the dentinal tubules at a significantly higher rate when compared with leaving the smear layer in place.[104]

The smear layer may also interfere with adhesion and penetration of sealers into dentinal tubules.[410] Evidence indicates that sealer penetration into dentinal tubules does not occur when the smear layer is present.[132,277] For example, one study found that removal of the smear layer permitted Roth 811 (Roth International, Ltd., Chicago, IL), Calciobiotic root canal sealer (CRCS; Coltène/Whaledent, Cuyahoga Falls, Ohio), and Sealapex (SybronEndo, Orange, California) to penetrate to between 35 and 80 μm, whereas the presence of the smear layer obstructed tubular penetration of all sealers.[208] Other studies found that smear layer removal increased bond strength and reduced microleakage in teeth obturated with AH-26 (DENTSPLY Maillefer, Ballaigues, Switzerland).[111,133] Another investigation found that a combination of smear layer removal, AH-26 as the sealer, and vertical compaction of gutta-percha had a cumulative effect in reducing leakage.[386]

There does not appear to be a consensus on removing the smear layer before obturation.[70,347,353] The advantages and disadvantages of the smear layer remain controversial; however, growing evidence supports removal of the smear layer before obturation.[177,353] The organic debris present in the smear layer might constitute a substrate for bacterial growth.[281] It has been suggested that the smear layer prohibits sealer contact with the canal wall and permits leakage.[29] Bacterial penetration in the presence of a smear layer in canals obturated with thermoplasticized gutta-percha and sealer has been shown to be significantly higher than with smear layer removal before obturation.[281] An additional consideration is the presence of viable bacteria that remain in the dentinal tubules and use the smear layer for sustained growth and activity.[49] Removal of the smear layer introduces the possibility of reinfecting the dentinal tubules if leakage occurs.[347] However, one study demonstrated that bacteria present before obturation are not viable after obturation.[99]

The smear layer may also interfere with the action of irrigants used as disinfectants.[272] When the smear layer is not removed, it may slowly disintegrate and dissolve around leaking obturation materials, or it may be removed by bacterial by-products such as acids and enzymes.[347]

The smear layer may interfere with the adhesion and penetration of root canal sealers. It also may prevent gutta-percha penetration during thermoplastic techniques.[155] Significant tubular penetrations of gutta-percha and sealers have been reported with thermoplasticized obturations[155] and with dentin-bonded composite resins.[221] Removal of the smear layer also enhances the adhesion of sealers to dentin and tubular penetration.[221,267,347,409] Root canal filling materials adapt better to the canal walls after smear layer removal.[101,267,409,410,411]

One investigation examined the penetration depth of three different root canal sealers into the dentinal tubules with and without the smear layer. Scanning electron microscopy of extracted single-rooted human teeth obturated by lateral compaction of gutta-percha, using AH Plus (DENTSPLY Maillefer), Apexit (Ivoclar Vivadent, Schaan, Liechtenstein), and Roth 811, demonstrated that the smear layer prohibited the sealers from penetrating dentinal tubules. Smear layer removal allowed the penetration of all sealers to occur to various depths.[205] Another study found that removal of the smear layer reduced both coronal and apical leakage regardless of the sealer tested.[79]

Another study examined the smear layer and the passage of bacteria through and around obturating materials,[77] using human maxillary incisors obturated with gutta-percha and AH-26. The teeth were exposed to standardized bacterial suspensions containing *Fusobacterium nucleatum, Campylobacter rectus,* and *Peptostreptococcus micros* for a period of 60 days, using a leakage model employing upper and lower chambers. Results indicated that 60% of the samples in which the smear layer was not removed demonstrated bacterial leakage. There was no leakage in specimens from which the smear layer was removed.

An additional method for removing the smear layer involves sonic and ultrasonic instruments. In early studies of ultrasonic instrumentation, investigators noted the technique was effective in removing the smear layer.[84] Another investigator also demonstrated smear layer removal with ultrasonication and NaOCl.[63] One study compared the cleaning efficacy of short-term sonic and ultrasonic passive irrigation with 5.25% NaOCl after hand instrumentation in the apical 3 to 6 mm of maxillary molar root canals.[319] Passive sonic or ultrasonic irrigation for 30 seconds resulted in significantly cleaner canals than hand filing alone, and ultrasonic irrigation produced significantly cleaner canals than irrigation. However, other studies found ultrasonication and NaOCl to be ineffective in removing the smear layer.[24,400] In a more recent study, a group of investigators reported that the use of the Vibringe, EndoActivator, or needle irrigation did not significantly improve sealer penetration when compared with conventional irrigation.[43]

After the completion of cleaning and shaping procedures, removal of the smear layer is generally accomplished by irrigating the canal with 17% disodium ethylenediaminetetraacetic acid (EDTA) and 5.25% NaOCl (Fig. 7-10).[25] Chelators remove the inorganic components, leaving the organic tissue elements intact. Sodium hypochlorite is necessary for removal of the

FIG. 7-10 Scanning electron microscopy of the canal wall after removal of the smear layer with 17% EDTA and 5.25% sodium hypochlorite.

remaining organic components. Citric acid has also been shown to be an effective method for removing the smear layer,[16,23,170,337] as has tetracycline.[19,164]

Chelating agents were introduced to endodontic treatment by Nygaard-Østby in 1957 for treatment of calcified narrow root canals.[266] Ethylenediaminetetraacetic acid is the chelating solution customarily used in endodontic treatment. It is available in both liquid and paste forms with common concentrations between 15% and 17%.[177]A detergent is frequently added to the liquid to decrease surface tension, to increase the cleaning ability, and to enhance the bactericidal action of the solution.[399] The effectiveness of EDTA is related to time of application, the pH, and the concentration.[254,266]

Demineralization results in increased dentin permeability[150] because of the removal of the smear layer and plugs and enlargement of the tubules. It appears that the tubular enlargement is due to selective removal of the peritubular dentin.[175] The action of chelators and acids appears to be more effective in the coronal and middle thirds of the root and is reduced apically.[177,228] This reduced activity may be a reflection of canal size.[210] This is a clinical concern because of the more irregular structure of dentin in the apical third. Another investigation demonstrated marked variations in the apical portion of the root,[250] including accessory root canals, areas of resorption and repaired resorptions, pulp stones, irregular or absent primary tubules, irregular secondary dentin, and cementum-like tissue lining the apical root canal wall. The variable structure of the apical region of human teeth presents challenges to the use of endodontic obturation techniques requiring adhesives, because this may influence the dentin bonding ability in the apical region.[250]

Ethylenediaminetetraacetic acid appears to be biocompatible when used clinically[266]; however, irreversible decalcification of periapical bone and neuroimmunologic disturbances have been noted.[342] Extrusion of both NaOCl and EDTA in clinical treatment should be avoided.[163,282,380]

The recommended time for removal of the smear layer is 1 to 5 minutes.[62,177,337] The small particles of the smear layer are primarily inorganic with a high surface-to-mass ratio that facilitates removal by acids and chelators. Investigators have found that a 1-minute exposure to 10 mL of EDTA was adequate to remove the smear layer and that a 10-minute exposure caused excessive removal of both peritubular and intratubular dentin.[62]

The use of EDTA in combination with NaOCl is recommended[371,381] and may enhance the cleaning[228] and antimicrobial effects of these solutions when compared with using them alone.[58] Although the use of EDTA alone does not cause erosion of the canal wall dentin, it should be noted the adjunctive use of NaOCl with EDTA may result in erosion of the intraradicular dentin, depending on the timing and the concentrations of irrigants employed.[236,300,345,433]

New smear layer–removing irrigants are commercially available that combine calcium chelation of the inorganic component of the smear layer with antimicrobial activities. Examples of these irrigants include BioPure MTAD (DENSPLY Tulsa Dental Specialties)[349] and QMix 2in1 Irrigating Solution (DENSPLY Tulsa Dental Specialties).[86]

THE IDEAL ROOT CANAL FILLING

Various endodontic materials have been advocated for obturation of the radicular space. Most techniques employ a core material and sealer. Regardless of the core material a sealer is essential to every technique and helps achieve a fluid-tight seal.

The American Association of Endodontists' *Guide to Clinical Endodontics* outlines contemporary endodontic treatment.[8] Nonsurgical root canal treatment of permanent teeth "involves the use of biologically acceptable chemical and mechanical treatment of the root canal system to promote healing and repair of the periradicular tissues." The process is accomplished under aseptic conditions with rubber dam isolation. Regarding obturation, the guide states, "Root canal sealers are used in conjunction with a biologically acceptable semi-solid or solid obturating material to establish an adequate seal of the root canal system." In this area the guidelines indicate that "Paraformaldehyde-containing paste or obturating materials have been shown to be unsafe. Root canal obturation with paraformaldehyde-containing materials is below the standard of care for endodontic treatment" (Fig. 7-11). Chapter 29 gives further information about this issue.

Assessment of nonsurgical treatment is based primarily on the posttreatment radiographic examination. The radiographic criteria for evaluating obturation include the following categories: length, taper, density, gutta-percha and sealer removal to the facial cementoenamel junction in anterior teeth and to the canal orifice in posterior teeth, and an adequate provisional or definitive restoration (Fig. 7-12).

Quality assurance is accomplished through a careful evaluation of treatment procedures. Only by this approach can deficiencies be identified and corrected. Although the anatomy and morphology of the radicular space vary tremendously, the obturated root canal should reflect the original canal shape. Procedural errors in preparation, such as loss of length, ledging, apical transportation, apical perforation, stripping perforation, and separated instruments, may not be correctable. Errors in obturation, such as length, voids, inadequate removal of obturation materials, and temporization, may be correctable.

Radiographic interpretation may vary among clinicians because of differences in radiopacity in root canal sealer/cements, constituents in specific brands of gutta-percha, interpretation of voids in vivo versus in vitro,[431] the overlying bony anatomy, radiographic angulation, and the limited two-dimensional view of the obturated root canal or canals.

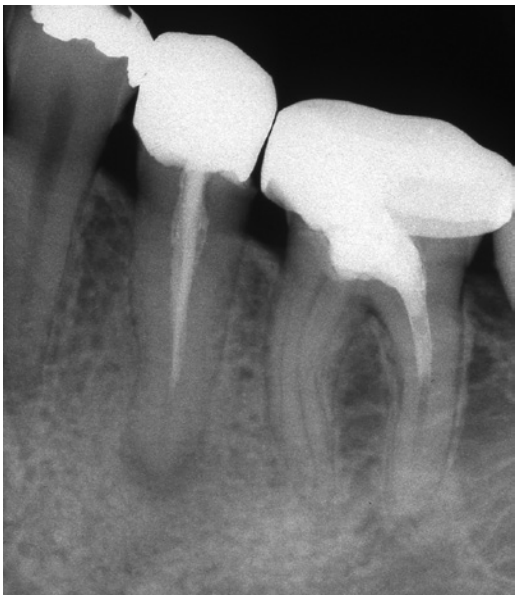

FIG. 7-11 A periapical radiograph of a mandibular left second premolar and first molar, demonstrating Sargenti paste root canal treatment. In addition to the toxic material, the technique often accompanies inadequate cleaning and shaping procedures.

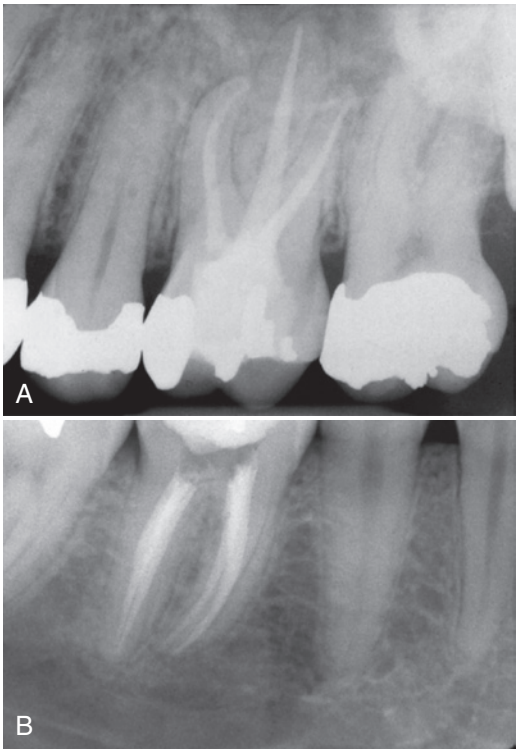

FIG. 7-12 A, Posttreatment radiograph of a maxillary right first molar, demonstrating adequate length, density, and taper. B, Posttreatment radiograph of a mandibular right first molar with an adequate obturation.

An often overlooked aspect in the assessment of root canal obturation is the density of the apical portion of the fill.[153] The apical third of the canal may be filled with a sea of root canal cement and a single master cone or poorly compacted mass of previously softened gutta-percha. Radiographically, the apical third of the canal appears less radiodense. An ill-defined outline to the canal wall is evident, along with obvious gaps or voids in the filling material or its adaptation to the confines of the canal. Because of the use of highly radiopaque root canal sealers/cements, the apical portion may be filled only with sealer, giving the clinician the false impression of a dense, three-dimensional obturation with gutta-percha.

Root canal sealers vary in radiopacity.[304,379] Some contain silver particles or significant amounts of barium sulfate to enhance their radiopacity. Although these components may enhance visualization of anatomic structures such as lateral canals, it is important to realize they do not increase the sealing ability of the sealer and the quality of the obturation. They may also give the impression that a canal is well obturated when voids are masked by the density of the sealer. It is erroneous to claim that obturations with highly radiopaque sealers are better than those made with less radiopaque materials. This type of comparison and claim to superiority are both unfounded and unwarranted. The radiographic appearance or aesthetic appearance of the obturated canal system should be secondary to meticulous cleaning and shaping. Although assessment of the root canal obturation is based on radiographic findings, root canal sealers do not have to be highly radiopaque to be effective.

BOX 7-1

Properties of an Ideal Sealer

- Exhibits tackiness when mixed to provide good adhesion between it and the canal wall when set
- Establishes a hermetic seal
- Radiopaque, so that it can be seen on a radiograph
- Very fine powder, so that it can mix easily with liquid
- No shrinkage on setting
- No staining of tooth structure
- Bacteriostatic, or at least does not encourage bacterial growth
- Exhibits a slow set
- Insoluble in tissue fluids
- Tissue tolerant; that is, nonirritating to periradicular tissue
- Soluble in a common solvent if it is necessary to remove the root canal filling

TYPES OF SEALERS

Root canal sealers are necessary to seal the space between the dentinal wall and the obturating core interface. Sealers also fill voids and irregularities in the root canal, lateral and accessory canals, and spaces between gutta-percha points used in lateral condensation. Sealers also serve as lubricants during the obturation process. Grossman outlined the properties of an ideal sealer (Box 7-1).[149] At present no sealer satisfies all the criteria.

Sealers should be biocompatible and well tolerated by the periradicular tissues.[367] All sealers exhibit toxicity when freshly mixed; however, their toxicity is greatly reduced on setting.[214] Sealers are resorbable when exposed to tissues and tissue fluids.[14] Tissue healing and repair generally appear unaffected by most sealers, provided there are no adverse breakdown products of the sealer over time.[42,50-52,54] Breakdown products from the

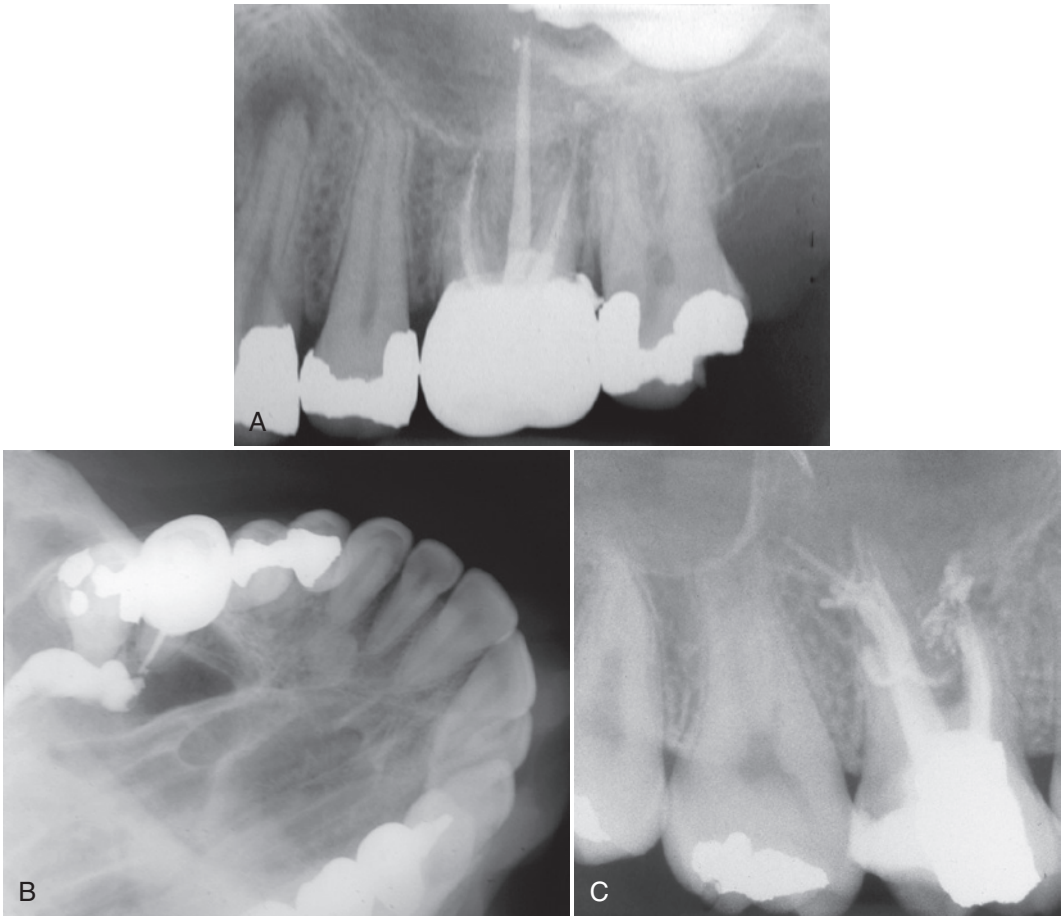

FIG. 7-13 **A,** Extrusion of sealer evident on this posttreatment radiograph of a maxillary first molar. The separated lentulo spiral in the mesiobuccal root indicates a possible method of sealer placement. **B,** Maxillary occlusal film demonstrates that the sealer is located in the maxillary sinus. Correction by nonsurgical techniques is not possible. **C,** Maxillary right first molar with extrusion of the sealer and gutta-percha.

sealers may have an adverse effect on the proliferative capability of periradicular cell populations.[146] As a result, sealers should not be placed routinely in the periradicular tissues as part of an obturation technique.[214] Although an osteogenic response has been observed with calcium hydroxide–based root canal sealers,[172,365,376,390] the ability of these sealers to sustain a high pH over time has been questioned.[207]

The most popular sealers are zinc oxide–eugenol formulations, calcium hydroxide sealers, glass ionomer sealers, resin-based (epoxy resin or methacrylate resin) sealers, and the recently introduced calcium silicate–based sealers. Despite claims by the manufacturers on the advantages of each class of sealers, there are no evidence-based data, based on randomized clinical trials, demonstrating the superiority of one class of sealer over another. Regardless of the sealer selected, all exhibit toxicity until they have set. For this reason, extrusion of sealers into the periradicular tissues should be avoided (Fig. 7-13).

Zinc Oxide and Eugenol

Zinc oxide–eugenol sealers have a history of successful use over an extended period of time. Zinc oxide–eugenol sealers will resorb if extruded into the periradicular tissues.[14] They exhibit a slow setting time,[6] shrinkage on setting,[192] solubility,[290] and they can stain tooth structure.[90,209,394] An advantage to this sealer group is antimicrobial activity.[4,18,167,249]

An early zinc oxide–eugenol sealer was introduced by Rickert and Dixon.[308] This powder/liquid sealer contained silver particles for radiopacity. Although it was possible to demonstrate the presence of lateral and accessory canals the sealer had the distinct disadvantage of staining tooth structure if not completely removed. Marketed as Pulp Canal Sealer (SybronEndo) and Pulp Canal Sealer EWT (extended working time), this sealer is popular with clinicians using thermoplastic techniques. Procosol (Procosol, Inc., Philadelphia, Pennsylvania) is a modification of Rickert's formula in which the silver particles have been removed (zinc oxide, hydrogenated resin, bismuth subcarbonate and barium sulfate; liquid eugenol).

Grossman modified the formulation and introduced a non-staining formula in 1958 (Table 7-1).[148] This is the formulation in Roth's Sealer (Roth International) Tubli-Seal (SybronEndo) is a catalyst/base zinc oxide–eugenol sealer that is convenient to mix but has a faster setting time when compared with the liquid/powder sealers. Tubli-Seal EWT provides an extended working time. Wach's Sealer (Balas Dental, Chicago, Illinois) contains Canada balsam, which gives the material a sticky or tacky property that softens the gutta-percha into a more homogeneous mass when used with lateral compaction.

Although zinc oxide–eugenol sealers possess marked cytotoxic and tissue-irrigating potencies in ex vivo cell culture

TABLE 7-1
Formula for Zinc Oxide–Eugenol Root Canal Sealer

Powder	Liquid
Zinc oxide	42 parts
Staybelite resin	27 parts
Bismuth subcarbonate	15 parts
Barium sulfate	15 parts
Sodium borate, anhydrous	1 part

studies,[134] their clinical usefulness has been well demonstrated in an in vivo animal model,[129] as well as in retrospective human clinical studies.[83] This discrepancy between the results of in vitro and in vivo cytotoxicity testing may be explained by the fact that most cell culture systems are represented by only one cell type (i.e. no cell-cell interactions) which is often monoclonal in origin. Another important issue to consider is the fact that culture conditions are not homeostatic and there is no elimination of toxic substances as there would be in vivo. By contrast, the human body possesses a lymphatic system and periapical defenses such as polymorphonuclear leukocytes, plasma cells, and macrophages to help eliminate toxic substances.[61] These mechanisms do not exist in a culture plate and must be taken into account for interpretations of the results of cell culture–based cytotoxicity studies reported in the endodontic literature.

Calcium Hydroxide Sealers

Calcium hydroxide sealers were developed for therapeutic activity. It was thought that these sealers would exhibit antimicrobial activity and have osteogenic–cementogenic potential. Unfortunately, these actions have not been demonstrated.[100,251] Solubility is required for release of calcium hydroxide and sustained activity. This is inconsistent with the purpose of a sealer. Calciobiotic root canal sealer (CRCS) is a zinc oxide–eugenol sealer with calcium hydroxide as one ingredient. Sealapex (SybronEndo) is a catalyst/base system. The base contains zinc oxide, calcium hydroxide, butyl benzene, sulfonamide, and zinc stearate. The catalyst contains barium sulfate and titanium dioxide as radiopacifiers in addition to resin, isobutyl salicylate, and aerosol R972. Apexit and Apexit Plus (Ivoclar Vivadent) consist of an activator (disalicylate, bismuth hydroxide/bismuth carbonate, and fillers) and a base (calcium hydroxide, hydrated colophonium [i.e., pine resin], and fillers).

Noneugenol Sealers

Developed from a periodontal dressing, Nogenol (GC America, Alsip, Illinois) is a root canal sealer without the irritating effects of eugenol. The base contains zinc oxide, barium sulfate, and bismuth oxychloride.

Glass Ionomer Sealers

Glass ionomers have been advocated for use in obturation because of their dentin-bonding properties. Ketac-Endo (3M ESPE, St. Paul, Minnesota) enables adhesion between the material and the canal wall.[128] It is also difficult to properly treat the dentinal walls in the apical and middle thirds with conditioning agents to receive the glass ionomer sealer. A disadvantage of glass ionomers is that they must be removed if retreatment is required.[229] This sealer has minimal antimicrobial activity.[167]

FIG. 7-14 Activ GP (Brasseler USA) glass ionomer–coated gutta-percha points and sealer.

Activ GP (Brasseler USA, Savannah Georgia) consists of a glass ionomer–impregnated gutta-percha cone with a glass ionomer external coating and a glass ionomer sealer (Fig. 7-14). Available in 0.04 and 0.06 tapered cones, the sizes are laser verified to ensure a more precise fit. This single cone technique is designed to provide a bond between the dentinal canal wall and the master cone (monoblock). A bacterial leakage study comparing Activ GP/glass ionomer sealer, Resilon/Epiphany, and gutta-percha (GP)/AH Plus demonstrated no statistically significant differences at 65 days.[125]

Resin Sealers

Resin sealers have a long history of use, provide adhesion, and do not contain eugenol. There are two major categories: epoxy resin–based and methacrylate resin–based sealers.

Epoxy Resin Sealers

AH-26 (DENTSPLY DeTrey, Konstanz, Germany) is a slow-setting epoxy resin that was found to release formaldehyde when setting.[204,368] AH Plus (DENTSPLY DeTrey) is a modified formulation of AH-26 in which formaldehyde is not released (Fig. 7-15).[222] The sealing abilities of AH-26 and AH Plus appear comparable.[96] AH Plus is an epoxy resin–amine based system that comes in two tubes. The epoxide paste tube contains a diepoxide (bisphenol A diglycidyl ether) and fillers as the major ingredients, while the amine paste tube contains a primary monoamine, a secondary diamine, a disecondary diamine, silicone oil, and fillers as the major ingredients. It exhibits a working time of approximately 4 hours.

Methacrylate Resin Sealers

Four generations of methacrylate resin–based root canal sealers have been marketed for commercial use.[200,278] The first generation of hydrophilic methacrylate resin–based material (Hydron; Hydron Technologies, Inc., Boca Raton, Florida) was designed for en masse root filling and appeared in the mid 1970s when

FIG. 7-15 AH Plus sealer is a resin formulation. (Courtesy DENTSPLY DeTrey, Konstanz, Germany.)

scientific foundations behind dentin bonding were at their infancy stage of development. The major component of Hydron was poly[2-hydroxyethyl methacrylate] (poly[HEMA]), which was injected into a root canal and polymerized in situ within the canal space without the adjunctive use of a root-filling material. Hydron became obsolete in the 1980s as subsequent clinical findings were unacceptable.[215]

Prior to the advent of contemporary methacrylate resin–based sealers that are specifically designed for endodontic application, there had been sporadic attempts on the use of low viscosity resin composites (i.e., resin cements) and dentin bonding agents as sealers for root-filling materials. Leonard and coworkers were the first to demonstrate, with the use of an etch-and-rinse technique (citric acid–ferric chloride etchant known as 10:3 solution), the formation of a hybrid layer in radicular dentin with C&B-Metabond (Parkell Inc., Edgewood, New York), an adhesive resin cement for cementation of indirect restorations and prostheses.[221] Following the marketing of self-priming, self-etching and self-adhesive resin cement technologies in restorative dentistry, functionally analogous, low viscosity methacrylate resin–based root canal sealers have since been available for use in endodontics. This type of bondable root canal sealers has been aggressively promoted with the highly desirable property of creating monoblocks within the root canal space.[383] The term monoblock refers to the idealized scenario in which the canal space becomes perfectly filled with a gap-free, solid mass that consists of different materials and interfaces, with the purported advantages of simultaneously improving the seal and fracture resistance of the filled canals.

The second generation of bondable sealer is nonetching and hydrophilic in nature and does not require the adjunctive use of a dentin adhesive. It is designed to flow into accessory canals and dentinal tubules to facilitate resin tag formation for retention and seal after smear layer removal with NaOCl and EDTA. EndoREZ (Ultradent Products Inc., South Jordan, Utah) is a dual-cured radiopaque hydrophilic methacrylate sealer that contains non-acidic diurethane dimethacrylate. The addition of triethyleneglycol dimethacrylate to the sealer composition renders it hydrophilic, so that it may be used in the wet environment of the root canal system and be very effective in penetrating dentinal tubules and forming long resin tags.[34,382] The sealer was found to seal best when applied to slightly moist intraradicular dentin.[440] EndoREZ is recommended for use with either a conventional gutta-percha cone or with specific EndoREZ points (resin-coated gutta-percha). A retrospective clinical and radiographic study evaluating the 10-year treatment outcome of one-visit root canal treatment using gutta-percha and the EndoREZ sealer reported accumulative probability of success of 92.1% after 10 years.[439] The authors concluded that EndoREZ may be recommended as an alternative to other commonly used root canal sealers. Unfortunately, no additional root canal sealer was used in that study for comparison.

New generations of self-etching (third generation) and self-adhesive (fourth generation) resin cements have been introduced to restorative dentists to simplify bonding procedures. They became commercially available shortly after the introduction of those resin cement systems. The third generation self-etching sealers contain a self-etching primer and a dual-cured resin composite root canal sealer. The use of self-etching primers reintroduced the concept of incorporating smear layers created by hand/rotary instruments along the sealer-dentin interface. An acidic primer is applied to the dentin surface that penetrates through the smear layer and demineralizes the superficial dentin. The acidic primer is air-dried to remove the volatile carrier and then a dual-cured moderately filled flowable resin composite sealer is applied and polymerized. Provided that these materials are sufficiently aggressive to etch through thick smear layers, the technique sensitivity of bonding to root canals may be reduced when smear layers are inadvertently retained in the apical third of instrumented canal walls.

Third-generation methacrylate resin–based sealers that incorporate the use of self-etching primers became popularized following the introduction of Resilon (Resilon Research LLC, Madison, Connecticut), a dimethacrylate-containing polycaprolactone-based thermoplastic root-filling material.[355] In RealSeal (SybronEndo), the self-etching primers are supplied as a single-bottle system and contain 2-acrylamido-2-methyl-propanesulfonic acid (AMPS) as the functional acidic monomer. The functional acidic monomer, solvent, water that is necessary for ionization of the acidic monomers, and self-cured catalysts are incorporated into "one-component" (i.e., incorporated inside a single bottle). This is similar to the so-called "one-component" type all-in-one adhesives that are currently available in restorative dentistry. The sealer that is used after application of the self-etching primer consists of bisphenol-A-glycidyldimethacrylate (BisGMA), ethoxylated BisGMA, urethane dimethacrylate (UDMA), and hydrophilic methacrylate with calcium hydroxide, barium sulfate, barium glass, bismuth oxychloride, and silica.[186] An ethoxylated bisphenol-A-dimethacrylate (EBPADMA)–based resinous solvent (e.g., RealSeal Thinning Resin, SybronEndo) is also available for adjusting the sealer viscosity.[301]

The fourth-generation methacrylate resin–based sealers (e.g., MetaSEAL, Parkell Inc.; RealSeal SE, SybronEndo) is functionally analogous to a similar class of recently introduced self-adhesive resin luting cements in that they have further eliminated the separate etching/bonding step.[302] Acidic resin monomers that are originally present in dentin adhesive primers are now incorporated into the resin-based sealer/cement to render them self-adhesive to dentin substrates. The combination of an etchant, a primer, and a sealer into an all-in-one self-etching, self-adhesive sealer is advantageous in that it reduces the application time as well as errors that may occur during each bonding step. MetaSEAL is the first commercially available fourth-generation self-adhesive dual-curable sealer.[217]

The liquid component of MetaSEAL comprises 4-META, HEMA and difunctional methacrylate monomers. The powder contains zirconium oxide as spherical radiopaque fillers, silica nanofillers, and a hydrophilic initiator. The inclusion of an acidic resin monomer, 4-methacryloyloxyethyl trimellitate anhydride (4-META), makes the sealer self-etching and hydrophilic in nature and promotes monomer diffusion into the underlying intact dentin to produce a hybrid layer after polymerization. According to the manufacturer, MetaSEAL is recommended exclusively for cold compaction and single-cone techniques and supports the use of either Resilon or gutta-percha as a root-filling material. The sealer purportedly bonds to thermoplastic root-filling materials as well as radicular dentin via the creation of hybrid layers in both substrates. MetaSEAL is also marketed as Hybrid Bond SEAL (Sun Medical Co. Ltd., Shiga, Japan) in Japan and had been reported to produce equivalent or slightly inferior sealing properties as conventional non-bonding epoxy resin-based sealers.[30,269]

RealSeal SE is the simplified dual-cured version of RealSeal and uses a polymerizable methacrylate carboxylic acid anhydride (i.e., 4-META) as the acidic resin monomer.[15,201,237] It contains EBPADMA, HEMA, BisGMA, benzoyl peroxide, tertiary amine, photoinitiators, silane-treated barium borosilicate glass, silica, bismuth oxychloride, Ca-Al-F silicate, tricalcium phosphate as additional components. It may be used with Resilon cones or pellets using cold lateral or warm vertical techniques, or with RealSeal 1, a carrier-based Resilon obturator system.[166]

Silicone Sealers

RoekoSeal (Coltène/Whaledent) is a polydimethylsiloxane that has been reported to expand slightly on setting.[273]

GuttaFlow and GuttaFlow2 (Coltène/Whaledent) are cold flowable matrices that are triturated. They consist of gutta-percha in particulate form (less than 30 μm) added to RoekoSeal (Fig. 7-16). The material is provided in capsules for trituration. The technique involves injection of the material into the canal, followed by placement of a single master cone. The material provides a working time of 15 minutes and it cures in 25 to 30 minutes. Evidence suggests that the material fills canal irregularities with consistency[435] and is biocompatible,[45,116] but the setting time is inconsistent and may be delayed by final irrigation with sodium hypochlorite.[45] The sealing ability appears comparable to other techniques in some studies and inferior in others.[45,47,206,276,396]

FIG. 7-16 GuttaFlow trituration capsule and injection syringe (Coltène/Whaledent).

Calcium Silicate Sealers

A new category of root canal sealers based on mineral trioxide aggregate (MTA) has recently been commercially available. These sealers are an outgrowth of the popularity of MTA materials, which are based on tricalcium silicate, a hydraulic (water-setting) powder used for various surgical and vital pulp therapy treatments.[279,280] This type of root canal sealer is attractive because of the bioactivity that has been reported for MTA-type materials,[131,384] which are also known for being hydrophilic.[65]

Calcium silicate sealers include some of the same hydraulic compounds found in Portland cement, primarily tricalcium silicate and dicalcium silicate powder.[65] The first use of hydraulic calcium silicate materials in dentistry dates to 1878, when a German, Dr. Witte, published a case report on using Portland cement to fill root canals.[103] Tricalcium silicate–based materials did not come into common practice until the 1990s, when Mineral Trioxide Aggregate (MTA) was introduced. MTA is a hydraulically active powder that contains primarily tricalcium silicate, dicalcium silicate, and a radiopaque powder, often bismuth oxide. Because of staining of crown dentin by the bismuth oxide component, which may be rendered brown (in NaOCl), gray (in chlorhexidine) or even black (in glutaraldehyde), the radiopacifier has now been replaced with other materials such as zirconia dioxide (zirconia) or tantalum oxide in some commercial formulations. The radiopaque agent, bismuth oxide, zirconia, or tantalum oxide, is important, without which MTA would not be distinguishable on a radiograph. Minor phases of tricalcium aluminate and calcium sulfate are often present. Some MTA-type products contain calcium carbonate, or tetracalcium aluminoferrite. The term MTA is used here to denote all the tri- and dicalcium silicate products.

Tricalcium silicate cements/sealers set by reaction with water and form a highly alkaline (pH of about 12) mixture consisting of a rigid matrix of calcium silicate hydrates and calcium hydroxide.[89] These hydrates form on the surface of the original calcium silicate particles and hydration gradually penetrates inward. When tricalcium silicate cement sets, the dimensional change is less than 0.1% expansion, which helps with creating a barrier, and is especially important for endodontics. Setting time for tricalcium silicate cements is lengthy, about 165 minutes for the initial set and less than 6 hours for the final set, which has been a major drawback for using them in some indications, but not for its use as a sealer. The consistency of the MTA products with water has not been suitable for use as a sealer. Also, the coarseness of the first MTA products, intended for surgical use, has meant they were not suitable for use as a sealer, as their film thickness was too high (>50 μm).

Four tricalcium silicate sealers are currently commercially available: MTA Fillapex (Ângelus Indústria de Produtos Odontlógicos Ltda; Londrina, Paraná, Brazil),[44,143,255,438] iRoot SP (Innovative BioCeramix Inc., Vancouver, Canada; aka Endosequence BC sealer; Brasseler USA),[44,66,231,432,434] Endo CPM Sealer (EGEO SRL, Buenos Aires, Argentina),[141,142,255,336,378] and MTA Plus (Avalon Biomed, Bradenton, Florida). The MTA Plus may be used as a cement[220,334] or a sealer by adjusting the powder:liquid ratio. Table 7-2 lists what is known about the components of these sealers. Other experimental tricalcium

silicate sealers include Generex B (aka ProRoot Endo Sealer),[404] MTAS[64] and MTA Flow.[130] The iRoot SP is premixed and MTA Fillapex has two pastes that are combined in a mixing tip. The Endo CPM Sealer and MTA Plus sealer are powder/gel systems that the user can mix to the consistency desired. The available materials' descriptions are vague; for instance, MTA Fillapex has "natural or diluent resins," with "filler and thickening agents." However, what is believed to be in common is that tricalcium silicate powder is a component of all four sealers.

The MTA Fillapex and iRoot SP sealers have non-aqueous vehicles in which the powders are dispersed. For the tricalcium silicate particles to contribute to sealing, they must become hydrated in the tooth by exchange of the non-aqueous vehicle for water in the root canal. EndoCPM Sealer and MTA Plus sealer rely on mixing with water-based gels just before use, without a non-aqueous resin. The proportions of the tricalcium silicate powders are not known in any of these materials, but are most likely to be highest in MTA Plus because no inert liquid vehicle is included. The inert vehicle is the liquid medium in the pastes of MTA Fillapex and iRoot SP that does not react with the powder. The bioactivity of MTA-type materials has made the use of tricalcium silicate powders in sealers of interest. The possibility of extrusion past the apex with a bioactive material leads to the supposition that healing in the periapical area would occur more readily with a tricalcium silicate product. However, two of the sealers have the tricalcium silicate powders dispersed in a non-reactive organic medium, which may detract from the potential benefit of the bioactive powder. To date, no peer-reviewed papers have been published to establish the benefits of tricalcium silicate powders in sealers in human clinical studies; all studies and reports are based on in vitro testing and in vivo animal models. Calcium carbonate is added to Endo CPM Sealer to reduce the pH from 12.5 to 10.0 after setting. By doing so, the manufacturer claimed that surface necrosis in contact with the material is reduced, thereby optimizing the conditions for the enzymatic action of alkaline phosphatase.[142]

The physical properties of some of these sealers have been published. Table 7-3 contains values that are known for comparison to the ISO 6876/ADA 57 methods and requirements and the AH Plus sealer. The flow, film thicknesses, solubility, dimensional stability, and radiopacity of the new sealers meet the ISO 6876 requirements. The flow of these sealers varies, but so do the values for AH Plus. The dimensional stability is excellent. The solubility of the sealers is higher than AH Plus, which may be attributed to the formation of partially soluble calcium hydroxide within the set tricalcium silicate. The radiopacities are less than AH Plus, which is known for its radiopacity.

The working and setting times of the iRoot SP and MTA Plus materials are longer than the MTA Fillapex sealer. iRoot SP has the longest setting time, and requires diffusion of water from the dentinal tubules into the sealer to set.[256] In a test where water was added to the EndoSequence BC sealer (i.e., iRoot SP), the setting time was reduced to about 150 hours, but the hardness was significantly diminished.[231] The Endosequence BC sealer has been tested for strengthening teeth when used with glass ionomer–coated cones and found to be stronger in vitro.[135]

Biocompatibility tests have been performed with some of these sealers. Endosequence BC sealer was more cytotoxic than AH Plus root canal sealer; the time to become noncytotoxic as judged from mitochondrial enzymatic (succinic dehydrogenase) activity was 5 weeks for Endosequence BC sealer and 3 weeks for AH Plus sealer.[231] Another study found that after setting, the cytotoxicity of MTA Fillapex decreased and the sealer presents suitable bioactivity to stimulate hydroxyapatite nucleation.[323]

Medicated Sealers

Sealers containing paraformaldehyde are strongly contraindicated in endodontic treatment (Fig. 7-17). Although the lead and mercury components may have been removed from these zinc oxide–eugenol formulations over time, the severely toxic paraformaldehyde content has remained a constant. These sealers are not approved by the U.S. Food and Drug Administration[12] and are unacceptable under any circumstances in clinical treatment because of the severe and permanent toxic effects on periradicular tissues.[348] A paste containing 6.5% paraformaldehyde as well as lead and mercury was advocated for use by Sargenti[325-327] and originally marketed as N-2. Lead has been reported in distant organ systems when N-2 is placed within the radicular space.[274] In another study the investigators reported the same results regarding systemic distribution of the paraformaldehyde component of N-2.[38] Removal of the heavy metals resulted in a new formulation: RC2B. Other

paraformaldehyde sealers include Endomethasone, SPAD, and Reibler's paste. The toxic in vivo effects of these materials on the pulp and periapical tissues have been demonstrated over time.[80,261]

In addition to the toxic nature of the material, clinicians employing the material place it with a lentulo spiral. Overextension has resulted in osteomyelitis and paresthesia.[117,202] One of these studies reported irreversible neurotoxicity, manifested as dysesthesia, in cases where paraformaldehyde pastes were forced through the apical foramen into the periapical tissues.[202] The reader is referred to Chapter 29 for further discussion about this harmful material and technique.

SEALER PLACEMENT

Various methods of sealer placement have been advocated, including the master cone, lentulo spirals, files and reamers, and ultrasonics. Investigators compared sealer placement using a file rotated counterclockwise, the lentulo spiral (Fig. 7-18), an ultrasonic file, and coating the master gutta-percha cone.[413] Placement did not differ with the various techniques; however, the investigators noted the most variation in sealer coating was in the apical area.[413] Another study compared sealer placement with a K-type file, the lentulo spiral, and using the master cone in curved canals. Results demonstrated no significant differences in the techniques after obturation; no technique covered more than 62.5% of the canal wall surface.[158] Other investigators reported that ultrasonics produced the best sealer distribution when used circumferentially.[369] These findings were supported by another study that reported ultrasonic placement to be superior to manual placement techniques.[1]

In the past, it has been assumed that instrumented canals need to be thoroughly dried prior to obturation with root-filling materials and sealers. Indeed, there were leakage studies reporting that a better apical seal might be achieved by drying the canals with 95% ethanol prior to obturation.[370] A recent study reported that for some root canal sealers (iRoot SP, AH Plus, Epiphany and MTA Fillapex), better adhesion to the dentinal walls might be achieved by leaving the canals slightly moist (i.e., drying the canals with low vacuum via a Luer-Lok adapter for 5 seconds, followed by one paper point for one second).[256] Similar results were also reported with the use of the EndoREZ sealer.[440] This, however, does not mean that canals should remain totally flooded with water prior to obturation, because such a level of residual moisture would adversely affect the adhesiveness of those root canal sealers to intraradicular dentin.[256]

The method of obturation does not seem to affect the sealer distribution on the canal wall in the apical portion of the canal; however, lateral compaction results in better distribution in the mid-coronal areas when compared with warm vertical compaction.[422] Another well-controlled study reported that none of five evaluated obturation techniques resulted in uniform sealer distribution along the entire length of the core obturation material.[176] Evidence indicates that the method of obturation affects the sealer penetration into tubules. This was exemplified by a study reporting that thermoplastic techniques produced deeper sealer penetration into tubules.[94] Removal of the smear layer enhances sealer penetration into the dentinal tubules.[93]

CORE MATERIALS

Although a variety of core materials have been used in conjunction with a sealer/cement, the most common method of obturation involves gutta-percha as a core material. Regardless of the obturating technique, emphasis should be placed on the process of cleaning and shaping the canal. The materials and techniques described do not routinely create an impervious seal of the canal system; all materials leak to some extent.[2] The choice of the obturation technique(s) depends on the unique circumstances with which each case presents.

The properties of an ideal obturation material have been outlined by Grossman (Box 7-2).[149] Historically, a variety of materials have been employed to obturate the root canal space. Solids, semisolid materials, and pastes have been employed. A common solid material used in the past was the silver cone.

Silver Cones

Jasper introduced cones made of silver, which he claimed produced the same success rate as gutta-percha and were easier to use.[183] The rigidity provided by the silver cones made them easier to place and permitted more predictable length control; however, their inability to fill the irregularly shaped root canal system permitted leakage (Fig. 7-19). Silver cones were believed to possess an oligodynamic property which, if true,

BOX 7-2

Properties of an Ideal Obturation Material

- Easily manipulated and provides ample working time
- Dimensionally stable with no shrinkage once inserted
- Seals the canal laterally and apically, conforming to its complex internal anatomy
- Nonirritating to the periapical tissues
- Impervious to moisture and nonporous
- Unaffected by tissue fluids—no corrosion or oxidization
- Inhibits bacterial growth
- Radiopaque and easily discernible on radiographs
- Does not discolor tooth structure
- Sterile
- Easily removed from the canal if necessary

would have resulted in the destruction of microbes within the root canal system. Unfortunately, it was not true. Moreover, when silver points contact tissue fluids or saliva, they corrode.[48] The corrosion products have been found to be cytotoxic and produce pathosis or impede periapical healing.[344]

With the introduction of rigid silver cones it became possible to easily place them to length. This resulted in clinicians often failing to properly clean and shape the canal before obturation. Treatment failures were the result of leakage and failure to remove the irritants from the root canal system. The use of silver cones today is considered to be below the standard of care in contemporary endodontic practice. For further information about this material and technique, the reader is referred to Chapter 29.

Gutta-Percha

Gutta-percha is the most popular core material used for obturation. Major advantages of gutta-percha are its plasticity, ease of manipulation, minimal toxicity, radiopacity, and ease of removal with heat or solvents. Disadvantages include its lack of adhesion to dentin and, when heated, shrinkage upon cooling. Gutta-percha is the *trans*-isomer of polyisoprene (rubber) and exists in two crystalline forms (α and β).[144] In the unheated β phase, the material is a solid mass that is compactable. When heated, the material changes to the α phase and becomes pliable and tacky and can be made to flow when pressure is applied. A disadvantage to the α phase is that the material shrinks on setting.[340]

Gutta-percha cones consist of approximately 20% gutta-percha, 65% zinc oxide, 10% radiopacifiers, and 5% plasticizers.[126] Attempts have been made to make gutta-percha more antimicrobial by the addition of materials such as iodoform,[75] calcium hydroxide,[230] chlorhexidene,[233] and tetracycline.[247] The clinical effectiveness of adding these materials has not been demonstrated. Moreover, to exert an antimicrobial pharmacological effect, the active ingredient must leach out of the gutta-percha, which could have a detrimental effect on long-term sealability.

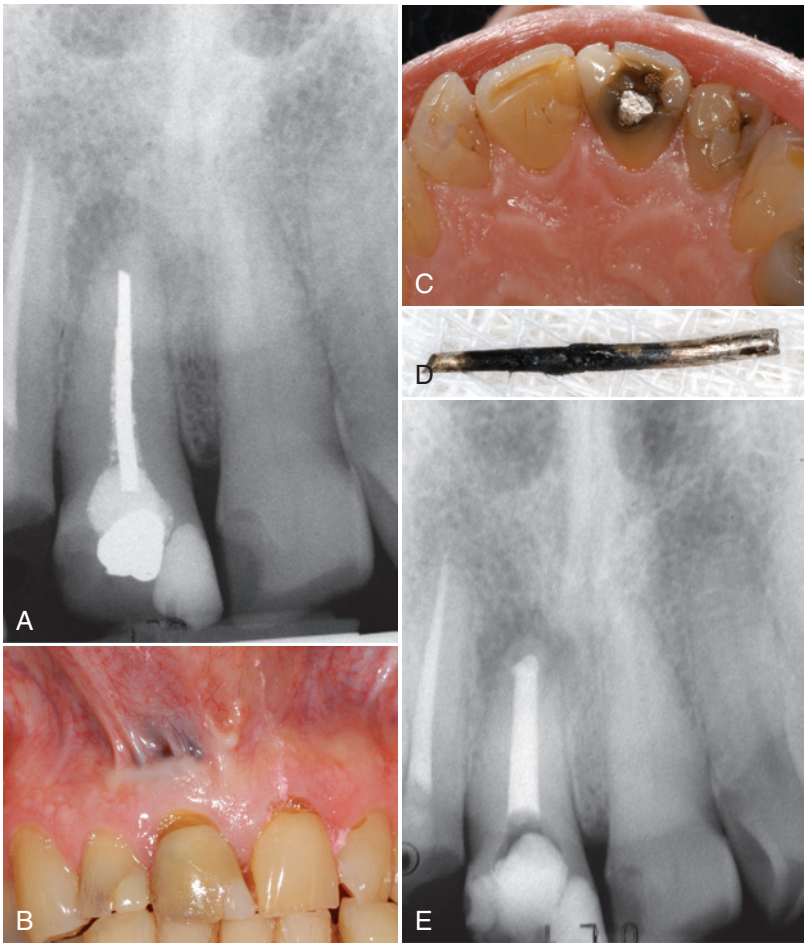

FIG. 7-19 Silver cones are advocated for ease of placement and length control. **A,** Radiograph of a facial maxillary right central incisor obturated with a silver cone. **B,** Tissue discoloration indicating corrosion and leakage. **C,** Lingual view indicates coronal leakage. **D,** Corroded silver cone removed from the tooth. **E,** Posttreatment radiograph of the tooth.

Unlike rubber, room temperature gutta-percha cannot be condensed or made to flow. Compaction results in transmission of forces to the material and the canal wall equally and may result in root fracture. Gutta-percha can be made to flow if it is modified by either heat or solvents such as chloroform. This permits adaptation to the irregularities of the canal walls.

The α form of gutta-percha melts when heated above 65°C. When cooled extremely slowly, the α form will recrystallize. Routine cooling results in the recrystallization of the β form. Although the mechanical properties for the two forms are the same, when α-phase gutta-percha is heated and cooled, it undergoes less shrinkage, making it more dimensionally stable for thermoplasticized techniques. The use of α-phase gutta-percha for obturation has increased as thermoplastic techniques have become more common.

Gutta-percha cones are available in standardized and nonstandardized sizes. Standardized sizes conform to requirements contained in specifications published by the International Organization of Standardization (ISO) or ADA American National Standards Institute (ADA ANSI). The nonstandard nomenclature refers to the dimensions of the tip and body (Fig. 7-20). A fine-medium cone has a fine tip with a medium body. Standardized cones are designed to match the taper of stainless steel and nickel-titanium instruments (Figs. 7-21 and 7-22). A size 40, 0.04 taper cone has a tip of 0.4 mm and a taper of 0.04 mm per millimeter. Unfortunately ISO and ADA ANSI standards allow tolerances and, coupled with a less than completely accurate manufacturing process, the actual cone size varies as does the tip and taper of the master apical file.[140,243]

Although gutta-percha points cannot be heat sterilized, a study reported that gutta-percha points can be sterilized by placing in 5.25% NaOCl for one minute. This study also reported that 2% glutaraldehyde, 2% chlorhexidine, and 70% ethyl alcohol were not effective in killing *Bacillus subtilis* spores, one of the hallmark organisms used for testing effective antimicrobial effectiveness.[359]

Activ GP

Activ GP (Brasseler USA) consists of gutta-percha cones impregnated on the external surface with glass ionomer (see Fig. 7-14). Single cones are used with a glass ionomer sealer. Available in 0.04 and 0.06 taper cones, the sizes are laser-verified to help ensure a more precise fit. The single cone technique is designed to provide a bond between the dentinal canal wall and the master cone. A bacterial leakage study comparing Activ GP/glass ionomer sealer, Resilon/Epiphany, and gutta-percha/AH Plus demonstrated no statistically significant differences in leakage at 65 days.[125]

Resilon

The resin-based obturation systems RealSeal (SybronEndo), and Resinate (Obtura Spartan, Algonquin, Illinois) have been introduced as alternatives to gutta-percha (Figs. 7-23 and 7-24). Resilon is a high-performance industrial polyester that has been adapted for dental use.

The resin sealer bonds to a Resilon core, and attaches to the etched root surface. The manufacturer claims that this forms a "monoblock" (Fig. 7-25). With traditional obturation techniques, there is a gutta-percha–sealer interface and a tooth-sealer interface. With Resilon the resin sealer bonds to both the canal wall and the Resilon cone. Whether a monoblock is achievable remains controversial.[303]An in-depth review article on the subject of monoblocks indicates that with current materials and techniques, the monoblock has yet to be achieved.[383]

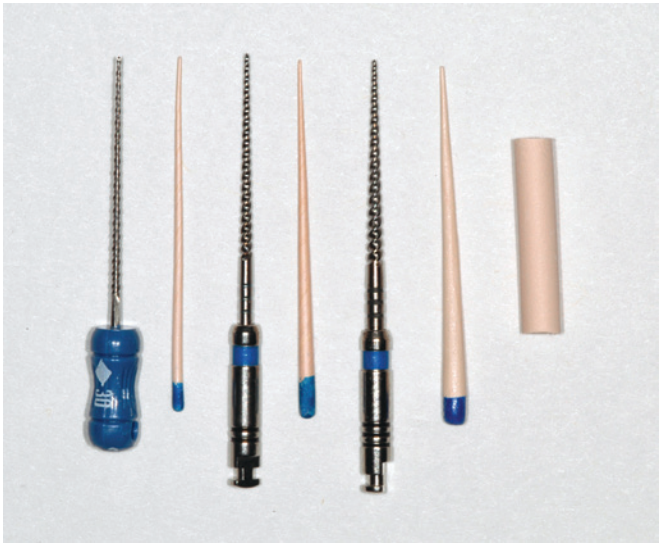

FIG. 7-24 Resilon #.02, #.04, and #.06 tapered points and a thermoplastic plug for use in the Obtura system.

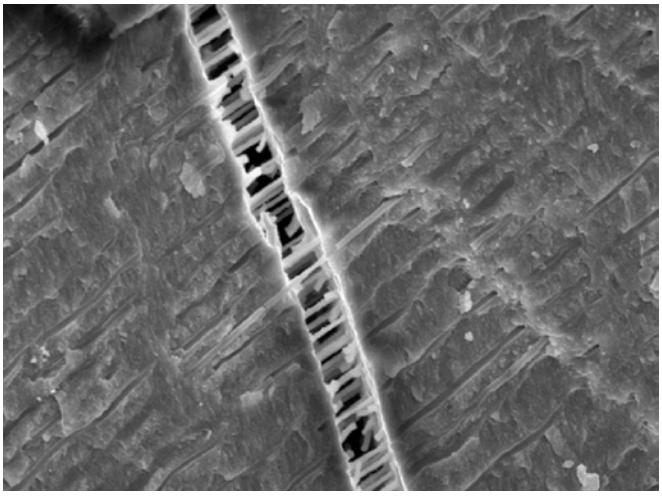

FIG. 7-25 Scanning electron microscopy view of Resilon tags extending into the dentinal tubules.

The system resembles gutta-percha and can be placed by lateral compaction, warm lateral or vertical compaction, thermoplastic injection, or with a core-carrier technique. It consists of a resin core material (Resilon) composed of polyester, difunctional methacrylate resin, bioactive glass, radiopaque fillers, and a resin sealer. Resilon is nontoxic, nonmutagenic, and biocompatible. The core material is available in nonstandard and standard cones and pellets for use in thermoplastic techniques (see Fig. 7-24).

After cleaning and shaping procedures an appropriate master cone is placed into the prepared canal and a radiograph image is exposed to verify the apical position. Because NaOCl may affect the bond strength of the primer, EDTA should be the last irrigant used before rinsing the canal with sterile water, saline, or chlorhexidine.

After drying the canal, a self-etch primer (sulfonic acid–terminated functional monomer, 2-hydroxyethyl methacrylate [HEMA], water, and polymerization initiator) is used to condition the canal walls and prepare them for bonding to the resin sealant (resin matrix of bisphenol A-glycidyl methacrylate [Bis-GMA], ethoxylated Bis-GMA, urethane dimethacrylate [UDMA], and hydrophilic difunctional methacrylates and fillers [70%] of calcium hydroxide, barium sulfate, barium glass, bismuth oxychloride, and silica). Two or three drops are placed in the canal with a pipette, a syringe, or a paper point that wicks the material to the working length. The excess primer is removed, the resin sealer is dispensed onto a mixing slab, and the viscosity is adjusted with the thinning resin. The sealer is applied with a paper point, Resilon point, or lentulo spiral. The canal is then obturated by lateral compaction, warm vertical compaction, or thermoplastic injection. The sealer takes approximately 25 minutes to set, so it is recommended that the coronal surface of the material be light cured for 40 seconds.

When using the System B (SybronEndo) for warm vertical compaction, the temperature setting should be 150°C at a power of 10. With the Obtura II thermoplasticized injection system (Obtura Spartan), the temperature settings vary depending on the needle tip employed. For the 25-gauge needle, a 160°C setting is selected; for the 23-gauge needle, a 140°C setting is used; and for the 20-gauge needle, the setting that is recommended is 120°C to 130°C.

Resilon appears to be comparable to gutta-percha in its ability to seal the radicular space.[22] Investigators evaluated coronal leakage of Resilon, using *Streptococcus mutans* and *E. faecalis* in roots that were filled by lateral and vertical compaction techniques with gutta-percha and AH-26 or Resilon and Epiphany sealer.[355] Resilon showed significantly less coronal leakage when compared with gutta-percha. In another study, investigators used a dog model to assess the ability of Resilon or gutta-percha and AH-26 to prevent apical periodontitis in teeth inoculated with microorganisms. Results indicated periapical inflammation in 18 of 22 roots (82%) obturated with gutta-percha and AH-26, whereas the Resilon group exhibited periapical inflammation in only 4 of 21 roots (19%).[356] Another study demonstrated that teeth filled with Resilon were more resistant to fracture than roots filled with gutta-percha and AH-26 sealer.[387] More recent evidence suggests that Resilon does not strengthen roots.[147,416]

Resilon appears to be biocompatible; implantation in the subcutaneous tissues of rats demonstrated fibrous encapsulation and negligible inflammation at 60 days.[41] One retrospective study compared the success and failure rates between obturation with gutta-percha and Kerr Pulp Canal Sealer and obturation with Resilon or Epiphany, with recall examination between 12 and 25 months. Statistical analysis indicated that the results were indistinguishable.[83] Another study demonstrated that 82 randomly selected clinical cases treated with Resilon produced success rates at 1 year that were comparable to cases treated with gutta-percha.[82] A recent review of the use of Resilon as a root-filling material reported that Resilon cannot be considered yet as an evidence-based replacement for the current gold-standard gutta-percha, due to the lack of long-term clinical outcome studies to demonstrate its clinical superiority over contemporary gutta-percha obturation techniques.[354]

Custom Cones

When the apical foramen is excessively large or the prepared root canal system is large, a custom cone may need to be fabricated (Fig. 7-26). This permits the adaptation of the cone to the canal walls, reduces the potential for extrusion of the core

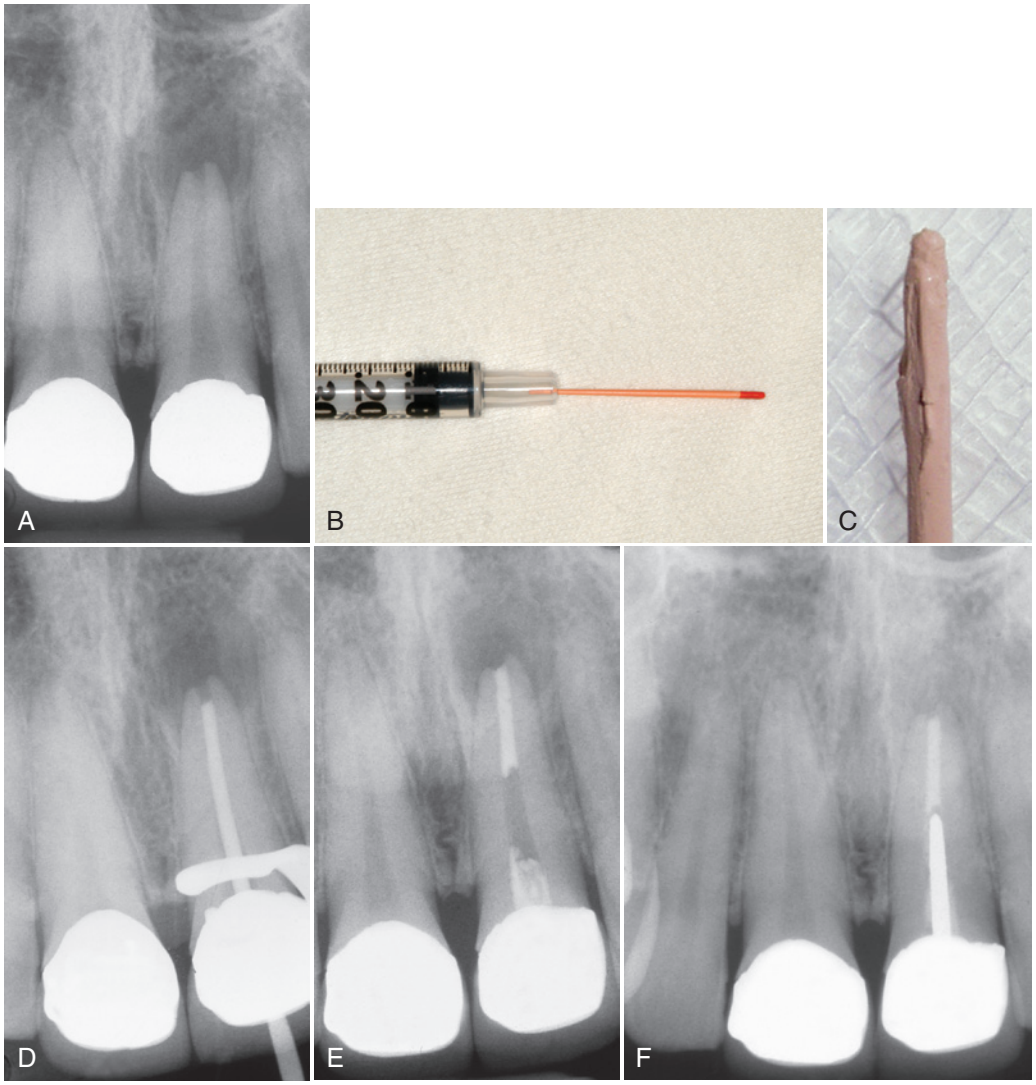

FIG. 7-26 Apical root resorption often results in an open apex requiring fabrication of a custom cone. **A,** Pretreatment radiograph of the maxillary left central incisor with pulp necrosis and chronic apical periodontitis. Apical root resorption is present. **B,** In fabricating a custom master cone a gutta-percha point is fit several millimeters short before softening in solvent and tamping into place. **C,** Softening the apical 2 to 3 mm in chloroform that has been placed in a tuberculin syringe. **D,** The completed custom cone represents an impression of the apical portion of the canal. **E,** The posttreatment radiograph with post space prepared. **F,** A 1-year follow-up radiograph demonstrating osseous regeneration.

material, and may improve the resultant seal.[28,194] The technique involves selection of a master cone and fitting that cone 2 to 4 mm short of the prepared length with frictional resistance. The cone is grasped with locking cotton pliers or a hemostat so that it can be placed into the canal in the same spatial relationship each time. The cone is removed and the tip is softened in chloroform, eucalyptol, or halothane for 1 or 2 seconds, depending on the clinical requirements. Only the outer superficial portion of the cone is softened. The central core of the cone should remain semi-rigid. The cone is then placed into the canal to the working length. The process can be repeated until an adequate impression of the canal is obtained at the prepared length. A radiograph is exposed to verify proper fit and position. An alternative to solvents is softening with heat.[196]

Large root canal systems may necessitate custom fabrication of a large master cone before canal adaptation. This may be accomplished by heating two, or more, large gutta-percha cones and rolling the mass between two glass slabs until an appropriate size is obtained (Fig. 7-27). A spatula may also be used to shape the cone.

METHODS OF OBTURATION

To date, little evidence exists to support one method of obturation as being superior to another based on outcome assessment investigations.[13,264] The prospective Toronto studies have suggested that warm vertical compaction may be superior to lateral compaction[92]; however, definitive evidence is lacking.[286]

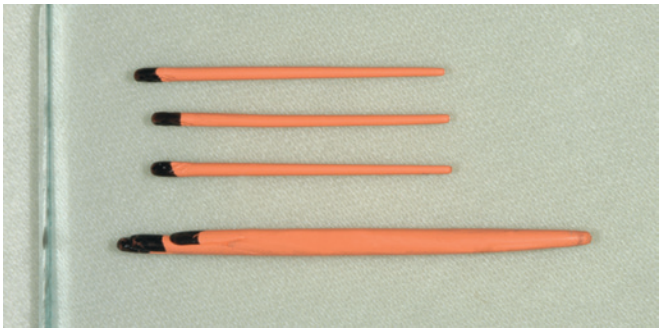

FIG. 7-27 For large canals, several gutta-percha points can be heated and rolled together, using a spatula or two glass slabs.

Lateral Compaction

Lateral compaction is a common method for obturation (Fig. 7-28).[59] The technique can be used in most clinical situations and provides for predictable length control during compaction.[136] A disadvantage is that the technique may not fill canal irregularities[427] as well as warm vertical compaction or other thermoplastic techniques.[424] The procedure can be accomplished with any of the acceptable sealers.

After root canal system preparation, a standard cone is selected that has a diameter consistent with the prepared canal diameter at the working length. Standard cones generally have less taper when compared with nonstandard cones and will permit deeper spreader penetration which will result in a better-quality resultant seal.[288] An alternative is to adapt an appropriately tapered nonstandard cone by cutting small

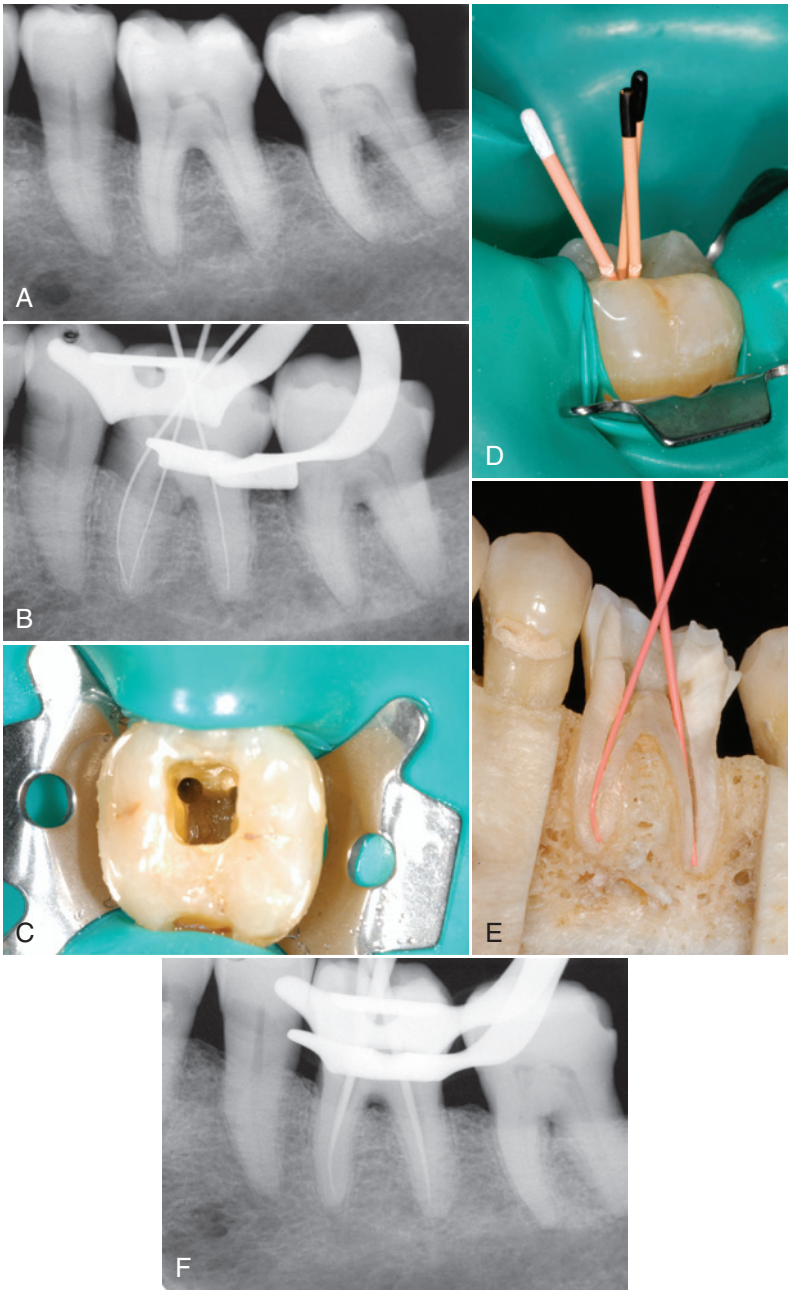

FIG. 7-28 Left first mandibular molar. **A**, Pretreatment radiograph. **B**, Working length radiograph. **C**, Coronal access opening, demonstrating the prepared mesiobuccal canal. **D**, Standardized master cones with coronal reference marked. **E**, Standard master cones fit to length as they exhibit minimal taper and permit deeper penetration of the spreader. **F**, Master cone radiograph.

increments from the tip. This "master cone" is measured and grasped with forceps so that the distance from the tip of the cone to the reference point on the forceps is equal to the prepared length. A reference point on the cone can be made by pinching the cone. The cone is placed in the canal, and if an appropriate size is selected, there will be resistance to displacement or "tug back." If the cone is loose it can be adapted by removing small increments from the tip. If the master cone fails to go to the prepared length a smaller cone can be selected. Devices are available to cut cones accurately at a predetermined length (Tip Snip; SybronEndo). When the cone extends beyond the prepared length a larger cone must be adapted or the existing cone shortened until there is resistance to displacement at the corrected working length.

The master cone placement is confirmed with a radiograph. The canal is irrigated and dried with paper points. Sealer is applied to the canal walls, and a spreader is prefitted so as to allow it to be inserted to within 1 to 2 mm of the working length. Appropriately sized accessory points are also selected to closely match the size of the spreader. The correlation between spreader size and nonstandard cones is variable,[53,437] and in small curved canals there does not appear to be a difference in the quality of obturation with nonstandard cones when compared with standard cones.[169,395]

Finger spreaders provide better tactile sensation and are less likely to induce fractures in the root when compared with the more traditional D-11T hand spreader.[88,223,224] In addition to the type of spreader, forces applied, and amount of dentin removed, spreader size may be a factor in root fracture, with large sizes inducing more stress.[294] Spreaders made from nickel-titanium are available and provide increased flexibility,[35] reduced stress,[109] and provide deeper penetration when

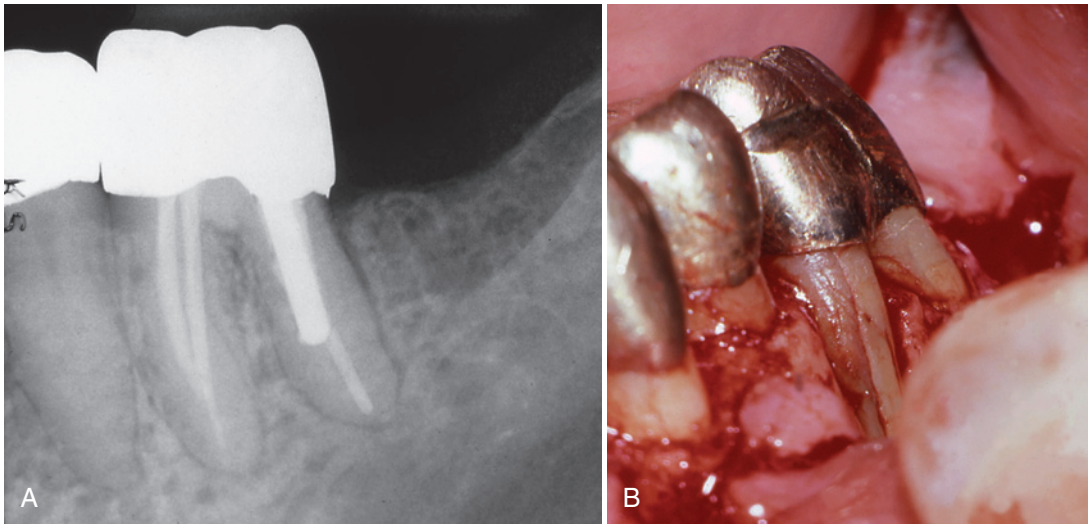

FIG. 7-29 Vertical root fractures can occur with excessive compaction forces. **A,** Follow-up radiograph of a mandibular left first molar. A deep isolated periodontal probing defect was associated with the buccal aspect of the mesiobuccal root. **B,** Flap reflection revealed a vertical root fracture.

compared with stainless steel instruments.[189,341,417] The spreader should fit to within 1 to 2 mm of the prepared length, and when introduced into the canal with the master cone in place, it should be within 2 mm of the working length.[7] There appears to be a correlation between the establishment of a higher quality seal and the depth of spreader penetration.[7,352]

After the spreader has been placed to its maximum depth, it is removed by rotating it back and forth as it is withdrawn. An accessory cone is placed in the space vacated by the spreader. The process is repeated until the spreader no longer goes beyond the coronal one third of the canal. The excess gutta-percha is removed with heat and the coronal mass is compacted with an appropriate unheated plugger. Only light pressure is required during lateral compaction because the gutta-percha is not condensed, and because as little as 1.5 kg of pressure is capable of fracturing a root (Fig. 7-29). In addition to the force applied, investigators have noted that removal of excessive amounts of dentin during preparation is a significant factor in root fracture.[415]

A disadvantage to lateral compaction is that the process does not produce a homogeneous mass. The accessory and master cones are laminated and remain separate. It is envisaged that the space between each of the cones is filled with sealer to aid in establishment of a water-tight seal.

The excess gutta-percha in the chamber is then seared off and vertically compacted with a heated plugger at the orifice or approximately 1 mm below the orifice in posterior teeth. Warm vertical compaction of the coronal gutta-percha enhances the seal.[429] In anterior teeth, the desired level is the cementoenamel junction on the facial surface to avoid aesthetic issues if the dentin should become stained. An alternative to lateral compaction with finger spreaders is ultrasonics.[21] For example, one study found that the technique produced adequate obturation and a 93% clinical success rate.[436]

Another study used ultrasonic-energized files in a warm lateral compaction technique and reported that the amount of gutta-percha, by weight, increased by 33% with two applications of ultrasonics when compared with lateral compaction.[98] Unfortunately, investigators found that the mean internal temperature rise was 29°C at the 6-mm level, with external heat generation exceeding the safe limit of 10°C.

Warm Vertical Compaction

Schilder introduced warm vertical compaction of gutta-percha as a method of obturating the radicular space in three dimensions.[339] Preparation requirements for the technique include preparing a root canal system with a continuously tapering funnel and keeping the apical foramen as small as possible.

The armamentarium includes a variety of pluggers and a heat source. Schilder pluggers come in a variety of sizes (#8 = 0.4 mm, # 8½ = 0.5 mm, etc., for sizes #9, #9½, #10, #10½, #11, #11½, #12) with increasing diameter. The instruments are marked vertically at 5-mm intervals. Various ISO standardized instruments are also available (Fig. 7-30).

The technique involves fitting a master cone short of the prepared working length (0.5 to 2 mm) with resistance to displacement (Fig. 7-31). This ensures that the cone diameter is larger than the prepared canal at the terminus. Nonstandard cones that closely replicate the canal taper are best because they permit the development of hydraulic pressure during compaction. After the adaptation of the master cone, it is removed and sealer is applied to the cone and the walls of the prepared canal. The cone is placed in the canal and the coronal portion is removed with a heated instrument. A heated spreader or plugger is used to remove portions of the coronal gutta-percha in successive increments and soften the remaining material in the canal. The Touch 'n Heat (SybronEndo) (Fig. 7-32), DownPak (Hu-Friedy, Chicago, Illinois), and System B (SybronEndo) (Fig. 7-33) are alternatives to applying heat with a flame-heated instrument because they permit improved temperature control. A plugger is inserted into the canal and the gutta-percha is compacted, forcing the plasticized material apically. The process is repeated until the apical portion has been reached. The coronal canal space is back-filled using small preheated pieces of gutta-percha. The sectional method consists of placing 3- to 4-mm sections of gutta-percha approximating the size of the canal into the root, applying heat, and compacting the mass with a plugger.

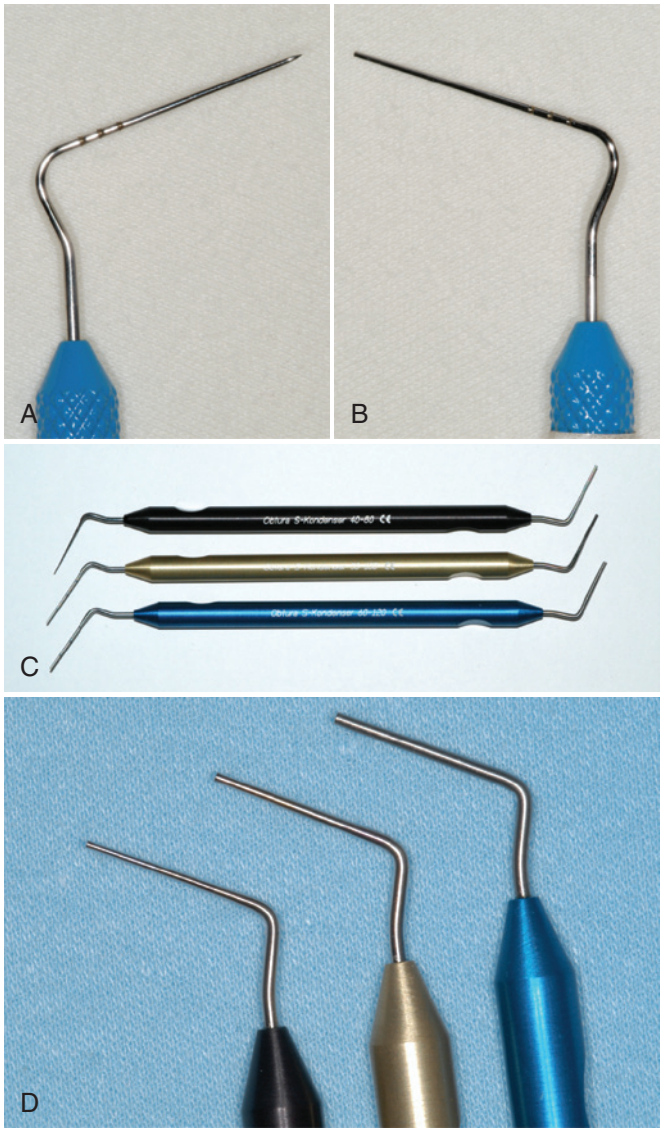

FIG. 7-30 Various pluggers are manufactured for compacting warm gutta-percha. **A**, ISO standard spreader. **B**, ISO standard plugger. **C**, Obtura S Kondensers. **D**, Closeup of Obtura S-Kondensers. (**C** courtesy Obtura Spartan, Algonquin, Illinois.)

One study measured temperature changes in a root canal system with warm vertical compaction.[40] The maximal temperatures occurred coronally and decreased apically. The authors reported that the maximal temperature in the canal was 118°C 8 mm from the apex. At 0 to 2 mm from the apical terminus, the maximal temperature had decreased to 44°C. Another study compared root surface temperatures for warm vertical obturation using the System B heat source, the Touch 'n Heat device, and a flame-heated carrier in maxillary and mandibular incisors and premolars 2 mm below the cemento-enamel junction. System B and the Touch 'n Heat produced a surface temperature rise that was less than 10°C for all maxillary incisors and premolar teeth. The Touch 'n Heat produced a greater than 10°C rise in mandibular incisors. The flame-heated carrier produced temperature changes greater than 10°C in all experimental teeth. Because the critical level of root surface heat required to produce irreversible bone damage is believed to be greater than 10°C the findings suggest that warm vertical compaction with the System B should not damage supporting periodontal structures; however, caution should be exercised with the Touch 'n Heat and flame-heated carriers.[219] The flame-heated spreader has no heat controls and the Touch 'n Heat controls only send heat to the tip and receive no feedback from the tip based on clinical conditions. The System B has a computer built in which allows it to receive feedback from the tip and adjust the tip temperature based on the clinical conditions, which allow the tip to remain at the dialed-in temperature.

The potential for vertical root fracture is also present with warm vertical compaction.[39] The forces developed appear to be equal to lateral compaction. Investigators compared warm vertical compaction and lateral compaction as a function of time. Results indicated that the forces developed with the two techniques were not significantly different. In a follow-up study, the mean value for wedging with warm vertical compaction was 0.65 ± 0.07 kg, whereas for lateral compaction it was 0.8 ± 0.1 kg.

Warm thermoplastic techniques have the advantage of producing movement of the plasticized gutta-percha within the obturated root canal system, resulting in a more homogeneous mass of gutta-percha, and filling irregularities and accessory canals better than lateral compaction.[105,421] This was illustrated in a study that reported a correlation between the quality of adaptation and the depth of heat application and canal size. Heat application close to the apical extent of the preparation produced the best results, and adaptation was better in small canals when compared with wide canals.[420] However, thermoplasticized techniques resulted in more extrusion of obturating materials.[213] There appeared to be no consistent differences between the techniques in sealing the canal space.[421]

Advantages of warm vertical compaction include filling of canal irregularities and accessory canals. Disadvantages include a slight risk of vertical root fracture because of compaction forces, less length control than with lateral compaction, and the potential for extrusion of material into the periradicular tissues. Warm vertical compaction is also difficult in more curved root canal systems, where the rigid pluggers may be unable to penetrate to the necessary depth. Occasionally, the canals have to be enlarged and tapered more to enable rigid carriers to penetrate within 4 to 5 mm of the apex. Additional removal of root canal dentin can weaken the root, making it more susceptible to root fracture.

Continuous Wave Compaction Technique

A variation of warm vertical compaction is the continuous wave compaction technique.[55] The increasing use of nickel-titanium rotary preparation techniques and the fabrication of greater taper standard cones have resulted in more clinicians using thermoplasticizing techniques. The manufacturing of gutta-percha cones to mimic the tapered preparation permits the application of greater hydraulic force during compaction when appropriately tapered pluggers are used. The continuous wave compaction technique employs the System B connected to 0.04, 0.06, 0.08, 0.10, or 0.12 tapered stainless steel dead-soft pluggers (see Fig. 7-33). The 0.06 tapered plugger also approximates the fine nonstandard gutta-percha cone, the 0.08 plugger the fine-medium cone, the 0.10 plugger the medium cone, and the 0.12 plugger the medium-large cone. Pluggers consistent with the ProFile GT instruments (DENTSPLY Tulsa

FIG. 7-32 The Touch 'n Heat unit. (Courtesy SybronEndo, Orange, Calif.)

Dental Specialties), and Autofit gutta-percha cones (SybronEndo) are also available.

The electric heat source permits a variable temperature setting. The recommended temperature setting for the System B unit is 200°C. One study evaluated internal and external temperature changes with the System B unit with varied tips and temperature settings of 200°C, 250°C, and 300°C. At 6 mm from the apex, the System B unit set at 300°C with a fine-medium plugger produced the highest mean internal temperature (74°C). However, the authors noted that the external temperature setting never exceeded the critical 10°C rise at the PDL with any temperature setting or tip configuration.[375] This was confirmed in another study that measured temperature changes 2 mm apical to the cementoenamel junction and 1.5 mm from the apex. Results indicated that temperature changes apically were negligible. The mean change near the cementoenamel junction was 4.1°C.[398]

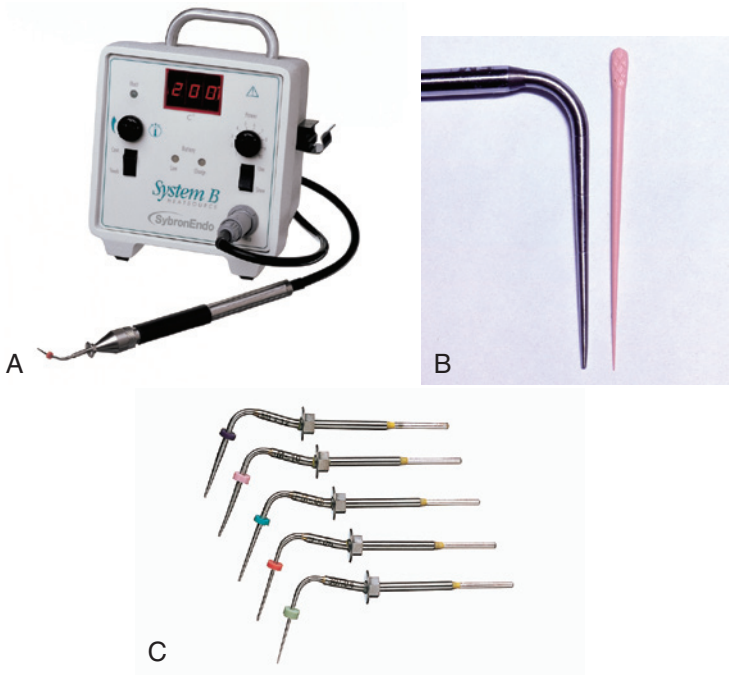

FIG. 7-33 Continuous wave obturation uses the System B unit. **A,** The System B unit. **B,** System B plugger with a nonstandard cone of similar taper. **C,** System B pluggers. (Courtesy SybronEndo, Orange, Calif.)

Another study reported that obturation temperature elevations produced during obturation with System B were significantly less than with traditional warm vertical compaction. An elevation of external root surface temperature by more than 10°C was noted with vertical compaction.[357] Investigators measured the root surface temperatures while using the System B heat source at various temperature settings from 250°C to 600°C. Results indicated that the highest temperature occurred 5 mm from the apex, and this was the only site that exceeded the 10°C rise. On the basis of this study, a temperature setting of 250°C or greater may be potentially hazardous.[101] For example, investigators using a thermocouple and simultaneous infrared analysis of temperatures found that the root surface temperature averaged 13.9°C, whereas the infrared technology indicated a 28.4°C rise at the same sites.[246]

After selecting an appropriate master cone, a plugger is prefitted to within 5 to 7 mm of the prepared length (Fig. 7-34). Placing the plugger deeper into the canal may enhance the flow of gutta-percha according to one investigator.[5] The point of plugger binding should be noted because once the instrument reaches this point the hydraulic forces on the gutta-percha will decrease and recompaction forces on the root will increase. There appears to be a correlation between the depth of the heated plugger relative to the working length and the quality of obturation and filling of canal irregularities.[46,190,424] Increasing the temperature settings does not seem to increase the effectiveness of obturation.[190]

The System B unit is set to 200°C in the touch mode. The plugger is inserted into the canal orifice and activated to remove excess coronal material. Compaction is initiated by placing a cold plugger against the gutta-percha at the canal orifice. Firm pressure is applied and heat is activated with the device. The plugger is moved rapidly (1 to 2 s) to within 3 mm of the binding point (Fig. 7-35). The heat is inactivated while firm pressure is maintained on the plugger for 5 to 10 seconds.

FIG. 7-34 System B plugger fit.

After the gutta-percha mass has cooled, a one-second application of heat separates the plugger from the gutta-percha and it is removed. The pluggers are designed to heat from the tip to their shank, which decreases the potential for dislodging the compacted mass and prevents a second application of heat to the material. Confirmation that the apical mass of gutta-percha is still present in the canal can be established with hand pluggers and/or radiographs. Two hand instruments are manufactured with tip diameters of 0.4 and 0.9 mm and 0.7 and 1.4 mm. It should be noted that with the continuous wave technique the heat source is placed only to within 5 to 7 mm from the tip of the gutta-percha; the apical portion of the gutta-percha remains essentially a single-cone technique as the heat transfer does not take place in the apical 2 to 5 mm of the gutta-percha.[145]

FIG. 7-35 System B activation and compaction.

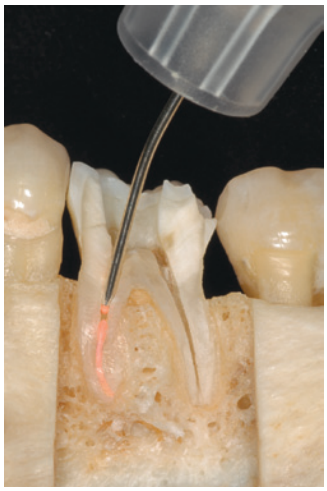

FIG. 7-36 Backfill by the Obtura II thermoplastic injection technique.

In ovoid canals, where the canal configuration may prevent the generation of hydraulic forces, an accessory cone can be placed alongside the master cone before compaction. With type II canals, the master cones are placed in both canals before compaction. A hand plugger is used to stabilize the cone in one canal while the other is being obturated.

Filling the space left by the plugger may be accomplished by a thermoplastic injection technique (Obtura or Ultrafil 3D [Coltène/Whaledent], Calamus [DENTSPLY Tulsa Dental Specialties], Elements [SybronEndo], or HotShot [Discus Dental, Los Angeles, California]) (Fig. 7-36)[187] or by fitting an accessory cone into the space with sealer, heating it, and compacting by short applications of heat and vertical pressure.

Warm Lateral Compaction

Warm lateral compaction of gutta-percha provides for predictable length control, which is an advantage over thermoplastic techniques. The Endotec II device (Medidenta, Las Vegas, Nevada) provides the clinician with the ability to employ length control while incorporating a warm gutta-percha technique (Fig. 7-37). Investigators demonstrated that the Endotec II produced a fusion of the gutta-percha into a solid homogeneous mass.[182] One study evaluated three thermoplasticized filling techniques and lateral compaction, using a bacterial

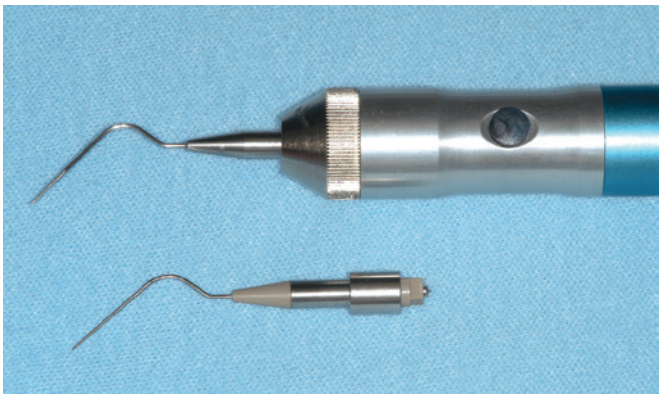

FIG. 7-37 Endotec II device (Medidenta) for warm lateral compaction.

FIG. 7-38 The Rootbuddy device (previously the DownPak device) for heat softening and vibrating gutta percha. (Courtesy Nikinc Dental, Eindhoven, The Netherlands.)

metabolite model, and found the Endotec to be superior to lateral compaction alone, lateral thermocompaction, and the Ultrafil 3D.[197] The use of warm lateral compaction with the Endotec demonstrated an increased weight of gutta-percha mass, by 14.63%, when compared with traditional lateral compaction.[227] Another study found a 24% increase in weight with warm lateral compaction when using the System B device.[260] Using the Endotec II, one investigation reported a statistically significantly better ability of warm vertical and warm lateral compaction techniques, versus cold lateral compaction, to reproduce artificially produced canal irregularities in a split-tooth model.[81] Another group of investigators used the EndoTwinn (Hu-Friedy), an instrument for warm lateral compaction, in a similar experiment. The EndoTwinn instrument also possesses the ability to vibrate the electronically heated tip. They reported that warm lateral compaction, using both heat and vibration, and warm vertical compaction of gutta-percha provided statistically better replication of defects than cold lateral compaction.[211] Hu-Friedy introduced the DownPak* (Fig. 7-38), a variation of the original EndoTwinn that can be used with either warm lateral or warm vertical compaction techniques. Other investigators compared the stress generated with lateral compaction and warm lateral compaction, using the Endotec II, and found that the warm lateral compaction technique created less stress during obturation.[242] An additional concern is the heat generated by the technique. Evaluation of the effects of warm lateral and warm vertical compaction on periodontal tissues demonstrated that neither technique produced heat-related damage.[69]

*Downpak products and service are now supplied by Nikinc Dental, Eindhoven, The Netherlands. It's new name is RootBuddy.

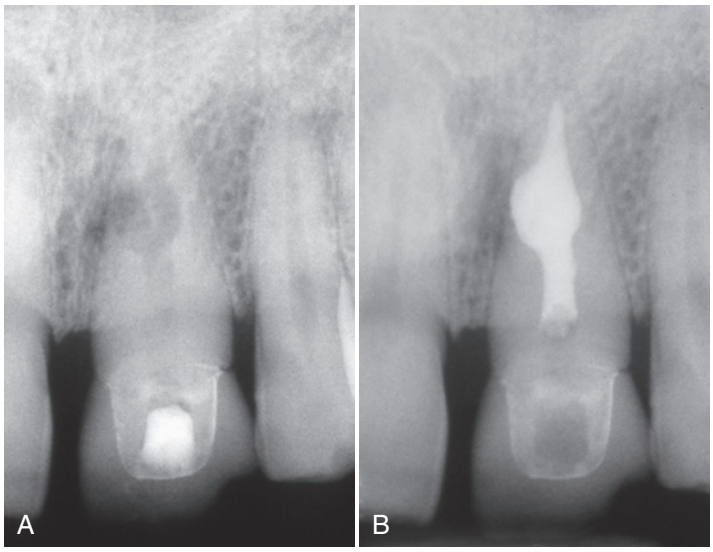

FIG. 7-39 Thermoplastic techniques are often used in cases with significant canal irregularities. **A**, A pretreatment radiograph of a maxillary central incisor exhibiting internal resorption. **B**, Posttreatment radiograph demonstrates a dense obturation of the resorptive defect with gutta-percha.

FIG. 7-40 Obtura III Max System. (Courtesy Kerr, Orange, CA.)

FIG. 7-41 The Calamus thermoplastic unit for heating and injecting gutta-percha. (Courtesy DENTSPLY Tulsa Dental Specialties, Tulsa, Okla.)

The warm lateral compaction technique involves adapting a master cone in the same manner as with traditional lateral compaction. An appropriate-size Endotec II tip is selected. Endotec II tips are available in various taper and tip diameters. The sizes consist of #0.02/20 and #0.02/40. The device is activated and the tip is inserted beside the master cone to within 2 to 4 mm of the apex, using light pressure. The tip is rotated for 5 to 8 seconds and removed. An unheated spreader can be placed in the channel created to ensure adaptation and then an accessory cone is placed. The process is continued until the canal is filled.

Thermoplastic Injection Techniques

Heating of gutta-percha outside the tooth and injecting the material into the canal is an additional variation of the thermoplastic technique (Fig. 7-39). The Obtura III (Fig. 7-40), Calamus (Fig. 7-41), Elements (Fig. 7-42), HotShot (Fig. 7-43), and Ultrafil 3D (Fig. 7-44) are available devices. The Obtura system heats the gutta-percha to 160°C, whereas the Ultrafil 3D system employs a low-temperature gutta-percha that is heated to 90°C.

Obtura III

The Obtura III system (Obtura Spartan) consists of a hand-held "gun" that contains a chamber surrounded by a heating element into which pellets of gutta-percha are loaded (see Fig. 7-40). Silver needles (varying gauges of 20, 23, and 25) are attached to deliver the thermoplasticized material to the canal. The control unit allows the operator to adjust the temperature and thus the viscosity of the gutta-percha. At 6 mm from the apex a study found that the highest internal temperature with the Obtura system was 27°C.[375]

Canal preparation is similar for other obturation techniques. The apical terminus should be as small as possible to prevent extrusion of gutta-percha. The technique requires the use of sealer, and once the canal is dried, the canal walls are coated with sealer, using the last file used to length or a paper point. Gutta-percha is preheated in the gun, and the needle is positioned in the canal so that it reaches within 3 to 5 mm of the apical preparation. Gutta-percha is then gradually, passively injected by squeezing the trigger of the "gun." The needle

FIG. 7-42 The Elements obturation unit for injecting and compacting gutta-percha. (Courtesy Kerr, Orange, CA.)

FIG. 7-43 The battery-powered HotShot unit (Discus Dental) for heating and injecting gutta-percha.

FIG. 7-44 The Ultrafil 3D system consists of an injection syringe, gutta-percha cannulas, and heating unit (Coltène/Whaledent).

backs out of the canal as the apical portion is filled. Pluggers dipped in alcohol are used to compact the gutta-percha. A segmental technique may also be used, in which 3- to 4-mm segments of gutta-percha are sequentially injected and compacted. In either case, compaction should continue until the gutta-percha cools and solidifies to compensate for the contraction that takes place on cooling.

The difficulties with this system include lack of length control. Both overextension and underextension are common results. To overcome this drawback, a hybrid technique may be used, in which the clinician begins filling the canal by the lateral compaction technique. When the master cone and several accessory cones have been placed so that the mass is firmly lodged in the apical portion of the canal, a hot plugger is introduced, searing the points off approximately 4 to 5 mm from the apex. Light vertical compaction is applied to restore the integrity of the apical plug of gutta-percha. The remainder of the canal is then filled with thermoplasticized gutta-percha injected as previously described.

Investigators studied, at 3, 6, and 12 months post treatment, the success rate of 236 teeth obturated with the Obtura system. Results indicated that 96% of the cases were successful, with the highest success rate being in teeth filled flush with the apex (97%) when compared with overextensions (93%) and filling short (93%).[377] Another study compared lateral compaction with Thermafil (DENTSPLY Tulsa Dental Specialties) and Obtura in root canal models and found that the Obtura produced the best adaptation to the canal walls.[408] Other investigators found that continuous wave obturation with the Obtura backfill initially produced a better bacterial seal when compared with lateral compaction, using bilaterally matched teeth and an anaerobic bacterial leakage model.[182]

Ultrafil 3D

Ultrafil 3D (Coltène/Whaledent) is a thermoplastic gutta-percha injection technique involving gutta-percha cannulas, a heating unit, and an injection syringe (see Fig. 7-44). The system employs three types of gutta-percha cannulas. The Regular Set is a low-viscosity material that requires 30 minutes to set. The Firm Set is also a low-viscosity material but differs in that it sets in 4 minutes. The manufacturer recommends compaction after the initial set with both materials. Endoset has a higher viscosity and does not flow as well. It is recommended for techniques employing compaction and sets in 2 minutes. The heater is preset at 90°C and does not require adjustment.

Each cannula has a 22-gauge stainless steel needle that measures 21 mm in length. The needles can be precurved. Cannulas can be disinfected but are not designed for heat sterilization procedures. Heating time varies, but for a cold unit it takes 10 to 15 minutes. In a warm heater the recommended time is 3 minutes. After removing the cannula from the heater the needle should be placed on the hot part of the heater for several seconds. The gutta-percha remains able to flow for 45 to 60 seconds depending on the viscosity.

Calamus

The Calamus flow obturation delivery system (DENTSPLY Tulsa Dental Specialties) is a thermoplastic device equipped with a cartridge system with 20- and 23-gauge needles (see Fig. 7-41). The unit permits control of temperature and also the flow rate. Pluggers are also available for use with the

system. The 360-degree activation switch allows great tactile sensation during use.

Elements

The Elements obturation unit (SybronEndo) consists of a System B heat source and plugger as well as a handpiece extruder for delivering thermoplastic gutta-percha or RealSeal from a disposable cartridge (see Fig. 7-42). The cartridges come with 20-, 23-, and 25-gauge needles for gutta-percha and 20- and 23-gauges for RealSeal.

HotShot

The HotShot delivery system (Discus Dental [now part of Philips Oral Healthcare]) is a cordless thermoplastic device that has a heating range from 150°C to 230°C (see Fig. 7-43). The unit is cordless and can be used with either gutta-percha or Resilon. Needles are available in 20, 23, and 25 gauges.

Carrier-Based Gutta-Percha

Thermafil, Profile GT Obturators, GT Series X Obturators, and ProTaper Universal Obturators

Thermafil (DENTSPLY Tulsa Dental Specialties) was introduced as a gutta-percha obturation material with a solid core (Fig. 7-45). Originally manufactured with a metal core and a coating of gutta-percha, the carrier was heated over an open flame. The technique was popular because the central core provided a rigid mechanism to facilitate the placement of the gutta-percha. Advantages included ease of placement and the pliable properties of the gutta-percha. Disadvantages were that the metallic core made placement of a post challenging and retreatment procedures were difficult. In addition, the gutta-percha was often stripped from the carrier, leaving the carrier as the obturating material in the apical area of the canal. Reports have stated that carrier-based systems result in minimal gaps and voids in the resulting obturation mass.[441] Other reports have stated that there was no difference in healing rates between carrier-based systems and lateral compaction of gutta-percha.[157]

Changes in the carrier systems include the development of a plastic core coated with α-phase gutta-percha (Fig. 7-46) and a heating device that controls the temperature (Fig. 7-47). Obturators are designed to correspond to the ISO standard file sizes, variable tapered nickel titanium rotary files, and the ProFile GT and GT Series X nickel-titanium rotary files (DENTSPLY Tulsa Dental Specialties) (see Fig. 7-46). Size verifiers are available to aid in selection of the appropriate carrier and should fit passively at the corrected working length (see Fig. 7-45).

As with all techniques, a sealer is required. Grossman formulation sealers and resin sealers consistent with AH-26 and AH Plus are acceptable; however, Tubli-Seal and Wach's paste are not recommended.

Removal of the smear layer is strongly recommended (see Chapters 5 and 7) and has been shown to enhance the seal with Thermafil.[29] After drying the canal a light coat of sealer is applied and a carrier is marked, set to the predetermined length. This is accomplished by using the millimeter calibration markings on the carrier shaft. Markings are made at 18, 19, 20, 22, 24, 27, and 29 mm. Gutta-percha on the shaft that may be obscuring the calibration rings can be removed with a surgical blade or knife. The carrier is disinfected with 5.25% NaOCl for 1 minute and rinsed in 70% alcohol.

The carrier is then placed in the heating device. When the carrier is heated to the appropriate temperature, the clinician

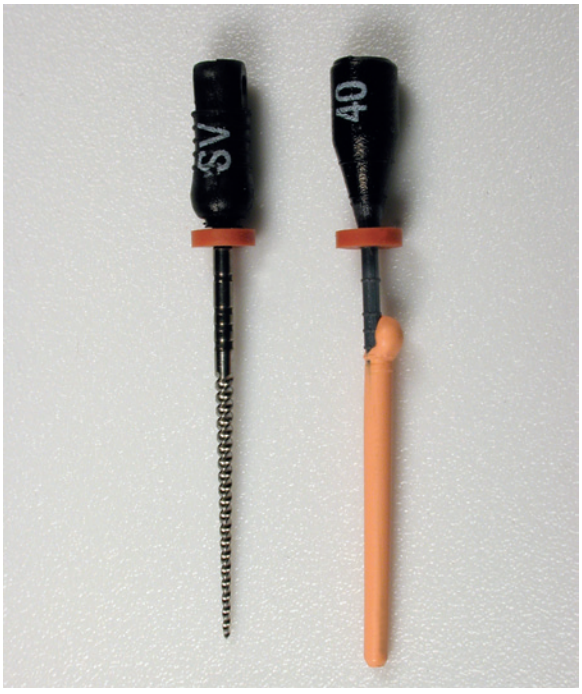

FIG. 7-45 Thermafil carrier and size verifier (DENTSPLY Tulsa Dental Specialties).

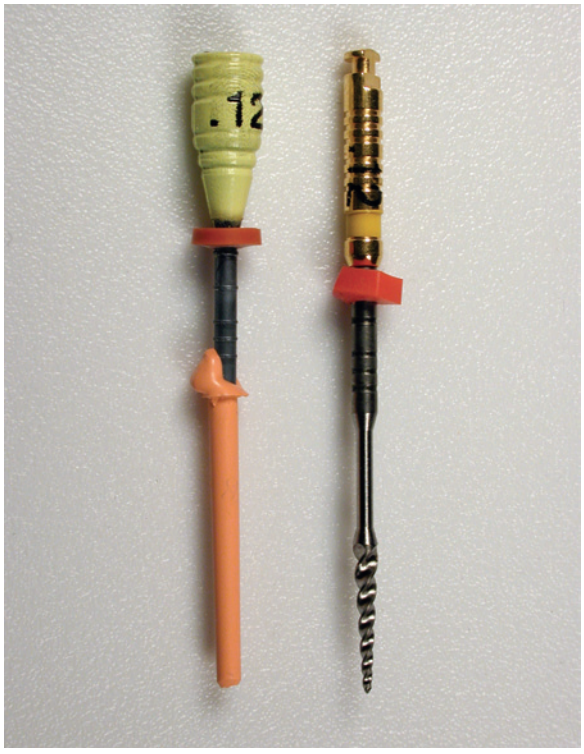

FIG. 7-46 GT obturator and instrument (DENTSPLY Tulsa Dental Specialties).

FIG. 7-47 The Thermafil oven with carrier in place (Thermaprep2 oven. Courtesy DENTSPLY Maillefer, Ballaigues, Switzerland.)

FIG. 7-48 Thermafil carrier placed in the distal canal.

has approximately 10 seconds to retrieve it and insert it into the canal (Fig. 7-48). This is accomplished without rotation or twisting. Evidence suggests that the insertion rate affects the obturation. The fill length and obturation of irregularities increase with increasing insertion rates.[225] A rapid insertion rate enhances obturation.[225]

The position of the carrier is verified radiographically. The gutta-percha is allowed 2 to 4 minutes to cool before resecting the coronal portion of the carrier, which can be several millimeters above the canal orifice. This is accomplished by applying stabilizing pressure to the carrier and cutting the device with an inverted cone, round bur, or a specially designed Prepi bur (DENTSPLY Tulsa Dental Specialties). Heated instruments are not recommended for this process because this may result in displacement.

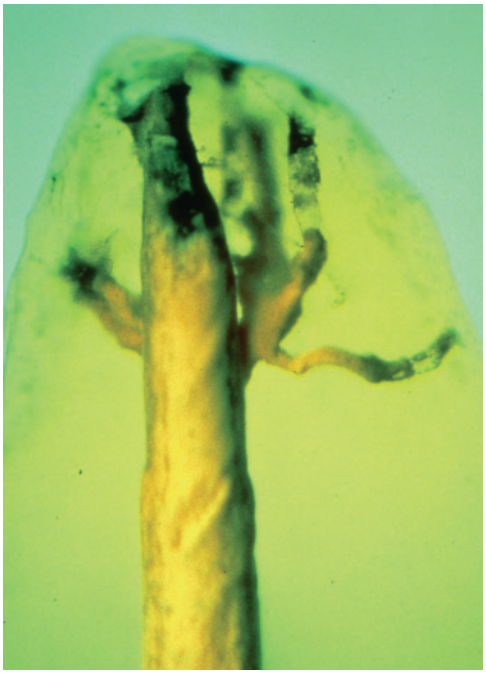

FIG. 7-49 Apical obturation of accessory canals by the Thermafil technique. (Courtesy DENTSPLY Tulsa Dental Specialties, Tulsa, Okla.)

Vertical compaction of the coronal gutta-percha can then be accomplished. When necessary, gutta-percha can be added, heat softened, and compacted. An advantage to this technique is the potential for movement of gutta-percha into lateral and accessory canals (Fig. 7-49)[419]; however, extrusion of material beyond the apical extent of the preparation is a disadvantage.[78,85,213]

Pro-Post drills (DENTSPLY Tulsa Dental Specialties) are recommended if post space is required for restoration of the tooth. The unique eccentric cutting tip keeps the instrument centered in the canal while friction softens and removes the gutta-percha and plastic carrier.

When retreatment is necessary the plastic carrier has a groove along its length to provide an access point for placement of a file. Chloroform and hand files can be used to remove the gutta-percha surrounding the carrier. Rotary #.04 and #.06 nickel-titanium files may also be used to remove the obturation materials. Retreatment rotary nickel-titanium files are available in three different sizes to facilitate removal of gutta-percha and the carrier.

The plastic carriers are composed of two nontoxic materials. Sizes #20 to #40 are manufactured from a liquid crystal plastic. Sizes #40 to #90 are composed of polysulfone polymer. Both have similar physical characteristics, with the polysulfone carriers being susceptible to dissolution in chloroform.

GuttaCore (DENTSPLY Tulsa Dental Specialties), the latest generation of core carriers, uses cross-linked gutta-percha as the carrier of the outer thermoplasticized gutta-percha. This makes retreatment simpler as the clinician can simply drill through the carrier to gain access into the canal space. A recent in vitro study comparing the time required to remove GuttaCore, Thermafil Plus and thermoplasticized gutta-percha from moderately curved root canals with ProTaper retreatment files reported that GuttaCore was removed in significantly less time when compared with the other two techniques.[26]

FIG. 7-50 SuccessFil is an additional carrier system (Coltène/Whaledent).

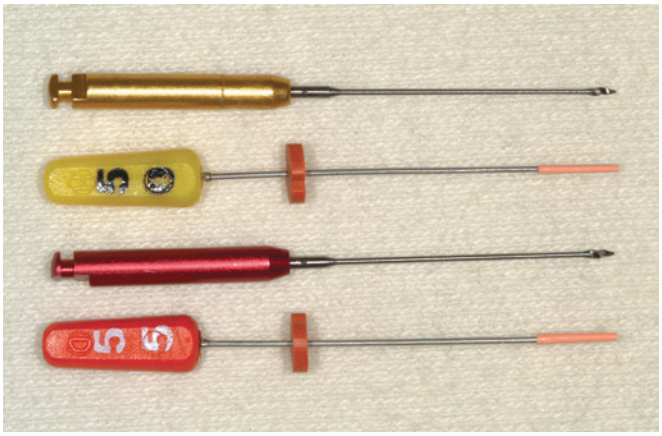

FIG. 7-51 SimpliFill carrier (SybronEndo) and LightSpeed file (LightSpeed Technology, San Antonio, Texas).

SuccessFil

SuccessFil (Coltène/Whaledent) is a carrier-based system associated with Ultrafil 3D (Fig. 7-50); however, the gutta-percha used in this technique comes in a syringe. Carriers (titanium or radiopaque plastic) are inserted into the syringe to the measured length of the canal. The gutta-percha is expressed on the carrier, with the amount and shape determined by the rate of withdrawal from the syringe. Sealer is lightly coated on the canal walls, and the carrier with gutta-percha is placed in the canal to the prepared length. The gutta-percha can be compacted around the carrier with various pluggers depending on the canal morphology. This is followed by severing of the carrier slightly above the orifice with a bur.

SimpliFill

SimpliFill (SybronEndo) is gutta-percha or Resilon manufactured for use after canal preparation with LightSpeed instruments (Fig. 7-51). The carrier has an apical plug with 5 mm of gutta-percha. The technique involves fitting a carrier that is consistent with the master apical rotary file (SybronEndo) to within 1 to 3 mm of the prepared length (Fig. 7-52). The apical gutta-percha plug can be modified by clipping the end in 1-mm increments to obtain an appropriate fit if the plug is too small.

FIG. 7-52 SimpliFill fitted to 1 to 3 mm from the prepared length.

Once the cone is fitted it is withdrawn and sealer is applied to the canal walls. AH Plus is recommended. The SimpliFill carrier is slowly advanced to the prepared length. This may require firm pressure. With the plug at the corrected working length the handle is quickly rotated a minimum of four complete terms in a counterclockwise direction to separate the shaft from the apical gutta-percha. The coronal space can then be filled with gutta-percha, using lateral compaction or the warm thermoplastic technique. When using lateral compaction it is recommended that the first cone be the same size as the SimpliFill carrier. This sectional technique is efficient, and leakage potential is similar to that of other common techniques.[324]

Thermomechanical Compaction

McSpadden introduced an instrument, the McSpadden Compactor, with flutes similar to a Hedström file but in reverse. When activated in a slow-speed handpiece, the instrument would generate friction, soften the gutta-percha, and move it apically. Rotary compactors similar in design have been developed and advocated. To increase flexibility, the instrument is available in nickel-titanium.

The technique requires fitting a master cone short of the prepared length and applying sealer. A compactor is selected on the basis of the size of the canal and inserted alongside the gutta-percha cone 3 to 4 mm from the prepared length. The handpiece is activated, and the friction of the rotating bur heats the gutta-percha. The pliable mass is compacted apically and laterally as the device is withdrawn from the canal.

Advantages include simplicity of the armamentarium, the ability to fill canal irregularities,[161,198,232,331,332] and time. Disadvantages include possible extrusion of material, instrument fracture,[270] gouging of the canal walls, the inability to use the technique in curved canals, and possible excessive heat generation.[27,124,159,245,332,333] Microseal condensers (SybronEndo) and the Gutta Condenser (DENTSPLY Tulsa Dental Specialties) are variations of this product.

Solvent Techniques

Gutta-percha can be plasticized with solvents, such as chloroform, eucalyptol, or xylol. Disadvantages include shrinkage caused by evaporation, voids, the inability to achieve predictable length control of the obturating material, and irritation of periradicular tissues. The Callahan and Johnston technique involved dissolving gutta-percha in chloroform and placing the mixture into the canal with a syringe.[60] A gutta-percha cone was then softened by immersion in this mixture and placed into the canal and the mass solidified as the solvent evaporated. Unfortunately, shrinkage occurred with the evaporation process.[299] Obturation techniques using solvents have been abandoned and replaced with materials and methods that exhibit minimum shrinkage.

Pastes

Pastes fulfill some of the criteria outlined by Grossman[149] and can adapt to the complex internal canal anatomy; however, the flow characteristic can result in extrusion or incomplete obturation. The inability to control the material is a distinct disadvantage, and when extrusion occurs it can be corrected only by surgical intervention. In addition, pastes are sometimes used as a substitute for complete cleaning and shaping procedures, and the addition of paraformaldehyde results in severe toxicity.

Immediate Obturation

Apical barriers may be necessary in cases with immature apical development, cases with external apical root resorption, and cases where instrumentation extends beyond the confines of the root. Dentin chips, calcium hydroxide, demineralized dentin, lyophilized bone, tricalcium phosphate, hydroxyapatite, and collagen have been advocated for placement as a barrier in canals exhibiting an open apex. The barriers are designed to permit obturation without extrusion of materials into the periradicular tissues but are often incomplete and do not seal the canal.[320]

Dentin chips appear to confine materials to the canal space during instrumentation/obturation and may encourage development of a biologic seal.[115,320] Enhanced healing, minimal inflammation, and apical cementum deposition have been noted histologically.[275] A concern with this technique is contamination of the dentin with bacteria or other nonhost materials, because investigators found that infected dentin adversely affected healing.[173]

Calcium hydroxide has also been extensively used as a common apical barrier. Calcium hydroxide has been shown to induce an apical barrier in apexification procedures. Calcifications similar to dentin plugs have been noted at the apical foramen.[295] Calcium hydroxide has the advantage of being free of bacterial contamination and may provide a better, although imperfect, apical seal.[406]

Immature teeth exhibiting pulp necrosis or teeth with apical resorption traditionally were treated with calcium hydroxide to establish an apical barrier (apexification) before obturation. Studies have demonstrated that teeth treated with calcium hydroxide for prolonged periods are more susceptible to fracture.[11,316] Immediate obturation is an alternative to apexification. An apical barrier material should confine obturation materials to the canal space[115] and enhance healing by inducing cementum and bone formation.[172,275,295] Mineral trioxide aggregate (MTA) (ProRoot MTA; DENTSPLY Tulsa Dental Specialties) has been successfully employed as an apical barrier material before obturation (Fig. 7-53).[350]

FIG. 7-53 Mineral trioxide aggregate is available as ProRoot MTA. This material is advocated for use in apexification, repair of root perforations, repair of root resorption, root-end fillings, and pulp capping. (Courtesy DENTSPLY Tulsa Dental Specialties, Tulsa, Okla.)

After cleaning and shaping procedures, the root canal system is dried and a small increment of MTA is placed to the radiographic apex and the location verified through a radiograph. If the material is overextended, it can be easily irrigated out with sterile saline. If it is short of the radiographic apex, it can be compacted with prefitted pluggers to move it to the radiographic apex. The material is compacted into the apical portion of the root to form a barrier. After the material sets, any thermoplasticized technique can be used to backfill with gutta-percha without concern of overextension (Fig. 7-54). Other investigators have reported that hand compaction of MTA provided better adaptation to the canal walls with fewer voids when compared with ultrasonic placement.[9] Another investigation reported that ultrasonic placement of a 4-mm apical plug of MTA improved the seal[430] and that placement of a composite resin as the obturation material enhanced the seal and strengthened the root.[216]

Mineral trioxide aggregate is sterile, biocompatible, and capable of inducing hard tissue formation.[112,174] The technique has been shown to be clinically successful and can be accomplished quickly, eliminating the need for numerous patient visits and possible coronal recontamination during the many months required for apexification.[73,87,138]

Clinical evidence supports this technique. In a study comparing calcium hydroxide with mineral trioxide aggregate in 15 children, each having paired immature teeth with necrotic pulps, two teeth treated with $Ca(OH)_2$ exhibited pathosis on recall examination, whereas all the teeth treated with MTA were clinically and radiographically successful.[114] A prospective clinical study found the success rate of MTA barriers and immediate obturation in 43 cases to be 81%.[358] In another study, 85% of 20 teeth with immature apical development were considered healed and 5% were considered healing after immediate barrier placement.[171] The time required for healing is

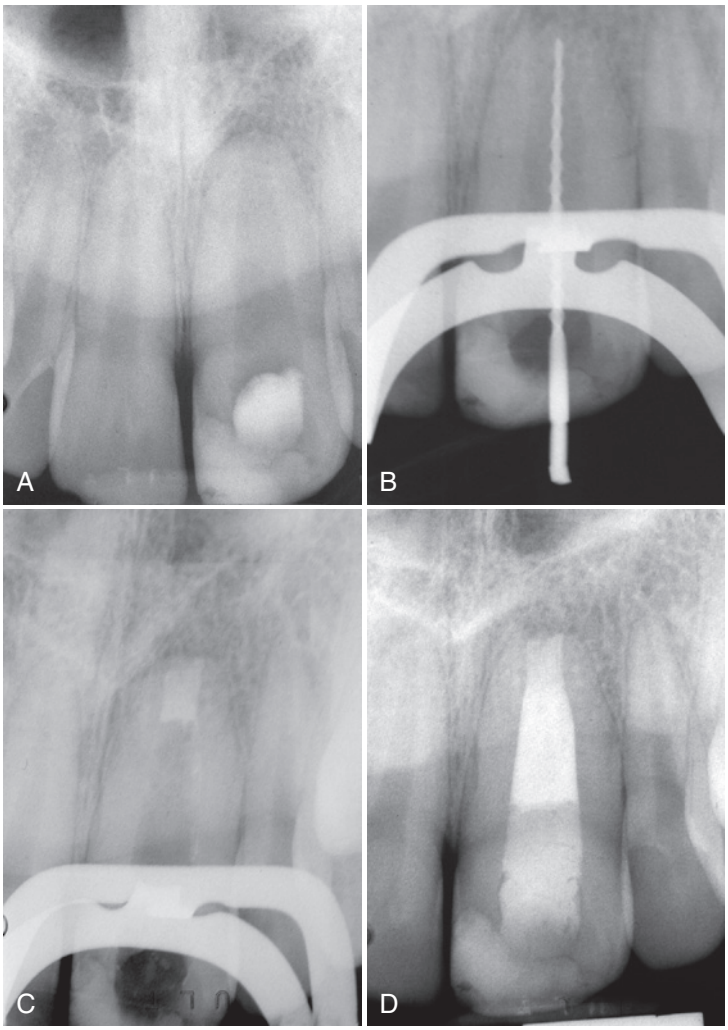

FIG. 7-54 Immediate obturation employs a barrier technique to prevent extrusion when the apex is open. This case involves a maxillary left central incisor with pulp necrosis caused by trauma. **A,** Pretreatment radiograph demonstrates a large canal with an open apex. **B,** Working length is established and the canal is prepared. **C,** Mineral trioxide plug is placed. **D,** The canal is obturated with gutta-percha.

comparable to traditional apexification with $Ca(OH)_2$ and treatment time is reduced.[298]

Another option for treating immature teeth with pulp necrosis involves regenerative endodontic techniques (see Chapter 10).[160,184,391,414] Advantages include continued increasing thickness of the canal walls, continued apical root development, and apical closure.[351] The technique involves copious irrigation, minimal canal preparation, and the use of an antibiotic paste as an interim medication. At a subsequent visit, bleeding is induced in the canal by placing a file beyond the root apex. When the bleeding comes within 3 mm of the canal orifice, the clot is lined with a resorbable membrane and then covered with MTA. When the MTA is set, a definitive restoration can be placed to ensure a coronal seal.[17]

CORONAL ORIFICE SEAL

No matter which technique is used to obturate the canals, coronal microleakage can occur within a short time through seemingly well-obturated canals,[68,389] potentially causing infection of the periapical area. Early research efforts focused on the quality of the seal in the apical part of the root canal system to prevent percolation of apical fluids. However, contemporary research efforts have identified the greater importance of maintaining a coronal seal to prevent bacterial leakage.[185] Leakage studies indicate that the coronal seal can be enhanced by the application of supplemental restorative materials over the canal orifice[293,407,418] and by placing a definitive coronal restoration as soon as is feasible.[305]

Cavit (3M ESPE) has traditionally been advocated as an acceptable material. One study demonstrated that placement of 3.5 mm of Cavit or Super EBA cement (Bosworth, Skokie, Illinois) decreased bacterial leakage by 85% and 65%, respectively, when compared with unsealed controls, which all leaked at 45 days.[293] In an animal study in which the access openings were left open for 8 months, placing a dentin-bonded composite resin or IRM in the orifice decreased periapical inflammation from 89% for teeth without orifice plugs to 39% with plugs.[428] Another study demonstrated in a dog model that MTA placed in the orifice decreased inflammation in teeth inoculated with bacteria.[235]

Another method to retard leakage through the obturated canal, should failure of the coronal restoration occur, is to cover the floor of the pulp chamber with a lining of bonded material after removal of excess gutta-percha and sealer to the canal orifice.[31,71,221] This results in the formation of a hybrid layer with microtags of resin in the tubules. A resin-modified glass ionomer cement is placed approximately 1 mm thick over the floor of the pulp chamber and polymerized with a curing light. Alternatively, a self-etching dentin adhesive and a flowable resin composite may be used. Investigators found that this procedure resulted in none of the experimental canals showing bacterial leakage at 60 days.[72] A material with a different color than dentin may be used for identification, in case subsequent placement of a post is required.

Prognosis of Retreatment
Summary

Nonsurgical root canal therapy has become a routine procedure in modern dentistry. Technical and scientific advances in endodontics have resulted in the retention of millions of teeth that would otherwise be lost. Even as advances in surgical and prosthetic restorative care have made tooth replacement less onerous than in the past, it is universally accepted that a natural tooth with a good prognosis is a superior choice to loss and replacement.

Unfortunately, not all treatments result in optimum long-term healing. Given the large numbers of treatments performed, the very small rate of unsuccessful outcomes translates into relatively large numbers of patients requiring further treatment. Dental clinicians should be able to diagnose persistent or reintroduced endodontic disease and be aware of the options for treatment. If they wish to approach treating these teeth, they should have the appropriate armamentarium and be capable of performing these specialized techniques at the highest level (Fig. 8-1). Also, clinicians must always have a scientifically sound, evidence-based rationale for every treatment decision that is made so that they may best serve the patients who entrust them with their care. The purpose of this chapter is to provide information to allow the reader to maximize the likelihood of success in the treatment of persistent endodontic disease.

ETIOLOGY OF POSTTREATMENT DISEASE

In the past, undesirable outcomes of endodontic therapy were described as failures. Clinicians quote failure rates based on published success/failure studies. Using the words *success* and *failure* may be a holdover from a time when clinicians felt they needed to congratulate themselves on their successes and blame themselves for the failures of their treatment endeavors. This thought process does not reflect reality and can be potentially destructive. There are many instances in which treatments performed at the highest level of clinical competence result in an undesirable outcome, and there are other instances in which a procedure is performed well below a scientifically acceptable standard and yet provides long-term success.[203] We must begin to dissect the science from emotion and ego, and this separation may start with nomenclature. Friedman stated that "most patients can relate to the concept of disease-treatment-healing, whereas failure, apart from being a negative and relative term, does not imply the necessity to pursue treatment."[64] He has suggested using the term *posttreatment disease* to describe those cases that would previously have been referred to as treatment failures. This will be the term used in the remainder of this chapter to describe persistent or reintroduced endodontic disease.

Almost 16 million root canal procedures were performed in 1999,[29] and, with success rates varying between 86% and 98%,[65,66] it has been shown to be a reliable treatment option. Conversely, the incidence of posttreatment disease, although small, translates into a large number of cases where further treatment is needed. When faced with such a situation, the clinician must determine the etiology of the persistent pathosis and devise a rationale and strategy for treatment.

There are many causes for "failure" of initial endodontic therapy that have been described in the endodontic literature (Fig. 8-2). These include iatrogenic procedural errors such as poor access cavity design, untreated canals (both major and accessory),[266] canals that are poorly cleaned and obturated,[37,112] complications of instrumentation (ledges, perforations, or separated instruments),[231] and overextensions of root-filling materials.[164] Coronal leakage[131,147,196,236,248] has also been blamed for posttreatment disease, as has persistent intracanal and extracanal infection[166,216,232] and radicular cysts.[162] These etiologies may be obvious at the time of diagnosing the diseased, root-filled tooth, or they may remain uncertain until the completion of successful therapy. Occasionally, the cause of posttreatment disease may take years to become discernible or may ultimately never be known. The most important causative factors for the clinician, however, are those related to treatment planning and determination of prognosis.

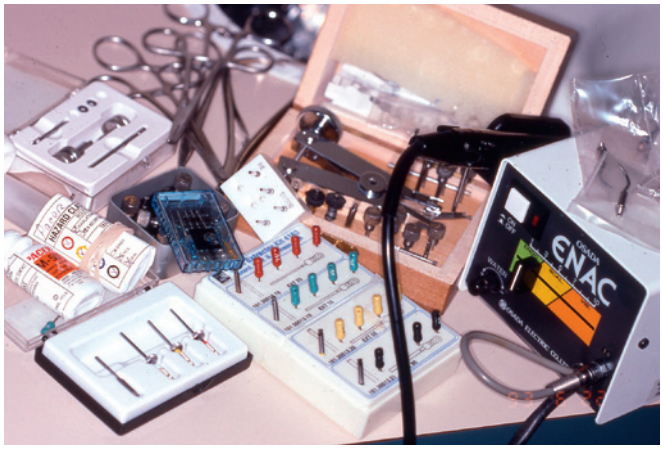

FIG. 8-1 Some of the armamentarium needed to perform retreatment at the highest level.

To treatment plan effectively, the clinician may place the etiologic factors into four groups[231] (Fig. 8-3):

1. Persistent or reintroduced intraradicular microorganisms
2. Extraradicular infection
3. Foreign body reaction
4. True cysts

Persistent or Reintroduced Intraradicular Microorganisms

When the root canal space and dentinal tubules are contaminated with microorganisms or their by-products and if these pathogens are allowed to contact the periradicular tissues, apical periodontitis ensues. As stated earlier, inadequate cleaning, shaping, obturation, and final restoration of an endodontically diseased tooth can lead to posttreatment disease. If initial endodontic therapy does not render the canal

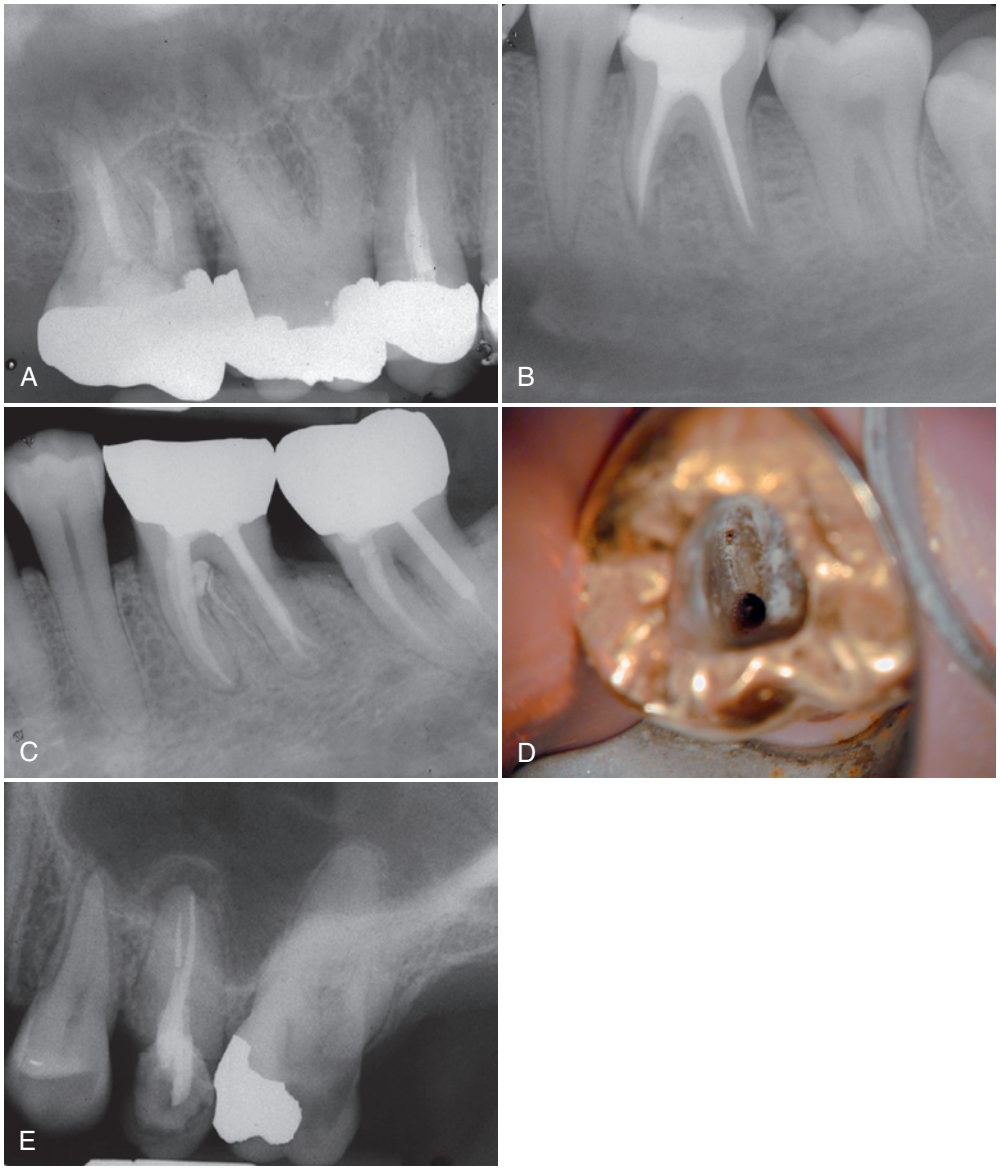

FIG. 8-2 Clinical presentations of posttreatment disease. A, Canals that are poorly cleaned, shaped, and obturated. B, Mesial canal with apical transport, ledge, and zip perforation. C, Strip perforation of the mesial root. D, Missed MB2 canal in an upper molar. E, Suspected coronal leakage of bacteria and a separated file.

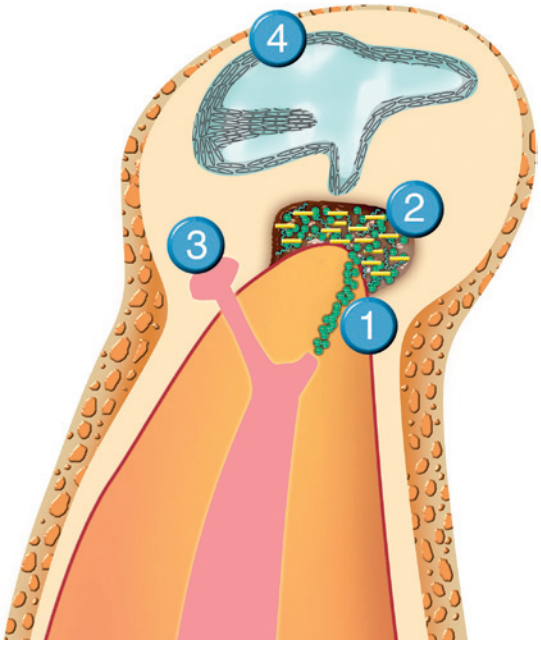

FIG. 8-3 The causes of posttreatment disease. *(1)* Intraradicular microorganisms. *(2)* Extraradicular infection. *(3)* Foreign body reaction. *(4)* True cysts. (Redrawn with permission from Sundqvist G, Figdor D. In Orstavik D, Pitt-Ford TR, editors: *Essential Endodontology,* London, 1998, Blackwell Science, p 260.)

space free of bacteria, if the obturation does not adequately entomb those that may remain, or if new microorganisms are allowed to reenter the cleaned and sealed canal space, then posttreatment disease can and usually does occur. In fact, it has been asserted that persistent or reintroduced microorganisms are the major cause of posttreatment disease.[163] Many iatrogenic treatment complications, such as creation of a ledge or separation of an instrument, result in persistence of bacteria in the canal system. It is not the complication itself, however, that results in persistent disease; rather, it is the inability to remove or entomb the microorganisms present that creates the pathologic state. While infected root canals of endodontically untreated teeth generally contain a polymicrobial, predominantly anaerobic flora,[230] cultures of infected, previously root-filled teeth produce very few or even a single species (see also Chapter 14). The infecting flora are predominantly gram positive, not anaerobic, and a commonly isolated species is *Enterococcus faecalis,*[71,182] which has been shown to be resistant to canal disinfection regimens.[16,33] Interestingly, if the previous root canal treatment is done so poorly that the canal space contains no obturating material in the apical half of the root canal space, its flora is more typical of the untreated necrotic infected pulp than that of classic "failed" root canal therapy.[231] Though posttreatment disease has been primarily blamed on bacteria in the root canal system, certain fungi, notably *Candida albicans,* are found frequently in persistent endodontic infections and may be responsible for the recalcitrant lesion.[214]

Extraradicular Infection

Occasionally bacterial cells can invade the periradicular tissues either by direct spread of infection from the root canal space via contaminated periodontal pockets that communicate with the apical area,[212] extrusion of infected dentin chips,[99] or by contamination with overextended, infected endodontic instruments.[257] Usually, the host response will destroy these organisms, but some microorganisms are able to resist the immune defenses and persist in the periradicular tissues, sometimes by producing an extracellular matrix or protective plaque.[249] It has also been shown[166,216,232] that two species of microorganisms, *Actinomyces israelii* and *Propionibacterium propionicum,* can exist in the periapical tissues and may prevent healing after root canal therapy.

Foreign Body Reaction

Occasionally, persistent endodontic disease occurs in the absence of discernible microorganisms and has been attributed to the presence of foreign material in the periradicular area. Several materials have been associated with inflammatory responses, including lentil beans[211] and cellulose fibers from paper points.[125] In the seemingly endless debate about which endodontic obturation technique is superior, there has been much discussion about the effect of overextended root canal filling materials upon apical healing. Outcomes assessments generally show that filling material extrusion (root filling flush to the radiographic apex or gross overextension) leads to a lower incidence of healing (see also Chapter 7).[63,215] Many of these cases involved not only overextension but also inadequate canal preparation and compaction of the root filling whereby persistent bacteria remaining in the canal space could leak out. Gutta-percha and sealers are usually well tolerated by the apical tissues, and if the tissues have not been inoculated with microorganisms by vigorous overinstrumentation, then healing in the presence of overextended filling materials can still occur.[63,70,137]

True Cysts

Cysts form in the periradicular tissues when nests of epithelial cells, retained from tooth development, begin to proliferate due to the chronic presence of inflammatory mediators. These epithelial cell rests of Malassez are the source of the epithelium that lines cystic walls, and cyst formation may be an attempt to help separate the inflammatory stimulus from the surrounding bone.[181] The incidence of periapical cysts has been reported to be 15% to 42% of all periapical lesions,[162,224] and determining whether a periapical radiolucency is a cyst or the more common periapical granuloma cannot be done with available radiographic methods.[23] There are two types of periapical cysts: the periapical true cyst and the periapical pocket cyst. True cysts have a contained cavity or lumen within a continuous epithelial lining and are therefore isolated from the tooth, whereas with pocket cysts, the lumen is open to the root canal of the affected tooth. True cysts, due to their self-sustaining nature, probably do not heal following nonsurgical endodontic therapy[112,165] and usually require surgical enucleation (Fig. 8-4).

When a patient presents with posttreatment disease, clinical decision making depends on determining the cause of the persistent disease and then making an assessment of how best to treat the pathologic condition. The following section presents a rationale and methods for performing endodontic diagnosis that offer the greatest likelihood of a successful outcome.

DIAGNOSIS OF POSTTREATMENT DISEASE

It has been stated that "there may be different ways of treating a disease; however, there can be but one correct diagnosis."[9]

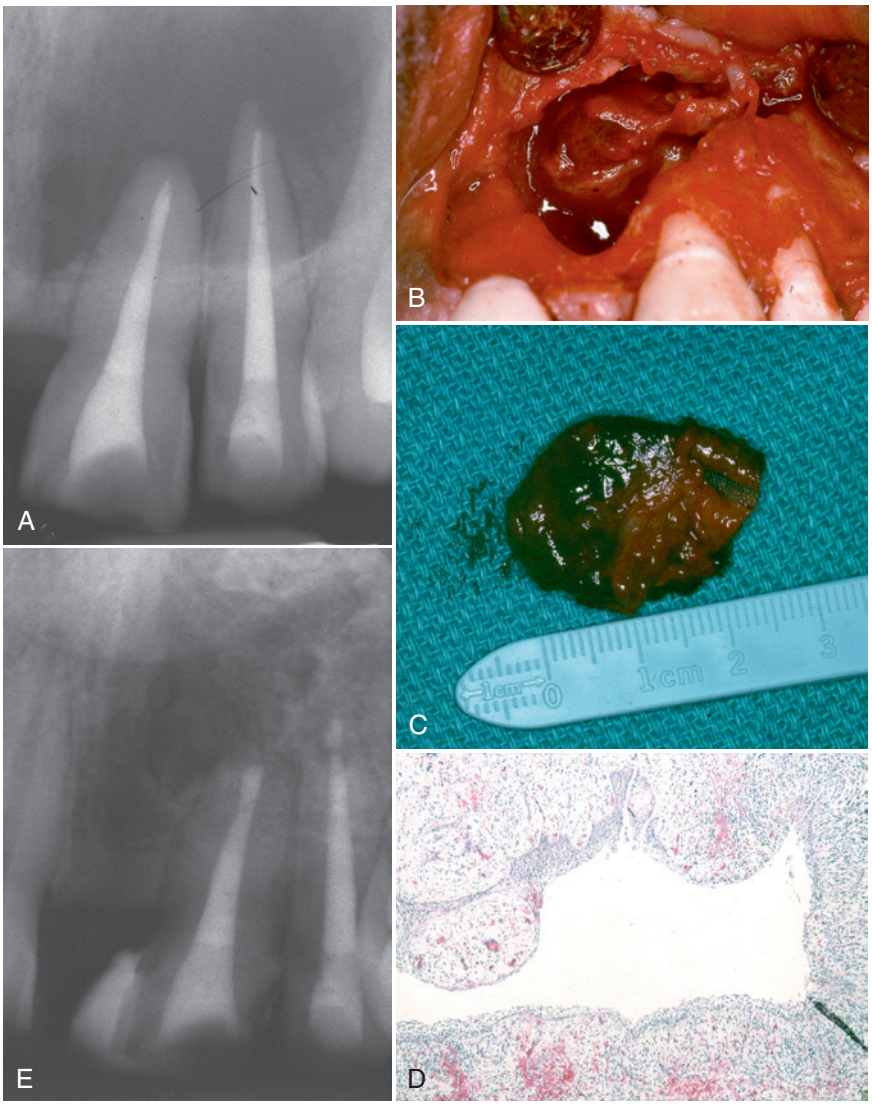

FIG. 8-4 A, Apparently good nonsurgical retreatment with large persistent lesion. B, Surgical exposure of apical lesion in situ. C, Large lesion removed in toto. D, Histopathologic section confirming cystic nature of the lesion. E, A 4-year post-operative film showing apical scar formation due to the large size of the lesion. The teeth were asymptomatic and in function.

The proper diagnosis is probably the most important portion of any endodontic procedure (see also Chapter 1). This is not as bold of a statement as one may first suspect when consideration is given to what the patient may undergo if treatment is performed based on an incorrect diagnosis (Fig. 8-5). To make a correct diagnosis, the clinician must rule out nonodontogenic etiology, perform all of the appropriate tests, properly interpret the patient's responses to these tests, derive at a definitive diagnosis, and decide on treatment options. When performing a diagnosis in endodontic cases where there is no history of previous endodontic therapy, both a pulpal and periradicular diagnoses are necessary. In cases of persistent disease, the diagnosis may not be as straightforward as the clinician may be dealing with partially treated pulp canals, missed canals, and many other types of problems associated with the previous treatment. These must be included in the diagnostic description for each case.

Endodontic diagnosis was thoroughly discussed in Chapter 1, and the reader is referred there for further details on these procedures. The diagnostic method requires collecting subjective information, developing objective findings, and using these to arrive at a diagnosis and plan of treatment.

The subjective information is collected by questioning the patient and then actively listening to the responses. Of particular interest in cases of suspected posttreatment disease is whether the patient recalls the use of aseptic techniques during the previous endodontic therapy. If a rubber dam was not used, for example, and this can be confirmed with a call to the previous clinician, nonsurgical retreatment will almost certainly be necessary because the canals can be assumed to be contaminated regardless of how aesthetically pleasing the previously filled case may appear on the radiograph. The diagnostician should be careful to avoid or to minimize communicating to the patient any negative feelings he or she has toward the

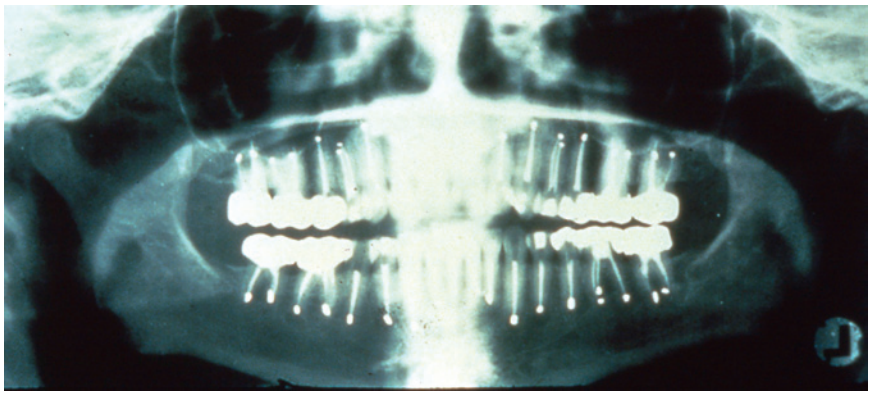

FIG. 8-5 This patient was misdiagnosed for years and underwent unnecessary endodontic therapy. The actual cause of the patient's complaint was nondental pain. (Courtesy Dr. Ramesh Kuba.)

previous treatment, however bad it may seem. This approach allows the patient to become more comfortable with the current clinician and the proposed corrective treatment. An irate patient is an irate patient, and negativity will color the patient's emotional state, level of trust, and ability to accept current or future treatment plans. If the patient asks a direct question about the previous treatment, an honest answer is necessary, but avoid the temptation to imply superiority by disparaging the former clinician. To state the situation honestly and correctly without being inflammatory, use a sentence such as "Well, it may be that your previous dentist (endodontist) had some difficulty with that tooth. Let's see if we can figure out what could have been the problem."

Following a thorough review of the patient's health history, the next step is to gather all of the objective information needed to obtain an accurate diagnosis. This information will include the clinical and radiographic examination. The clinical examination should include a visual extraoral and intraoral examination, and a thorough periodontal evaluation. Visual examination is greatly aided by magnification and illumination, which can allow the clinician to identify significant conditions invisible to the naked eye, such as fine fractures on root surfaces (Fig. 8-6). Exposed dentin from recession and narrow based probing defects may be the result of an endodontic infection draining through the sulcus; however, they sometimes indicate vertical root fracture.[40] The presence of occlusal wear facets indicates the presence of occlusal trauma that may complicate diagnosis and treatment outcome by predisposing the tooth to fracture,[90] and it has been associated with posttreatment disease.[113] Further information on diagnosis and management of cracks and fractures is provided in Chapter 21.

Radiographic assessment is obligatory. Even though radiographs may be a critical aid to the clinician, they should never be the sole support for a conclusive diagnosis. They are only one piece of the puzzle in determining endodontic etiology.[58] In cases with previous endodontic therapy, radiographs are useful in evaluation of caries, defective restorations, periodontal health, the quality of the obturation, existence of missed canals, impediments to instrumentation, periradicular pathosis, perforations, fractures,[238] resorption, and canal anatomy. Radiographs should be properly exposed and have a sharp, clear image. They should include the tooth and surrounding tissues, and multiple angulated films should be used to determine endodontic etiologies using the buccal object moves most

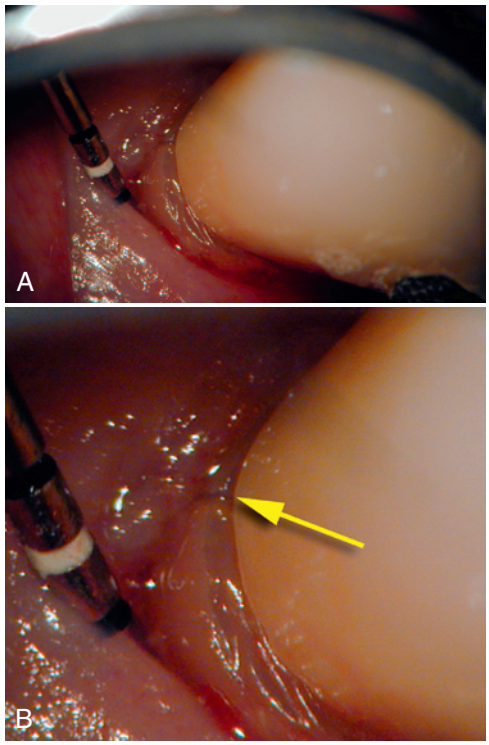

FIG. 8-6 A, Buccal aspect of a premolar with posttreatment disease. B, Higher magnification reveals a vertical fracture.

rule (Fig. 8-7).[80] Bitewing radiographs are useful for determining periodontal bone height and looking for caries or fractures. All sinus tracts should be traced with a cone of gutta-percha followed by a radiograph to localize their origin.[111]

Cone beam computed tomography (CBCT) has been introduced into endodontics, and its usefulness in the management of endodontic retreatment is unquestioned. It has provided a quantum leap in our ability to determine the causes of posttreatment apical periodontitis by giving the clinician, for the first time, the ability to easily, safely, and inexpensively visualize the tooth and surrounding structures in three dimensions (3D). CBCT use in endodontics is discussed in detail in Chapter 2, but when faced with a tooth needing retreatment, it is especially helpful. The CBCT allows the clinician to determine the true size, extent, and position of periapical and resorptive lesions

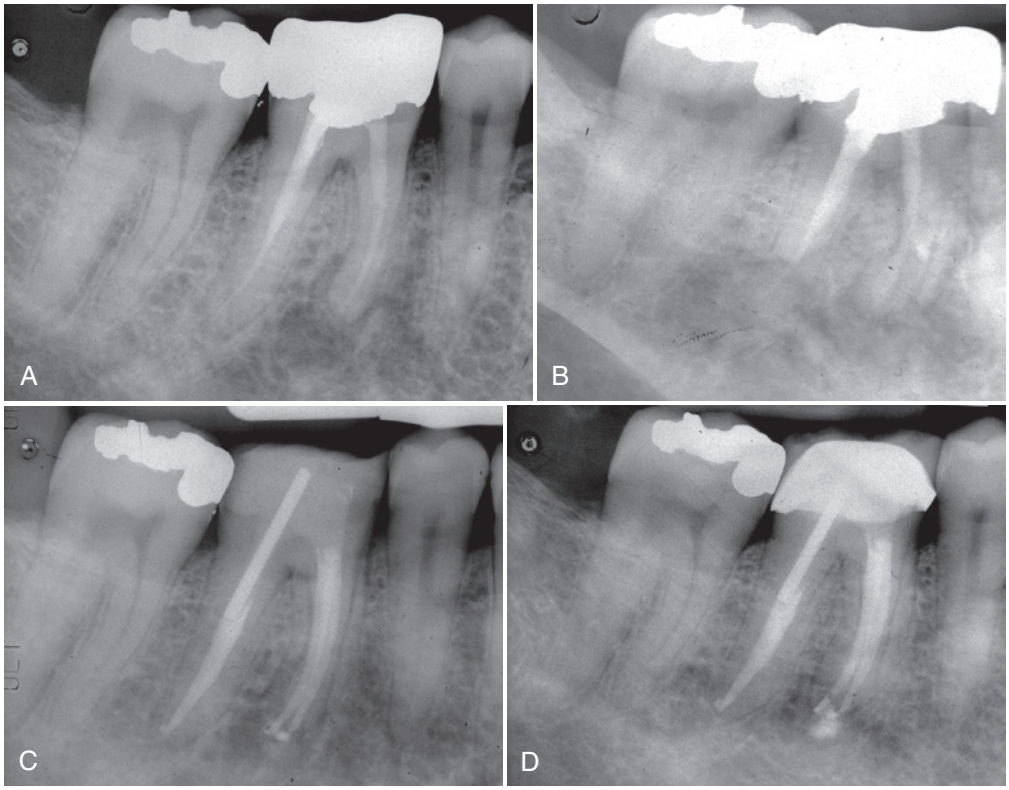

FIG. 8-7 **A**, Posttreatment disease. Previous endodontic therapy performed 3 years previously. **B**, Distal angle radiograph reveals asymmetry indicating the presence of an untreated mesiobuccal canal. **C**, Immediate postobturation film showing treated MB canal. **D**, A 14-month postoperative view. The patient was asymptomatic.

and gives added information about tooth fractures, missed canals, root canal anatomy, and the nature of the alveolar bone topography around teeth.[42] CBCT technology has greatly enhanced presurgical diagnosis and treatment planning, because the relationship of adjacent anatomic structures such as the maxillary sinus and inferior alveolar nerve to the root apices can be clearly visualized. This helps the clinician to decide on when to perform endodontic retreatment surgically or nonsurgically. CBCT is more accurate than periapical radiography in the diagnosis of apical periodontitis, and it can reveal the details of the lesions and adjacent structures, thus providing enhanced clinical diagnosis and treatment planning.[42,175,176]

There are many manufacturers and brands of CBCT machines on the market today, but the most useful ones for endodontic retreatment are those that produce the clearest image with the highest resolution.[155] These would be the small field of view (FOV) machines that image a small volume and use the smallest picture element (voxel) dimensions available. Radiation exposure to the patient with these machines is in the range of 23 to 488 μSv,[142] which is very small, but the "as low as reasonably achievable" (ALARA) principle applies, so its use in every diagnostic case cannot be encouraged. In a joint position statement in 2010, the American Association of Endodontists and the American Association of Oral and Maxillofacial Radiologists stated that "CBCT should only be used when the question for which imaging is required cannot be answered adequately by lower dose conventional dental radiography or alternate imaging modalities."[1] When managing posttreatment disease, however, almost every case will benefit from the use of three-dimensional imaging.

One major cause of posttreatment apical periodontitis is untreated canals, and the CBCT gives an unprecedented ability to discover those (Fig. 8-8). In one study, endodontist evaluators failed to identify at least 1 root canal system in approximately 4 of 10 teeth when using images obtained by conventional digital radiography compared with images from cone-beam computed tomography.[152]

Avoiding treatment, which will lead to a predictable failure, is beneficial for both the clinician and the patient. The ability to obtain 3D images of teeth will help the clinician to avoid these mishaps. The diagnosis of root fractures frequently frustrates the clinician, as a definitive diagnosis is often difficult and treating these teeth has a high likelihood of a poor outcome. Although visualizing root fractures in teeth with root fillings is still not predictable using CBCT,[45,50,96,122] the patterns of bone loss indicative of root fracture can sometimes be seen,[275] and this helps the clinician to infer their presence. The prognosis for the treatment of root resorption is directly related to the extent of the resorption, and this usually cannot be determined accurately using conventional radiography. Using small FOV CBCT, however, the extent of the lesions and the prognosis can be determined,[54] usually saving the patient from an exploratory procedure that may be doomed to fail (Fig. 8-9).

Though most clinicians believe that CBCT is not necessary for every patient treated, there are many retreatment situations where the additional information gained (relative to conventional radiography) is extremely valuable. In the future, specific protocols for use will be developed; but for now, the authors recommend that clinicians use their best judgment on when to use this new technology.

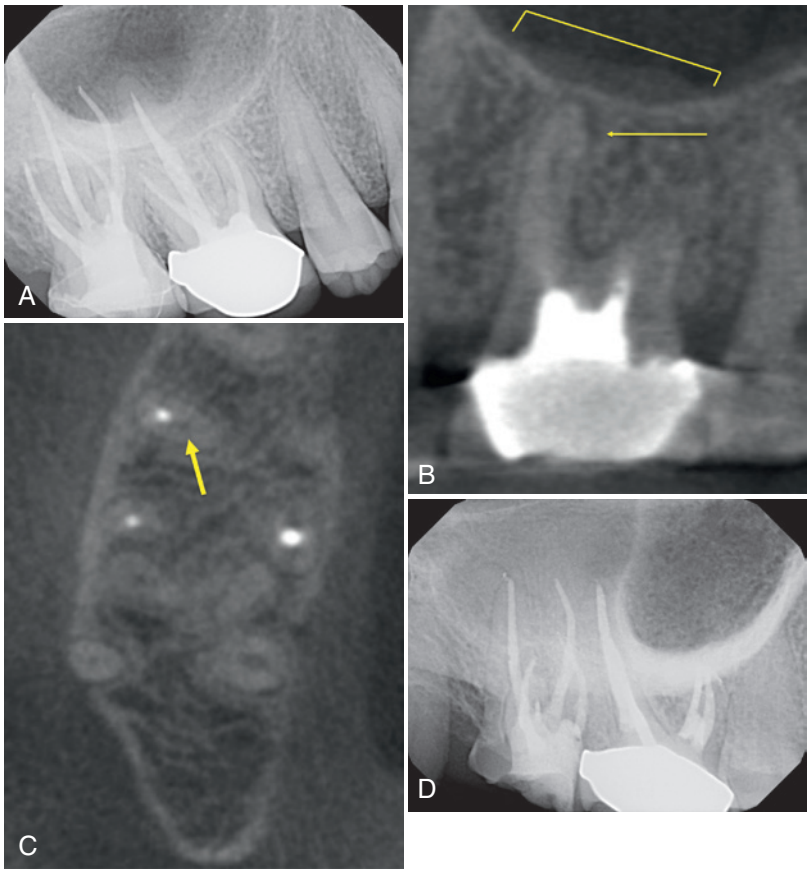

FIG. 8-8 A, Preoperative radiograph of symptomatic tooth #3. B, Sagittal slice of tooth #3 showing periodontal ligament thickening and associated sinus mucosal thickening. C, Axial slice showing untreated MB2 canal *(arrow).* D, Treated case.

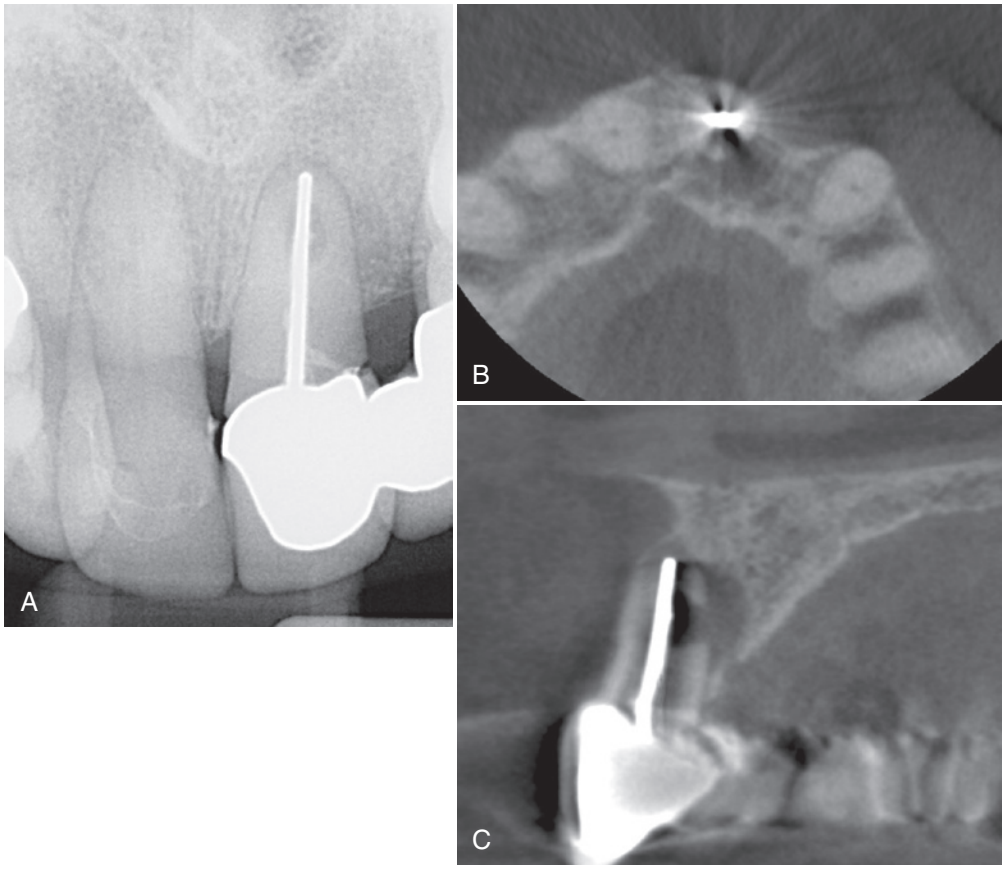

FIG. 8-9 A, Preoperative radiograph showing suspected small area of resorption associated with an endodontically treated tooth filled with a silver cone. B, Axial slice showing how beam hardening artifact from the metallic root filling obscures the image. C, Sagittal view showing very large palatally oriented external root resorption. The prognosis for retention of this tooth was poor, and the patient elected to extract it.

Comparative testing is the next procedure performed to collect objective information about the pulpal and periradicular status. Most useful are the periradicular tests that include percussion, bite, and palpation.[256] These allow the diagnostician to begin developing a sense of the status of the periradicular tissues. These tests are of great importance anytime an endodontic diagnosis is needed. However, they are of even greater importance when evaluating teeth that have been previously treated with endodontic therapy due to the lack of significant and consistent evidence that can be gained from pulp vitality tests in these cases. If a tooth exhibits percussion tenderness, it may be due to persistent endodontic disease, but recent trauma or occlusal trauma may also cause this finding,[90] as can periodontal disease.[256]

Pulp vitality tests are often of little value when examining teeth with previous endodontic therapy. However, if the patient's chief complaint reveals the need for these tests, they must be performed because it is possible that the pain may be referred from a nearby vital tooth and not from the root canal–treated tooth. When there is vital tissue remaining in the canals of a previously root-filled tooth, either by way of a completely missed canal or from an improperly cleaned canal, patients may complain of sensitivity to heat or cold.[90] Pulp vitality tests should then be performed to assess the situation. They are also useful in testing adjacent and opposing nonendodontically treated teeth to rule out those as etiologies for poorly localized pain. Once the tissue is removed from the pulp chamber after root canal therapy, the results of these tests should almost always be negative, even with radicular pulp remaining. Thus, a negative response with previously treated teeth is not necessarily conclusive; whereas a positive response usually means there is responsive pulp tissue remaining in the tooth.[90] Care is always warranted in interpreting pulp test results, however, as false positive and negative results may occur.[204] As with cold tests, the same limits apply to heat tests as far as the reasons for false results and accuracy relative to retreatment cases.

The remaining pulp vitality tests—electric pulp test, test cavity, and direct mechanical dentin stimulation—are of even lesser value than thermal testing when evaluating teeth that have already received endodontic therapy. These are usually precluded by the existing restoration or endodontic therapy.

When all diagnostic information is collected, a diagnosis must be developed. It is important to record the diagnosis in the patient's record so that anyone reading the record can discern the clinician's rationale for treatment. The pulpal diagnosis will usually be recorded as previous endodontic treatment, but the periradicular diagnosis will vary depending on the clinical picture presented. In the case of previous endodontic treatment, however, a brief note about the suspected etiology of the persistent disease is warranted.

TREATMENT PLANNING

Once the diagnosis is complete, the cause of the persistent disease will usually become apparent. At this point in the clinical process, information must be given to the patient by the clinician as to what treatment options are available and the likely outcomes of each choice. The patient is then allowed to make a decision based on his or her own perceptions of the options, not by the clinician's opinion as to what is "best" for the patient. The reader is reminded, however, that if the cause of the posttreatment condition remains unknown despite thorough diagnostic workup, then any decision results in an empirical "trial and error" type of treatment. This approach should be avoided if possible, and prior to definitive treatment, consultation with an endodontist or other colleague is in order. This consultation may be as simple as a brief conversation or even referral of the patient, but a second opinion is extremely useful in these situations. In most instances due to the interdisciplinary nature of modern dentistry, consultation with other clinicians who are treating the patient becomes a necessity to enhance the potential for successful treatment outcomes.

Occasionally, a patient will have persistent symptoms that mimic posttreatment disease, but these symptoms are actually the result of nonendodontic conditions such as occlusal trauma, concurrent periodontal disease, or nondental pain conditions. Appropriate diagnostic procedures should allow the clinician to sift through these options and treat accordingly.

The patient harboring true endodontic posttreatment disease has four basic options for treatment, which are as follows:

1. Do nothing
2. Extract the tooth
3. Nonsurgical retreatment
4. Surgical retreatment

The first option is to do nothing with the condition and allow it to take its course (Fig. 8-10). This approach is sometimes a useful, short-term option if the etiology of the

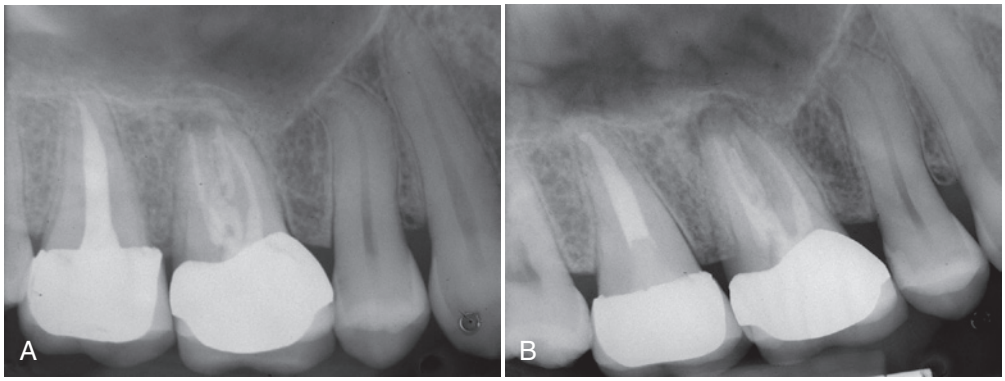

FIG. 8-10 A, Radiograph indicating presence of asymptomatic persistent apical periodontitis 7 years after initial treatment. The patient elected no treatment at that time. B, The 6-year follow-up. Lesion has enlarged, and the tooth has become symptomatic.

condition remains unknown and the clinician feels that another diagnostic sampling would help with diagnosis. Even though most clinicians would find this approach to be a less than desirable long-term course of action, the decision belongs to the patient. The clinician is bound, however, to ensure that the patient has complete information about what will happen if nothing is done. The events in the progression of the disease and a reasonable timeline are necessary, and the conversation needs to be thoroughly documented in the patient record to avoid possible subsequent accusations of abandonment. The question of whether the clinician is required to follow up with the patient or dismiss the patient from the practice is one that each clinician must make based on the clinician's experience, judgment, and knowledge of the patient.

Extraction of the tooth is usually considered a viable option. Advances in both prosthetic reconstruction techniques and dental implantology have made extraction and replacement a more desirable option in certain cases where previously "heroic" (read "expensive with an unknown prognosis") methods were needed to "save" the tooth. This alternative, however, provides results that are inferior, more expensive, and much more time consuming than preserving the natural tooth. The average titanium root-form implant restoration can take up to 6 months to finish, not counting preimplant site preparation, which can add months more. Despite published long-term success rates for dental implants,[4] postimplant disease does occur[4,85,86] (Fig. 8-11) and can leave the patient with few options. The cost of implant treatment is high and usually not covered under dental benefit plans, so the net financial impact on the patient is large. Implant aesthetics can be inferior to that of natural teeth in the aesthetic zone of the mouth, and some patients are just not candidates for implant procedures.[4] Fixed partial dentures are another replacement alternative with a long history of successful use, but negative outcomes are also possible. Most concerning to the endodontist is the likelihood that retainer fabrication procedures will result in endodontic disease of the abutment teeth,[154] which may potentially occur at a rate of up to 10%[150,253] (Fig. 8-12). Removable partial dentures are a less desirable option to the patient because they are generally less comfortable, usually require a long period of patient adaptation, and frequently result in damage to adjacent oral tissues (tooth, gingiva, and mucosa) if not meticulously cleaned. Due to these factors, patient compliance with removable dentures is relatively low, and their use is declining. Occasionally, a patient will choose to have a tooth extracted and not pursue replacement. This decision is usually disastrous for the patient, but there are a few situations where this choice is a reasonable alternative. Diseased maxillary second molars with no opposing tooth, or with an opposing tooth in class I or class III occlusion that articulates with another tooth, may be extracted without concern for future inappropriate movement of the remaining teeth, which can be so occlusally and periodontally damaging. In most instances, however, removal of a tooth will result in the need for replacement, and unless the tooth is hopelessly nonrestorable, retaining the tooth with endodontic procedures is better for the patient.

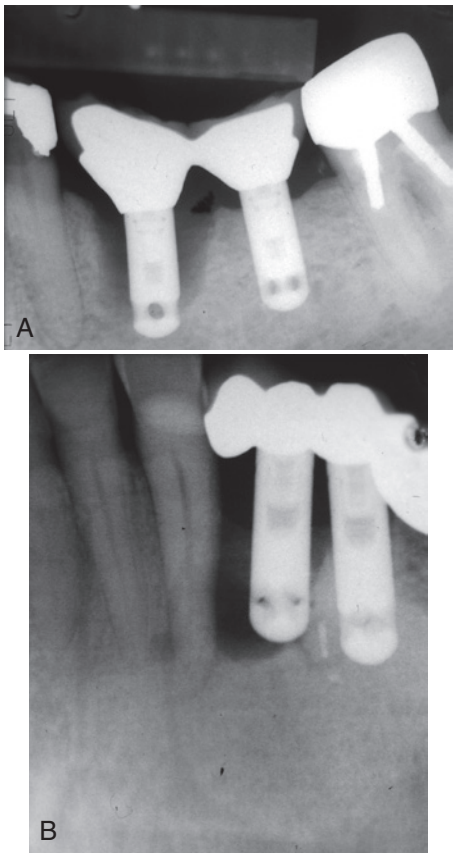

FIG. 8-11 A, Classic peri-implantitis. The implant needed removal. B, Another peri-implantitis. Note the endodontically treated root tip apical to the implant that may have contributed to the persistent disease. Perhaps apicoectomy should have been performed.

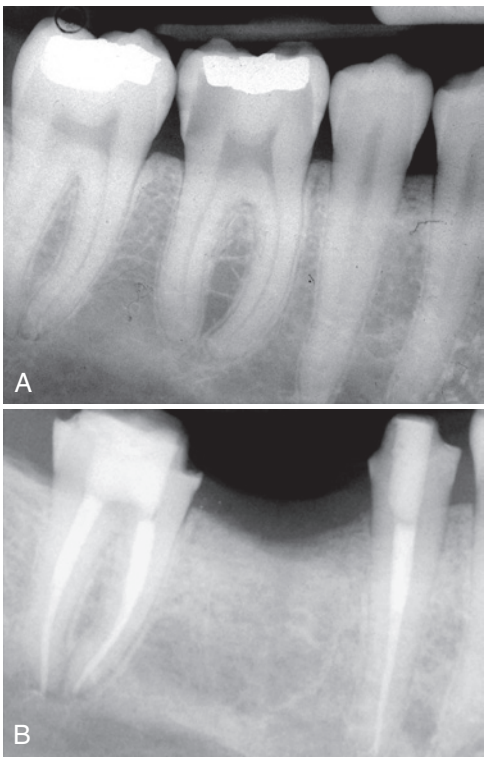

FIG. 8-12 A, Preoperative film showing deep caries approaching the pulp. The patient's holistic dentist advised extraction and replacement rather than endodontic therapy to retain the tooth. B, Fixed partial denture fabrication procedures resulted in irreversible pulpitis on both abutments requiring endodontic therapy.

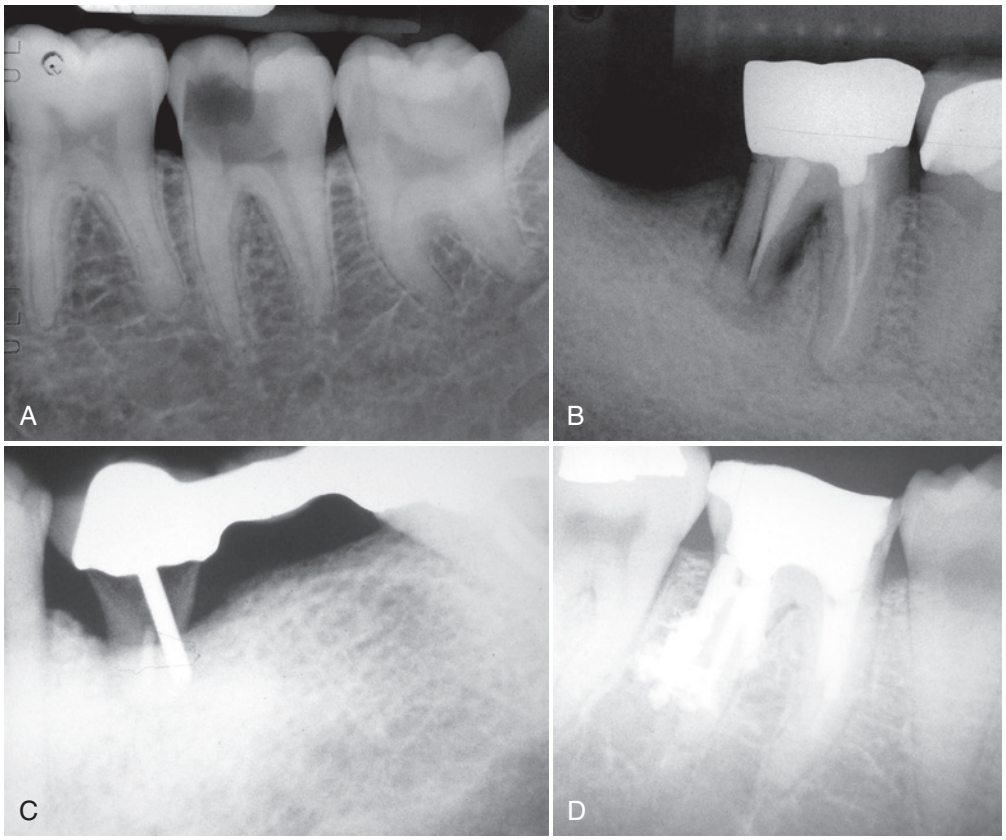

FIG. 8-13 **A,** Deep caries approaching the furcation and the biologic width. Necessary crown-lengthening surgery would open the furcation to bacterial invasion and persistent periodontal disease. **B,** Distal root vertical fracture resulting in a split root. **C,** Severe caries and post perforation. Inadequate root structure remaining to restore. **D,** Multiple distal root perforations so weaken the root as to make it nonrestorable. Note that cases A, B, and D could have resective endodontic surgery such as hemisection, but long-term prognosis is poorer than for extraction and replacement.[31,128]

Various situations may render a tooth nonrestorable (Fig. 8-13); however, the line of demarcation between restorable and nonrestorable is a movable one, depending on who is evaluating the tooth. There are several widely agreed upon situations that render a tooth nonrestorable. These include extensive caries or coronal fracture approaching or entering the furcation or the biologic width. This situation may render preprosthetic periodontal procedures ineffective (leaving a furcation involvement or poor crown-to-root ratio, for example) or, worse, removes bone that would otherwise be useful for implant procedures. Terminal periodontal disease (extensive pocketing or mobility) or root fracture[39] generally result in loss of the tooth despite all efforts at treatment. If the patient has a life-threatening endodontic infection with extensive trismus, most oral surgeons are going to extract the tooth rather than allow less aggressive management. Some previously root-filled teeth may have endured procedural complications, such as a nonretrievable separated instrument or irreparable ledge formation. In combination with the proximity to vital anatomic structures, such as the inferior alveolar canal, endodontic retreatment, either surgical or nonsurgical, may not be feasible and extraction may be the only option. These situations are, fortunately, quite rare, and in most instances, teeth presenting with posttreatment disease can be retained with endodontic procedures.

Once the decision has been made to retain the tooth, there are several choices for treatment. These can be grouped together into either nonsurgical or surgical endodontic treatments. The surgical options can be further broken down into periradicular curettage, apical root resection (with or without root filling), root amputation or hemisection, and intentional replantation (extraction/replantation).[89,170] Occasionally, a situation arises that will require both nonsurgical and surgical types of treatment to effect healing. The American Association of Endodontists has published guidelines that may help the clinician with clinical decision making.[7] However, the choice of which option to undertake will be determined by the clinician's experience, knowledge, patient considerations, and the preoperative diagnosis. If the etiology of the posttreatment disease can be made known, the choices become more obvious. In a previous section, four basic etiologies were presented. If the suspected etiology is in the first group, which is persistent or reintroduced microorganisms, then several choices are available. However, if the cause of the posttreatment disease is persistent extraradicular infection, foreign body reaction, or the presence of a true cyst, then nonsurgical root canal therapy has little likelihood of allowing healing to occur, and surgical methods should be employed.[231] The problem for the clinician is that in most instances, it cannot be determined which of these etiologies exist, so the treatment becomes more empirical.

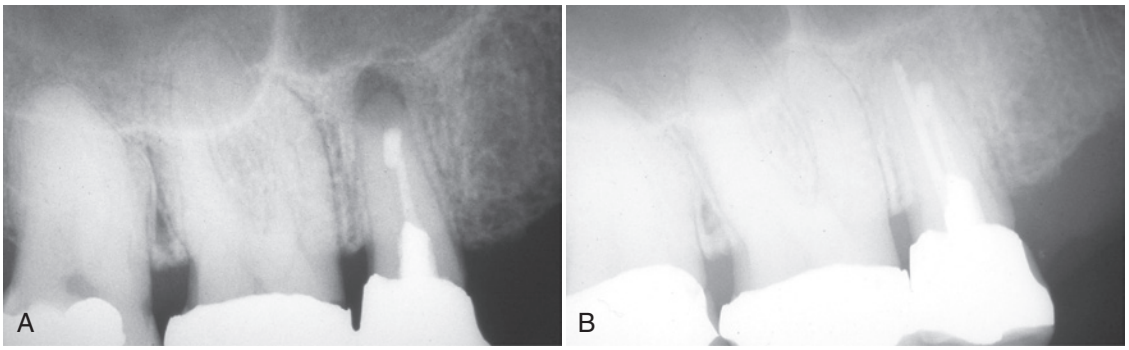

FIG. 8-14 A, Posttreatment disease following apical surgery. Off-center positioning of the root filling indicates the presence of a second, untreated canal. B, One year following nonsurgical retreatment showing complete healing.

The choice of nonsurgical retreatment versus apical surgery becomes the focus of the decision in most instances. Outcomes assessment studies provide some help in making this decision. The reported healing rates of nonsurgical retreatment range between 74% to 98%,[66,222,136,221,208] but with apical surgery alone, only 59% heal completely.[63] When apical surgery is preceded by orthograde retreatment, however, the incidence of complete healing rises to 80%.[63] In general, nonsurgical retreatment will be the preferred choice, because it seems to provide the most benefit with the lowest risk. It has the greatest likelihood of eliminating the most common cause of posttreatment disease, which is intraradicular infection. Nonsurgical retreatment is usually less invasive than surgery and has a less traumatic postoperative course. There is less likelihood of incurring damage to adjacent vital structures such as nerves, adjacent teeth, and sinus cavities. However, nonsurgical retreatment may be more costly than surgical treatment, especially if large restorations must be sacrificed during disassembly procedures prior to the retreatment. In addition, the amount of time needed for retreatment is usually longer than surgical intervention. There are times when the clinician may not be able to achieve the complete elimination of microorganisms from the canal space, and complete obturation may not be possible. Apical surgery is chosen, therefore, when nonsurgical retreatment is not possible or when the risk-to-benefit ratio of nonsurgical retreatment is outweighed by that of surgery.[64,144]

There are many factors to consider when deciding whether to retreat surgically or nonsurgically (see also Chapter 9). The patient must be fully aware of the proposed treatment and the alternatives, and he or she must be motivated to follow through with all treatment including the final restoration. The patient must have adequate time to undergo the required procedures. If he or she does not, then apical surgery alone may be indicated although the patient must be made aware of the potentially compromised nature of the treatment. Clinicians must be armed with the best equipment and knowledge available, and critical self-evaluation should allow experienced clinicians to know what they can treat and what they cannot. The tooth must be restorable and retreatable. Attempting nonsurgical retreatment on teeth where there is little likelihood of improving the previous treatment provides little benefit to the patient. Thus, in disease situations where there is an apparently adequate root filling and no evidence of coronal leakage, surgery may be indicated. If the previous treatment falls below any acceptable standard and there is no evidence of apical periodontitis, then there is no indication for any treatment unless a new coronal restoration is planned. In that case, conservative retreatment is indicated, and the reported success rates are very high.[63,66] If there has been a previous procedural complication, such as a ledge that cannot be bypassed or a separated instrument that cannot be removed, then surgery may become a better option. Most times, however, it is still prudent to attempt the retreatment because ledges or separated instruments that appear impenetrable on diagnostic films can frequently be bypassed. Even if they cannot, nonsurgical retreatment can enhance the success of subsequent apical surgery as noted previously. The clinician must be careful not to worsen the situation by overly vigorous attempts to treat the previous complication, as root perforation, worsening of a ledge, or another separated instrument may be the result. Previous failed apical surgery should be retreated nonsurgically and then followed up because many surgical failures are due to poorly cleaned and filled canal systems[187] (Fig. 8-14). In many instances, performing the surgery a second time can be avoided altogether. If there is evidence of root fracture (narrow-based probing defect or a "J"-shaped radiolucency encompassing the root apex and progressing in a coronal direction[237] (Fig. 8-15), then nonsurgical retreatment would be unlikely to improve that situation. Apical exploratory surgery may be necessary, which could result in root resection or even extraction of the tooth.

Each case should be approached as a unique set of considerations that need to be reviewed and interpreted prior to selecting a treatment method. Once the selected option is undertaken, however, the prudent clinician is always watchful, as additional pieces of information can be discovered during treatment that may modify previous decisions.

NONSURGICAL ENDODONTIC RETREATMENT

The primary difference between nonsurgical management of primary endodontic disease and that of posttreatment disease is the need to regain access to the apical area of the root canal space in the previously treated tooth. After that, all of the principles of endodontic therapy apply to the completion of the retreatment case. Coronal access needs to be completed, all previous root-filling materials need to be removed, canal obstructions must be managed, and impediments to achieving full working length must be overcome. Only then can cleaning

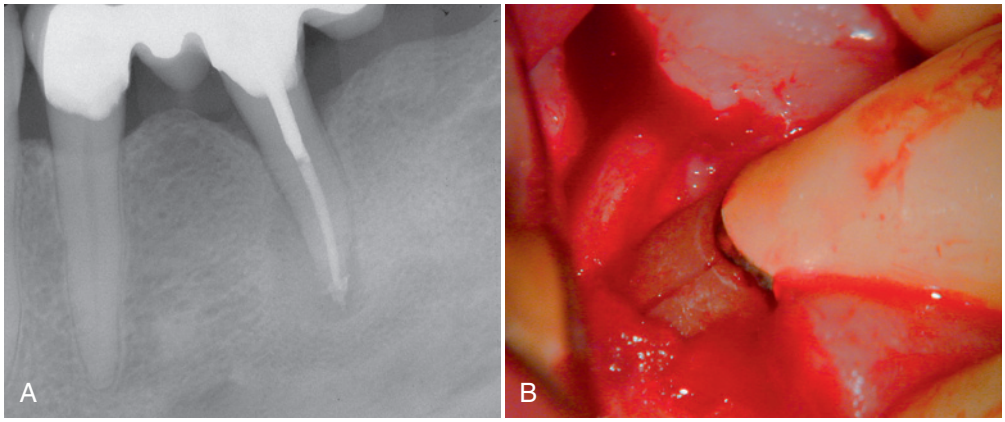

FIG. 8-15 A, "J"-shaped radiolucency possibly indicating root fracture. B, Exploratory surgery confirms presence of vertical root fracture.

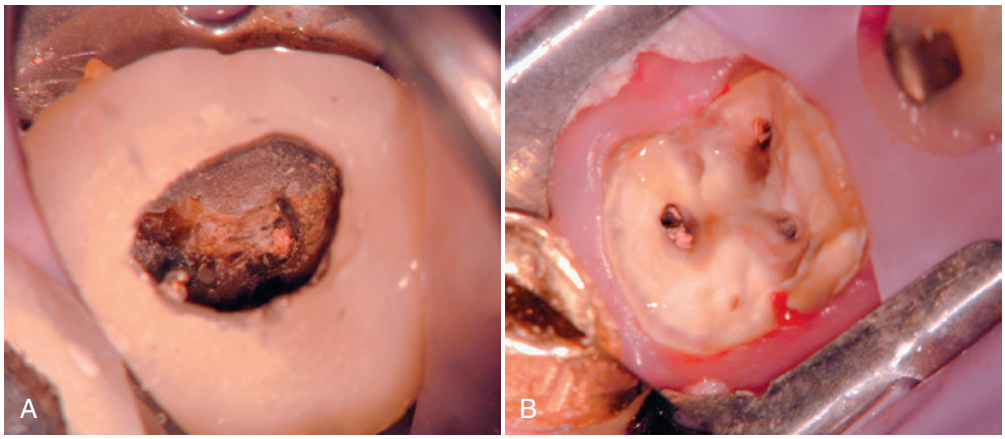

FIG. 8-16 A, Limited visibility and access with crown present. B, Enhanced visibility and access with crown off. Note that isolation was achieved by using a Silker-Glickman clamp and sealing putty.

and shaping procedures be instituted that will allow for effective obturation and case completion. The remainder of this chapter is devoted to these topics in the order that they generally present themselves to the clinician treating the previously root-filled tooth.

Coronal Access Cavity Preparation

Retreatment access has been called coronal disassembly[187,188] because of the frequent need to take apart or remove the previous coronal and radicular restoration. Following initial endodontic therapy, most teeth require and receive a full coverage restoration, and many times that restoration is supported by a post and core. Coronal-radicular access for retreatment is much more complicated in these cases when compared with endodontically treated teeth that have been minimally restored. The goal of the access preparation is to establish straight-line access to the root canal system while conserving as much tooth structure as possible. The ideal access preparation allows for instruments to enter the canals without being deflected by the access cavity walls. This is reasonably easy to achieve when the tooth is completely intact and a pulp chamber is present, because surface and internal anatomic landmarks can guide the search for the canals. Unfortunately, when endodontic retreatment is necessary, the tooth structure has almost always been altered and is commonly quite misrepresentative of the original anatomy of the tooth.

When presented with a tooth in need of retreatment that has a full coverage restoration, the decision for the clinician becomes whether to attempt to preserve the restoration or to plan its replacement. This decision is made simpler if there is a defect or caries associated with the restoration or if the treatment plan calls for a new crown. The old one is simply removed and replaced later in the treatment sequence (Fig. 8-16). When the crown is considered to be satisfactory, the decision becomes more complex. If the restoration is maintained, the cost for replacement can be avoided, isolation is easier, the occlusion is preserved, and the aesthetics will be minimally changed. Even if the crown requires replacement, the clinician may elect to retain it during the endodontic retreatment to allow for better isolation with the rubber dam. Unfortunately, retreatment may be more difficult with the crown in place, as this could lead to an increased chance for an iatrogenic mishap due to restricted visibility. In addition, removal of canal obstructions, such as posts, will be more difficult, and there is an increased chance the clinician may miss something important such as hidden recurrent caries, a fracture, or an additional canal. To preserve the restoration, two approaches can be taken: access through the crown or crown removal and replacement when retreatment

is completed. The simplest choice is to prepare an access cavity through the existing crown, although there is a significant risk of damaging the restoration resulting in the need to replace it.[160] This risk must be communicated to the patient prior to instituting therapy. If the clinician decides to access through the existing restoration, there are several choices of access burs to use, depending on what material the preparation will be cut through. If the access will be primarily cut through metal (amalgam alloy or cast metal) or composite resin, carbide fissure burs such as the #1556 are usually chosen. With many restorations, it is advisable to consider using a combination of burs to achieve access. For example, when a porcelain fused to metal crown is encountered, a round diamond is used to cut through the porcelain layer. Once the metal substructure is encountered an end-cutting bur, such as the Transmetal bur (Dentsply Maillefer, Ballaigues, Switzerland) or the Great White bur (SS White, Piscataway, NJ) can be used to cut through to and remove the core material efficiently. An important consideration for the clinician is the potential for porcelain fracture, which may occur during the preparation or possibly at a later date after completion of the treatment. This damage is especially common with porcelain jacket crowns. Restorations fabricated completely of porcelain are becoming more and more popular, thus creating added concern due to the increased likelihood of crack formation during access. Porcelain is a glass, and drilling through this material will create many microfractures, which in turn, may weaken the structure of the restoration, making it more prone to future failure.[94] Copious coolant water spray and the use of diamond burs are recommended during access through porcelain to minimize occurrence of this event.[235] In a novel approach, Sabourin and colleagues[189] recently showed that, compared with the use of drills, air abrasion produced almost no defects in the porcelain structure of all ceramic crowns when used for endodontic access. It was, however, significantly more time consuming to access through the crown this way.

If the decision is made to remove the crown for reuse, the visibility is increased, allowing for much easier removal of canal obstructions and a decrease in the potential for operator error; however, rubber dam clamp placement and tooth isolation may become a bigger problem. Also, despite all of the varying techniques and armamentaria available for removal of an existing restoration, the procedure remains unpredictable and many times can also result in damage to the restoration or the inability to remove it at all.

The clinician must decide how to remove the crown. If the crown is of no value, even as a temporary, then the clinician can take the easiest road and simply cut it off. However, if the crown is to be preserved, then a more conservative approach must be used. Two considerations, which may influence the decision about removal of a crown or bridge, are what material the restoration is made of and what is it cemented with. Conservative removal efforts are difficult with traditional, all-metal restorations cemented with nonbonded cements. This situation has been even more of a concern lately due to the increasing popularity of tooth-colored restorations, mainly different types of porcelain or porcelain fused to metal (PFM) restorations, which are being bonded to the tooth. These restorations are less likely to withstand the stresses of removal than those fabricated entirely of metal, and restorations that are bonded are much more difficult to remove due to the adhesive strengths of bonding agents. Each new generation of bonding agent is stronger than the previous, making removal increasingly more difficult as cosmetic dentistry advances.

Many devices have been developed specifically for the conservative removal of crowns. Some of the more commonly used devices are forceps that have been designed specifically for crown removal such as the K.Y. Pliers (GC America, Alsip, IL) (Fig. 8-17), which use small replaceable rubber tips and emery powder to enable a firm grasp of the crown without damaging it. Other instruments of this type include the Wynman Crown Gripper (Integra Miltex, York, PA), the Trial Crown Remover (Hu-Friedy, Chicago, IL), and the Trident Crown Placer/Remover (CK Dental, Orange, CA). Unfortunately, a crown that has been cemented with long-term cement or has been bonded to the tooth will usually not be removed with one of these instruments. There are also forceps designed specifically to engage the margins of the crown while using an adjacent tooth as a fulcrum. Squeezing the handles together will cause the crown to be elevated off of the tooth. The Roydent Bridge Remover (Roydent, Rochester Hills, MI) works in this fashion and can be effective in crown removal, but care must be taken to avoid damage to fine, fragile margins, especially on porcelain crowns. Another type of instrument can be engaged under the margin, and a subsequent impact delivered at this site will dislodge the restoration. The Easy Pneumatic Crown and Bridge Remover (Dent Corp, White Plains, NY) and the Coronaflex (KaVo, Lake Zurich, IL) create this impact from compressed air, whereas the Morrell Remover (Henry Schein, Melville, NY) applies the force manually using a sliding weighted handle. The ATD Automatic Crown & Bridge Remover (J. Morita, Irvine, CA) uses vibrations to break the crown-to-preparation bond, and the Crown-A-Matic (Peerless International, N. Easton MA) delivers a shock impulse to loosen the crown. As mentioned earlier, crown margin damage may result, as can inadvertent extraction of the tooth if the periodontium is compromised[183] (Fig. 8-17, *E*). A different approach to conservative crown removal involves drilling a small hole through the crown to allow a device to thread a screw through the hole. This approach creates a lifting force that separates the crown and the tooth. The instruments that work in this manner are the Metalift (Classic Practice Resources, Baton Rouge, LA), the Kline Crown Remover (Brassler, Savannah, GA), and the Higa Bridge Remover (Higa Manufacturing, West Vancouver, BC, Canada). Although very effective on metal crowns, these instruments may cause damage to porcelain occlusal surfaces on PFM restorations, and their use in both anterior teeth and in all porcelain restorations is generally precluded.

Another interesting technique designed to remove a crown without causing damage is performed using the Richwil Crown & Bridge Remover (Almore, Portland OR). This material is a water-soluble resin, which is softened using warm water (Fig. 8-18). The small block of material is placed on the crown to be removed, and the patient bites into this material until the resin cools and hardens at which point the patient opens his or her mouth, generating enough force to pull the crown off. The clinician must be careful to avoid using this technique when the opposing tooth is extensively restored, because the opposing restoration may inadvertently be removed during the procedure. None of these techniques works in every case, and they may produce damage to the restoration being removed or possibly others. These are, however, methods that are available and may work while permitting reuse of the restoration.

Endodontic therapy was performed in hand and the tooth was replanted, a procedure known as unintentional replantation. **F,** Kline Crown Remover (Brasseler USA).

Post Removal

Once the access is prepared, it is common to encounter a post, as posts are frequently used in the restoration of endodontically treated teeth. The clinician may encounter many different types of posts during retreatment (Fig. 8-19). They can be classified into two categories: prefabricated posts and custom cast posts. Historically, cast posts were more commonly used than prefabricated posts; however, since the 1990s, cast posts have become much less popular.[201] The main reason for this decrease is the convenience of placing the prefabricated post immediately after post preparation as opposed to waiting for a laboratory to fabricate the casting. There is also less likelihood of the interappointment contamination that frequently occurs with temporary post/core/crowns that are needed for cast/custom post and core fabrication. Prefabricated posts come in a variety of shapes, designs, and materials. The shapes can be subclassified into two groups: parallel sided or tapered. The design of posts also can be subclassified into active (threaded), passive, vented, fluted, and acid-etched groups. There are also many materials that have been used to fabricate posts, such as stainless steel, gold, titanium, ceramic, zirconium, and fiber-reinforced composite posts. Cast posts, which are fabricated in a laboratory, will always be made up of precious or nonprecious metal alloys. These posts also come in a variety shapes and configurations because they are custom manufactured for each root in which they are placed. Most of these have some degree of taper, and many will be cast in one piece with the core included.

In addition to the shape, design, and material of posts, there are two more very important factors that will have some influence on the clinician's ability to remove them. These factors are the adhesive material used to cement the post and the location in the arch of the tooth that requires post removal.

The same concerns regarding cements that were discussed in the section on crown removal apply to post removal. The main consideration is whether the post was cemented with traditional cement or bonded with a composite resin and dentin-bonding agent. Several post systems on the market today, such as the ProPost (Dentsply, York, PA), use acid-etched metal posts that are bonded into the canal with cements, such as Panavia (Kuraray America, New York, NY) or C&B Metabond (Parkell, Edgewood, NY). Removal of these posts is

FIG. 8-18 A, Richwil Crown and Bridge Remover (Almore). B, Using hot water to soften the material. C, The remover is placed on the restoration to be removed and the patient bites into the material. D, Image showing the removed crown adhering to the material.

(Diagrams courtesy DENTSPLY Endodontics.)

extremely difficult and occasionally impossible, regardless of which technique is used.[84] One study has shown that heat generation with ultrasonic vibration may help to decrease retention of resin cemented posts,[73] but concern for heat-generated periodontal ligament damage may preclude this technique.[201]

With regard to location, the more posterior in the arch, the more difficult the post is to remove. This predicament is a result of accessibility. The more accessible the tooth is, the easier the post is to remove because the clinician will have more techniques and instruments available to use.[2] Also, the more anterior the tooth is, the less the opposing occlusion will interfere with post removal.

Post Removal Techniques

After initial access and after the post to be removed has been located, the clinician is faced with the decision of how to remove it. Many techniques have been developed for the sole purpose of post removal. Regardless of which technique is chosen, there is one simple yet extremely important rule to follow: it is not only what is removed but what is left behind that is important. This rule applies to the removal of all intracanal obstructions. The reason for this rule is to make sure that the remaining tooth, after removal of the obstruction, can be restored predictably with a good long-term prognosis. For example, there is little use in successfully removing a post and leaving behind a root that is eggshell thin and prone to fracture (Fig. 8-20).

The first step in post removal is to expose it properly by removing all adjacent restorative materials. With preformed posts, the bulk of the core material around the post and within the chamber can be removed with a high-speed handpiece using cylindrical or tapered carbide or diamond burs. When the majority of the restorative material is removed, a less aggressive instrument, such as a tapered bur in a slow-speed handpiece or a tapered, midsized ultrasonic tip, should be used to remove the last of the embedding core material. This process is greatly facilitated by use of magnification and illumination. Once there is minimal restorative material remaining, a smaller-sized ultrasonic instrument should be used to minimize the risk of removing unnecessary tooth structure or thinning of the post. The more post that is left, the more options for removal, and the more tooth structure that is left, the more options for restoration. At this point, a high-speed bur is too risky to use. When the core is cast in one piece with the post, a high-speed instrument can perform this process to generate a shape that can facilitate removal.

Once the post is well isolated and freed from all restorative materials, the clinician can begin the retrieval process. There are many instruments and kits on the market that can be used to remove posts; however, prior to using one, the retention of the post should be reduced. The clinician can usually continue to use the same medium-sized ultrasonic tip that was used to get to this point. Using this instrument at the interface between the post and the tooth (the cement line) and constantly moving it around the circumference of the post will disrupt the cement structure along the post/canal wall interface and decrease post retention facilitating removal,[19,32,119] although the effects of ultrasonic vibration may be minimal in reducing retention of well-fitted, long, large-diameter titanium posts.[20] Titanium has a lower modulus of elasticity than stainless steel, so it may dampen the ultrasonic vibrations, which may decrease the effectiveness of the ultrasonic; however, one study failed to duplicate this effect.[98] Nonetheless, care should be taken not to push the ultrasonic tip against the post with too much force, as this will dampen the ultrasonic wave and actually reduce the effectiveness of this technique. Taking away a small amount of the dentin around the coronal aspect of the post is not critical at this time, as this will aid in the reduction of post retention without unduly weakening the root. If the root is thin, however, and the amount of space between the cement line and the root surface is restricted, the size of the tip that can be used may be limited. Unfortunately, the smaller tips are not only less effective for post removal, but they are also more prone to breakage. At this point, the ultrasonic handpiece should be used with copious air-water spray as a coolant. Due to the heat that can be generated from this procedure, the tip should be removed from the access every 10 to 15 seconds to allow the use of an air/water syringe not only to clean the area of debris but also to reduce the temperature produced that could potentially cause damage to the periradicular tissues.[201,274] If a rubber dam is in place, the area around the post may be flooded with a solvent such as chloroform prior to activating the ultrasonic instrument, as this will help dissolve the cement around the post. Using a solvent in conjunction with removal of cemented obstructions may prove beneficial because the ultrasonic energy produced will set up shock waves in the solvent and make it penetrate

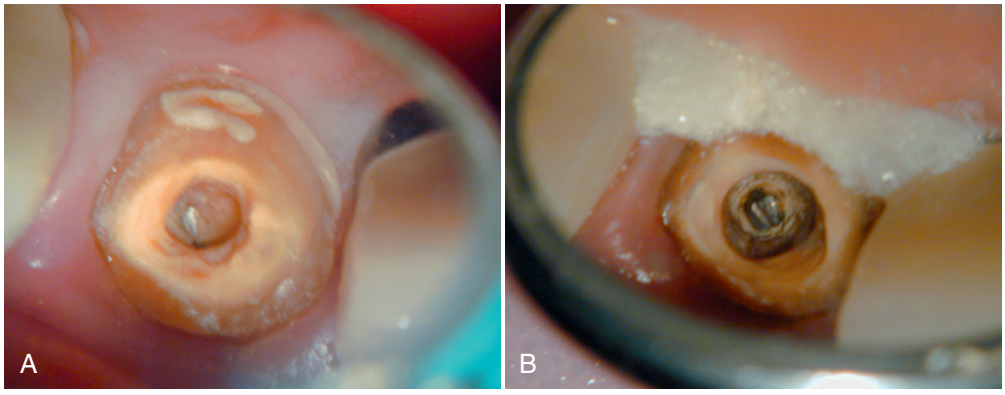

FIG. 8-20 A, Broken post (incisal view before excavation). B, Root has been so thinned and weakened by excavation procedures that restorability is questionable.

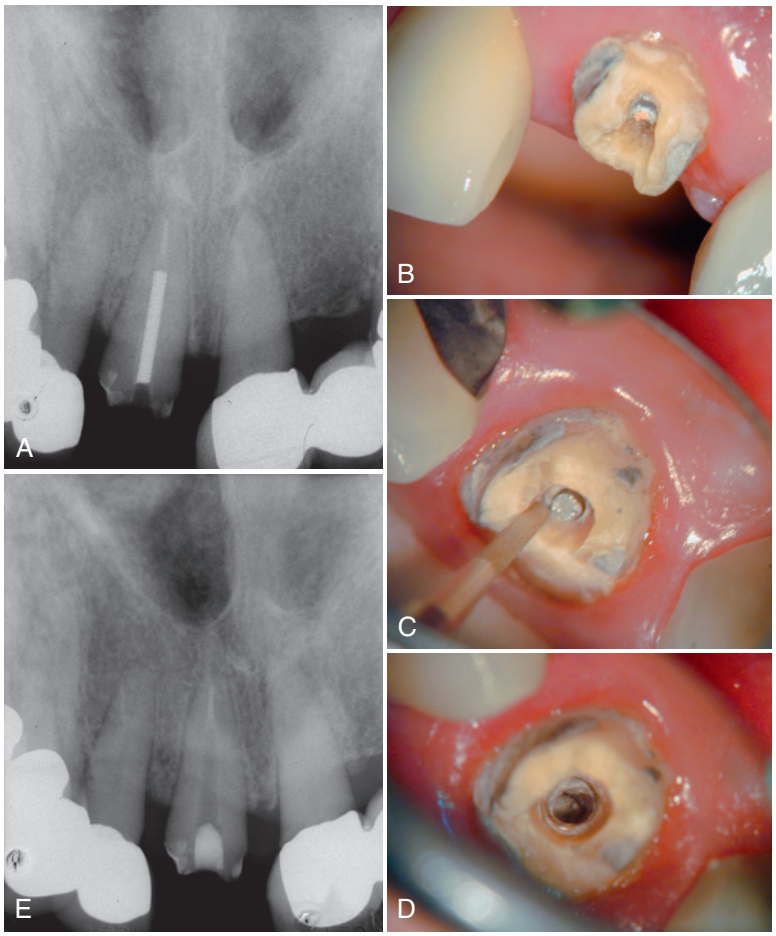

FIG. 8-21 A, Radiograph of fractured post. B, Fractured post, labial view. C, Ultrasonic troughing. D, Post removed by ultrasonic alone. E, Check film confirming complete post removal.

deeper into the canal space, exerting a faster solvent action on the cement.[78]

Using an ultrasonic instrument in this fashion is not simply helpful in reducing post retention; this may also prove to be all that is needed to remove the post. Many times, after judicious use of the ultrasonic instrument, the post will loosen and actually spin out of the preparation, completing post removal (Fig. 8-21). In addition, if post removal cannot be accomplished in this manner, the resulting post exposure will be very beneficial in contributing to the predictable use of other techniques, as many of the instruments to be discussed involve using a trephine bur to shape the coronal end of the post. Ultrasonic exposure will facilitate this process. Another instrument to consider for exposing and loosening a post is the Roto-Pro bur (Ellman International, Hicksville, NY) (Fig. 8-22). There are three shapes available, all of which are six-sided, noncutting tapered burs that are used in a high-speed handpiece around the circumference of the post. The vibrations created when the noncutting flutes come in contact with the post decrease the retention of the post, facilitating its removal.

If retention reduction does not remove the post, some form of vice is needed to pull the post from its preparation. Many post removal kits are available on the market today with varying degrees of effectiveness. One such device is the Gonon Post Removing System (Thomas Extracteur De Pivots, FFDM-Pneumat, Bourge, France), which is a very effective instrument for removing parallel or tapered, nonactive preformed posts.[145,191] This kit utilizes a hollow trephine bur that is aligned with the long axis of the post and placed over its newly exposed end. The trephine then cuts in an apical direction, shaving off the post's outer layer not only to remove tooth structure adjacent to the post but also to reduce the circumference of the post to a specific size and shape. This procedure is necessary to allow a specific, matched-size extraction mandrel to create or tap a thread onto the exposed milled portion of the post. Once the extraction mandrel with its associated washer/bumpers (Fig. 8-23) is attached to the post, the extraction forceps or vice is applied to the tooth and post. Turning the screw on the handle of the vice applies a coronal force in a similar fashion as a corkscrew removes a cork from a bottle of wine. This method is effective because all the force is applied to the bond between the tooth and the post, ideally in the long axis of the root. The main problem with this technique is the size of the vice that can make access in the molar region and between crowded lower incisors difficult. Also, if the extraction force applied is not directed in the long axis of the root, root fracture may occur.[35]

The Thomas Screw Post Removal Kit (Thomas Extracteur De Pivots, FFDM-Pneumat) (Fig. 8-24) is an instrument designed specifically for the removal of active or screw posts. The trephine burs are identical to those used with the Gonon Post Removal System, although the extraction mandrels are threaded in the opposite direction. The mandrels are reverse threaded to enable them to tap onto the screw post in a counterclockwise direction so that continued torquing force while creating the thread will unscrew the post.

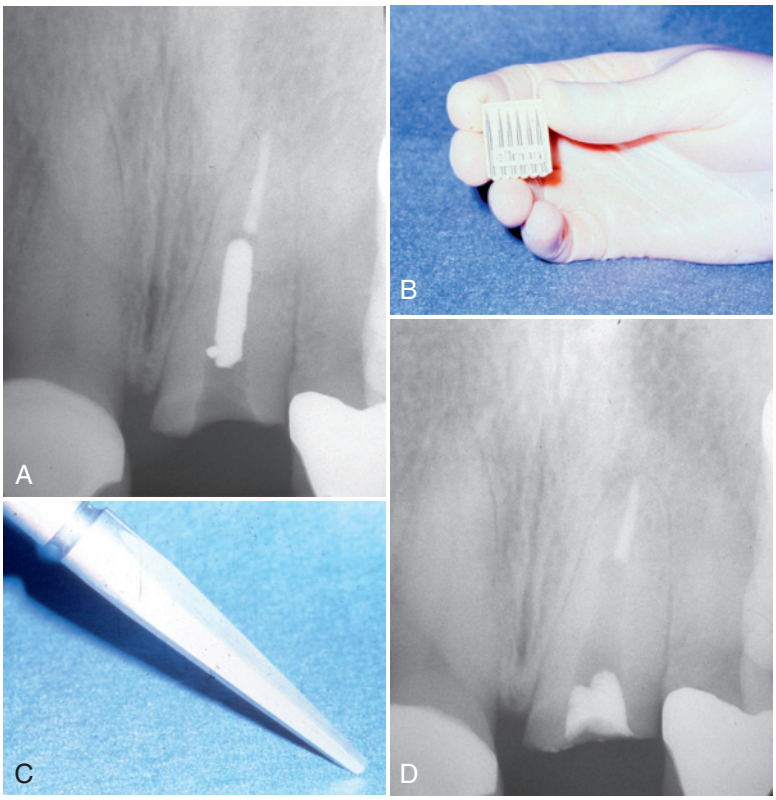

FIG. 8-22 A, Radiograph of fractured post. B, Roto-Pro Kit. C, Roto-Pro Bur. D, Post removed by vibration of the instrument alone.

The Ruddle Post Removal System (Sybron Dental Specialties)[187] (Fig. 8-25) and the Universal Post Remover (Thomas Extracteur De Pivots, FFDM-Pneumat) were designed to combine the properties of both the Gonon and Thomas kits. Both of these very similar kits are useful not only for removing parallel or tapered passive types of posts but also for removing screw posts. They can even be adapted to remove large separated instruments in the coronal straight portion of a large canal. These kits also use a trephine bur to machine the post to a specific size that will dictate which mandrel to use. These mandrels tap in the counterclockwise direction so that the same taps can be used for both passive and active posts. Once the mandrel is tapped onto the post, the extraction jaws, or vice, can be applied and activated, enabling removal of passive posts, or the tap is continuously rotated counterclockwise to unthread screw-type posts.

Another device that works in a similar fashion as the Gonon and the Ruddle Post Removal System is the JS Post Extractor (Roydent Dental Products). The biggest advantage of this kit is the size, as this is the smallest of the kits that work using a pulling action, which may help in cases where access is difficult. However, this kit does have one disadvantage: it does not have as large of a variety of trephine burs and extraction mandrels as some of the others. Therefore, the size of the post may be a limiting factor.

Another post removal device is the Post Puller, also known as the Eggler Post Remover (Automaton-Vertriebs-Gesellschaft, Germany)[228] (Fig. 8-26). This device works in a similar manner as some of the others; however, there are no trephine burs or extraction mandrels. The design of this instrument enables it to be used more efficiently with the crown removed. In addition, the design also allows this instrument to be used for cases in which the post and core are cast as one unit. This device consists of two sets of jaws that work independently of one another. With this device, both the post and the tooth are reduced to allow attachment of the post puller. Because there are no trephine burs, this reduction is done with a high-speed handpiece and bur. Next, the first set of jaws are attached to the post while the second set of jaws push away from the tooth in line with the long axis of the tooth removing the post from the canal.[228] Care must be taken to align the pulling forces of this instrument with the long axis of the root to prevent fracture,[35] and also, this technique is not recommended for the removal of screw posts. In a survey of the Australian and New Zealand Academy of Endodontists, this was the most commonly used technique for post removal.[34] However, in a survey of the American Association of Endodontists, this was one of the least used techniques.[229] Clearly, techniques that are common in one country are not always that common in another.

The increased popularity of cosmetic dentistry has created an impetus toward the use of tooth-colored posts that are fabricated from ceramic, zirconium, or various types of fiber-reinforced composite. Unfortunately, as with all posts, cosmetic posts also will need to be removed periodically. Neither the use of the Gonon Kit nor ultrasonic instruments allows for removal of fiber posts, whereas the use of a high-speed bur to channel down through the post may result in a high rate of root perforation.[178,201] The use of the Largo Bur (Dentsply)[75] and the Peeso drill[178] to remove these posts has been advocated, and most of the post manufacturers have removal burs in the kit.[47] These manufacturers' removal kits have been shown to be more efficient at removing their own fiber posts than the use of diamond burs and ultrasonics.[138] In addition, a new bur, the

GyroTip (MTI Precision Products, Lakewood, NJ), has been designed for the specific purpose of removing fiber-reinforced composite posts (Fig. 8-27). These drills consist of a heat-generating tip designed to soften the matrix that binds the fibers within the fiber-reinforced post. The fibers within the post are parallel, which assists the axial travel of the drill through the center of the post. The fluted zone of the drill allows the fibers to be safely removed, creating access to the root canal filling. Above the fluted zone, a layer of plasma-bonded silica carbide reduces the heat generation that would otherwise occur if a smooth carbide surface were rotating in contact with enamel or dentin. This abrasive zone also provides for a straight-line access preparation and facilitates the placement of a new post. Ceramic and zirconium posts are usually impossible to retrieve. They are more fragile than metal posts, and though ceramic posts may be removed by grinding them away with a bur (a procedure with a high risk of root perforation), zirconium has a hardness approaching that of diamond and cannot be removed by this method.[201]

Regardless of the post type or retrieval method used, once the post has been removed, the final step in exposing the underlying root filling material is to ensure that none of the post cement remains in the apical extent of the post space. This step can be easily accomplished by visualizing the cement using magnification and illumination and then using a straight ultrasonic tip to expose the underlying canal filling.

Potential Complications of Post Removal

As with many dental procedures, post removal has risks. These risks include fracture of the tooth, leaving the tooth nonrestorable, root perforation, post breakage, and inability to remove the post.[229] An additional concern is ultrasonically generated heat damage to the periodontium.[201]

Even though there may still be some who feel posts strengthen teeth, it is widely accepted that they do not.[201] Actually, it has been shown that post preparation alone weakens teeth.[250] Therefore, it seems obvious that any additional work, which may require removal of further tooth structure, will further weaken the tooth, increasing the likelihood of fracture. An in vitro study showed that cracks can form in radicular dentin during post removal using both the Gonon Kit and ultrasonics, but there was no significant difference between these two groups, and teeth with posts that were not removed.[6] The authors speculated that the potential for vertical root fracture might increase; however, the clinical significance of this

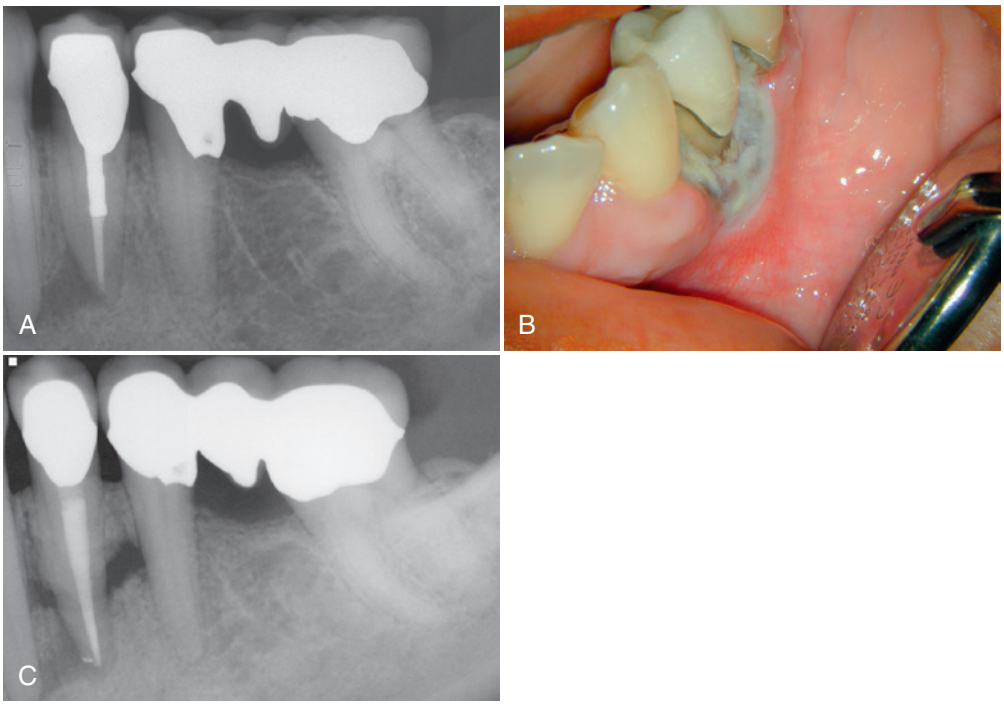

FIG. 8-28 Tissue damage from heat generated by ultrasonic application to a post during removal. The ultrasonic tip was applied to the post for no more than 5 minutes at high power with the assistant applying a constant water spray. **A**, Preoperative radiograph. **B**, and **C**, These images were taken 1 month after the retreatment. remains unknown. A more recent study, however, concluded that the incidence of root fracture during post removal was extremely low and that with good case selection, post removal is, in fact, a predictable procedure.[2] If, however, post removal would also leave the remaining tooth structure in a state that may not be predictably restored with a good prognosis and if this situation can be predicted ahead of time, surgery may be the preferred treatment option.

Perforation is an additional possible complication that can happen during post removal, especially if the post is removed by simply attempting to drill it out with high-speed burs.[178] If perforation occurs, the clinician should repair it immediately, as the prognosis will worsen as the time between perforation and repair lengthens.[24,206] Once a perforation occurs, the clinician must reconsider the prognosis and determine whether the tooth should be salvaged. Terminating the procedure and pursuing a different treatment option could be considered at this point. Extraction and replacement with an implant or a fixed prosthesis was a treatment option prior to initiating the retreatment, and some may consider this treatment the best option once a perforation has occurred. However, with the development of mineral trioxide aggregate (Pro-Root MTA, Dentsply, York, PA), perforations can be repaired with a favorable prognosis.[184] The techniques and materials for perforation repair will be discussed in detail in a later section of this chapter.

Another complication is separation of the post, causing removal of the coronal segment leaving a small portion of the post with even less accessibility. This separation will decrease the likelihood of removal and occurs more frequently when attempting to retrieve titanium posts.[201]

The use of ultrasonic energy for prolonged periods of time can generate excessive amounts of heat. The heat generated can cause damage to the surrounding periodontium.[78,201] This damage may be as serious as both tooth and permanent bone loss (Fig. 8-28). For this reason, stopping periodically to cool off the area with a water spray is necessary. This will be discussed in detail in a later section.

If the clinician is unable to remove the post, he or she will be faced with a decision of what to do. This decision is based on whether the post is being removed for restorative purposes or due to the persistence of disease. If the reason is for restorative purposes and the clinician can adequately restore the tooth with the existing post or post segment, then he or she should do so. If the tooth cannot be properly restored without removal of the post and placement of a new post, then extraction and replacement with an implant or fixed prosthesis will be needed. If the reason for post removal is the persistence of disease, the tooth should be treated surgically and restored as well as possible.

Regaining Access to the Apical Area

Once the coronal-radicular access is made and all posts and obstructing restorations have been removed, then the clinician must regain access to the apical area by removing the previous root-filling materials (Fig. 8-29). This part of nonsurgical retreatment is complicated by the large variety of types of root fillings used. Today, the majority of root fillings are performed using gutta-percha in various forms; however, many other materials have been and are still being used. Silver points were popular until the 1970s and various types of pastes are,

unfortunately, still in use. The authors have seen cases of definitive root filling with phenol-soaked paper points and sometimes no root filling at all. New materials, such as Resilon (Resilon Research LLC), a soft polyester material that is bonded into the canal space, are coming on the market all the time. Though all root-filling materials have their advocates and their critics, the only certainty is that all will have some incidence of persistent disease and will need retreatment.

During the diagnostic phase, it is important to ascertain the nature of the root filling to minimize surprises when attempting retreatment. Sometimes this is readily apparent, but, in other instances, this determination may require contacting the previous clinician to discover what type of root filling was used. Occasionally, this information cannot be determined until canal entry, so extreme caution should be used when performing access so as not to possibly remove parts of the root filling that may be useful in its removal, such as the core material in solid core obturators.

Gutta-Percha Removal

One of the great advantages of using gutta-percha for root filling is its relative ease of removal. When the canal contains gutta-percha and sealer or a chloropercha filling, it is relatively easy to remove this material using a combination of heat, solvents, and mechanical instrumentation.[69,187] Upon access, it is usually relatively easy to find the treated canal orifices with the visible pink gutta-percha material inside. Initial probing with an endodontic explorer into the material can help rule out the possibility that there is a solid core carrier. If there is a plastic carrier, then heat should not be used to remove the coronal gutta-percha (more on this later). If there is no carrier, heat is applied using an endodontic heat carrier that has been heated to a cherry red glow in a torch. Unfortunately, the carrier begins to cool upon removal from the flame, so many endodontists are now using a heat source, such as the Touch 'n Heat (SybronEndo, Orange, CA) (Fig. 8-30, *A*), to provide constant, consistent heat application to soften the gutta-percha in the coronal portion of the canal.[141] Care must be exercised, however, not to overheat the root, which can cause damage to the periodontal ligament.[132,193,194] Thus, the heat should be applied in a short burst to allow the instrument to penetrate the gutta-percha mass, followed by cooling, which will cause the material to adhere to the heat carrier facilitating its removal (Fig. 8-30, *B*). After removing as much gutta-percha as possible with the heated instrument, then remove any remaining coronal material with small Gates-Glidden drills, taking care not to over enlarge the cervical portion of the canal. However, because the previously treated tooth may have had an underprepared cervical third of the canals, these drills can also be used to flare the coronal aspect in an anticurvature direction to facilitate enhanced straight line access to the apical one third of the canal and to create a reservoir for potential solvent use.[149] Again, probe the canal, this time using a #10 or #15 K-file. It is sometimes possible to remove or bypass the existing cones of gutta-percha if the canal has been poorly obturated, thus eliminating the need for solvents.[223] If that is not possible, then a gutta-percha solvent must be used to remove the remaining material in the apical portion of the canal.

Several solvents have been recommended to dissolve and remove gutta-percha for retreatment (Fig. 8-31) including chloroform,[153] methylchloroform,[259] eucalyptol,[273] halothane,[105,127] rectified turpentine,[120] and xylene.[93] All of the solvents have some level of toxicity,[14,38] so their use should be avoided if possible; however, a solvent is usually needed to

FIG. 8-29 Accumulation of materials removed from retreated teeth in a 3-month period.

remove well-condensed gutta-percha. The most popular solvent is chloroform because it dissolves the gutta-percha rapidly and has a long history of clinical use. In 1976, the U.S. Food and Drug Administration (FDA) banned the use of chloroform in drugs and cosmetics due to a report of suspected carcinogenicity.[251] There was no associated ban on its use in dentistry[153]; however, the report did result in the search for alternatives, some of which are listed earlier. When used carefully, chloroform is regarded as a safe and effective endodontic solvent.[38,153] All of the others generally have been reported to be less effective or have some other drawback that limits their use. Xylene and eucalyptol dissolve gutta-percha slowly and only approach the effectiveness of chloroform when heated.[269] Rectified turpentine has a higher level of toxicity than chloroform,[14] and it produces a very pungent odor in the operatory. Halothane has been shown to be as effective a solvent as chloroform in several studies,[105,127] but a more recent study indicated that the time for removal of the root filling was longer than when using chloroform.[263] The increased cost and volatility of halothane and the potential for idiosyncratic hepatic necrosis make it less desirable to use as a gutta-percha solvent.[38] Although methylchloroform is less toxic than chloroform, it is also less effective as a solvent for gutta-percha.[259] Both halothane and chloroform have been shown to affect the chemical composition of dentin[51,121] and may affect bonding strengths of adhesive cements to the altered dentin.[52] The clinical significance of these effects remains unknown, however. The evidence for the carcinogenicity of chloroform in humans is suspect,[153] but with careful use, its toxicity may be eliminated as a risk factor to both the patient[38] and the personnel in the operatory.[5] As such, its continued use as a gutta-percha solvent is recommended.

Using an irrigating syringe, the selected solvent is introduced into the coronal portions of the canals, which will then act as a reservoir for the solvent. Then, small hand files (sizes #15 and 20) are used to penetrate the remaining root filling and increase the surface area of the gutta-percha to enhance its dissolution. This procedure can be facilitated by using precurved, rigid files such as the C+ file (Dentsply Maillefer) (Fig. 8-32), which can penetrate the gutta-percha mass more efficiently than the more flexible types of K-files. The newly introduced C+ file is a stainless steel, end-cutting hand file that is twisted from a square blank. The secret to its stiffness is that the taper varies along the shaft, giving it the rigidity and strength to cut through well-condensed gutta-percha efficiently. The gutta-percha must be removed carefully, however, to avoid overextending the resultant mixture of gutta-percha and solvent beyond the confines of the canal to minimize the risk of severe postoperative pain.[141] Electronic apex locators are accurate in treatment and nonretreatment situations[123]; however, they seem

FIG. 8-32 C+ files. These rigid instruments remove gutta-percha more efficiently than more flexible types of K-files. (Courtesy Dentsply Maillefer, Ballaigues, Switzerland.)

to misread the working length frequently when gutta-percha is initially being removed. This clinical observation may be due to the file being covered with chloropercha that may affect its conductivity. It has been shown that apex locators may be less accurate in retreatment situations[258]; however, in this study the error was that readings indicated a working length that was too short. In a more recent study, an apex locator built into a rotary handpiece indicated working lengths that were too long in simulated retreatment situations.[252] It is recommended that a radiograph be made to gain a preliminary measurement when the estimated length is approached in order to avoid overextending root-filling materials into the periodontium. Well into the retreatment, after the root fillings have been thoroughly removed, the apex locator will regain its accuracy if a clean file is used. Once the working length is reached, progressively larger diameter hand files are rotated in a passive, nonbinding, clockwise reaming fashion to remove the bulk of the remaining gutta-percha until the files come out of the canal clean (i.e., with no pink material on them). The solvent should be replenished frequently, and when the last loose fitting instrument is removed clean, the canal is flooded with the solvent, which then acts as an irrigant. The solvent is then removed with paper points. The wicking action of the absorbent points[187] will remove much of the remaining film of gutta-percha and sealer that remains adhered to the canal walls and in the irregularities of the canal system.[265] Verification of the cleanliness of canals after gutta-percha removal is not improved by merely using a microscope[12]; however, using kinked small files, the clinician should probe the canal wall looking for irregularities that may harbor the last remnants of gutta-percha. These irregularities can usually be felt rather than seen and should be cleaned using this method.[141]

It should be noted that there exists a glass ionomer based endodontic sealer (Ketac-Endo, ESPE, Seefeld, Germany) that is used in conjunction with gutta-per cha.[180] This sealer is virtually insoluble in both chloroform and halothane,[261] and it must be retreated by removing the gutta-percha and then by using ultrasonics to debride the canal walls. Canal cleanliness can approach that of other gutta-percha retreatment cases, but it is difficult and time consuming to achieve this result.[67,159]

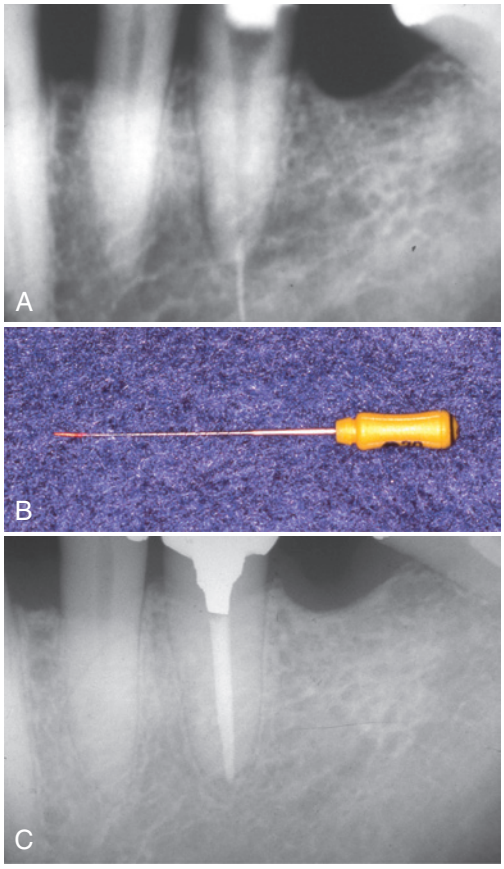

FIG. 8-33 Removal of overextended gutta-percha **A**, Preoperative radiograph showing overextended filling material. **B**, A small Hedstrom file pierces the overextended material and retrieves it. **C**, The 18-month reevaluation. The tooth is asymptomatic.

Overextended gutta-percha removal can be attempted by inserting a new Hedstrom file into the extruded apical fragment of root filling using a gentle clockwise rotation to a depth of 0.5 to 1 mm beyond the apical constriction, which may engage the overextended obturation. The file is then slowly and firmly withdrawn with no rotation, removing the overextended material[156] (Fig. 8-33). This technique works frequently, but care must be taken not to force the instrument apically, which furthers the extrusion of the gutta-percha; in addition, the file may separate. The overextended apical fragment should not be softened with solvent, as this application can decrease the likelihood of the Hedstrom file getting a solid purchase of the apical extrusion.[227]

Using rotary systems to remove gutta-percha in the canals has been advocated due to enhanced efficiency and effectiveness in removing gutta-percha from treated root canals.[187] This has generally been borne out in the literature. Several types of mechanical rotary systems are available for gutta-percha removal, including rotary file systems such as the ProFile (Dentsply) (Fig. 8-34), a mechanical push-pull, quarter-turn file system; the Canal Finder (Endo Technique Co., Tustin CA); and dedicated gutta-percha removal instruments, such as the GPX (Brasseler USA), the ProTaper Universal retreatment files (Dentsply) (Fig. 8-35), and the Mtwo R (Sweden and Martina, Due Carrare, Italy). These engine-driven instruments mechanically chop up the gutta-percha and sealer

FIG. 8-34 Nickel-titanium rotary Profile thermoplasticizing and removing gutta-percha. Optimum rotary speed is 1500 rpm.

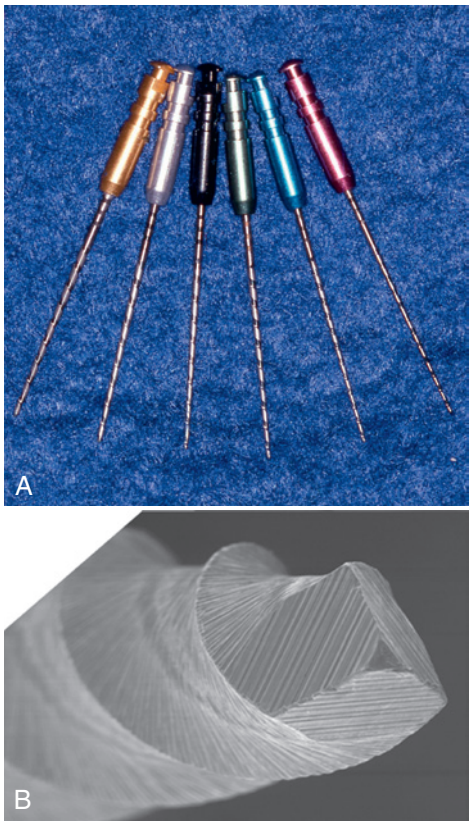

FIG. 8-35 Rotary gutta-percha removal instruments. A, Brasseler GPX instruments. B, ProTaper Universal retreatment file has a cutting tip for enhanced penetration of the root-filling materials.

while thermoplasticizing the root filling mass via frictional heat to aid in removal. A survey of Australian dentists showed that 54% of the respondents who perform endodontic retreatment used rotary instrumentation to remove gutta-percha either always (15%) or sometimes (39%) with an increased likelihood of rotary gutta-percha removal if the clinician had more experience with the use of these instruments.[173] In vitro studies have generally shown these systems to be efficient in that they typically need less time to remove the bulk of the gutta-percha filling material than is needed for hand removal,[13,59,77,103,104,190,242] although in two studies, they were slower to remove the root filling than hand filing[15,108] Assessments of canal cleanliness and extruded apical debris generally indicated that there were no overall differences between hand and mechanical gutta-percha removal.[15,59,103,104,109,168,190,218,242,277] In one study using Quantec SC instruments (Kyocera Tycom Corporation, Irvine, CA), however, it was found that hand files with solvent cleaned canals more effectively.[22] This finding has been repeated using the ProTaper retreatment files[92]; however, in another study in the same journal issue, ProTaper retreatment files were found to leave canals cleaner than hand files.[77] Clearly, this is an area where further research is warranted. It is recommended that after rotary gutta-percha removal, subsequent hand instrumentation is needed to remove the residual obturating materials completely from the canal. In several studies of mechanical gutta-percha removal, either the mechanical instruments or the tooth root fractured.[13,22,27,104,108,242] However, this result was reported to occur less frequently when the instrument rotary speed was increased from 350 to 1500 rpm,[27] and one study showed no separation or other canal defects when using dedicated retreatment files, the ProTaper Universal and Mtwo R instruments.[220] The dedicated retreatment files have end-cutting tips to enhance penetration and removal of the root filling mass, thus increasing their efficiency[239] (Fig. 8-35, *B*). This, in combination with flute design and techniques advocated, may be the reason for the potential reduced risk of separation. Although the mechanical gutta-percha removal systems may provide an enhanced efficiency, the increased risk of instrument separation, further complicating retreatment, may outweigh this benefit. Dedicated retreatment files may reduce this risk.

Engine-driven instruments can also help with the removal of residual root-filling materials after the bulk of the gutta-percha has been removed. A new instrument, the Self-Adjusting File (SAF; ReDent, Ra'anana, Israel), has been recommended for removal of the root-filling residue that remains after root-filling removal. When the Self-Adjusting Files were used after rotary retreatment files, reduction of canal residues were 66%, 68%, and 81% in the coronal, apical, and middle thirds of the canal, respectively, when compared with using ProTaper Universal retreatment files alone.[3] Another study compared the use of ProTaper Retreatment files followed by F1 and F2 ProTaper instruments with the use of a #25 .06 Profile followed by the Self-Adjusting File for their effectiveness in removing gutta-percha-based root fillings.[219] With the use of high-resolution micro-CT and an arbitrarily selected threshold of less than 0.5% residue remaining as effectively cleaned, none of the ProTaper group cases met this threshold, whereas 57% of the cases in the ProFile/SAF group met the threshold. Unfortunately, in both of the previously mentioned studies, none of the retreatment methods rendered all of the treated canals completely free of all root-filling residue.

FIG. 8-36 Epiphany Obturation System using Resilon material.

FIG. 8-37 Endosolv-E *(left)* and Endosolv-R *(right)*.

Use of the Nd:YAG laser to remove gutta-percha from root-filled teeth has been investigated in vitro.[254] The time taken to remove the gutta-percha was within the range of other studies of mechanical gutta-percha removal, and the addition of solvents did not improve the performance of the laser. As in most other studies, gutta-percha, in varying amounts, was left in the canals after laser removal. Root surface temperatures did increase, however, and without further investigation proving safety and efficacy, laser gutta-percha removal cannot be recommended at this time.

Resilon (Resilon Research LLC) (Fig. 8-36) is a thermoplastic polyester polymer that is bonded into the canal space using an unfilled resin bonding system (Epiphany, SybroEndo, Orange, CA). It is also marketed as RealSeal (SybroEndo). It has been advocated as a root canal obturating material to replace traditional gutta-percha and sealer due to its apparent, enhanced sealing ability[210] and potential to strengthen root resistance to fracture as a result of internal bonding.[241] Resin-bonded obturation systems have been advocated in the past[135]; however, the difficulty to retreat canals filled with this obturating material has prevented its widespread use. The Resilon polymer itself is reported by the manufacturer to be soluble in chloroform and may be removed by heat application, a behavior that is similar to gutta-percha. Studies have shown that the polycaprolactone polymer of the Resilon is removed easily and leaves canal walls cleaner than removal of gutta-percha and AH+ sealer,[44,46,56,199] although this finding has been disputed. Hassanloo and colleagues found that there was less residue on the walls when removing gutta-percha/AH+ if the materials were allowed to set for a longer period.[97] This finding has been corroborated[199,240] and indicates that there may be a temporal effect, which introduces a methodological bias in these studies. There may also be a problem with removal of the unfilled Epiphany resin sealer, especially because the sealer tags have been shown to penetrate deep into dentinal tubules[210] and presumably also into anatomic ramifications of the canal that need cleaning during retreatment. More research into this interesting material and technique is warranted, especially to determine the best technique for retreatment. After the Resilon core has been removed using heat and chloroform, the authors would recommend the use of a resin solvent such as Endosolv-R (Septodont, Paris, France) (Fig. 8-37) to attempt elimination of the unfilled resin sealer prior to instrumentation.

Managing Solid Core Obturators

Solid core canal obturation systems, such as Thermafil, Dens-Fil, and the GT Obturator (DENTSPLY Tulsa Dental Specialties, Tulsa, OK), have become popular since their introduction several years ago (see also Chapter 7). After cleaning and shaping procedures are completed, the clinician, using this technique, heats a solid core obturator (alpha-phase gutta-percha surrounding a core that is attached to a handle) in an oven and places the carrier in the canal. The solid core carries the gutta-percha down in the canal and condenses it while the material is cooling. This system provides a rapid and simple technique for warm gutta-percha endodontic obturation; however, as with any obturating material, retreatment will be necessary occasionally.

Retreatment of solid core materials is considered to be more complex and difficult than is the case with removal of gutta-percha alone due to the presence of the solid carrier within the mass of gutta-percha. The nature of the carrier will determine the method used and complexity of the retrieval. Three types of carriers are found in these systems: metal (stainless steel or titanium), plastic, and modified gutta-percha. The plastic carriers are smooth sided, as are some brands of metal carriers; however, most metal carriers are fluted and resemble endodontic hand files with a layer of gutta-percha on the outside. The fluted metal carriers present an exceptional challenge to the retreating clinician because many times they are improperly inserted and either wedged or screwed into the canal to make up for inadequate canal shaping or the lack of skilled use of the size verifying techniques available. This makes them especially difficult to remove. Once the carrier has been placed, it is cut off in the pulp chamber using a bur and the tooth is restored. The level at which the metal carrier is severed is important in its retrieval. If it is cut down to the level of the canal orifice, retrieval is difficult,[141] so the prudent clinician plans for retrievability by severing the handle from the carrier leaving 2 to 3 mm of carrier exposed in the access above the pulp chamber floor to allow easier removal if retreatment is ever needed. Unfortunately, this is not always the case. Some clinicians place a nick in the midcanal level of the carrier to

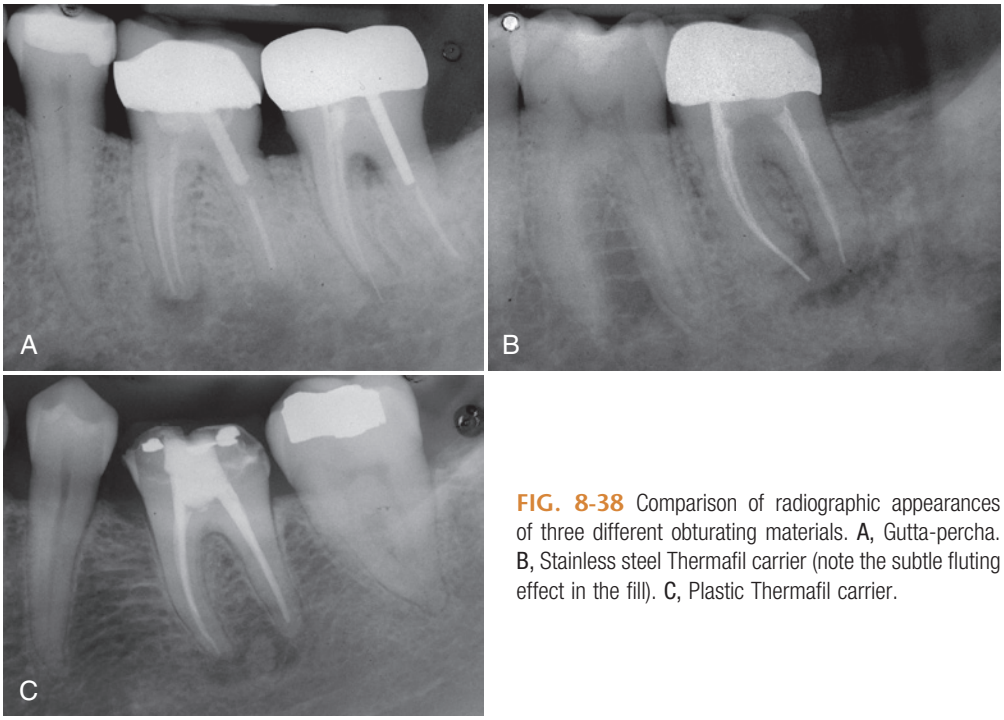

FIG. 8-38 Comparison of radiographic appearances of three different obturating materials. **A,** Gutta-percha. **B,** Stainless steel Thermafil carrier (note the subtle fluting effect in the fill). **C,** Plastic Thermafil carrier.

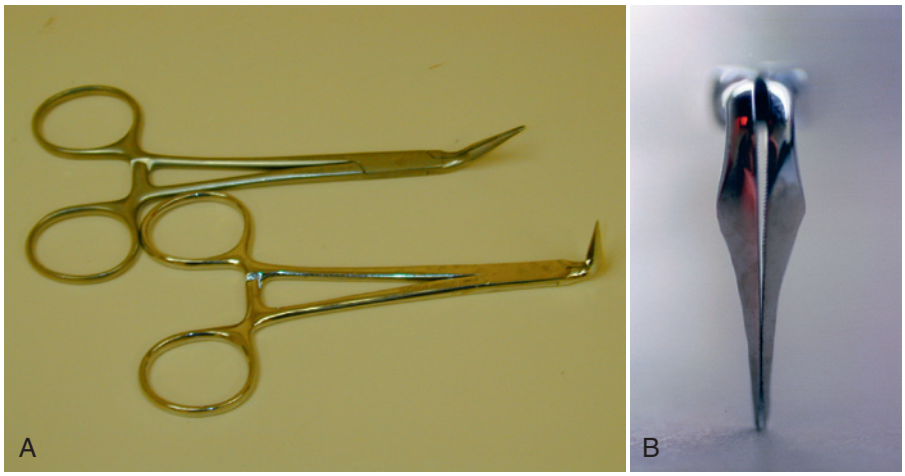

FIG. 8-39 **A,** Steiglitz forceps in 45- and 90-degree head angles. **B,** Tips of the Steiglitz forceps ground to a thinner contour to create the "modified" instrument. This allows deeper penetration into the tooth to enhance removal of obstructions. (*B,* Courtesy Dr. Daniel Erickson.)

allow the clinician to rotate the carrier handle and sever the obturator deep in the canal. This technique is used to allow creation of a post space; however, the rotational force used to create the "twist off" apical plug can engage the flutes of a metal carrier, increasing the complexity of removal if retreatment is needed.[276]

It is advantageous to determine prior to initiating treatment if there is a solid core obturation in the root-filled tooth. The preoperative radiograph may show this because the stainless steel carriers will exhibit a fluting effect on the radiograph (Fig. 8-38); however, the titanium carriers rarely are distinguishable from gutta-percha, and the plastic ones never are. Unfortunately, in most instances, the clinician finds that he or she is dealing with a carrier-based obturator after initial access to the pulp chamber. This is why, as stated in an earlier section, careful access and probing of the root-filling material is necessary when entering a canal. If there is a carrier, it will be detected as either a metallic structure embedded in the gutta-percha mass or a black or gray spot indicating a plastic or modified gutta-percha carrier. Occasionally, the carrier may be found embedded in the coronal core material, so careful excavation with small burs and straight, tapered ultrasonic tips may be necessary to preserve the carrier intact to help with removal.[141]

Removal of a metal carrier is accomplished with initial use of heat application to the carrier that can soften the gutta-percha surrounding it, facilitating its removal with Peet silver point forceps (Silvermans, New York, NY) or modified Steiglitz forceps (Union Broach, York, PA)[141,187,262,264] (Fig. 8-39). Often, there is not enough of the carrier remaining in the access to

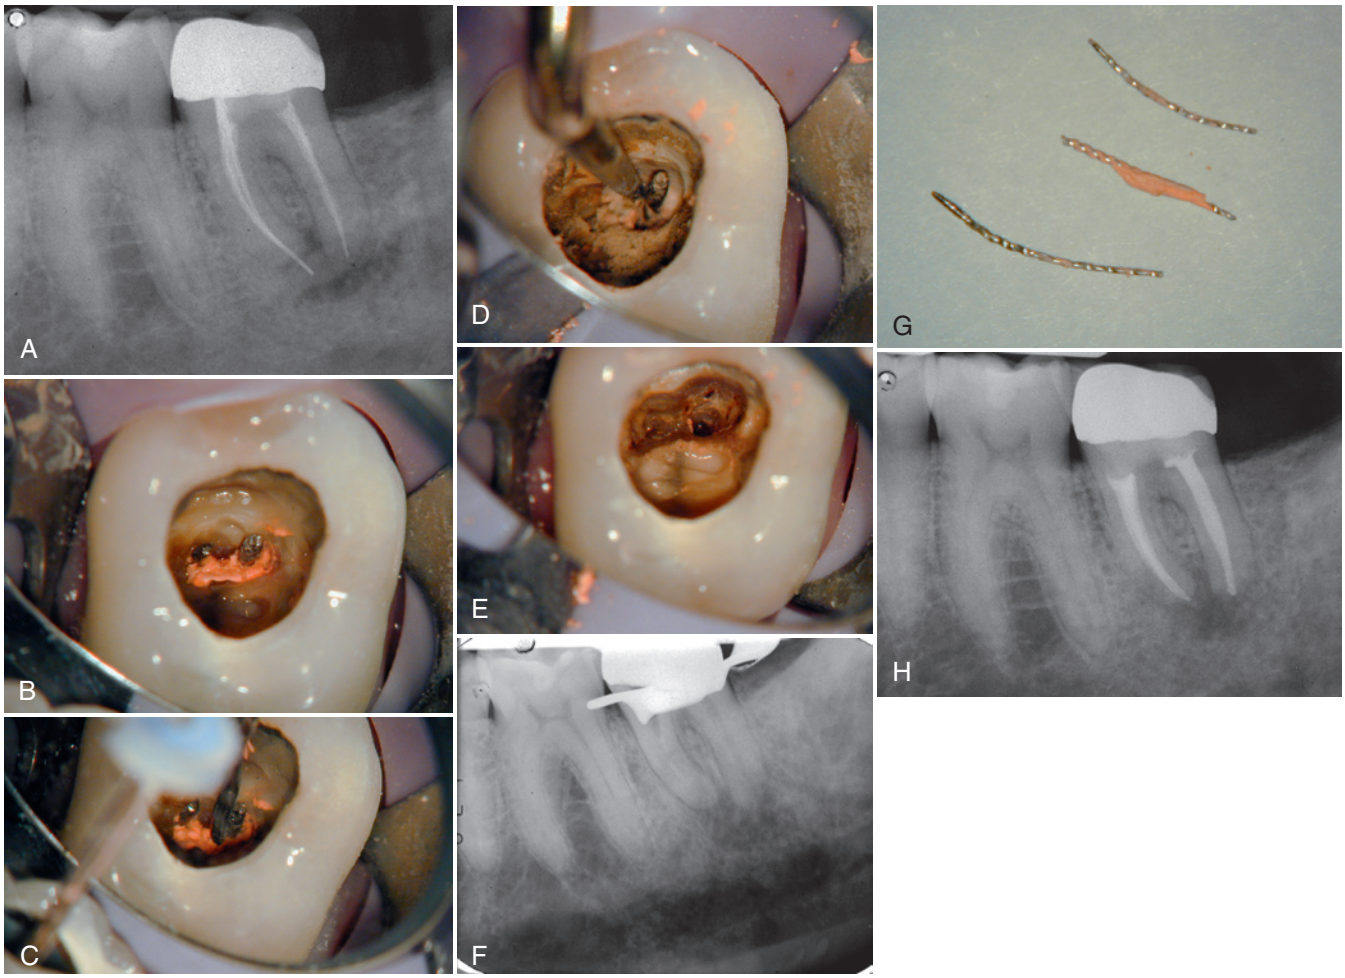

FIG. 8-40 Metal carrier retreatment **A,** Preoperative radiograph. **B,** Metal carriers exposed by careful excavation of gutta-percha. **C,** Use of the Touch 'n Heat instrument to heat the carriers and soften the gutta-percha. This allowed removal of one of the carriers using modified Steiglitz forceps. The other could not be removed using heat or solvents. **D,** Ultrasonic troughing around the carrier to facilitate grasping it with forceps. **E** and **F,** Carriers removed and confirmed with a radiograph. **G,** Metal carriers showing gutta-percha still adhering to them. **H,** Final obturation of the tooth.

grasp with forceps, so removal will require solvent application and removal of the surrounding coronal gutta-percha using small hand instruments, usually followed by ultrasonic excavation around the carrier and removing it like a separated instrument[141,187] (Fig. 8-40), as described in a later section of this chapter. Care should be exercised to avoid excessive heat generation during this procedure. This is also the case if the metal carrier has been sectioned for post space preparation. The metal carrier has been shown to be much more difficult to remove than plastic ones,[62,276] frequently resulting in nonretrieval. Fortunately, their use in endodontic therapy has been declining.

Removal of plastic carriers is similar to removal of gutta-percha root fillings, except that, in general, heat should be avoided to minimize the likelihood of damaging the carrier.[141] The older Thermafil plastic carriers were made of two different materials depending on their size. In the smaller sizes (up to size #40), the material used was Vectra, which is insoluble in available solvents, whereas the larger sizes used polysulfone, which is soluble in chloroform.[174] Solvents, on the other hand, seem not to affect the newer GT plastic carriers, so their use can be recommended[21] (Fig. 8-41). The access is flooded with a solvent, such as chloroform, and the gutta-percha surrounding the carrier is removed with hand files in a larger to smaller sequence (#25, 20, 15, etc.) each file progressively penetrating deeper around the carrier. The solvent should be replenished frequently, and when a #08 file can penetrate to the apical extent of the carrier and there is little remaining gutta-percha, a larger Hedstrom file is inserted into the canal alongside the plastic carrier and gently turned clockwise to engage the flutes. When the file is withdrawn, it invariably brings the carrier with it, and the rest of the gutta-percha and sealer removal proceeds as described earlier. Care must be taken to avoid overstressing the Hedstrom file. It should not be "screwed" into the canal, or the file or the carrier may separate.[21] Occasionally, grasping pliers will be needed to remove the carrier if it is accessible[110,187] after the gutta-percha has been removed. Another potential problem with retrieval is present if the carrier has been overextended beyond the apical foramen during the previous root canal treatment. This overextension may make it

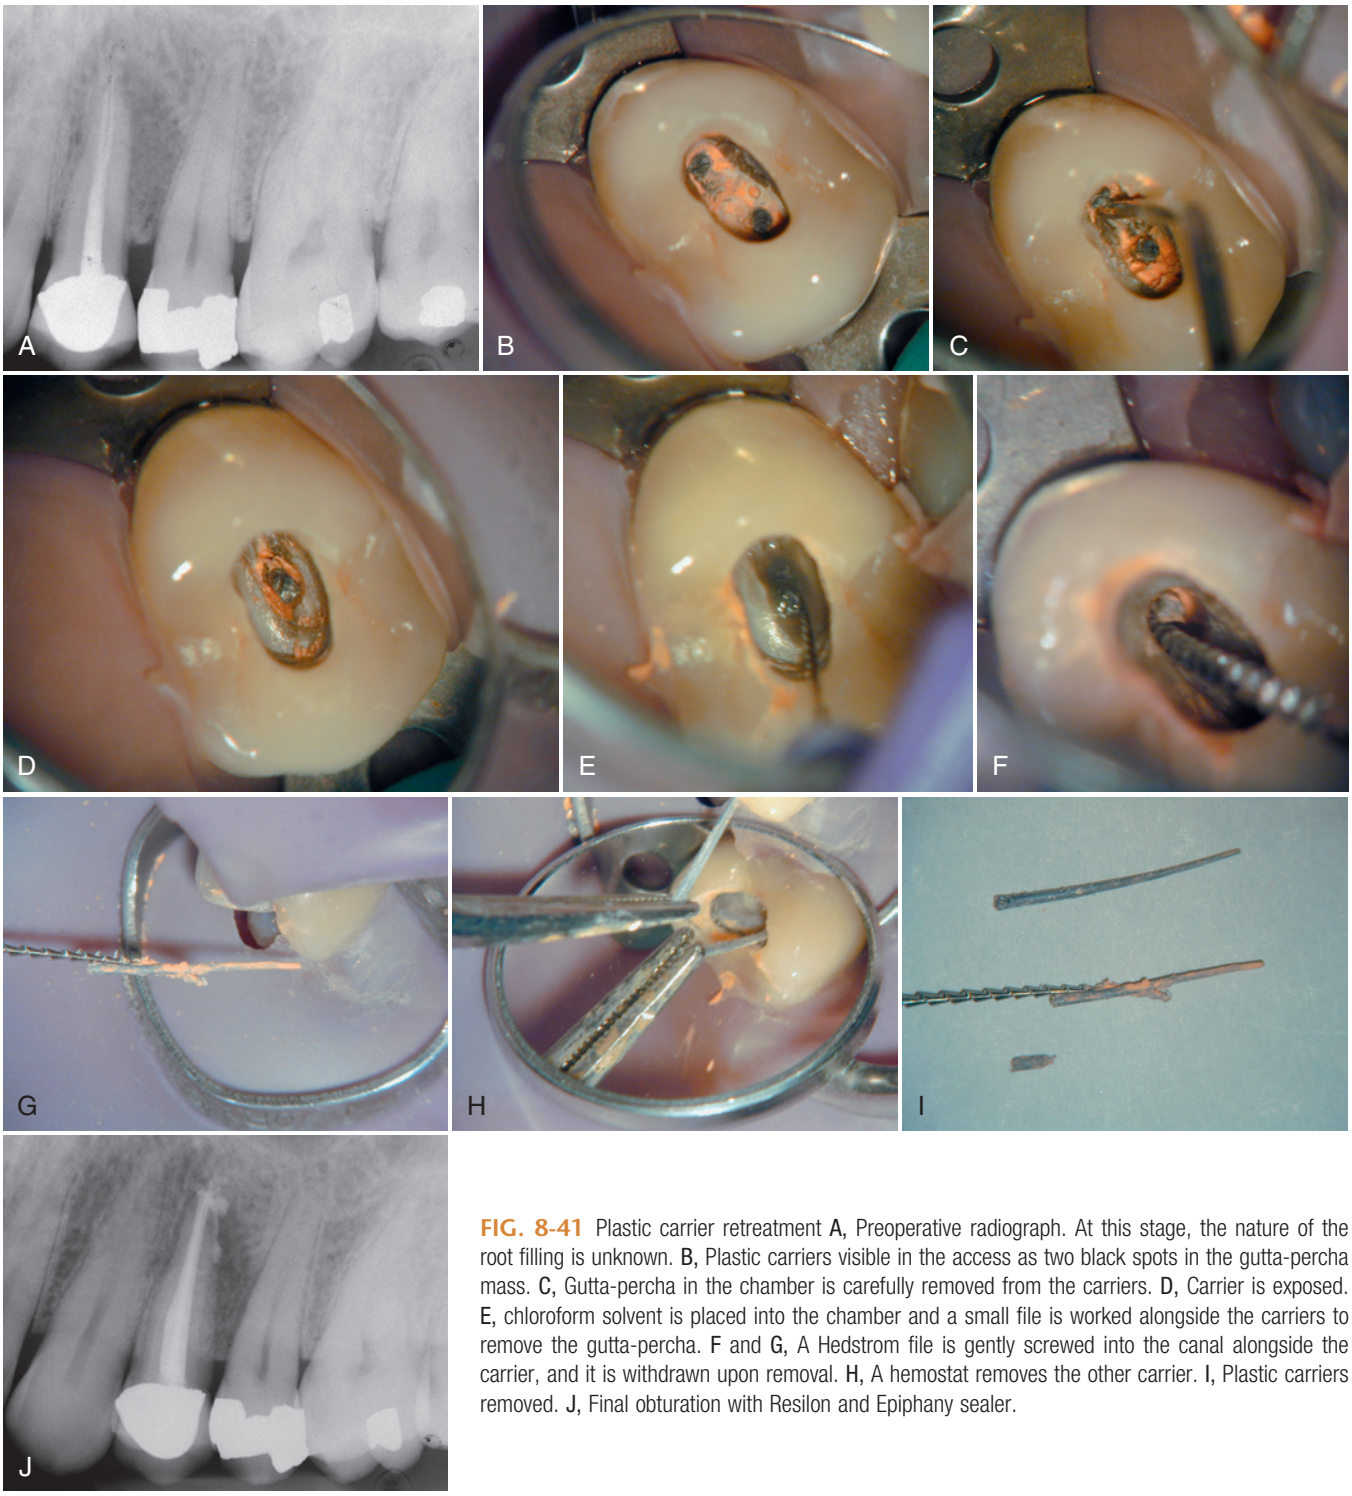

FIG. 8-41 Plastic carrier retreatment **A**, Preoperative radiograph. At this stage, the nature of the root filling is unknown. **B**, Plastic carriers visible in the access as two black spots in the gutta-percha mass. **C**, Gutta-percha in the chamber is carefully removed from the carriers. **D**, Carrier is exposed. **E**, chloroform solvent is placed into the chamber and a small file is worked alongside the carriers to remove the gutta-percha. **F** and **G**, A Hedstrom file is gently screwed into the canal alongside the carrier, and it is withdrawn upon removal. **H**, A hemostat removes the other carrier. **I**, Plastic carriers removed. **J**, Final obturation with Resilon and Epiphany sealer.

prone to separation and unable to be retrieved, potentially resulting in the need for apical surgery.[107]

A technique for plastic carrier removal has been described using a System B HeatSource (SybronEndo) to soften the gutta-percha surrounding the carrier without melting the carrier itself.[267] The temperature is set at 225° C, and the heat plugger is placed buccal and lingual to the carrier after which #50-55 Flex-R hand files are placed around the carrier and braided to engage the carrier and remove it. This technique has been shown to require significantly less time to remove the carrier compared with using solvent[267]; however, concerns regarding heat generation in the periradicular tissues have been raised,[139] with the authors concluding that caution should be exercised when using this technique. When other techniques have been unsuccessful and the plastic carrier has been sectioned apical to the orifice resulting in limited access, the clinician may attempt to retrieve the carrier by placing a heated System B tip directly into it. As apical pressure is maintained, the heat is

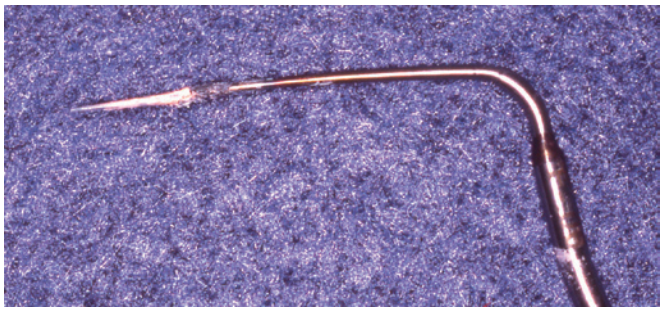

FIG. 8-42 Plastic Thermafil carrier adhering to a System B heat plugger.

turned off. This allows the plastic carrier to adhere to the tip while cooling and may result in its removal upon withdrawal of the heat tip (Fig. 8-42).

Rotary instruments have been advocated for use in removal of plastic carriers and gutta-percha, and one study showed that removal of plastic carriers was successful in all but one of the teeth obturated with them.[13] Unfortunately, root fracture occurred in the lone specimen that did not have a successful retrieval, and two instances of rotary instrument fracture also occurred in the study. As with gutta-percha removal, the clinician must carefully weigh the risks of rotary carrier removal against the perceived benefits.[186]

Modified gutta-percha has been introduced as a core material for solid core obturation. This obturation system is called GuttaCore (DENTSPLY Tulsa Dental Specialties) and, at first glance, it appears similar to plastic carrier based systems. With GuttaCore, however, the carrier is fabricated from cross-linked gutta-percha rather than plastic. The cross-linking connects the polymer chains, which changes the material and gives the carrier different properties than the plastic carriers. The gutta-percha surrounding the carrier is alpha-phase gutta-percha, which is identical to that which encompasses the plastic carrier based systems.

To understand how to effectively remove this type of filling material, one must understand how it is used. Obturation with GuttaCore is performed in a similar manner as obturation with Plastic Thermafil. The obturator is heated in a proprietary oven and then gently placed into the canal. Although it is flexible, the modified gutta-percha carrier is much more brittle than the plastic carrier and too much insertion force will cause the shank to collapse and the handle can break off prior to full insertion. Thus, it is difficult to wedge these obturators into underprepared canals and usually, in that instance, a short fill will result. This forces the operator either to accept a short fill or, ideally to enlarge the canal preparation prior to inserting the obturator, but in either case, retrieval of the root filling during retreatment is made easier by not having the carrier wedged into the canal.

While performing initial obturation, when it is time to section the carrier, the clinician will experience another difference from plastic carriers. Although the use of a heat-generating Prepi bur (DENTSPLY Tulsa Dental Specialties) or a System B Heat Source (SybronEndo) has been shown to produce predictably reliable results in terms of sectioning plastic carriers at the desired level, heat has virtually no effect on the GuttaCore carrier, and the authors found using heat to section the carrier to be unsuccessful. The modified gutta-percha core will not melt, even when probed with a Touch 'n Heat (SybronEndo) tip at full power.

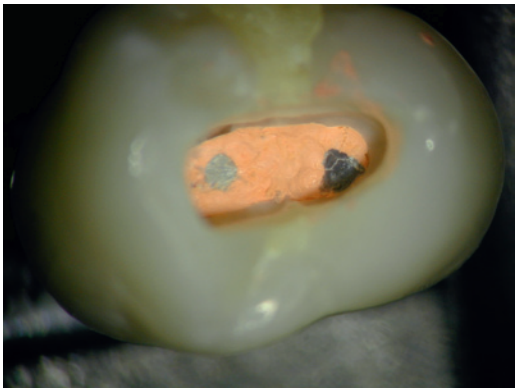

FIG. 8-43 Two different solid core carriers in an endodontic access preparation upon initial exposure. GuttaCore is on the left and a plastic carrier Thermafil Plus is on the right. Note the lighter gray color of the new modified gutta-percha core compared with the plastic carrier.

Because of the brittleness of the modified gutta-percha carrier, GuttaCore will separate by simply bending the carrier away from the access cavity wall. The material has little ability to resist even the smallest of lateral forces without separation, so simply pushing down laterally on the carrier handle will separate the carrier handle from the canal fill. This has implications for retreatment because this separation method generally results in the carrier being separated at or near the canal orifice level, leaving little or nothing to grasp with forceps when attempting to remove the carrier.

Removal of the GuttaCore obturators is directly affected by the properties of the modified gutta-percha carrier, so it is somewhat different from the approach taken to remove plastic carriers. For this reason, it is imperative that clinicians who discover a solid core, nonmetallic obturator while disassembling a tooth for nonsurgical retreatment can discern what type of core they are trying to remove. There are two ways to do this. First, the color of the plastic carrier is black, whereas the color of the modified gutta-percha carrier was originally gray (Fig. 8-43); however, the manufacturer recently changed the color of the carrier to pink. Second, because the GuttaCore carrier is heat resistant, the clinician can lightly touch the coronal extent of the unknown carrier to see if it melts (plastic carrier) or if it does not (modified gutta-percha carrier). Once the nature of the carrier is determined, then the clinician can proceed with removal. If it is plastic, then the methods of removal described previously can be used, but if it is a GuttaCore carrier, then a different approach will be needed.

The use of heat and solvents, which are two of the most common methods for endodontic retreatment, have no effect on the GuttaCore carrier. To date the authors are unaware of any known solvents or chair side heat sources that can soften the cross-linked gutta-percha carrier. Also, the use of hemostats or other grasping pliers have shown inconsistent results. When straight-line access can be achieved, and a few millimeters of the carrier is able to be grasped, removal may be accomplished; however, due to the brittleness of the GuttaCore carrier, often the carrier will separate at the apical extent of the grasping forceps. In spite of those concerns, the authors have found that GuttaCore can be removed easily with predictable results using a variety of hand, rotary, and retreatment instruments. One study found that when using ProTaper retreatment files, GuttaCore was more efficiently removed from moderately

curved canals than either thermoplasticized gutta-percha or plastic carrier obturation.[17] However, the authors' experience shows that upon removal of the segment of the carrier within the canal, any overextended tip of the carrier will separate, remaining in the periapical tissues. This potentially contaminated foreign material becomes difficult and many times impossible to remove. If this occurs, and postretreatment apical periodontitis persists or recurs after initial resolution, then apical surgery or extraction will be necessary.

Another approach is to treat the carrier like some hard paste fills that the clinician is unable to find a solvent for. Using this approach, the clinician will find that using ultrasonic instruments in a similar fashion as they are used to remove pastes to be helpful. Once a proper access preparation has been created, GuttaCore can be safely and easily removed with the use of ultrasonic instruments in the straight coronal portion of the canal. Upon reaching the canal curvature, the authors recommend using hand files or rotary files with safe noncutting tips to avoid perforation or excessive thinning of canal walls.

Once the carrier has been removed, the remaining gutta-percha and sealer must be removed from the canal, and like removal of root-filling materials described previously, there is no technique that completely removes all materials from the canal system. Canal cleaning may be even more difficult when removing carrier-based obturations because the more highly processed gutta-percha used with these carriers may be more difficult to remove than other forms of the material. Wilcox and Juhlin described a sticky film of gutta-percha and sealer adhering to the canal walls upon removal of metal carrier obturators and found more of it than if the canals had been obturated with lateral condensation.[264] Their findings have not been corroborated, however, and other studies have shown no difference in residual debris remaining after carrier-based removal.[62,110,276] It is important to remove as much of the residual gutta-percha and sealer from the pulpal anatomic spaces as possible, so flooding the canal with solvent and "wicking" it out with paper points is also recommended for carrier based retreatment.[187]

Paste Retreatment

Various pastes have been used as root canal obturating materials, especially outside of North America. Because of the wide variety of paste compounds used in endodontics, it is impossible to categorize them all. The individual clinician who is using it formulates most pastes, so the ultimate composition of a paste found in a tooth with persistent disease is generally indiscernible. Many of the pastes used, such as N2 or RC2B, contain formaldehyde and heavy metal oxides and so are toxic and potentially present a danger to the patient's health, both local and systemic, if overextended beyond the confines of the root canal system.[25,172] None has the potential to seal the canal effectively,[91] and many render a tooth impossible to retreat,[200] so their use is strongly discouraged. On radiographic examination, they can usually be discerned due to their lack of radiopacity, the presence of voids, and they usually show evidence of inadequate canal shaping and poor length control (Fig. 8-44). When a paste fill is suspected or found in a tooth, a telephone call to the previous treating dentist should be made, if possible, to find out the exact formulation of the paste because this information may help in its removal.

For purposes of retreatment, paste fills can be categorized as soft or hard, and all should be considered potentially toxic. Great care should be exercised when removing the paste to avoid overextension, potentially severe postoperative pain,[87] and possible paresthesia/dysesthesia from the paste's potential neurotoxicity.[28,207] Soft pastes are generally easy to remove using crown down instrumentation with copious sodium hypochlorite irrigation to minimize extrusion.[141] Greater difficulty arises when the paste is set hard.[200] Because the nature of the paste remains unknown, removing it becomes an empirical process. Following access preparation and coronal orifice exposure, the paste is probed with an endodontic explorer and files. If hard and impenetrable, then the coronal paste can be removed with burs[69] or a straight, tapered ultrasonic tip in the easily accessible straight portions of the canal using magnification and illumination.[187] Once the canal curvature is reached, further use of this method will result in damage to the canal walls and possible perforation. Precurved, small hand files are inserted to probe the apical area. Many times the density of the paste filling material decreases in the apical extent of the fill so that penetration to the apex may be possible.[187] If not, a solvent must be used to attempt to soften the remaining paste. The choice of solvent is usually made by trial and error starting with chloroform. If that does not soften the material in a reasonable amount of time and does not allow penetration with small files, then the chloroform is wicked out of the canal and another solvent is chosen. There are two frequently used solvents for paste fills: Endosolv-E and Endosolv-R (Septodont, Paris, France) (see Fig. 8-37). The Endosolv-E is selected if the paste contains zinc oxide and eugenol, and the Endosolv-R is chosen for resin-based pastes. The obvious problem is that the nature of the paste is usually unknown at the time of removal, so contacting the previous clinician, if possible, can help with this choice. Otherwise, the choice is just a guess. The chosen solvent should be placed in the access, and attempts should be made to penetrate the paste with hand or ultrasonic files; however, care must be taken to avoid creating a ledge or other defect in the canal that may preclude successful retreatment. The progress is frequently slow,[72] and the clinician may elect to leave some solvent in the canals between appointments to soften the paste.[187] Care should be taken in the choice of temporary restoration because the solvent left in the canal may also soften the temporary, potentially leading to breakdown of the interappointment seal.[158]

Ultrasonically activated files have been advocated for use in penetrating hard-set pastes in the curved apical segments of canals[117,126] (Fig. 8-45). The ultrasonic energy breaks up the paste, and the irrigation floats the fragments in a coronal direction until the apical terminus is reached.[69] This technique is reported to be time consuming, and care must be exercised to avoid instrument separation, perforations, or alteration of canal morphology. On occasion despite all best efforts, the paste cannot be removed from the tooth, so apical surgery or extraction should be considered in these cases.[87]

Biocalex 6.9 (currently known as Endocal 10) (Fig. 8-46) is a hard-setting calcium oxide paste that has been popular in Europe since the 1980s but is now being used in North America since its recent FDA approval.[83] The paste seems to seal well, but there is an unacceptably high incidence of root fracture due to the large amount of expansion on setting.[83] Retreatment will be complicated by the hard setting nature of this material; however, as it is a calcium oxide paste, ethylenediaminetetraacetic acid (EDTA) may soften it, facilitating its removal. Because EDTA also softens dentin, care must be taken not to

gouge or ledge the canal walls during retreatment, and root fractures must be suspected as a potential complicating factor in the outcome.

Silver Point Removal

Historically, the use of silver points for endodontic therapy has been extremely popular and quite successful, because of their ease of handling and placement, ductility, radiopacity, and that silver appears to have some antibacterial activity.[202] However, the use of silver points has dramatically diminished, so presently they are considered a deviation from the standard of care.[274] The main reason for this change is because they corrode over time (Fig. 8-47), and the apical seal may be lost.[26] Also, silver points do not produce an acceptable three-dimensional seal of the canal system; rather, they simply produce a plug in the apical constriction while not sealing the accessory canals that are frequently present[143,198] (Fig. 8-48). The corrosion of silver points occurs when they come in contact with tissue fluids and certain chemicals used in endodontics, including sodium hypochlorite and some sealers.[88] This corrosion produces chemicals such as silver sulfide, silver sulfate, silver carbonate, and silver amine hydrate,[205] which have been shown to be cytotoxic in tissue culture.[202] Corrosion occurs mainly at the apical and coronal portions of the points indicating that leakage is responsible.[205] Gutta-percha root-filling techniques

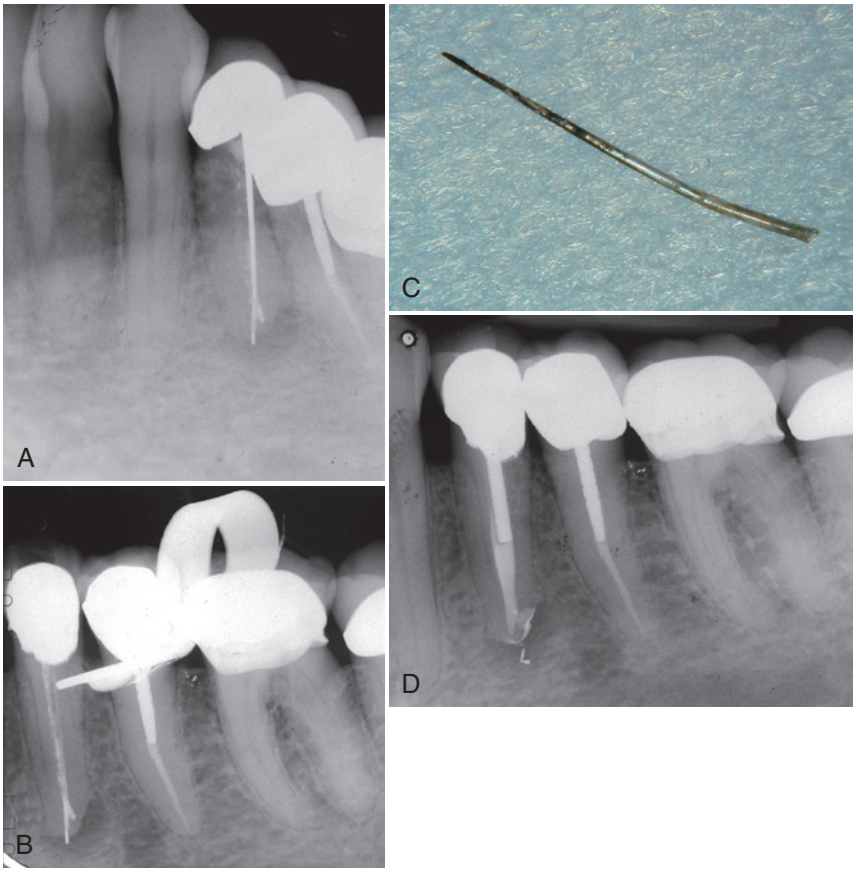

FIG. 8-47 A, Persistent disease in a silver point filled tooth. B, Silver point removed. Note the radiopaque material in the apical portion of the canal system. This represents corrosion products remaining in the canal and a possible separated apical segment of the cone. C, Removed silver point showing black corrosion products adhering to the apical one half. D, Crown-down instrumentation prevents extrusion of most of the corrosion products into the periradicular tissues.

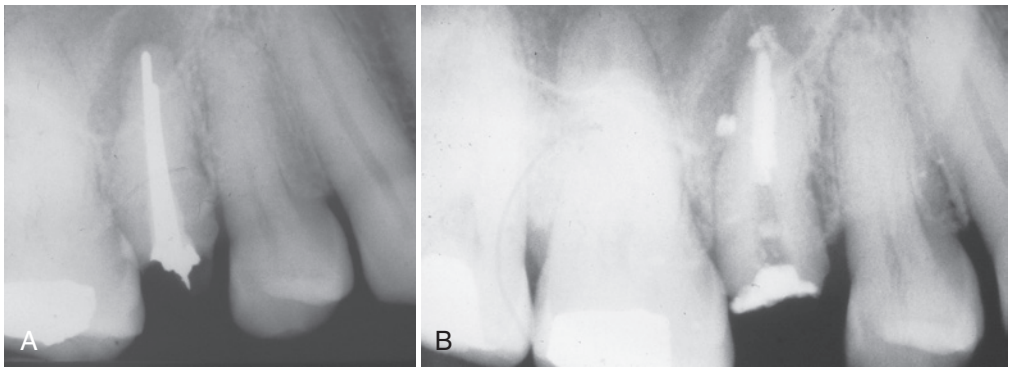

FIG. 8-48 A, Preoperative view of a silver point case with persistent disease. Note that the periapical radiolucency extends coronally on the distal aspect of the root end, indicating the presence of an unfilled lateral canal. B, Postobturation radiograph showing the cleaned and filled distal canal branch.

do not suffer from these disadvantages and have replaced the use of silver points in endodontics. Due to this decrease in use since the late 1980s, the quantity of cases the clinician will come across that will require silver point removal has also decreased. Nevertheless, there are still occasions when their removal will be necessary.

Many of the same techniques described for removing separated instruments in the following section apply to the removal of silver points. Silver points have a minimal taper and are smoothed sided, and corrosion may loosen the cone within the preparation. Therefore, the clinician should encounter a much easier time removing them than would be the case with separated instruments, which may be mechanically engaged into canals. Silver point canal preparation techniques produced a milled, round preparation in the apical 2 to 3 mm of the canal and, coronal to that, the clinician will frequently find space between the round silver point and the flared canal walls that can usually be negotiated with hand files facilitating point removal.[187]

The first step in removal of silver points is to establish proper access. Frequently, the coronal portion of the cone is embedded in the core material. This material must be carefully removed with burs and ultrasonics, taking care not to remove any of the silver point within the access cavity preparation. The more of the silver point the clinician has to work with, the more predictable will be its removal. Once proper access is established, the clinician should flood the access preparation with a solvent, such as chloroform, to soften or dissolve the cement, enabling easier removal. An endodontic explorer or small file may be used to carry the solvent down along the silver point to dissolve as much of the cement as possible. The chamber can be rinsed and dried, and this step may be repeated because fresh solvent enhances the efficiency of cement removal. At this point, the easiest technique, which is also predictable, is to grasp the exposed end of the silver point with Stieglitz pliers (Henry Schein) (see Fig. 8-39) or other appropriate forceps and gently pull it out of the access cavity preparation. If too much extraction force is needed, however, the point may separate, so slow force application is advised. The clinician will need a variety of sizes and angles of forceps available to deal with the variety of cases that will need to be treated. Occasionally, the forceps may not get a good purchase on the silver cone and will slip off. In these instances, gripping the cone with the forceps and then gripping the forceps in a hemostat or needle driver to increase the squeezing force of the forceps will allow removal of the cone[141] (Fig. 8-49). If the silver point is held tight by the frictional fit in the preparation, indirect ultrasonics may be employed to loosen it. The silver point is retained in a pair of forceps and ultrasonic energy is applied to the forceps, not the point (Fig. 8-50). This transmits energy down the cone and may loosen it. If there is not much of the silver point exposed in the chamber, the clinician can attempt to remove it using the Caufield silver point retrievers (Integra Miltex). This instrument is a spoon with a groove in the tip (Fig. 8-51) that can engage the exposed end of the silver point so it may be elevated from the canal or possibly elevated to the point where it may be grasped by forceps.[141] The

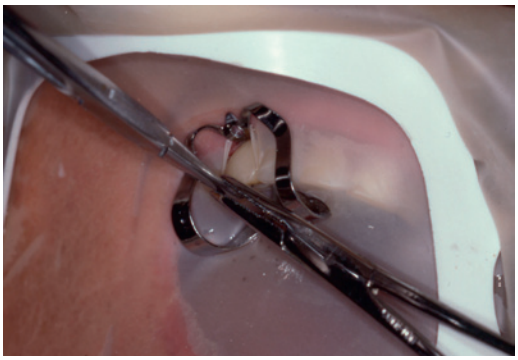

FIG. 8-49 Removal of a highly retentive silver point using a needle driver to squeeze the tips of the Steiglitz forceps. This applies increased gripping force to aid in removal.

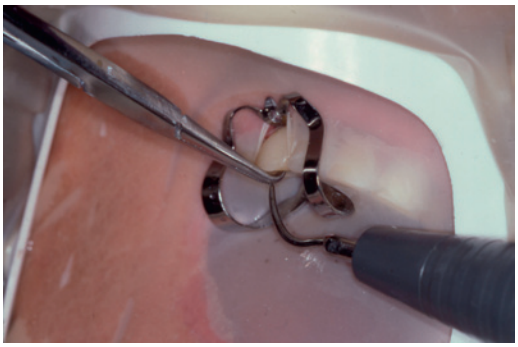

FIG. 8-50 Application of indirect ultrasonic energy to a silver point by placing the ultrasonic tip against forceps that are holding the silver point.

Caufield silver point retrievers are available in three sizes: 25, 35, and 50.

If the silver point cannot be dislodged by the forgoing techniques, the clinician should consider using Hedstrom files to remove the silver point. The Hedstrom file technique requires at least some coronal length of canal space around the silver point to be negotiated first.[140] The sealer is dissolved as previously mentioned, and then files are negotiated as far apically as possibly in two to three areas around the silver point. If only one space can be negotiated, this technique may still be effective. The spaces surrounding the silver point are carefully instrumented to size 15, and then small Hedstrom files are gently screwed in as far as possible apically. They should not be screwed in too tightly so as to prevent breakage. The flute design of Hedstrom file allows for much better engagement into the silver point compared with other file designs. The files are then twisted together and pulled out through the access (Fig. 8-52). If the first attempt fails, this technique may be repeated, possibly using larger Hedstrom files. If this technique does not completely remove the silver point from the canal, it may still be dislodged to the point where it can be grasped by forceps and removed.

If the clinician needs to expose more of the silver point to enable removal, the use of trephine burs and microtubes or ultrasonics may be necessary.[69] Trephine burs are used in the same manner as described for separated instrument removal; however, the clinician must be more careful when using ultrasonic instruments for retrieval of silver points. When using ultrasonics for post removal, or separated instrument removal, the tip of the ultrasonic instrument can be placed at the interface between the obstruction and the canal wall. Although applying the ultrasonic energy directly to a post or file may prove beneficial in vibrating them loose, silver points are much softer, and if ultrasonic instruments are applied directly to them, the portion in contact may be shredded leaving a smaller segment to work with because elemental silver rapidly erodes during mechanical manipulation.[187] The ultrasonic instrument is used on tooth structure circumferentially around the silver point. This is a delicate process requiring a microscope or other powerful source of magnification. The energy supplied by the careful use of the ultrasonic instrument can safely expose silver points as well as break up the cement around them.

In many cases, a silver point may have been sectioned deep in the canal to allow post space preparation. In these cases, where the most coronal portion of the silver point is well below the orifice, the use of Gates-Glidden burs to obtain straight-line access to the most coronal extent of the point may be necessary. The burs should be used in a brushlike manner, cutting on the outstroke while applying gentle pressure in an anticurvature direction to decrease the risk of root perforation. Following this step, techniques that involve the use of an end-cutting trephine bur to remove tooth structure around the point and then use of an extraction device to remove it may be employed (Fig. 8-53). There are many kits that use these principals with slight variations from one another, including the Endo Extractor (Brasseler USA),[226] the Masserann Kit (Medidenta International, Woodside, NY), and the Extractor System (Roydent, Johnson City, TN) (Fig. 8-54). Additional techniques, which are effective for removing silver points, include the S.I.R. (Separated Instrument Retrieval) System (Vista Dental Products, Racine, WI), the use of a dental injection needle with a 0.14-mm wire, the use of stainless-steel tubing with a Hedstrom file,[187] and the Instrument Removal System (Dentsply Tulsa Dental Specialties).

These kits are not only effective in the removal of silver points but also in the removal of separated instruments, and because of this common approach to removing both during endodontic retreatment, these techniques will be discussed

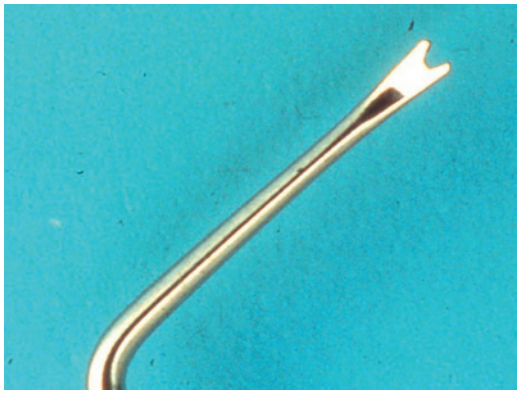

FIG. 8-51 Caufield elevator tip, useful for gripping and elevating silver points that are protruding a small amount into the pulp chamber.

in detail in the following section on separated instrument removal.

After the silver point is removed, it is important that subsequent instrumentation procedures be performed in a crown-down manner to minimize extrusion of the silver corrosion products into the periradicular tissues to decrease the occurrence of painful acute flare-ups. This goal is complicated by the fact that ledges are frequently encountered at the level of the apical extent of the silver point due to the type of milled preparation that was frequently used in this technique. Managing ledges will be discussed in a following section of this chapter.

Occasionally, the apical portion of a silver point will separate upon the removal attempt. If it cannot be bypassed or removed, then the case should be completed and followed carefully (Fig. 8-55). Apical surgery or extraction could be necessary in the future (Fig. 8-56).

Removal of Separated Instruments

Causes of Instrument Separation

Occasionally during nonsurgical root canal therapy, an instrument will separate in a canal system blocking access to the apical canal terminus. This instrument is usually some type of file or reamer but can include Gates-Glidden or Peeso drills, lentulo spiral paste fillers, thermomechanical gutta-percha compactors, or the tips of hand instruments, such as explorers or gutta-percha spreaders. During retreatment, it may be obvious after completing the diagnostic phase that there is a separated instrument in the canal system or it may only become apparent after removal of the root-filling materials (Fig. 8-57). It is useful, therefore, to expose a check radiograph after removal of the root filling to see if there is any metallic obstruction in the canal. Regardless of which type of instruments the clinician uses, whether stainless steel or nickel-titanium, and

FIG. 8-54 A, Brasseler Endo Extractor Kit. B, Masserann Kit. C, Roydent Extractor System. D, Separated Instrument Retrieval System (SIR). E, Instrument Removal System (IRS). (*B*, Courtesy Dr. Daniel Erickson.)

how they are used, by hand or engine driven, the potential for separation exists. The incidence of hand instrument separation has been reported to be 0.25%,[114] and for rotary instruments it ranges from 1.68% to 2.4%.[114,268] The most common causes for file separation are improper use, limitations in physical properties, inadequate access, root canal anatomy, and possibly manufacturing defects.

A common cause for instrument separation is improper use. Included in this category are overuse and not discarding an instrument and replacing it with a new one when needed. The following is a list of guidelines for when to discard and replace instruments[79]:

1. Flaws, such as shiny areas or unwinding, are detected on the flutes.
2. Excessive use has caused instrument bending or crimping (common with smaller-sized instruments). A major concern with nickel-titanium instruments is that they tend to fracture without warning; as a result, constant monitoring of usage is critical.
3. Excessive bending or precurving has been necessary.
4. Accidental bending occurs during file use.
5. The file kinks instead of curving.
6. Corrosion is noted on the instrument.
7. Compacting instruments have defective tips or have been excessively heated.[79]

Another type of improper use is to apply too much apical pressure during instrumentation,[247] especially when using rotary nickel-titanium files. This pressure can lead to deflection of the instrument within the canal system or increased frictional binding against the canal walls that can overstress the metal, resulting in separation. Regardless of which type of files the clinician uses, they should never be used in a dry canal, as attempting to instrument a dry canal will cause excessive frictional stresses on an instrument.[247] Continual lubrication of the canal with either irrigating solutions or lubricants is required,[79] as this will reduce the frictional resistance as well as increase the efficiency of the instrument. All files have flutes that have the ability to build up with dentin shavings, which will decrease the efficiency of the instrument leading to greater frictional forces and ultimately separation. Therefore, files should be periodically removed and cleaned during the instrumentation process.

Inadequate access cavity preparations can lead to many problems, one of which is excessive or unnecessary force

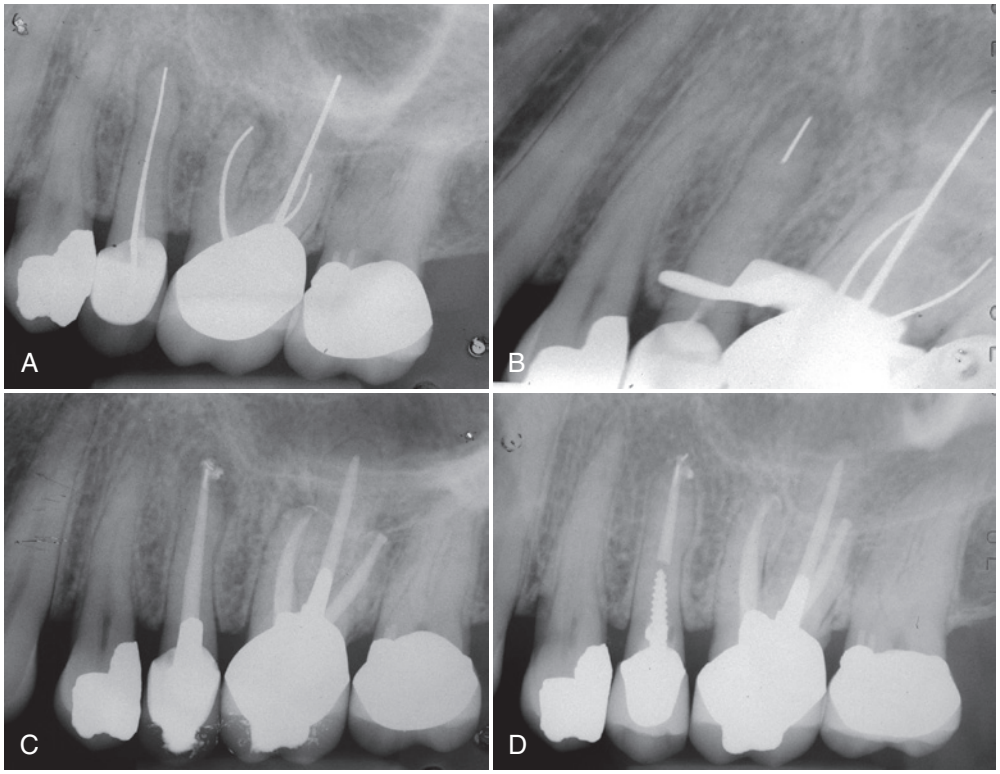

FIG. 8-55 Case illustrating healing despite inability to remove a separated silver point **A**, Preoperative radiograph showing persistent disease in an upper premolar and molar. **B**, Working film showing the separated cone that could not be retrieved despite extensive clinical efforts. **C**, Final obturation after a two-appointment procedure using a calcium hydroxide interappointment medicament. **D**, The 4-year follow-up showing apical healing.

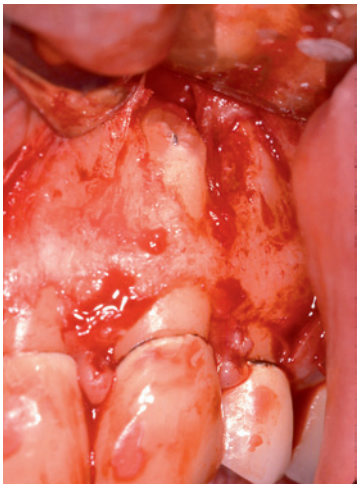

FIG. 8-56 If silver point retreatment is unsuccessful, then apical surgery may be needed. Note the silver point visible on the resected root end. If the point cannot be pulled out in a retrograde direction, then ultrasonic root-end preparation may be complicated by its presence, and root-end preparation using rotary burs may be necessary.

applied to the instrument if it is not allowed to enter the canal freely without interference from the access cavity walls. If the file is in contact with the access cavity wall during instrumentation, the chance for separation is greatly increased. Inadequately enlarged access preparations also increase the number and severity of curvatures that the file must negotiate. This underprepared access can lead to the creation of an iatrogenic "S" curve that can overstress the instrument. This situation is especially hazardous when using rotary instrumentation because traversing an "S" curve greatly stresses the rotating file, leading to separation (Fig. 8-58).

Anatomy, such as abrupt curvatures or anatomic ledges, increases the likelihood of instrument fracture. When the file's progress is hindered, it is natural to try to force it further. This approach will rarely result in the file advancing along the naturally occurring path and indeed may result in file separation, perforation, or ledge creation. Some clinicians would like to blame instrument separation on manufacturing defects; however, this has never been shown to be of clinical relevance and is quite rare.[247]

The best treatment for the separated instrument is prevention. If proper techniques for cleaning and shaping of the root canal system are followed, file separation should be an infrequent occurrence. Nevertheless, an occasional event may take place. When instrument separation occurs, a radiograph should be taken immediately.[247] This radiograph will not only confirm the separation, it will give the clinician information that may aid in removal, such as location, size of the file segment, root canal anatomy, and, ultimately, the possibility of removal. The patient should be advised of the accident as well as its effect on the prognosis.[41] In addition, when a file separates, as with other procedural accidents, detailed documentation is necessary for medical-legal considerations,[247] and the remaining segment of the file should not be discarded but, rather, placed in a coin envelope and kept in the patients record.[41,274]

D, A 13-month recall film. The patient was asymptomatic.

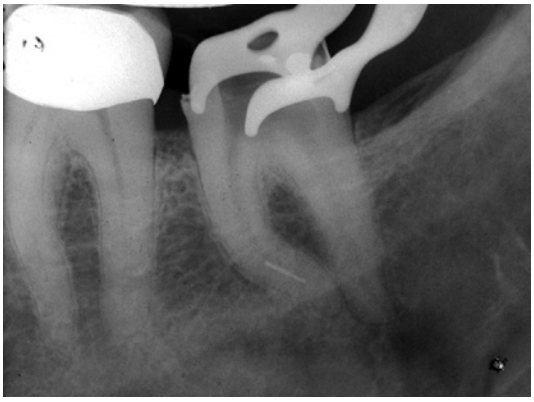

FIG. 8-58 Complicated canal anatomy can increase stress on rotary instruments, leading to separation such as in this "S"-shaped canal.

Prognosis

A separated instrument does not necessarily mean surgery or loss of the tooth. Actually, the prognosis may not be reduced at all depending on what stage of instrumentation the separation occurs, the preoperative status of the pulp and periradicular tissues, and whether or not the file can be removed or bypassed.[225] The presence of a separated instrument in the canal in itself does not predispose the case to posttreatment disease. Rather, it is the presence of any necrotic, infected pulp tissue that remains in the apical canal space that determines the prognosis. The outcome is better if the canal was instrumented to the later stages of preparation when the separation occurs.[247] If the preoperative pulp was vital and noninfected (irreversible pulpitis, for example), and there was no apical periodontitis, the presence of the separated instrument should not affect the prognosis.[43] If the file can be removed without excessive over enlargement of the canal or causing an additional iatrogenic mishap, such as a perforation, the prognosis will not be affected. Bypassing the instrument and incorporating it into the obturation should also have no effect on the prognosis. However, if the instrument cannot be removed or bypassed in a tooth with a necrotic, infected pulp and apical periodontitis, the prognosis will be uncertain. These cases should be followed closely and, if symptoms persist, apical surgery or extraction should be considered.[247,271]

The potential to remove a separated instrument depends on many factors that should be considered during the diagnostic workup. The location of the separated instrument is critical. If the separated instrument extends into the straight, coronal portion of the canal, retrieval is likely. If, however, the instrument has separated deep in the canal and the entire broken segment is apical to the canal curvature, then orthograde removal will not be possible and attempts to do so could lead to a much higher rate of iatrogenic complication.[209,223] If there is persistent disease and the file cannot be bypassed safely, either apical surgery or extraction will be necessary. Because of the need to enlarge the coronal radicular access, root curvatures, external root concavities, and root thickness all will be important factors to consider when deciding which treatment option will provide the best chance of long-term success. Teeth with thin roots and deep external root concavities have a greater likelihood of being perforated during the coronal radicular access, so surgery should be considered as an alternative to orthograde instrument retrieval. The type of material the separated instrument is made of will affect the chances of removal. Nickel-titanium files tend to shatter when ultrasonic

FIG. 8-59 The surgical operating microscope is not only invaluable in helping to remove separated instruments, but it is in fact a necessary tool for these procedures.

energy is applied to them, hindering removal, whereas stainless steel instruments are more robust and more easily removed with ultrasonics.[187]

Removal Techniques

Many different instruments and techniques will be discussed in this section, all of which are important to include in the armamentarium for separated instrument removal. None, however, is more important than the operating microscope (Fig. 8-59). This instrument will not only increase visibility by the use of magnification and light, but it will also increase the efficiency and safety of almost all of the techniques to be discussed. The use of a headlamp and magnifying loupes will help with the removal of many canal impediments. However, the use of the operating microscope has caused a quantum leap in visualization due to the enhanced lighting and magnification that it offers,[124] and many of the techniques to be described should not even be attempted without the use of this valuable tool.[234]

Once the patient has been advised of the treatment options and the decision has been made to attempt removal, the clinician's first choice in treatment will be based on the location of the instrument. If the file is clinically visible in the coronal access and can be grasped with an instrument, such as a hemostat or Stieglitz Pliers (Sullivan-Schein, Port Washington, NY) (see Fig. 8-39), then these should be used to obtain a firm hold of the file and extract it out through the access cavity preparation. Many sizes and angles of forceps are available, and almost all are necessary in order to have the ability to remove obstructions from the many different angles and levels of accessibility presented to the clinician. These will work well if the object is loose fitting within the canal and if the clinician has good access. However, establishing a firm purchase can sometimes be difficult without removing excessive tooth structure. Once a purchase onto the file has been achieved, it is best to pull it from the canal with a slight counterclockwise action. This action will unscrew the flutes that are engaged in the dentin as the file is being removed. This is the easiest technique for removal of a separated file; however, unfortunately, many files separate at a point where these forceps cannot be used.

Frequently, a file will separate at a point deeper in the canal where visibility is difficult. To remove separated root canal instruments predictably, the clinician must create straight-line coronal radicular access. Either removing the crown or creating a large access cavity preparation establishes adequate coronal access to allow the use of the appropriate instruments. Straight-line radicular access can be created with the use of modified Gates-Glidden drills. These drills may be ground down or sectioned with a bur at their maximum cross-sectional diameter. This process will create a circumferential staging platform to facilitate ultrasonic use (Fig. 8-60).[187] One study showed that use of similarly modified Lightspeed nickel-titanium rotary instruments (Lightspeed Technology Inc, San Antonio, TX) created a staging platform that was more centered in curved canals than the Gates-Glidden drills.[115]

Ultrasonic instruments have been shown to be very effective for the removal of canal obstructions.[36,161,187] The ultrasonic tip is placed on the staging platform between the exposed end of the file and the canal wall and is vibrated around the obstruction in a counterclockwise direction that applies an unscrewing force to the file as it is being vibrated. This technique will help with removing instruments that have a clockwise cutting action. If the file had a counterclockwise cutting action (such as the hand GT files), then a clockwise rotation will be needed. The energy applied will aid in loosening the file, and occasionally, the file will appear to jump out of the canal. It is prudent to cover the orifices of the adjacent open canals with cotton or paper points to prevent the removed file fragment from falling into them, causing further case complication[187] (Fig. 8-61). Many sizes and angles of ultrasonic tips are available for this purpose, but in general, the deeper in the canal the obstruction is, the longer and thinner an ultrasonic tip must be. It should be remembered that long, thin tips must be used on very low power settings to prevent tip breakage (Fig. 8-62). Occasionally, if the separated instrument can be bypassed, the use of ultrasonic files can loosen it. Care must be taken, however, to avoid ultrasonic file separation or root perforation.[102] As mentioned previously, nickel-titanium instruments often break into fragments when subject to the energy supplied by an ultrasonic instrument. Clinicians may be tempted to use this information to their advantage by applying the tip of the ultrasonic directly onto nickel-titanium files. Occasionally, this method may work; however, the chance of pushing the separated file further into the canal or beyond the apical foramen may increase the risk of this technique.

If the direct application of ultrasonic energy does not loosen the separated instrument sufficiently to remove it, the fragment must be grabbed and retrieved. This is accomplished with a variety of techniques most using some variant of a microtube. The staging platform is further reduced by ultrasonics until enough of the separated instrument is exposed to retrieve (about 2 to 3 mm).[187] This reduction must be done carefully to avoid root perforation. One relatively simple microtube technique is to use a short piece of stainless-steel tubing that is pushed over the exposed end of the object. A small Hedstrom file is then pushed between the tube and the end of the object using a clockwise turning motion that produces a good mechanical lock between the separated instrument, the tube, and the Hedstrom file. The three connected objects can then be removed by pulling them in a coronal direction[233] (Fig. 8-63).

Another technique is to use a 25-gauge dental injection needle along with a 0.14-mm-diameter steel ligature wire. The needle is cut to remove the beveled end as well as the opposite

end so it no longer extends beyond the hub. Both ends of the wire are then passed through the needle from the injection end until they slide out of the hub end, creating a wire loop that extends from the injection end of the needle. Once the loop has passed around the object to be retrieved, a small hemostat is used to pull the wire loop up and tighten it around the obstruction and then the complete assembly is withdrawn from the canal.[185] Occasionally, a larger diameter tube and thinner (0.11-mm) ligature wire will facilitate assembly of this extractor (Fig. 8-64).

Another effective technique, especially in cases where access or obtaining an adequate purchase on the file is difficult, is to use an end-cutting trephine bur to remove tooth structure around the file and then use an extraction device to remove it. There are many kits that use these principals with slight variations from one another, including the Endo Extractor (Brasseler USA), the Masserann Kit (Medidenta International), and the Extractor System (Roydent) (see Fig. 8-54).

The Endo Extractor kit includes a cyanoacrylate adhesive, which is used to bond a hollow tube to the exposed end of the file for removal. This kit also includes four sizes of trephine burs and extractors. The most important factor in using this kit is the snugness of fit between the extractor tube and the obstruction. It has been shown that, even with only 1 millimeter of overlap between the extractor tube and the obstruction, if there is a snug fit, the bond created with the cyanoacrylate may be strong enough to remove many obstructions. However, the recommended amount of overlap between the tube and the obstruction is 2 millimeters. The time needed for the adhesive to set to ensure adequate bond strength for removal is 5 minutes for a snug fit and 10

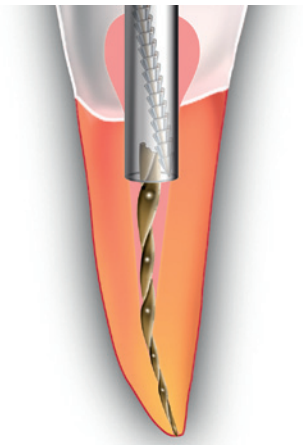

FIG. 8-63 Tube and Hedstrom file removal technique. The tube is slipped over the obstruction and a Hedstrom file is gently screwed into the space between the tube and the obstruction. Pulling the tube and Hedstrom file together can withdraw the obstruction. (Diagram courtesy DENTSPLY Tulsa Dental Specialties, Tulsa, OK.)

minutes for a loose fit.[76,226] One disadvantage of this instrument is that the trephine burs are much larger than their International Standards Organization ISO equivalents, so the manufacturer has also added a separate smaller trephine bur, which is sold separately from the kit. This bur corresponds better with the smaller extractors and removes less dentin that can decrease the likelihood of weakening the root leading to fracture.[61] Another disadvantage is that the burs cut aggressively when new but dull rather quickly. When new, this aggressive cutting may lead to perforation, or even separation of the obstruction. Therefore, great care is needed when using this instrument (Fig. 8-65). Once the separated instrument has been removed, the extractors may be reused, either by using the debonding agent that is included in the kit to remove the embedded instrument from the extractor tube or by simply cutting the extraction device with a bur beyond the extent that the separated instrument has penetrated.

The Masserann technique has also been recommended for the removal of separated instruments.[151] This technique is similar to the Endo Extractor in that it uses trephine burs and a specific extraction device. This kit comes with a convenient gauge that aids in predicting the size of the bur and the extractor to be used, and it contains many sizes of trephine burs. In addition, the trephine burs with this kit cut in a counterclockwise direction that provides an unscrewing force on separated files. The extraction mandrels have an internal stylus that wedges the file against the internal wall of the mandrel allowing the obstruction to be removed. Although effective, this technique may require removal of an excessive amount of radicular dentin,[69] leading to root weakening and the risk of perforation[272]; therefore, this instrument must be used with caution.

The Extractor System from Roydent comes with only one bur and three extraction devices. The bur is very conservative

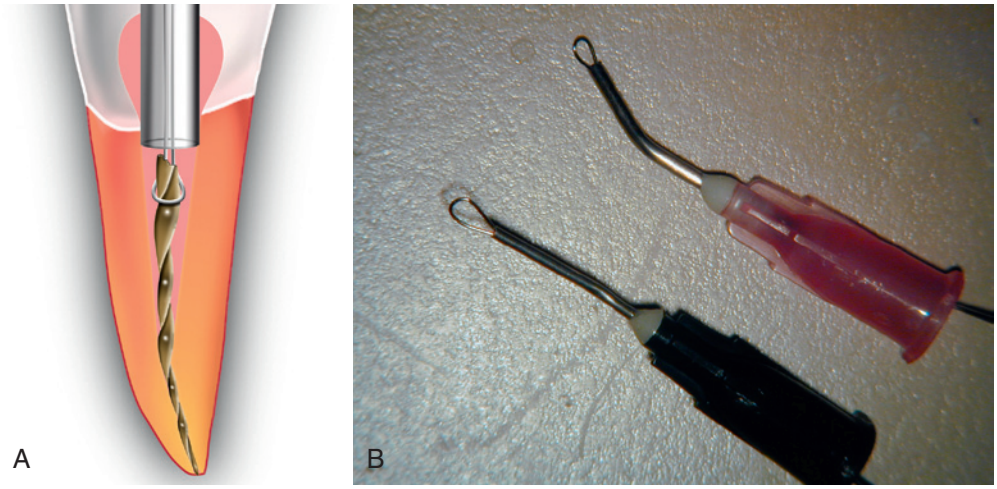

FIG. 8-64 A, Diagram illustrating the wire loop and tube method of obstruction removal The wire loop is carefully placed around the obstruction, tightened, and then removed. and removes a minimal amount of tooth structure, enabling access to the obstruction. The extractor tubes are also quite small and, therefore, will only work for the removal of small obstructions. The extractor surrounds the obstruction with six prongs that can be tightened onto the object, enabling removal. This works in the same way a drill chuck tightens onto a drill bit (Fig. 8-66). The disadvantages of this kit are the lack of variety of instruments, the possibility of separating the obstruction with the bur, and the potential problem of breakage of the prongs in the extractor if they are submitted to bending rather than applying strict tensile force during removal.

Two techniques have been designed specifically for removing instruments in conjunction with the operating microscope:

FIG. 8-66 Close-up view of the Roydent Extractor tip. The tip is placed over the separated instrument and tightened to grasp the obstruction.

the Cancellier instrument and the Mounce extractor (Sybron-Endo) (Fig. 8-67). The Cancellier instrument works in a similar manner to the Brasseler Endo Extractor in that it is used in conjunction with cyanoacrylate adhesive to bond onto the separated end of the instrument. Unlike the Brasseler extractors, the Cancellier extractors are attached to a handle that enables them to be used without blocking visibility when using the operating microscope. The Brasseler extractors are finger instruments that interfere with the line of sight the microscope requires. There are no trephine burs in the Cancellier kit; rather, it is used in conjunction with ultrasonic exposure of the separated instrument. Four sizes of extractor tubes are available, each of which corresponds to specific file sizes. The Mounce extractors are also hand instruments that enable use with the operating microscope. These instruments are similar to a ball burnisher with slots cut into the ball end. These slots are cut at various angles and are designed to slide onto the broken end of the file. Cyanoacrylate is used to bond the extractor to the file allowing removal. This instrument can be used when the separated file is lying against the canal wall; however, the ball tip is relatively large and is only useful in retrieving instruments that are in the most accessible coronal portion of the canal.

Another device designed specifically for the purpose of separated file removal is the Instrument Removal System (DENTSPLY Tulsa Dental Specialties) (see Fig. 8-54). This kit consists of two different sizes of extraction devices that are tubes with a 45-degree bevel on the end and a side cutout window. Each tube has a corresponding internal stylus or screw wedge. Prior to use of this instrument, 2 to 3 mm of the obstruction is exposed by troughing around it with an ultrasonic instrument. Once the file is exposed, the appropriate size microtube is selected and slid into place over the obstruction. Once in place, the screw wedge is turned counterclockwise to engage and displace the head of the obstruction through the

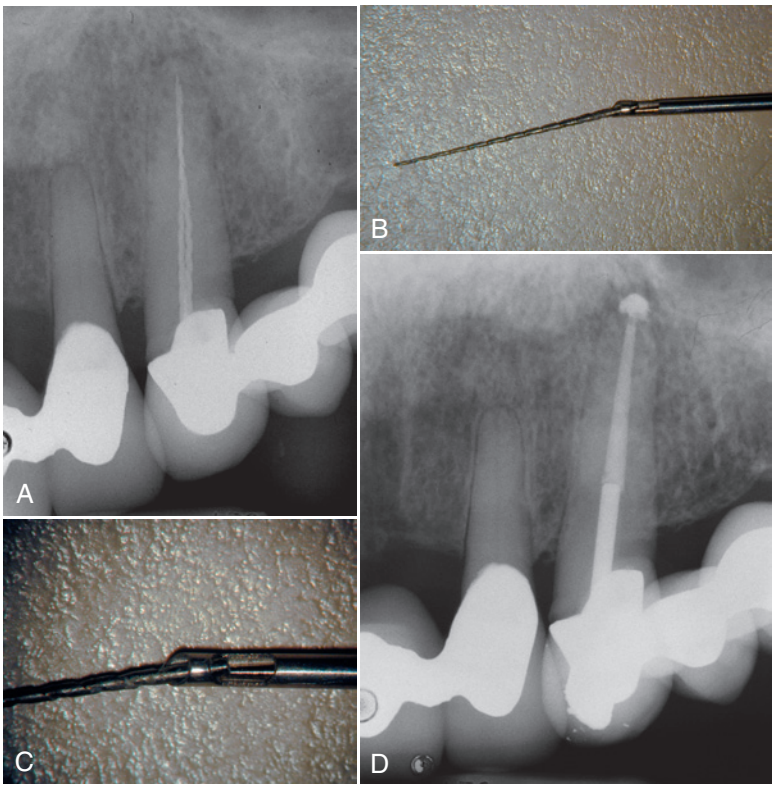

FIG. 8-68 A, Preoperative radiograph showing two separated instruments in one tooth. B, IRS instrument with a removed file. C, Note that large size files are difficult to push through the cutout window. D, Postoperative radiograph.

side window. The assembly is then removed.[187] This instrument is useful in the straight portion of the canal, but it is difficult to force large-diameter separated files through the cutout window, hampering their removal (Fig. 8-68).

The S.I.R. (Separated Instrument Retrieval) System (Vista Dental Products) (see Fig. 8-54) is another microtube method of separated instrument retrieval. Like the Cancellier instrument, it utilizes extractor tubes bonded onto an obstruction, enabling removal. Once the obstruction is exposed using ultrasonics or the trephine burs from one of the other kits described, the bendable dead-soft tubes are bonded onto it. Once the adhesive is set, the obstruction is removed through the access cavity preparation. Included in this kit are the necessary bonding agent, a bottle of accelerator, five different sizes of tubes, assorted fulcrum props, and a hemostat. The accelerator causes the bonding agent to set almost instantaneously. The ability to bend these tubes allows for access in most areas of the mouth. A hemostat allows the clinician to establish a firm purchase onto the tube, creating the ability to lever the bonded obstruction out of the canal. A vinyl, autoclavable instrument prop provides protection for the next most anterior tooth, which is to be used as a fulcrum; however, if the clinician has access to grasp the extractor with his or her fingers to remove the extractor/obstruction unit, the hemostat may not be necessary.

Heat Generation During Retreatment Procedures

There are many procedures in endodontic therapy that can generate heat, but perhaps the area with the greatest risk of heat related tissue damage occurs during nonsurgical retreatment. Use of heat to soften canal filling materials to aid in their removal[132,139] and use of ultrasonics to dislodge posts[192] and separated instruments[95,146] can potentially generate enough heat to raise the temperature of the external root surface by 10° C or more. Temperature elevations of the periodontal ligament in excess of 10° C can cause damage to the attachment apparatus.[11,53,194,195]

The greatest danger of heat-related damage occurs with the use of ultrasonic energy to dislodge foreign objects in the canal space in order to gain access to the apical portion. As described earlier, this has recently become an extremely important and useful part of the clinician's armamentarium due to the ability of ultrasonic energy application to conserve tooth structure while removing the obstruction. These instruments have allowed clinicians to perform predictable retreatment when surgery would have been previously indicated. As with most instruments used in dentistry, however, these devices must be used with caution as in vitro research and clinical case reports imply that they have the potential to damage the tooth attachment apparatus due to the heat generated during use.[30,78,201] One in vitro study has showed that ultrasonic vibration for post removal without coolant can cause root surface temperature increases approaching 10° C in as little as 15 seconds.[48] Thermal damage to the periradicular tissues may be so serious as to result in both tooth loss and permanent bone loss (see Fig. 8-28). This is not to say that ultrasound energy should be avoided for the removal of canal obstructions because it is many times the only way to reach the apical area of the canal.

The factors that may contribute to a heat-induced injury are the length of the post, post diameter, post material, and type

of luting cement. Studies need to be done to establish heat reduction protocols based on these variables. Some have proposed that the dentin thickness between the outer surface of the post and the root surface may affect root surface temperature rise,[81,82] and one study showed this.[192] However, a more recent study has shown that the dentin thickness is statistically insignificant as a factor in root surface temperature rise.[101] One possible mitigating factor would be the effect of the periradicular blood supply, which could act as a heat sink dissipating the generated thermal energy and thus helping to prevent injury. This may be why the effect of seemingly similar conditions of ultrasonic application can have such differing results on different patients. Clearly, more in vivo research is needed in this area.

It has become accepted that the heat-induced damage to periradicular tissues during the usage of ultrasound energy for post removal is time dependent.[30,106] Studies have advised cooling of the ultrasonic tips can greatly reduce heat buildup[30,106] despite reducing the efficiency of debonding resin bonded posts.[48,73] The amount of time the clinician can use these instruments safely is difficult to determine, as specific protocols that are evidence based using in vivo research have yet to be established. Therefore, the authors feel any specific recommendations regarding rest intervals between usage of ultrasound energy, ways of monitoring heat buildup, or duration of consistent activation cannot be made based on the available research at the time of publication. However, the authors do feel strongly with regard to several recommendations for the use of ultrasound energy during the removal of canal obstructions, and they are as follows:

- Use ultrasonic tips with water ports whenever possible.
- If your ultrasound device does not have tips with water ports, have your assistant use a continuous coolant air/water spray during usage.[55]
- Take frequent breaks to let the tooth cool down.
- Avoid using the ultrasound on the high power setting.[55]

Prudent clinicians must take extreme care when applying ultrasound energy to a canal obstruction, as it has been shown that even with the use of water coolant, the temperature of root surfaces can increase rapidly.[48,192] Thus, until evidence-based heat reduction protocols are developed, caution is required when using instruments that can generate heat in the periodontal ligament.

Management of Canal Impediments

Following removal of all root-filling materials, further progress to the apical constriction may be prevented by the presence of a block or a ledge in the apical portion of the canal. Most of these impediments are iatrogenic mishaps resulting from vigorous instrumentation short of the appropriate working length and failure to confirm apical patency regularly during instrumentation. A blocked canal contains residual pulp tissue (sometimes necrotic, often fibrosed or calcified) and packed dentinal "mud" in the apical several millimeters of the canal system.[187] This debris is frequently infected, resulting in persistent disease, and must be removed if possible. A ledge is the result of placing non-precurved, end-cutting instruments into curved canals and filing with too much apical pressure.[79,116] It is a type of canal transportation that results in a canal irregularity on the outside of the canal curvature that is difficult or impossible to bypass. The canal space apical to the ledge is not thoroughly cleaned and sealed, so ledges frequently result in posttreatment disease. The best treatment for blocked and ledged canals, as with all iatrogenic problems, is prevention. If the clinician is careful and attentive during the instrumentation process, the chance for an impediment to develop is minimized. When the clinician becomes careless or hurried, problems occur. The strategies for preventing blocks and ledges are found in Chapter 19.

During the treatment-planning phase, blocks and ledges may be detectible on radiographs as a root filling short of the ideal working length, and the patient should be warned that they might prove impenetrable and require future apical surgery or extraction.[68] This should not deter the clinician from choosing nonsurgical retreatment, however. In one study, 74% of teeth showing short root fillings were successfully negotiated to adequate length, with the authors stating that presence of a short fill should not be considered a technical contraindication to retreatment.[57] The clinical encounter usually occurs after removal of the previous root-filling material when apical advancement of small files is impeded. At this point, the clinician may be unaware of which type of impediment exists, but a common approach to management is helpful in the early stages of the process. The coronal portion of the canal should be enlarged to enhance tactile sensation and remove cervical and middle third obstructions in the canal space. The canal should be flooded with irrigant, and instrumentation to the level of the impediment should be accomplished using non-end-cutting rotary files, such as the Lightspeed (Lightspeed Endodontics, San Antonio, TX), the Profile or GT instruments (Dentsply, York, PA), or the K-3 instrument (Sybron Endodontics, Orange, CA), in a crown-down manner. This procedure will enlarge and flare the canal space coronal to the impediment while minimizing the likelihood of worsening any ledge present.

At this point, the impediment should be gently probed with a precurved #8 or #10 file to determine if there are any "sticky" spots that could be the entrance to a blocked canal. A directional rubber stop should be used so that the clinician knows in which direction the tip of the instrument is pointing, which helps in visualizing the three-dimensional layout of the canal system. Frequently, evacuating the irrigant and using a lubricant, such as RC Prep (Premier, Plymouth Meeting, PA) or Pro-Lube (Dentsply), will enhance the ability to place the small file into the apical canal segment. If repeated, gentle apical pressure or "pecking" of the hand file against the blockage results in some resistance when withdrawing the instrument on the outstroke ("stickiness"), then the clinician should continue to peck at the "sticky" spot until further apical advancement is accomplished.[187] This is frequently a slow and tedious process. The endeavor can be made more efficient by using precurved stiff files such as the C+ file (Maillefer, Baillagues, Switzerland), but there is a risk of deviating from the original canal path, creating a ledge, and ultimately a false canal leading to zip perforation.[79] It is prudent to make a working radiograph when some apical progress has been made to confirm the placement of the instrument into the suspected apical extent of the canal. The clinician should resist the urge to rotate the file excessively. If the tip of a small instrument is tightly bound in the blocked segment of the canal and the tip has been worked by pecking, it is prone to fracture in the apical area further complicating the case.[187] The separated file tip is frequently irretrievable, and surgery or extraction may be the result. Dropping down to the next smaller size file and using a gentle reciprocal rotational motion ("twiddling") will aid in

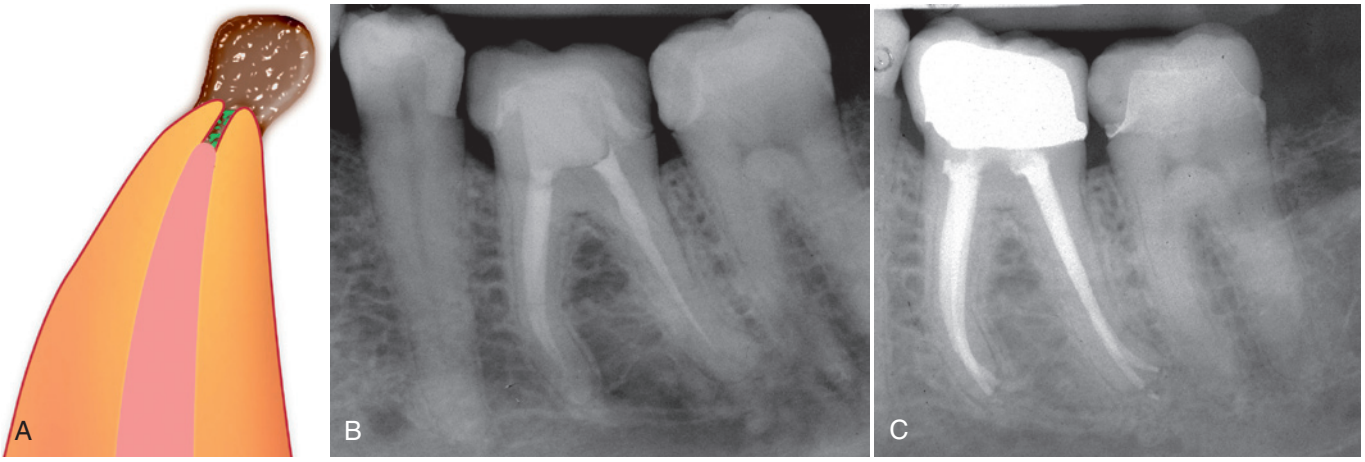

FIG. 8-69 A, Diagrammatic representation of a canal block. Fibrotic or calcified pulp and debris that is potentially infected remains in the apical segment of the canal when the canal is instrumented short of the apical constriction. B, Preoperative radiograph showing obturation short of ideal length. The patient was symptomatic and the canals were blocked. C, The 3-month posttreatment. Treatment took a total of 3.5 hours over three appointments due to the time-consuming nature of bypassing blocked canals. (*A,* Diagram courtesy DENTSPLY Tulsa Dental Specialties, Tulsa, OK.)

advancement through the blocked canal. Frequently, as apical progress is being made, the clinician will be using an electronic apex locator to gauge the proximity of the apical constriction. Unfortunately, the apex locator is sometimes not able to give an accurate reading in a blocked canal, and because of the continued "sticky" feel that occurs even as the instrument bypasses the foramen and penetrates apical tissues, an overextension may result. To prevent this complication with its attendant risk of a painful postoperative flare-up, when the estimated working length is reached, a working length radiograph is necessary.[149] Once apical working length is achieved, apical patency should be confirmed, and gentle, short amplitude 1- to 2-mm push pull strokes should be made until the file can pass freely to the apical constriction (Fig. 8-69).

If, after a reasonable amount of time, no sticky spot can be found, the clinician must consider the possible presence of a ledge despite possibly not detecting it on the preoperative radiograph. The main problem with ledges is that instruments will invariably find their way to the ledge while finding the original canal is many times impossible. They feel like a hard brick wall, short of length when encountered, and care must be used to prevent worsening the ledge by indiscriminately burrowing into it.[255] To manage a ledge, the tip of a small #08 or #10 file has a small bend placed in it 1 to 2 mm from the end,[116,247] so the tip of the file forms an approximately 45-degree angle with the shaft of the instrument. The directional stop is oriented to the bend, and the file is carefully negotiated to the level of the ledge. Because ledges form mainly on the outside of curvatures, the directional stop (and thus the bent tip of the file) is turned in the direction of the suspected apical curvature away from the ledge (Fig. 8-70). The file tip is slowly scraped along the internal wall of the canal curve slightly coronal to the level of the ledge[247] in an effort to find another sticky spot. This spot will be the entrance to the apical canal segment, and gentle reciprocal rotation will usually allow the file to be negotiated to the canal terminus. Confirm with a radiograph. Once the ledge has been bypassed, short amplitude push-pull and rotational forces keeping the file tip apical to the ledge will be needed to clean and enlarge the apical canal space. When the

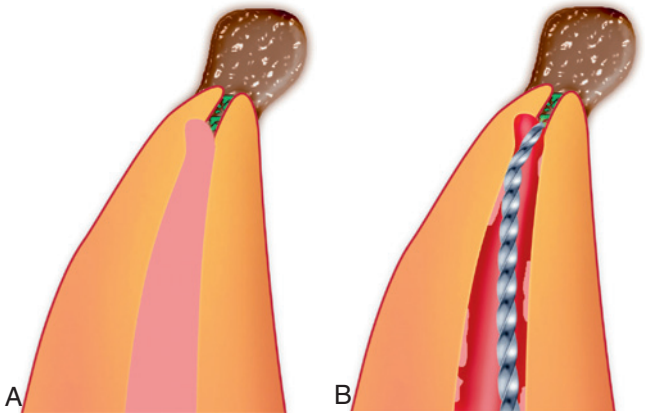

FIG. 8-70 A, Diagrammatic representation of a ledged canal. Potentially infected debris remaining in the apical segment can result in posttreatment disease. B, Attempting to bypass the ledge with a small file having a 45-degree bend in the tip. Note that the opening to the apical canal segment is on the inside of the canal curvature and coronal to the level of the ledge. (Diagrams courtesy DENTSPLY Tulsa Dental Specialties, Tulsa, OK.)

file can be easily negotiated around the ledge, anticurvature filing will enable the clinician to blend the ledge into the canal preparation (Fig. 8-71). Many times this cannot be completely accomplished,[255] but as long as the apical segment can be cleaned and obturated, the prognosis should not be adversely affected.

The use of Greater Taper (GT) NiTi hand files (DENTSPLY Tulsa Dental Specialties) for the blending of ledges has been advocated.[187] The advantage these instruments have is that they are non-end cutting, and their rate of taper is two to six times that of conventional 0.02 tapered files, so they can do the work of multiple 0.02 tapered hand files. Once the ledge has been bypassed and the canal can be negotiated with a conventional size #15 or 20 K-file, a GT hand file is selected. The K-file creates a pilot hole so that the tip of the GT file can passively follow this glide path beyond the ledge. The GT file must have

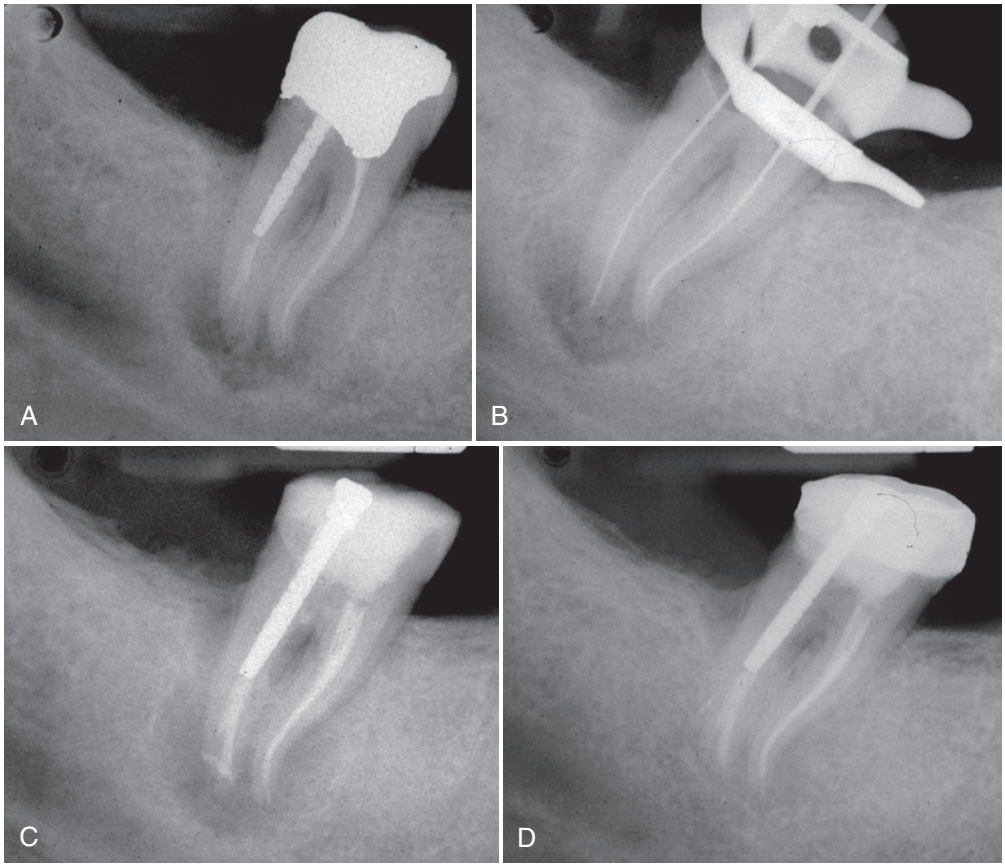

FIG. 8-71 **A,** Preoperative radiograph showing a distal canal ledge with a small amount of sealer that has entered the apical segment. The ledge prevented proper cleaning and sealing of the canal system resulting in posttreatment disease. **B,** The ledge has been bypassed. The attempt is made to blend the ledge into the contour of the prepared canal wall. **C,** Final obturation showing the filled ledge and apical segment. **D,** A 13-month recall showing healing. The patient was then directed to have a definitive coronal restoration placed.

a tip diameter of 0.2 mm (#20) and a taper that will vary depending on the requirements of the preparation. The largest taper that will enter the apical segment is used; however, these instruments must be precurved, which presents a challenge because they are made from nickel-titanium alloy. To precurve this superelastic shape memory alloy, a file-bending tool, such as the Endo Bender Pliers (SybronEndo), is needed. The pliers grasp the tip of the instrument, and the file is overcurved between 180 and 270 degrees to plastically deform the alloy. At this time, the appropriate tapered GT file is then carried into the canal, and the rubber stop is oriented so that the instruments precurved, working end can bypass and move apical to the ledge. The GT file is then worked to length, and the ledge is either reduced or eliminated (Fig. 8-72).

If the canal blockage or ledge cannot be negotiated, then the canal space coronal to the impediment should be cleaned, shaped, obturated, and coronally sealed. The patient must be informed of this complication, the guarded prognosis, and the need for regular reevaluation (Fig. 8-73). If symptoms of posttreatment disease arise subsequently, apical surgery or extraction will be needed.[187,247]

Finishing the Retreatment

After regaining the apical extent of the canal system, routine endodontic procedures are instituted to complete the retreatment. Any missed canals must be found using magnification, micro-excavation techniques and, most important, the knowledge of canal anatomy that is discussed in another section of this text (Fig. 8-74). One cannot find a canal unless one suspects it is there. Cleaning and shaping procedures must focus on a crown-down approach to minimize extrusion of irritants into the periradicular tissues and also must emphasize enlargement of the apical portion of the preparation to ensure complete removal of apical debris. These aims are best accomplished using technique hybridization during instrumentation and keeping the goals of the retreatment procedure in mind. These matters are covered in detail in Chapter 6. Canal disinfection procedures are, however, paramount after the completion of cleaning and shaping. Because the primary cause of posttreatment disease is usually microbial[64,163] and these microbes (i.e., *Enterococcus faecalis*) are frequently resistant to traditional canal disinfection regimens,[16] every effort must be made to eliminate these organisms from the canal system. This effort is complicated by the fact that no instrumentation regimen can predictably remove the entire previous root filling from the canal space after retreatment.[12] This leaves areas where microbes can reside underneath fragments of root-filling materials and remain protected from standard antimicrobial canal irrigants such, as sodium hypochlorite. Whether the canal space can be adequately disinfected when completing treatment in one visit or whether an interappointment medicament such as calcium hydroxide is needed is still a matter of debate, and the reader

is directed to the appropriate chapter of this text for details of the problem. It is important to keep in mind, however, that teeth that require retreatment also require the highest level of disinfection possible to ensure the most favorable outcome.

REPAIR OF PERFORATIONS

Occasionally posttreatment endodontic disease will be the result of root perforation.[112] Root perforations are created pathologically by resorption and caries, and iatrogenically during root canal therapy (zip, strip, and furcation perforations) or its aftermath (e.g., post preparation perforation)[184] (Fig. 8-75). When they are present, perforations may usually be found during the diagnostic phase as areas where the root-filling materials or possibly restorative materials such as posts are found to radiographically leave the confines of the presumed canal space and approach or cross the radiographic interface between the dentin and the periodontal ligament. Angled radiographs are of paramount importance in determining whether a perforation exists and locating which surface or surfaces of the root have been perforated. This information is necessary when deciding upon treatment options. Frequently, cervical and occasionally midroot perforations are associated with epithelial downgrowth and subsequent periodontal defects, so thorough periodontal assessment is required[148,206] (Fig. 8-76). If there were no evidence of posttreatment disease associated with the defect or tooth, then no treatment would be indicated. If, however, there is evidence of periradicular periodontitis, repair may be instituted in one of two ways,

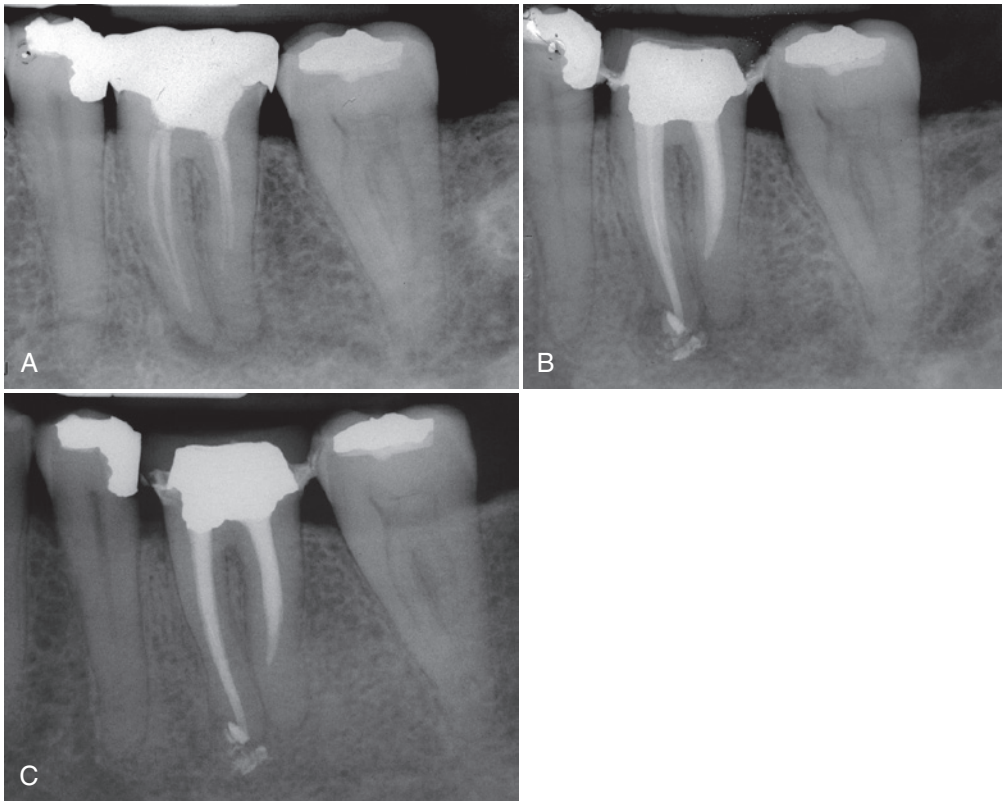

FIG. 8-73 A, Preoperative radiograph showing mesial canal blockages and potential distal root ledging with accompanying posttreatment disease. B, Final film showing mesial blockages bypassed but inability to negotiate beyond the distal ledge. The patient elected to pursue no further treatment at this time. C, One-year recall. Despite not achieving all of the aims of conventional endodontic therapy, periradicular healing is apparent. The patient is asymptomatic and will now begin the final restoration with the knowledge that apical surgery may be needed in the future.

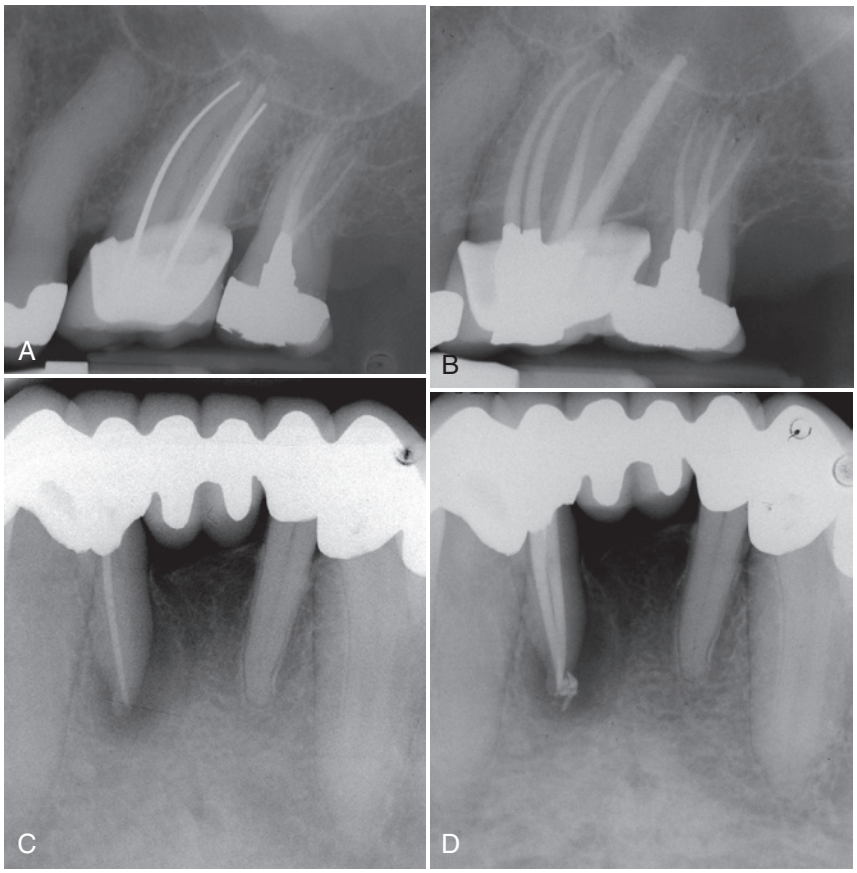

FIG. 8-74 Frequently missed canals that may result in posttreatment disease **A**, Missed second mesiobuccal canal (MB2) in an upper molar. **B**, Final obturation showing cleaned, shaped, and filled MB2 canal. **C**, Missed lingual canal on a lower incisor results in posttreatment disease. **D**, Immediate postoperative film showing management of the missed canal.

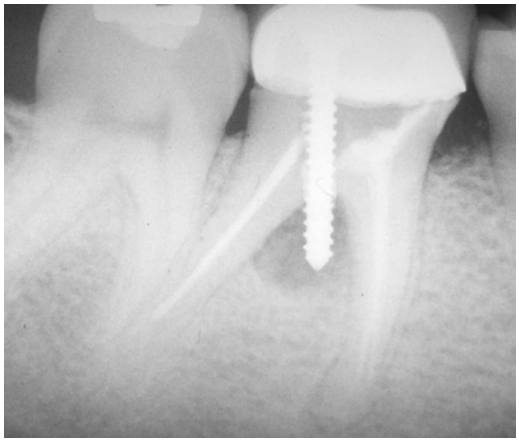

FIG. 8-75 Furcal post perforation resulting in persistent infection and furcal bone loss.

either nonsurgically by approaching the defect internally through the tooth or surgically by using an external approach through the periradicular tissues.[184] In general, if all other factors are considered equal, internal nonsurgical perforation repair will be the preferred method, as it is usually less invasive, produces less destruction of periradicular tissues via the surgical access wound needed, and usually enhances isolation from microbes and disinfection. If, however, the defect is readily accessible surgically and disassembly of the existing restorations would impose an unacceptably high cost and long treatment time to the patient, surgical repair should be selected. If a longstanding defect has a periodontal lesion that has formed around it, surgery perhaps with guided tissue regeneration will usually be needed. However, in most of these cases, nonsurgical retreatment and internal perforation repair prior to surgery will be beneficial to the treatment outcome. A multidisciplinary approach will be required, usually in consultation with the restorative dentist, a periodontist, and perhaps an orthodontist.[187,260]

Factors that affect the prognosis of perforation repair include location of perforation, time delay before perforation repair, ability to seal the defect, and previous contamination with microorganisms.[129,206,213] In general, the more apical the perforation site, the more favorable is the prognosis; however, the converse is true for the repair procedure itself. The difficulty of the repair will be determined by the level at which the perforation occurred. If the defect is in the furcal floor of a multirooted tooth or in the coronal one third of a straight canal (access perforation), it is considered to be easily accessible. If it is in the middle one third of the canal (strip or post perforations), difficulty increases, and in the apical one third of the canal (instrumentation errors), predictable repair is most challenging and, frequently, apical surgery will be needed.

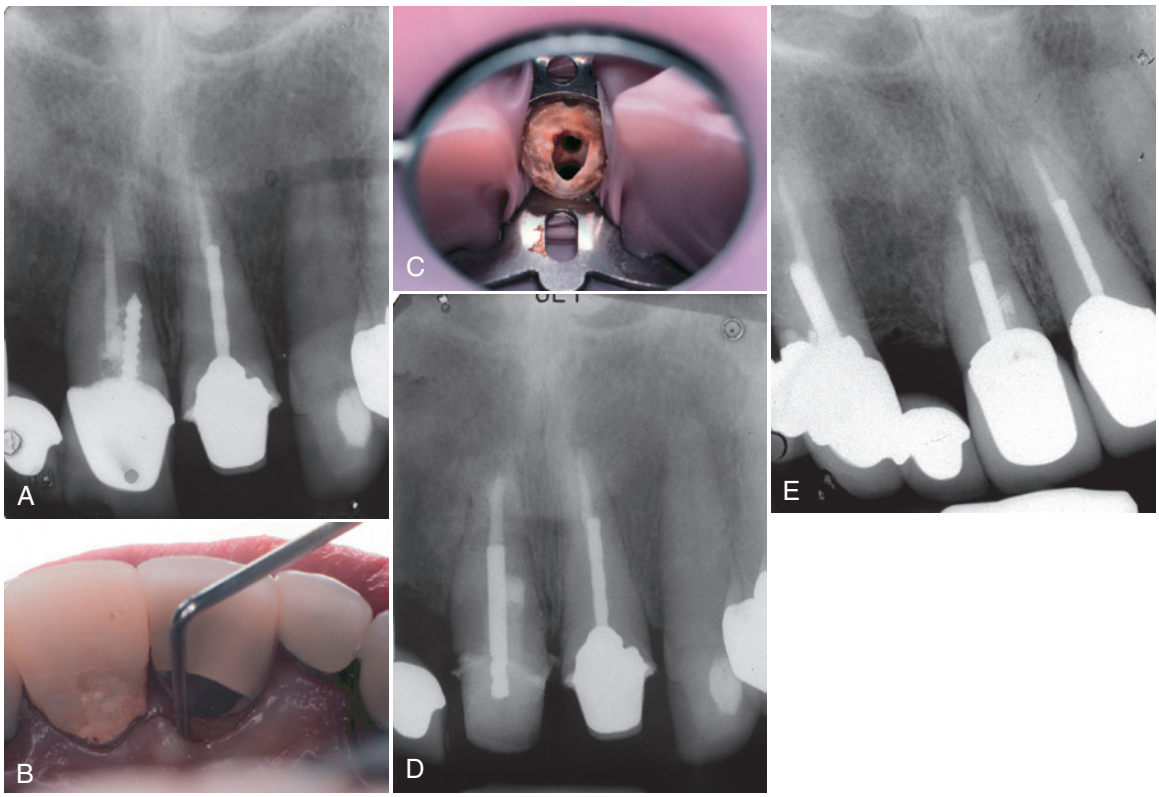

FIG. 8-76 A, Mesially angulated preoperative radiograph showing a palatally oriented post perforation in an upper incisor. B, An 8-mm narrow-based probing defect on the mesiopalatal corner of the tooth. C, Following coronal disassembly, the true canal can be seen lying in a facial direction relative to the palatal post preparation. D, The perforation was repaired with an external matrix of Colla-Cote and MTA. Subsequently, in conjunction with a periodontist, periodontal flap surgery was used to remove periodontal disease etiology from the longstanding pocket, and guided tissue regeneration procedures were instituted. E, The 3-year reevaluation. The tooth is asymptomatic, and the mesiopalatal probing depth is 4 mm.

Immediate repair is better than delayed repair, as delay can cause breakdown of the periodontium, resulting in endo-perio lesions that are difficult to manage,[118,212] and elimination of microbial contamination of the defect and sealing it properly is critical to success. Many materials have been advocated for the repair of perforations in the past; however, none provided predictable healing after treatment. Commonly used materials include amalgam, Super EBA cement (Bosworth, Skokie, IL), various bonded composite materials, and, more recently, mineral trioxide aggregate (Pro-Root MTA, DENTSPLY Tulsa Dental Specialties)[187] (Fig. 8-77).

Since the recent introduction of mineral trioxide aggregate for perforation repair, the choice of which repair material to use is more clear.[148,184] MTA has many advantages over other restoratives when being used for perforation repair. This material seals well,[167,270] even when the cavity preparation is contaminated with blood.[243] It is very biocompatible,[171,179,244,246] rarely eliciting any response from the periradicular tissues, and a cementum-like material has been consistently shown to grow directly on the material after placement.[100,179] MTA has also been shown to have a high degree of clinically favorable long-term outcomes when used as a perforation repair material.[148,184] The main disadvantage of MTA is the long time required for setting,[245] which makes this material inappropriate for transgingival defects such as those associated with cervical

FIG. 8-77 ProRoot MTA is a medical grade of Portland cement that has had the arsenic removed so that it can be used in the human body. It is the material of choice for endodontic perforation repair. (Courtesy DENTSPLY Tulsa Dental Specialties, Tulsa, OK.)

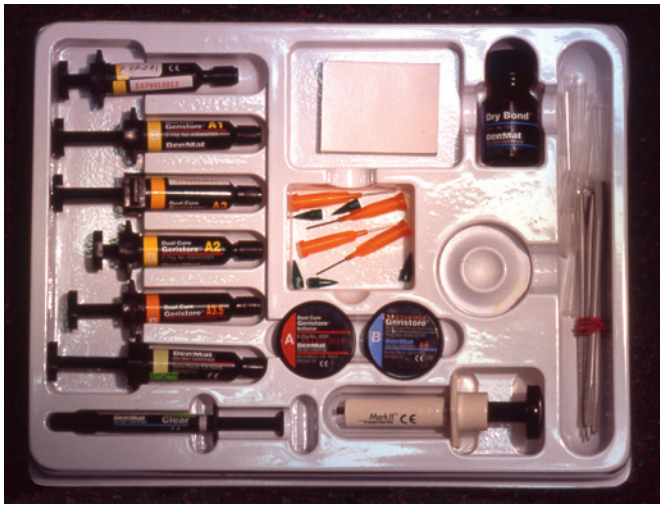

FIG. 8-78 Geristore Kit. This and other resin-ionomers have been advocated for cervical perforation repair due to good biocompatibility and the shorter more controlled setting times that make them useful for transgingival root fillings.

resorption. If the material is in contact with oral fluids, it will wash out of the defect prior to setting, so a more rapid setting resin-ionomer such as Geristore (Den-Mat, Lompoc, CA) is recommended for lesions that cross the gingival margin[18,49,197] (Fig. 8-78). MTA is available in the original gray-colored formulation and a newer, more aesthetic off-white color for treatments in the aesthetic zone of the mouth, although there is little research on the differences between the two formulations. Their sealing ability seems comparable,[60] but questions remain as to whether white MTA exhibits the same biocompatibility[177] and will have the same long-term success as the older variety.

If the perforation is to be repaired nonsurgically through the tooth, coronal-radicular access to the defect is prepared as stated previously (Fig. 8-79). First, the root canals are located and preliminarily instrumented to create enough coronal shape to allow them to be protected from blockage by the repair material. The defect is cleaned and sometimes enlarged with the use of ultrasonics or appropriate rotary drills such as the Gates-Glidden to remove any potentially contaminated dentin surrounding the perforation. Use of a disinfectant irrigating solution such as sodium hypochlorite should be considered if the perforation is not so large as to allow the irrigant to significantly damage the periradicular tissues. If the perforation is large, then sterile saline should be used as an irrigant, and disinfection of the margins of the defect is performed using mechanical dentin removal. Arens and Torabinejad have advocated the use of copious flushing of the defect with 2.5% hypochlorite,[10] but in light of the potential severe complications of hypochlorite overextension through a perforation,[74] extreme care should be used. After the defect has been cleaned, vigorous bleeding may result. Hemostasis should be undertaken using collagen (Colla-Cote, Integra Life Sciences, Plainsboro, NJ) (Fig. 8-79, *B*), calcium sulfate (Capset, Lifecore Biomedical, Chaska, MN), or calcium hydroxide[187]; however, astringents such as ferric sulfate should be avoided, as the coagulum they leave behind may promote bacterial growth and may compromise the seal of the repair.[134]

When the bleeding has been controlled, some easily removable material should be placed over the entrances to the deeper portion of the canals to prevent the repair material from blocking reaccess to the apical terminus. The canals may be protected with cotton, gutta-percha cones, paper points, or shredded collagen. The use of severed files is not recommended, as removal of the files after placement of the repair material is difficult because the material tends to lock into the instrument's flutes (Fig. 8-79, *F*). After protecting the canals, the perforation site is inspected to determine if an external matrix is needed to ensure a proper contour of the restoration.[133] If the surrounding bone is closely adapted to the defect margins, minimal to no matrix material will be necessary; however, if the perforation is associated with a large osseous defect, this must be filled with an external matrix to minimize overcontouring of the repair restoration. The matrix material should be a biocompatible, usually absorbable material such as collagen, freeze-dried demineralized bone allograft (FDDB), hydroxyapatite, Gelfoam, or calcium sulfate.[184,187] Care must be exercised so that the external matrix material is not condensed so forcefully that it damages adjacent vital structures, such as the mental nerve or the floor of the sinus.

Following the preparation of the defect, the repair material is placed. It may be carried in a small syringe or amalgam carrier, and it is condensed with pluggers or microspatulas. In the case of MTA in an accessible defect, the butt end of paper points make an excellent condenser because they can wick some of the water out of the material giving it a firmer consistency, aiding condensation. When the MTA has been positioned, a moist cotton pellet is placed over it to hydrate the material and the tooth is sealed to allow the MTA to set. Upon reentry, the material should be set hard and well retained in the perforation site[217] (see Fig. 8-79, *F*). If there is an overextension of the material beyond the normal external root contour, it seems not to affect the prognosis of the repair.[10,184]

If the perforation is deeper in the canal, the objectives and principles of repair as just outlined all apply, except that access to the defect is more complicated (Fig. 8-80). Protecting the canal from blockage is somewhat more difficult, and placement of the repair material requires the enhanced vision that is provided by the surgical operating microscope. Ideally, the canal should be fully shaped prior to the repair attempt,[187] and a canal patency protector should be placed apical to the defect. In some of these instances, the canal can be protected by using a severed file, notwithstanding the previous warning, because not only can it protect the canal from blockage, but it can also be used as an indirect carrier for transmitting ultrasonic energy to the MTA, causing it to "slump" into the defect when direct condensation is impossible. The file is placed into the canal to a level well below the defect, and the MTA is carried to place. Once condensation has been performed as well as possible, the coronal extent of the file is touched with an ultrasonic tip to vibrate the MTA into the defect. After this is accomplished, the file must be vigorously instrumented in a short 1- to 2-mm amplitude push-pull motion to free it from the placed MTA so that it can be easily removed after the material is set[187] (Fig. 8-81). There is some evidence that ultrasonic placement of MTA may enhance the seal against bacteria in an apexification model,[130] although other researchers have not agreed with this conclusion and found poorer canal wall adaptation when filling the apical extent of canals using ultrasonic condensation compared with hand filling.[8] Further study of ultrasonic MTA placement is warranted, but clinical observation suggests that this method has merit.

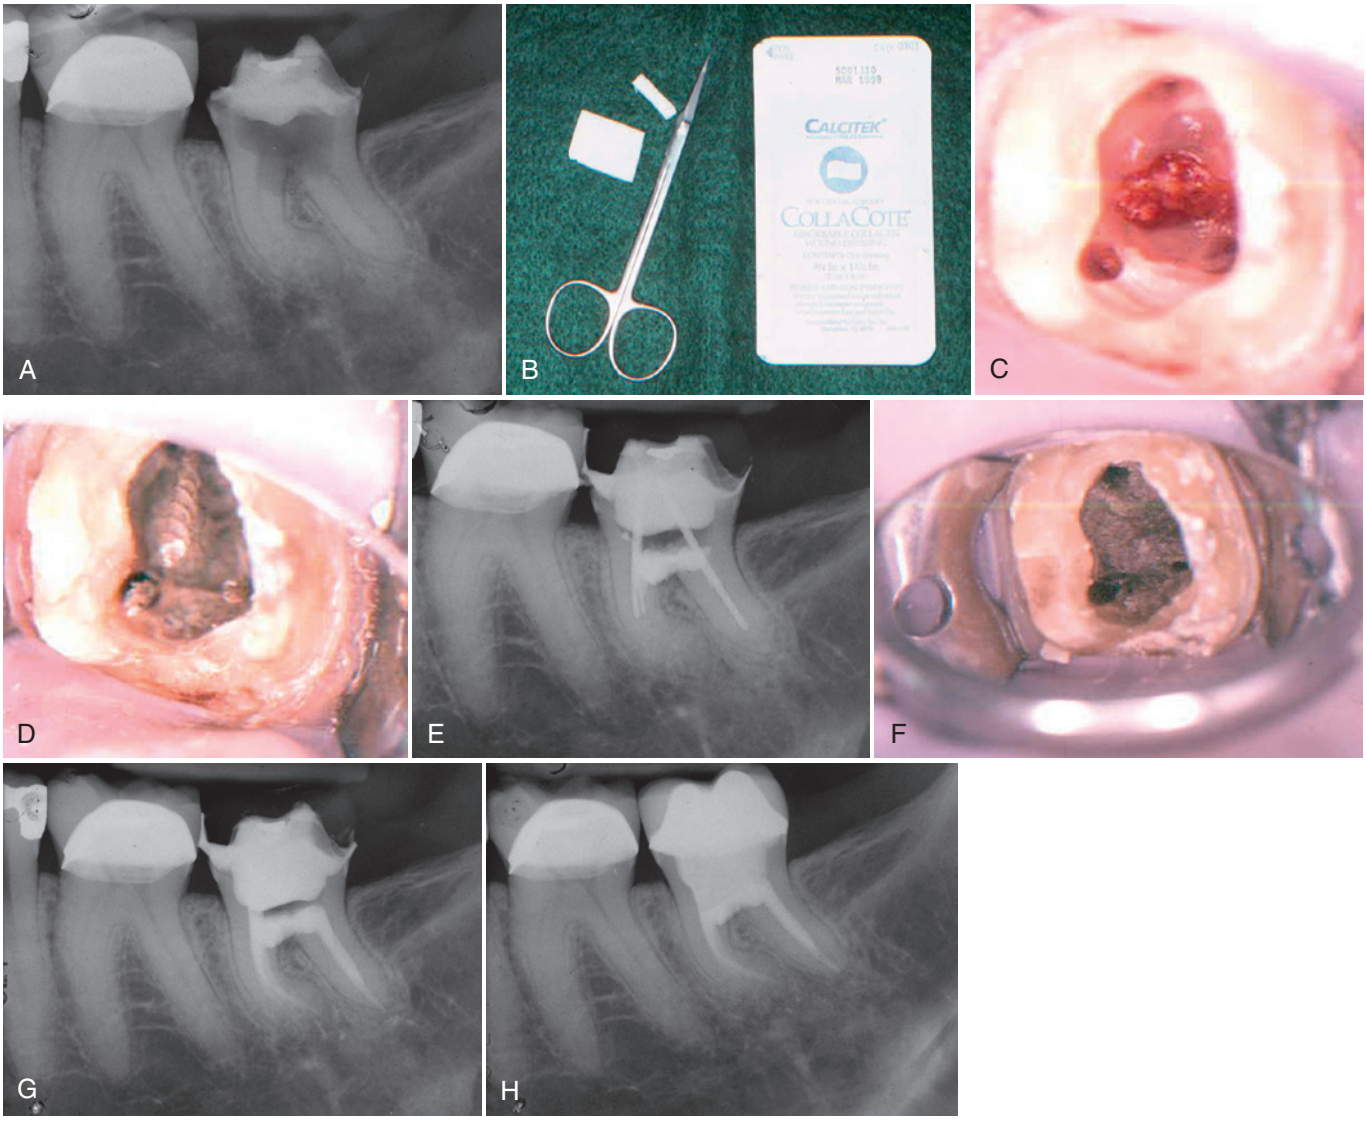

FIG. 8-79 A, Large furcal perforation created during an attempt at endodontic access. B, Colla-Cote (Integra Life Sciences, Plainsboro, NJ) to be used as an external matrix material to recreate the external root contour. C, Canals have been found, preliminarily instrumented, and the external matrix has been placed. D, Canals are protected from being blocked using large endodontic files cut off above the orifice. MTA has been placed into the defect. E, Radiograph showing the initial repair with MTA recreating the vault of the furcation. F, On the second appointment, the blocking files are removed with difficulty because the MTA has flowed into the flutes and set. At this time, endodontic therapy is completed as normal. G, Postobturation radiograph. Note the radiolucency in the furcal vault, which represents the Colla-Cote external matrix material. H, The 19-month reevaluation. The patient is asymptomatic, and there is evidence of healing in the furcal vault area.

If the perforation is in the apical portion of the canal, it is usually due to a procedural accident during instrumentation of a curved canal and is invariably accompanied by a block or ledge. This type of perforation is the most difficult to repair, because repair not only involves cleaning and sealing the defect but also finding, cleaning, and filling the apical canal segment. All of the aforementioned techniques for managing blocks and ledges are required to find and clean the apical canal segment. When this has been accomplished, the decision is made as to whether the canal should be filled with MTA or with gutta-percha and sealer. The MTA is undoubtedly more effective in sealing the canal (especially if it cannot be dried) and is much more biocompatible, but carrying it predictably to the apical extent of a curved canal is problematic. If a holding file is placed in the apical canal segment to anticipate eventual gutta-percha placement after the MTA repair material is set, then the presence of the file precludes consistent extension of the MTA into the apical end of the defect, even when ultrasonically vibrated. If a holding file is not placed, the MTA will also flow into the prepared apical segment, which may not be completely three-dimensionally obturated. In general, whichever choice is made, the outcome will be unpredictable, so the patient must be advised that regular reevaluation is necessary and apical surgery or extraction may ultimately be needed.

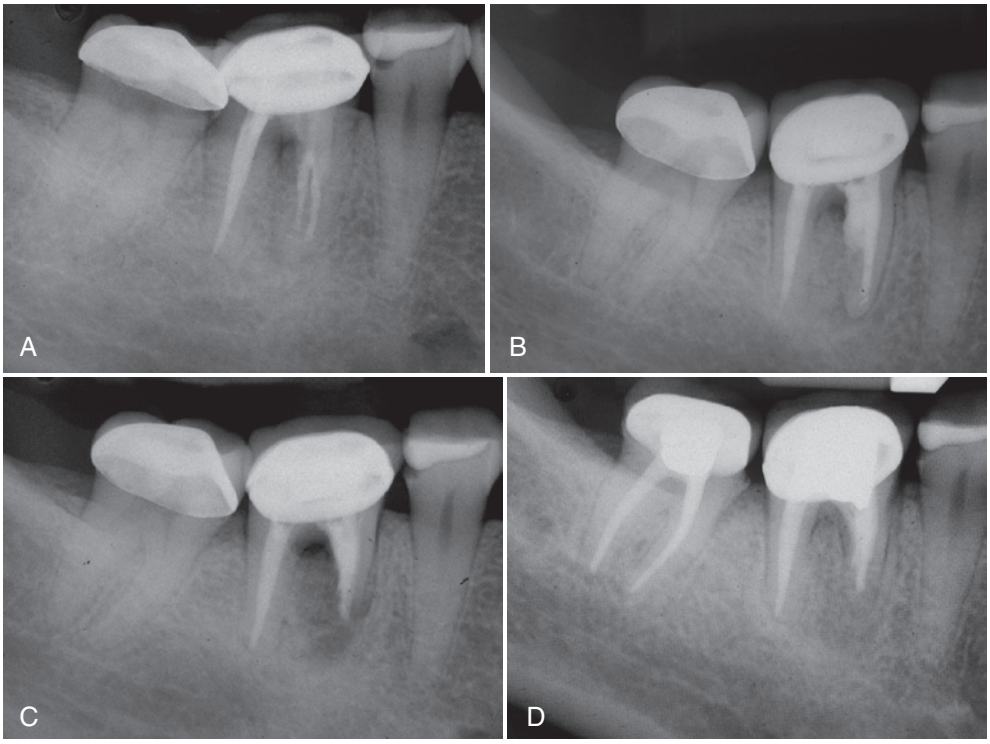

FIG. 8-80 Midroot level perforation repair. **A,** Preoperative film showing mesial strip perforation with bone loss. **B,** Nonsurgical internal repair with inability to negotiate canals to the apical terminus and MTA overextension into the furca. **C,** Apical and perforation repair surgery performed. **D,** he 1-year follow-up showing complete healing.

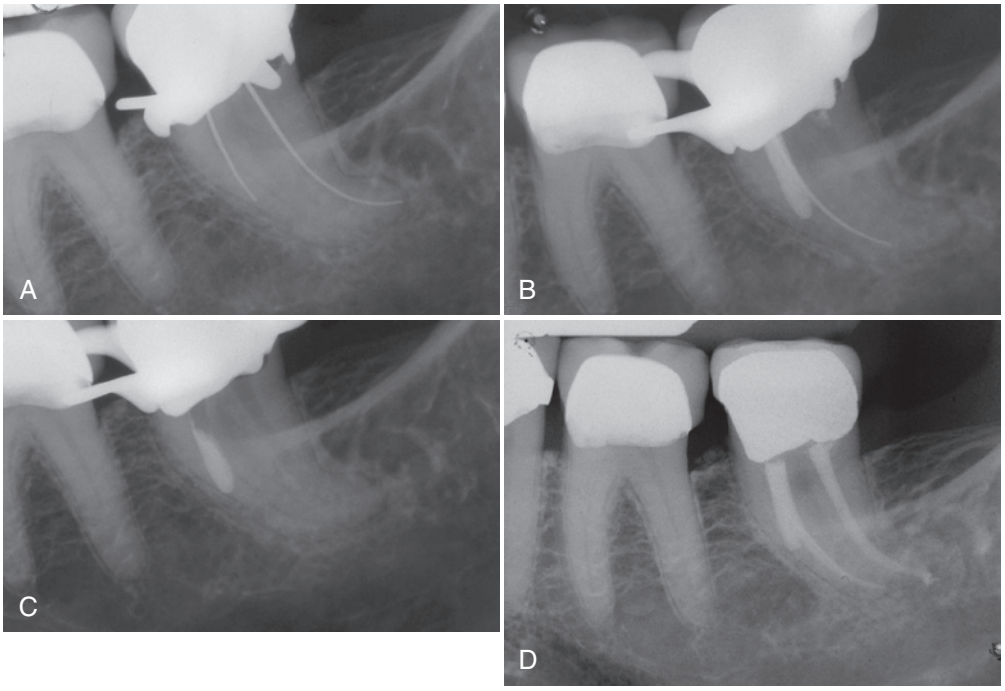

FIG. 8-81 **A,** This patient was in extreme pain following initial endodontic instrumentation by her dentist. Midroot level perforation found on access. **B,** The original canal was found and protected with an endodontic file. MTA was vibrated using ultrasonic energy applied to the file, and it flowed into the defect. Then the file was moved in a push-pull manner to dislodge it from the MTA prior to closure. Note that the defect was intentionally enlarged to allow for more predictable application of the MTA. **C,** On the second appointment, the file was withdrawn easily because it was detached from the MTA repair material. The endodontic therapy could then be concluded as normal. The patient has been asymptomatic since the end of the first appointment. **D,** The 27-month follow-up showing complete healing.

C, Using the trephine bur from the Ruddle Post Removal kit to mill the endo of the post. D, The screw post is removed using the wrench from the Ruddle kit. E, After removal of the post and gutta-percha, a plastic solid core carrier is found in the canal and removed using the techniques described in this chapter. F, Postoperative radiograph showing MTA perforation repair, canal seal with gutta-percha, and post and core fabrication. G, The13-month recall showing healing around the perforation repair site.

PROGNOSIS OF RETREATMENT

When the proper diagnosis has been made and all of the technical aspects of retreatment are carefully performed, orthograde retreatment can be highly successful (Fig. 8-82). The prognosis depends to a large extent on whether apical periodontitis exists prior to retreatment.[169] In a systematic review of outcomes studies,[66] Friedman and Mor reported that in the absence of prior apical periodontitis, the incidence of healed cases after both initial treatment and orthograde retreatment ranges from 92% to 98% up to 10 years after treatment. When prior apical periodontitis is present, the incidence of healing drops to 74% to 86% regardless of whether initial treatment or orthograde retreatment was performed. The authors stated that this "similar potential to heal after initial treatment and orthograde retreatment challenges the historic perception of the latter having a poorer prognosis than the former."[66]

Unfortunately, these numbers mean that the desired outcome will not occur in potentially one quarter of retreatment cases. Many techniques and devices for endodontic retreatment have been mentioned here to aid the clinician. However, none of this will guarantee success. Even when strict endodontic principles and fundamentals are followed, the result may be persistent posttreatment disease. When healing does not occur, the clinician is faced with the decision of what to do next. The choice is between four treatment options: observation, endodontic surgery, extraction-replantation, or extraction.

Many times a tooth that has persistent apical periodontitis may remain in asymptomatic function for an extended period of time, a state that has been referred to as functional retention of the tooth.[66] If the patient's goal of treatment is not necessarily complete healing of the tooth, but simply to retain it in function and without pain, then regular evaluation by the clinician is warranted. If signs and symptoms of worsening infection such as progressive enlargement of a periapical

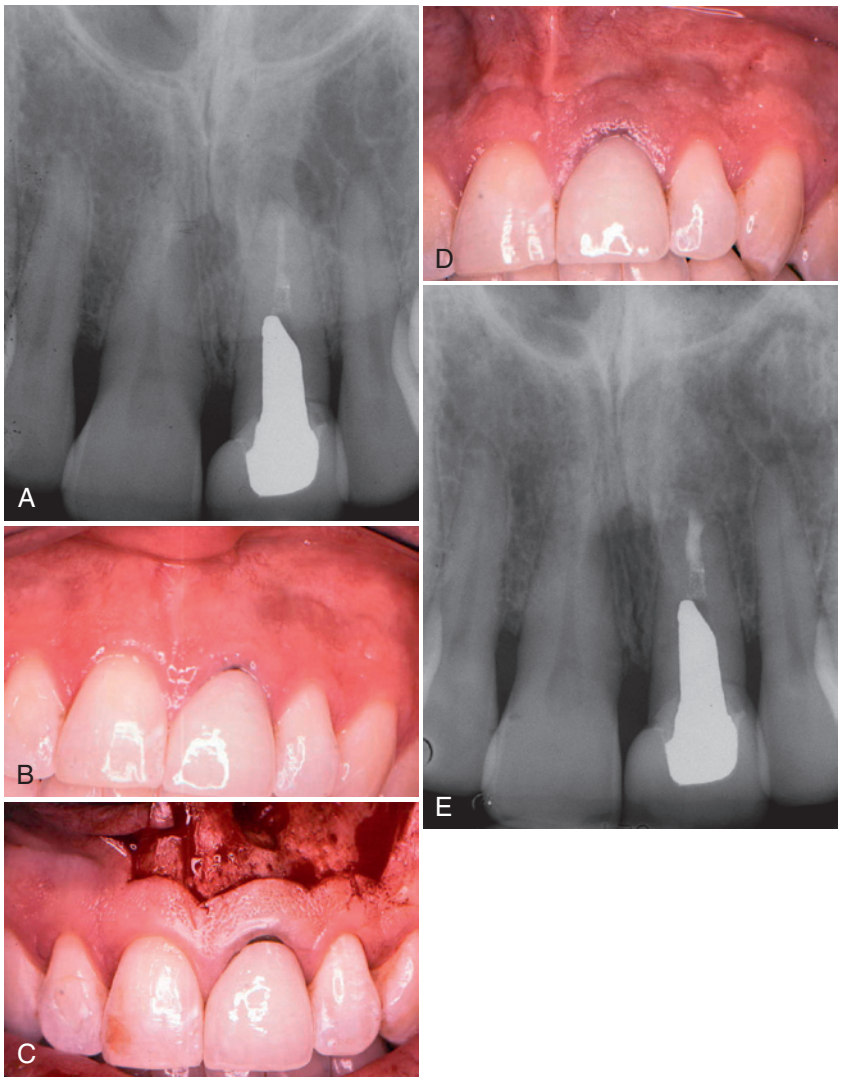

FIG. 8-83 A and B, Preoperative images showing posttreatment disease in the upper left central incisor and a large custom cast post. The patient elected to leave the post and perform surgery rather than risk damage to his new crown. C, Submarginal rectangular flap design. D, The 3-week follow-up showing excellent soft tissue healing. E, The 18-month follow-up showing excellent healing of the periradicular tissues.

radiolucency, pain, periodontal pocket formation, or sinus tract eruption occur, then further treatment may be needed. However, many teeth classified early on as uncertain healing may indeed be retained for many years.[157]

Endodontic surgery (Fig. 8-83) is a very predictable procedure[66,89] that can be performed on most teeth; however, there are some anatomic and medical concerns regarding treatment planning for this procedure, which are covered in detail in another chapter. Extraction-replantation (Fig. 8-84), also referred to as intentional replantation,[170] is another treatment option. This involves extraction of the tooth and performing the apicoectomy and root-end filling while the tooth is out of the patient's mouth, followed by replantation and splinting if indicated. This procedure is also discussed in detail in Chapter 9. Extraction and replacement should be the treatment of last resort to be selected only when the tooth has been shown to be nonrepairable. If the decision is made to extract the tooth, usually replacement will be necessary to prevent shifting of the dentition with its attendant problems. Replacement can be with an implant, a fixed partial denture, or a removable partial denture.

SUMMARY

Posttreatment endodontic disease does not preclude saving the involved tooth. In fact, the majority of these teeth can be returned to health and long-term function by current retreatment procedures. In most instances the retreatment option provides the greatest advantage to the patient because there is no replacement that functions as well as a natural tooth. Armed with the information in the preceding section, appropriate armamentaria, and the desire to do what is best for the patient, the clinician will provide the foundation for long-term restorative success.

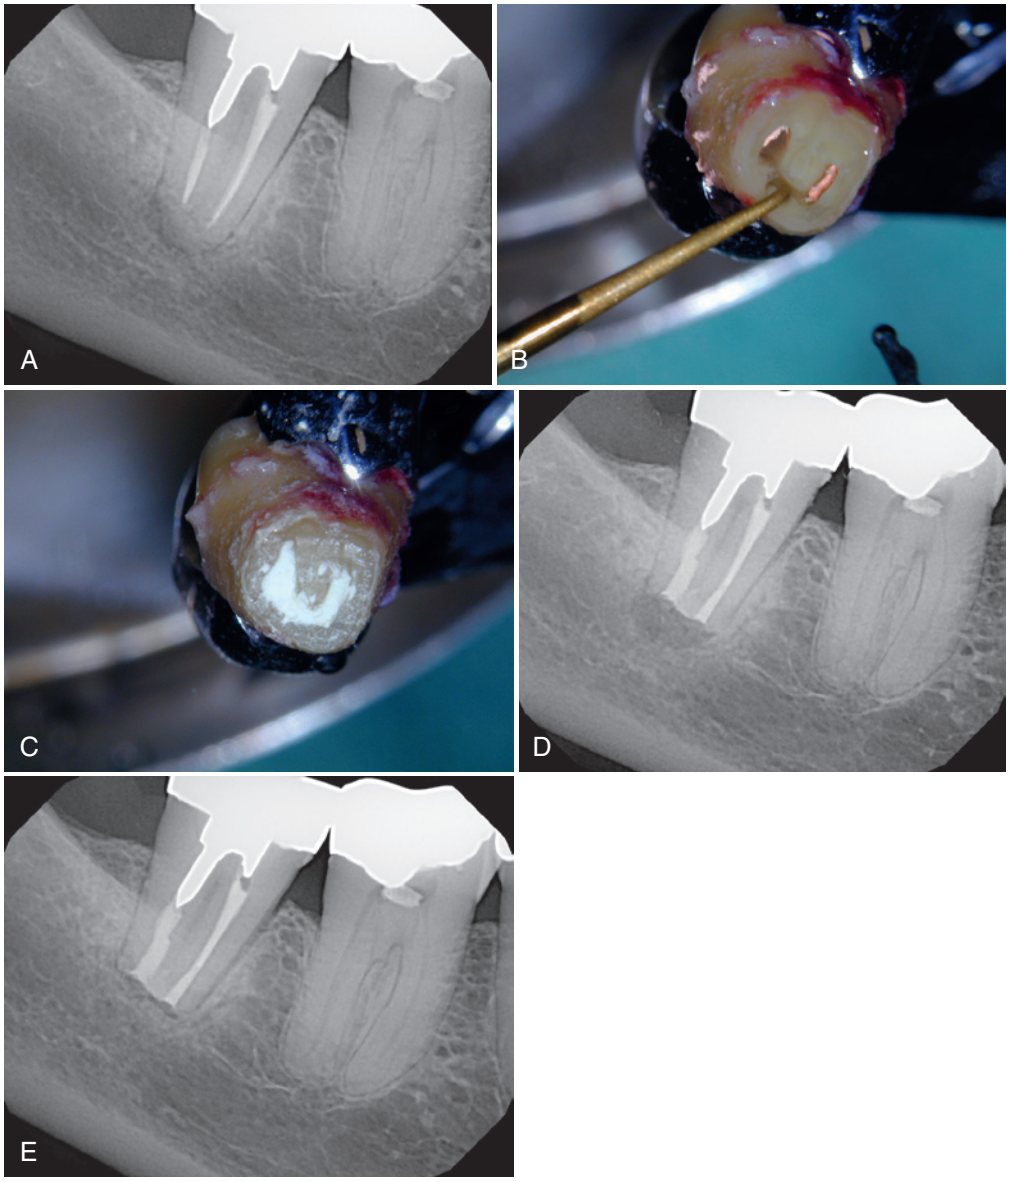

FIG. 8-84 **A,** This lower second molar became symptomatic many years after nonsurgical treatment. Nonsurgical retreatment had a guarded prognosis due to the large multiroot cast custom post and core. Surgery was precluded by the poor access and proximity of the inferior alveolar canal. **B,** Ultrasonic root end preparation is made in the extracted tooth. **C,** A white MTA retrograde filling was placed. Note the C-shape. **D,** Immediate postimplantation radiograph. **E,** The 7-month reevaluation showing apical healing. The patient was asymptomatic.

Management of Surgical Complications
Summary

*The authors would like to acknowledge the contributions of David Witherspoon for his involvement with previous editions.

Although nonsurgical endodontic treatment is a highly predictable option in most cases, surgery may be indicated for teeth with persistent periradicular pathoses that have not responded to nonsurgical approaches. Surgical root canal therapy, including root-end resection, has been practiced since at least the mid-1800s.[211] In 1906, Schamberg[473] described using radiographs to assist diagnosis and the use of surgical burs to perform a rapid osteotomy and root-end "ablation."

Perhaps the single most important development in dental practice in the early 20th century was the introduction of safe, effective local anesthesia, which allowed for more meticulous and comfortable surgical treatment. Formal recognition of endodontics as a specialty in 1963 ushered in a new era of basic and clinical research focused on the prevention and treatment of pulpal and periradicular pathosis.

Since the 1990s, periradicular surgery has continued to evolve into a precise, biologically based adjunct to nonsurgical root canal therapy. The parallel development of new instruments and materials, along with a better understanding of the biology of wound healing, has made surgical treatment a viable alternative to extraction and tooth replacement, rather than a treatment of last resort.

Periradicular surgery, when indicated, should be considered an extension of nonsurgical treatment, because the underlying etiology of the disease process and the objectives of treatment are the same: prevention or elimination of apical periodontitis. Surgical root canal treatment should not be considered as somehow separate from nonsurgical treatment, although the instruments and techniques are obviously quite different. Surgical treatment accounts for about 3% to 10% of the typical endodontic specialty practice.[1,75,374] A web-based survey found that 91% of active endodontists perform some type of root-end surgery, and almost all are using a dental operating microscope and ultrasonics.[115] Endodontists perform almost 78% of surgical root canal treatments; general dentists and other specialists perform 15.5% and 6.6%, respectively.[242] Although appropriately trained general dentists and other dental specialists may perform periradicular surgery, individuals with advanced training in endodontics have developed most of the current periradicular surgery techniques and science presented in this chapter. We believe that endodontists must continue to include periradicular surgery as a routine part of clinical endodontic practice and not abrogate this treatment option to others, who may not possess the same background, skills, or values.[343,424,439] When patient preferences and quality of life measures are considered, patients can be expected to place high value on endodontic treatment and the retention of a natural tooth.[153,180]

INDICATIONS FOR PERIRADICULAR SURGERY

Etiology of Persistent Periradicular Disease

The first and arguably most important step in treatment decision making is attempting to determine the cause of persistent periradicular disease. Treatment then is directed at eliminating the etiology, which most often is the presence of bacteria and other microbial irritants in the root canal space.[492] Nonsurgical retreatment, when possible, often is the first choice for attempting to correct obvious deficiencies in the previous treatment (see Chapter 8).[564] However, microorganisms can survive even in apparently well-treated teeth in dentinal tubules, canal irregularities, deltas, and isthmus areas.[275,307,568] If residual microorganisms remain completely entombed in the root canal system, periradicular healing should occur. Sealing off all potential routes of microbial escape from the root canal system is the goal of both nonsurgical and surgical treatment. When microorganisms of sufficient pathogenicity and number gain access to the periradicular tissues, pathosis develops.

Enterococcus faecalis is commonly isolated from failing root canal–treated teeth and is known to be especially difficult to eliminate with standard instrumentation and irrigation techniques.[510] Unlike primary endodontic infections, which predominantly are associated with mixed anaerobic microbiota, it has been commonly accepted that treatment failures are more frequently associated with one or two microorganisms.[492] However, research using more sophisticated techniques (16S ribosomal RNA gene clone library analysis) has determined that multiple, previously uncultivated phylotypes can be identified in the majority of teeth with persistent apical periodontitis.[464] Fungi and viruses have also emerged as potential causes of root canal failure and may play either a primary or secondary role in persistent periradicular pathosis.[369,399,462,575]

Established extraradicular colonies of microorganisms also may be a reason for failure of some teeth to respond to nonsurgical treatment. When microorganisms are able to arrange in an extraradicular biofilm, they may be particularly resistant to elimination by host defense mechanisms and antimicrobial agents.[490] Persistent extraradicular root surface colonization cannot be diagnosed by noninvasive methods but may be suspected in well-treated cases that are refractory to nonsurgical treatment.[166,218,465,495,511] Although the presence of extraradicular microbial colonies has been somewhat controversial, studies using DNA-DNA hybridization techniques have confirmed the persistence of microorganisms in the periradicular tissues of some root canal–treated teeth.[187,509]

Overextended filling materials may contribute to treatment failure, presumably as a result of a chronic inflammatory response.[369] Although this is possible and even likely with certain toxic materials (e.g., pastes containing formaldehyde[376]), the role of relatively inert materials such as gutta-percha and set sealer is less clear, and these materials probably become a significant contributing factor only if microorganisms are present. If the root apex is close to the buccal cortical plate, apical fenestration may occur, leading to persistent symptoms, especially tenderness to palpation over the root apex.[72] Some have suggested that overextension of filling materials may contribute to endodontic failure because certain dental materials may induce periodontal ligament (PDL) cell apoptosis.[467] This specific interaction between filling materials and periradicular tissues is not fully understood and deserves further research. The poorer prognosis often reported with overextended root canal fillings also may be related simply to lack of an adequate apical seal and subsequent egress of microorganisms from the root canal space. Regardless, minor overextension of filling material is rarely a sole indication for surgery except when symptoms or periradicular pathosis develops. Significant overextension of filling material, especially when important anatomic areas and possibly toxic materials are involved, is an indication for referral to an endodontist or oral surgeon for evaluation and, possibly, treatment.

The presence of periradicular cholesterol crystals may interfere with healing after nonsurgical root canal treatment.[365]

Although relatively uncommon, true periradicular cysts (completely enclosed, epithelium-lined cavities) may not be expected to resolve after nonsurgical treatment.[364] As with other extraradicular causes of failure, surgery is indicated, because definitive diagnosis and treatment require an excisional biopsy and removal of the periradicular tissue.

Vertical root fractures are a significant cause of failure and may be difficult to diagnose in the early stages.[90] Exploratory surgery often is required to confirm a root fracture. Cone-beam computed tomography (CBCT) is a promising tool for noninvasive diagnosis of root fractures[155,165] and is discussed in greater detail later in this chapter and in Chapter 2. Although several promising approaches to the management of vertical root fractures have been proposed,[226,268,506] the prognosis generally is believed to be poor. Extraction usually is the treatment of choice, especially if appropriate tooth replacement options are available (see Chapter 21). Root amputation or hemisection may be considered in a multirooted tooth if the remaining tooth structure is uninvolved and sufficient periodontal support is present.

The relationship between systemic disease and periradicular healing is not completely understood. The possible influence of certain systemic medications on wound healing is discussed later in the chapter. Compromised host healing capacity may be a contributing factor in delayed healing and failure of some root canal–treated teeth. For example, complete healing after nonsurgical root canal treatment is less likely in diabetic patients with preoperative periradicular pathosis.[78,175] Patients undergoing immunosuppressive therapy may be at greater risk for delayed healing, treatment failure, or acute exacerbation of a subclinical infection, although two studies involving subgroups of immunocompromised patients (bone marrow transplant and acquired immunodeficiency syndrome [AIDS]) did not find these patients to be at higher risk for complications related to endodontic treatment.[197,406]

Rationale for Surgical Treatment

Although nonsurgical retreatment generally is believed to be the preferred first approach in the management of persistent apical periodontitis,[77,492,510,564] periradicular surgery is indicated when nonsurgical retreatment is impractical or unlikely to improve on the previous result (see Chapter 8). In particular, a surgical approach may be the first choice for managing teeth with long posts or irretrievable separated instruments, nonnegotiable ledges and canal blockages or transportation, hard cement filling materials, failure of previous nonsurgical retreatment, and suspected vertical root fracture, or when a biopsy is indicated (Figs. 9-1 to 9-4). Even when surgical treatment is the likely definitive approach, nonsurgical therapy before the procedure may be recommended to help reduce the number of microorganisms in the root canal system and ensure a more favorable long-term prognosis.[230] On the other hand, surgery may be the first choice even if a tooth can be treated nonsurgically if the risks and costs of retreatment are considered excessive. For example, disassembling a recently restored bridge abutment tooth to allow endodontic retreatment may be technically possible but not economically feasible. One study found that endodontic microsurgery may be the most cost-effective option for management of persistent periapical disease, compared to nonsurgical retreatment, extraction and placement of a fixed partial denture, and extraction and placement of a single tooth implant.[284] Case-specific variables and clinical judgment are key elements in the decision-making process, as current evidence supports the contention that the prognosis for surgical treatment is approximately the same as that for nonsurgical retreatment.[127,128,135,293,468,577]

FIG. 9-1 Previously treated maxillary lateral incisor with persistent periradicular disease. Nonsurgical retreatment is possible but would involve disassembly of an otherwise adequate coronal restoration. Periradicular surgery is a reasonable option.

Clinical Decision Making

Clinical decision making is a process that combines the best available evidence, clinical judgment, and patient preferences. Treatment choices are always made under conditions of at least some uncertainty. Surgical root canal treatment rarely is the only possible choice. Clinicians and patients must weigh the relative benefits, risks, and costs of two or more acceptable alternatives. Patients and clinicians can be expected to hold different attitudes about the value of potential treatment outcomes.[269] In a prognosis study of single-tooth dental implants, Gibbard and Zarb[193] reported that factors considered significant by health care professionals may not be important to patients. Even among groups of dentists and dental specialists, the threshold for treatment varies widely and treatment recommendations may depend more on personal values and experience than objective analysis of treatment costs, prognosis, risks, and alternatives.[56,343,439]

Shared decision making, in which the patient and clinician consider outcome probabilities and patient preferences and agree on the appropriate treatment, is preferable to a clinician-directed treatment decision.[46,179] Such a two-way exchange allows the clinician to provide the best available current evidence and case-specific clinical judgment while encouraging a decision that considers the patient's personal values and preferences. This decision-making model has been shown to increase patient knowledge about and satisfaction with the treatment choice.[262,386,387] In general, most patients prefer to be actively involved in the decision-making process but want to leave the specifics of the treatment to the clinician.[179] That is, the risks,

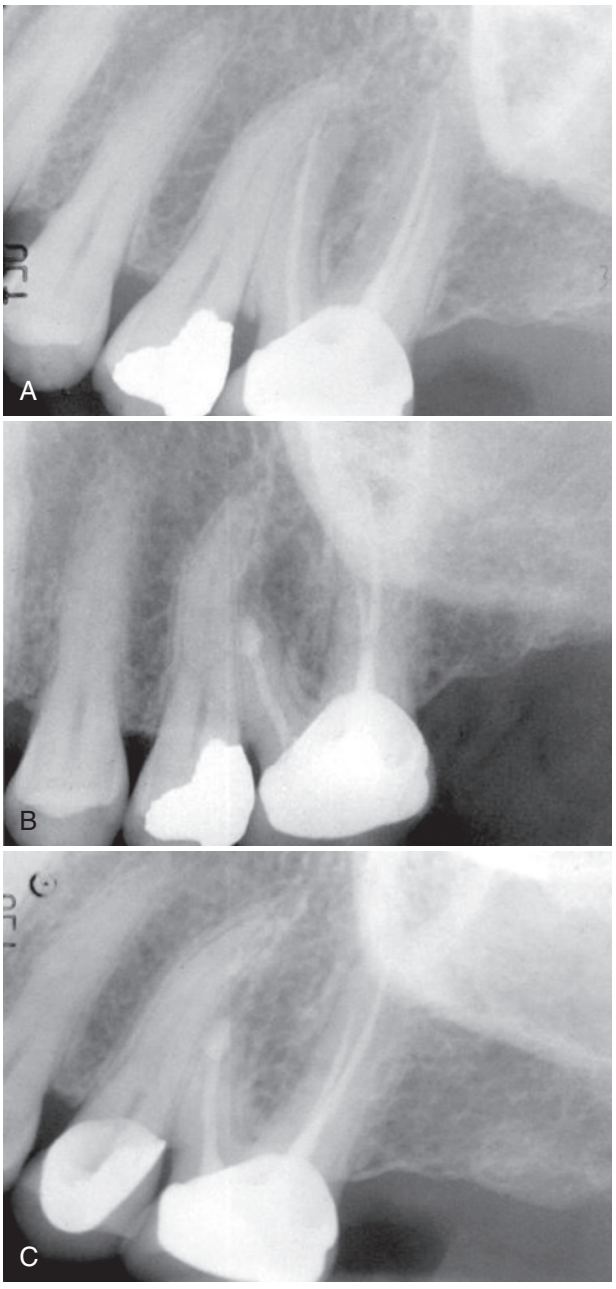

FIG. 9-2 A, Previously treated maxillary first molar with persistent periradicular disease and obvious transportation of the main mesiobuccal (MB-1) canal. Nonsurgical retreatment is unlikely to correct this iatrogenic condition, and surgery is the preferred choice. B, Immediate postsurgery radiograph. The root-end preparation and fill was extended from the MB-1 canal in a palatal direction to include the isthmus area and the second (MB-2) canal. C, One-year follow-up examination: the tooth is asymptomatic, and periradicular healing is apparent radiographically. Although surgery was the first-choice treatment in this case and the outcome was favorable, a good argument could be made for nonsurgical retreatment before surgery to ensure disinfection of the canal and to attempt to locate a MB-2 canal.

benefits, and costs of treatment alternatives are important to patients, but the details of the procedure usually are not. Shared decision making is particularly relevant in light of the current trend in some areas to recommend implants as an alternative to root canal treatment.

Comparative probabilities for a successful outcome after surgical root canal treatment, nonsurgical retreatment, or extraction and replacement with a fixed prosthesis or implant are difficult to project. Many treatment variables are complex and not easily quantified, such as the affected location in the mouth, bone quality, practitioner's skill, possible influence of systemic disease on healing, periodontal support, bulk of the remaining tooth structure and resistance to fracture, quality of the coronal restoration, patient susceptibility to recurrent caries, materials used, and other factors. In addition, the definition of success varies considerably and is inconsistent from study to study.

Boioli and colleagues[66] performed a meta-analysis of implant studies and reported a 93% survival rate at 5 years. The 5- to 10-year success rate for implant retention routinely is reported to be 90% to 97%, depending on the location in the mouth and other variables.[302,309] Surgical root canal treatment was previously reported to have a lower success rate than implant placement.[230,546] However, most of these older studies would be considered weak by today's evidence-based standards and, more important, do not reflect the use of many of the newer surgical materials and techniques. With careful case selection, surgical skill, and the use of materials and techniques described later in this chapter, many studies have demonstrated success rates over 90% for surgical root canal treatment.[326,448,500,501,546,609] von Arx reported that the 5-year success for teeth receiving endodontic microsurgery was 8% less than observed at 1 year.[566] A similar study found an 85% success rate after 10 years.[500] A systematic review and meta-analysis comparing traditional root-end surgery to modern endodontic microsurgery (ultrasonic root-end preparation; root-end filling with IRM, Super EBA, or MTA; and high power [> ×10] magnification and illumination) found that the outcome for endodontic microsurgery using current materials and techniques was 94%, compared to 59% success with traditional root-end surgery.[483]

In broad terms and under ideal conditions, the prognoses for nonsurgical retreatment, surgical treatment, and implant placement should be roughly equal. The choice of treatment should be based on the best available evidence, case-specific clinical judgment, and the patient's preferences. As a stronger evidence base continues to develop, we predict that algorithms encompassing multiple patient and treatment variables will be devised to assist clinical decision making.

GENERAL BIOLOGIC PRINCIPLES OF WOUND HEALING

Wound healing varies from region to region in the body and depends on several factors, including the type of tissue, the type of wound, and the type of healing. In periradicular surgery, the tissues include free and attached gingiva, the alveolar mucosa, periosteum, bone, the periodontal ligament, and cementum. The wound may be intentional surgical trauma, which includes incision, blunt dissection, and excision (surgical), or pathologic or traumatic wounds. Healing occurs by primary or secondary intention.[212]

An incisional blunt dissectional wound, for example, can be considered to heal typically by primary intention, whereas a dissectional wound involving the resected root surface and osseous crypt heals by secondary intention. An important concept of the wound healing process in general is the difference between regeneration and repair. The goal of all surgical

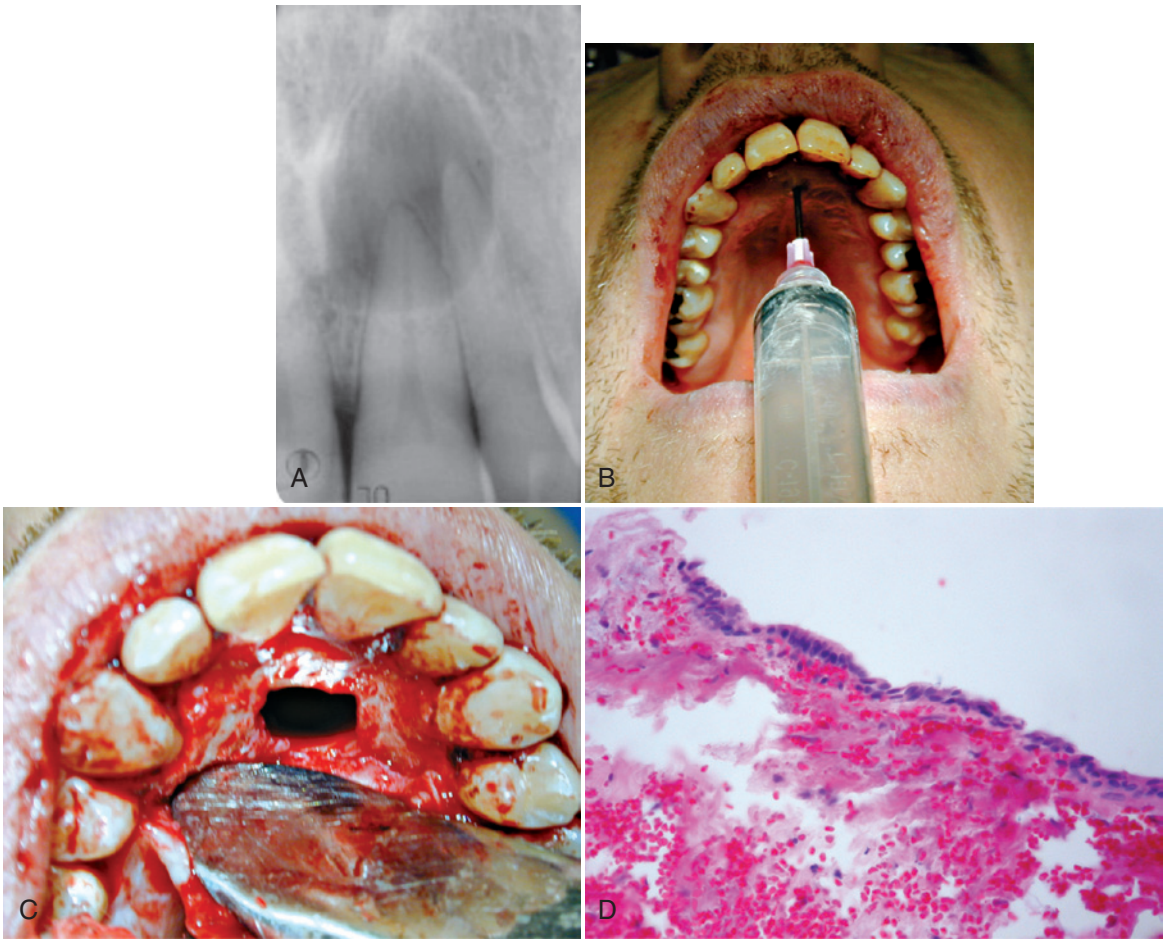

FIG. 9-3 A, Indication for surgery (biopsy): large radiolucent lesion in the area of the maxillary left central and lateral incisors was detected on routine radiographic examination. All anterior teeth responded within normal limits to pulp vitality testing. B, After administration of a local anesthetic but before surgery, the lesion was aspirated with a large-gauge needle to rule out a vascular lesion. C, Buccal and palatal flaps were reflected. The lesion was directly accessible from the palate. An excisional biopsy was performed, and the sample was submitted for evaluation. D, Light microscopic section of the biopsy specimen; the lesion was diagnosed as a nasopalatine duct cyst. (×400.) (Courtesy Dr. Vince Penesis.)

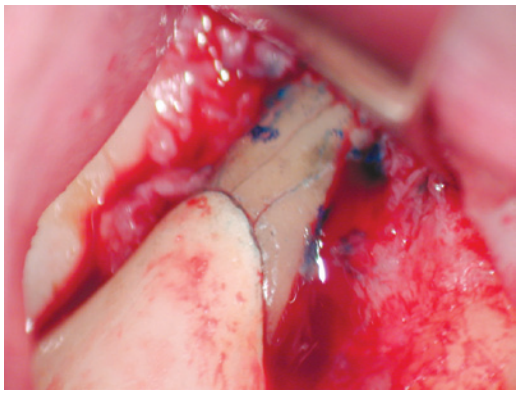

FIG. 9-4 Exploratory surgery was indicated to rule out or confirm a root fracture. Magnification and staining with methylene blue dye confirmed the presence of multiple root fractures. The tooth was subsequently extracted. (Courtesy Dr. Martin Rogers.)

procedures should be *regeneration,* which returns the tissues to their normal microarchitecture and function, rather than *repair,* a healing outcome in which tissues do not return to normal architecture and function. Repair typically results in the formation of scar tissue.

The wounding process varies, depending on the types of tissue and injury. However, all wounds progress through three broad, overlapping phases in the process of healing; these are the inflammatory phase, the proliferative phase, and the maturation phase.[240,570] Although these phases can be identified in healing tissue, none of them has a clear beginning or end. Furthermore, in a wound such as an endodontic surgical site, which involves more than one tissue type, these phases progress at different rates in each type of tissue.

SOFT-TISSUE WOUND HEALING

Inflammatory Phase

Broadly speaking, the inflammatory phase of healing is similar for all tissues.[543] This phase can be broken down further into clot formation, early inflammation, and late inflammation.

Clot Formation

Clot formation begins with three events: (1) blood vessel contraction is initiated by platelet degranulation of serotonin, which acts on the endothelial cell and increases the permeability of the vessel, allowing a protein-rich exudate to enter the wound site; (2) a plug composed of platelets forms, primarily through intravascular platelet aggregation; (3) both the extrinsic and intrinsic clotting mechanisms are activated. Several other events occur simultaneously, including activation of the kinin, complement, and fibrinolytic systems and the generation of plasmin.[34,247,521] These events stabilize hemostasis, begin the production of a number of mitogens and chemoattractants, and initiate the process of wound decontamination. The result is a coagulum consisting of widely spaced, haphazardly arranged fibrin strands with serum exudate, erythrocytes, tissue debris, and inflammatory cells. Compression of the surgical flap with sterile iced gauze immediately after surgery is designed to minimize the thickness of the fibrin clot and thereby accelerate optimal wound healing.

Early Inflammation: Polymorphonuclear Neutrophil (PMN) Organization

As a result of production of chemoattractants by the various components of the clot, polymorphonuclear neutrophils (PMNs) begin to enter the wound site within 6 hours of clot stabilization. The number of PMNs increases steadily, peaking at about 24 to 48 hours after the injury. Three key steps mark PMN migration into the wound site: (1) *pavementing,* in which the red blood cells undertake intravascular agglutination, allowing the PMNs to adhere to the endothelial cells; (2) *emigration,* in which the PMNs actively pass through the vascular wall; and (3) *migration,* in which the PMNs use ameboid motion, under the influence of the various chemotactic mediators, to move into the injured tissues.[212]

The principal role of the PMNs is wound decontamination by means of phagocytosis of bacteria. The high number of PMNs in the wound site is relatively short lived; the number drops rapidly after the third day.

Late Inflammation: Macrophage Organization

About the time the PMN population is declining (48 to 96 hours after injury), macrophages begin to enter the wound site. They reach a peak concentration by approximately the third or fourth day. These cells, which are derived from circulating monocytes, leave the bloodstream under the influence of the chemoattractants in the wound site. The monocytes subsequently evolve into macrophages. Macrophages have a much longer life span than PMNs; they remain in the wound until healing is complete. Similar to PMNs, macrophages play a major role in wound decontamination through phagocytosis and digestion of microorganisms and tissue debris.

Macrophages are considerably more bioactive than PMNs and can secrete a vast array of cytokines. A key action of many of these bioactive substances is initiation of the proliferative phase of wound healing, which is accomplished by prompting the formation of granulation tissue. Two other major functions of macrophages are ingestion and processing of antigens for presentation to T lymphocytes, which enter the wound after the macrophages. Unlike PMNs, macrophages play an essential role in the regulation of wound healing.[109,224] A reduction in the number of macrophages in the wound site delays healing, because the wound does not progress to the next phase. For example, the age-related reduction in healing potential appears to be partly the result of loss of estrogen regulation of macrophages in healing tissues.[33]

Proliferative Phase

The proliferative phase is characterized by the formation of granulation tissue in the wound. Two key cell types, fibroblasts and endothelial cells, have a primary role in the formation of granulation tissue. Granulation tissue is a fragile structure composed of an extracellular matrix of fibrin, fibronectin, glycosaminoglycans, proliferating endothelial cells, new capillaries, and fibroblasts mixed with inflammatory macrophages and lymphocytes. Epithelial cells also are active during this phase of soft-tissue healing and are responsible for initial wound closure. Guided tissue regeneration (GTR) procedures are based on control of the epithelial cell growth rate during this phase.

Fibroblasts: Fibroplasia

Undifferentiated mesenchymal stem cells in the perivascular tissue and fibroblasts in the adjacent connective tissue migrate into the wound site on the third day after injury and achieve their peak numbers by approximately the seventh day. This action is stimulated by a combination of cytokines (e.g., fibroblast growth factor [FGF], insulin-like growth factor–1 [IGF-1], and 2-15 platelet-derived growth factor [PDGF]), which are produced initially by platelets and subsequently by macrophages and lymphocytes. As the number of macrophages declines and the fibroblast population increases, the tissue in the wound transforms from a *granulomatous* tissue to a *granulation* tissue.

Fibroblasts are the crucial reconstructive cell in the progression of wound healing, because they produce most of the structural proteins forming the extracellular matrix (e.g., collagen). Collagen is first detected in the wound about the third day after injury. The fibroblasts produce type III collagen initially and then, as the wound matures, type I collagen. As this network of collagen fibers is laid down, endothelial and smooth muscle cells begin to migrate into the wound. Subsequently, as wound healing progresses, the collagen fibers become organized by cross-linking. Regularly aligned bundles of collagen begin to orient so as to resist stress in the healing wound.[108,286,413,516]

A focused type of fibroblast, known as a *myofibroblast,* plays a significant role in wound contraction, particularly in incisional-type wounds.[316,524] Myofibroblasts align themselves parallel with the wound surface and then contract, drawing the wound edges together. These cells are eliminated by apoptosis after wound closure.[137,138]

Endothelial Cells: Angiogenesis

Capillary buds originate from the vessels at the periphery of the wound and extend into the wound proper. This occurs concurrently with fibroblast proliferation and can begin as early as 48 to 72 hours after injury. Without angiogenesis, the wound would not have the blood supply needed for further active healing. The capillary sprouts eventually join to form a network of capillary loops *(capillary plexuses)* throughout the wound.

In addition to a low oxygen concentration in the wound proper,[198,289] several factors have been identified as potent stimulators of angiogenesis, including vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), acidic FGF (aFGF), transforming growth factor–alpha

(TGF-alpha) and transforming growth factor–beta (TGF-beta), epidermal growth factor (EGF), interleukin-1 (IL-1), and tumor necrosis factor–alpha (TNF-alpha),[145] as well as lactic acid.[248,258,503] All of these have been shown to stimulate new vessel development.

Epithelium

The first step in epithelial healing is the formation of an epithelial seal on the surface of the fibrin clot. This process begins at the edge of the wound, where the basal and suprabasal prickle cells rapidly undergo mitosis. The cells then migrate across the fibrin clot at a remarkable rate (0.5 to 1 mm per day). This monolayer of epithelial cells continues to migrate by contact guidance along the fibrin scaffold of the clot below. Migration stops as a result of contact inhibition of the epithelial cells from the opposing wound edge. Once the epithelium from both sides of the wound is in contact, an epithelial seal is achieved. In wounds healing by primary intention, formation of an epithelial seal typically takes 21 to 28 hours after reapproximation of the wound margins.[222]

Maturation Phase

Under ideal conditions, maturation of the wound begins 5 to 7 days after injury. A reduction in fibroblasts, vascular channels, and extracellular fluids marks the transition to this phase of healing. During the early stages of wound maturation, the wound matrix is chiefly composed of fibronectin and hyaluronic acid. As the tensile strength of the wound increases, significant upregulation of collagen fibrogenesis occurs. Collagen remodeling ensues, with the formation of larger collagen bundles and alteration of intermolecular cross-linking. The result is a conversion of granulation tissue to fibrous connective tissue and a decreased parallelism of collagen to the plane of the wound. Aggregated collagen fibril bundles increase the tensile strength of the wound. As healing progresses in the wound, the collagen gradually reorganizes; this requires degradation and reaggregation of the collagen. The degradation of collagen is controlled by a variety of collagenase enzymes. Remodeling results in a gradual reduction in the cellularity and vascularity of the reparative tissue; the degree to which this occurs determines the extent of scar tissue formation. Active remodeling of scar tissue can continue very slowly for life.[138,247]

Maturation of the epithelial layer quickly follows formation of the epithelial seal. The monolayer of cells forming the epithelial seal differentiates and undergoes mitosis and maturation to form a definitive layer of stratified squamous epithelium. In this way an epithelial barrier is formed that protects the underlying wound from further invasion by oral microbes. The epithelial barrier typically forms by 36 to 42 hours after suturing of the wound and is characterized by a significant increase in wound strength.[222]

HARD-TISSUE HEALING: EXCISIONAL DENTOALVEOLAR WOUND

The inflammatory and proliferative phases of healing for hard tissue are similar to those for soft tissue. A clot forms in the bony crypt, and an inflammatory process ensues that involves PMNs initially and macrophages subsequently. This is followed by the formation of granulation tissue with an angiogenic component. However, the maturation phase of hard-tissue healing differs markedly from that for soft tissues, primarily because of the tissues involved: cortical bone, cancellous bone, alveolar bone proper, endosteum, periodontal ligament, cementum, dentin, and inner mucoperiosteal tissue.

Osteoblasts: Osteogenesis

The healing of an excisional osseous wound that is approximately 1 cm in diameter is similar to that of a fractured long bone. It progresses from hematoma to inflammation, eradication of nonvital debris, proliferation of granulation tissue, callus formation, conversion of woven bone to lamellar bone and, finally, remodeling of the united bone ends. The coagulum that initially forms delays healing and must be removed to allow wound healing to progress.

A major difference between soft- and hard-tissue wound healing is found in the role of the osteoclast. Functionally, osteoclasts act as organizational units to debride necrotic bone from the wound margin, much as macrophages remove tissue debris from the clot. Granulation tissue begins to proliferate from the severed periodontal ligament by 2 to 4 days after root-end resection.[223] This tissue rapidly encapsulates the root end. Simultaneously, endosteal proliferation into the coagulum occurs from the deep surface of the bony wound edge. The coagulum in the bony crypt is quickly converted into a mass of granulation tissue. In addition to those already discussed, several cell types migrate into the coagulum, including osteoprogenitor cells, preosteoblasts, and osteoblasts. These cells begin the formation of woven bone within the mass of granulation tissue. New bone formation is apparent about 6 days after surgery.[223]

Bone formation can be categorized into two types, each having several phases. The phases differ, depending on which type of formation is involved. One type of bone formation is a matrix vesicle–based process, and the other type is based on osteoid secretion. In both processes, osteoblasts produce the bone matrix. They secrete a collagen-rich ground substance that is essential for mineralization. Osteoblasts also cause calcium and phosphorus to precipitate from the blood.

In the formation of woven bone, which occurs by the matrix vesicle–based process, osteoblasts produce matrix vesicles through exocytosis (the release of substances contained in a vesicle within a cell by a process in which the membrane surrounding the vesicle unites with the membrane forming the outer wall of the cell) of their plasma membranes. As hydroxyapatite crystals accrue in the vesicles, they become enlarged and eventually rupture. This process begins with the deposition and growth of hydroxyapatite crystals in the pore regions. The crystals then amalgamate to form structures known as *spherulites*. Union of the separate spherulites results in mineralization.

The formation of lamellar bone does not require the production of matrix vesicles; rather, it proceeds by the osteoblast secretion process. Osteoblasts secrete an organic matrix composed of longitudinally arranged collagen matrix fibrils (mainly type I collagen). Mineralization occurs by mineral deposition directly along the collagen fibrils.[239,240] This stage has been associated with a rise in pH, most likely because of the enzyme alkaline phosphatase, which is secreted by osteoblasts and other cells and plays an important role in mineralization. The exact role of alkaline phosphatase during mineralization is unclear. The balance of evidence favors a positive catalytic role.[19,20] Some hypothesize[71,70,552,553] that alkaline phosphatase promotes mineralization through a combination of mechanisms involving various cells, extracellular matrix proteins, and elements. The interaction of alkaline phosphatase and

phosphoproteins in both bone and dentin appears to be especially critical to the mineralization process.[71,72,557,558]

Inhibitor molecules, such as pyrophosphate and acidic noncollagenous bone proteins, regulate mineralization. Several growth factors also have been identified as key components in the production of osseous tissue. These include TGF-beta, bone morphogenetic protein (BMP), PDGF, FGF, and IGF.[97,191,476,513] One clinical study demonstrated that the addition of autologous platelet concentrate to the surgical site decreased postsurgical pain and may accelerate the healing process.[134]

Three to 4 weeks after surgery, an excisional osseous wound is 75% to 80% filled with trabeculae surrounded by intensely active osteoid and osteoblastic cells. A reforming periosteum can be seen on the outer surface of the wound; it is highly cellular and has more fibrous connective tissue oriented parallel to the plane of the former cortical plate. At 8 weeks after surgery, the trabeculae are larger and denser and the osteoblasts are less active; these cells occupy about 80% of the original wound. Also, fewer osteoid cells are associated with the maturing trabeculae. The overlying periosteum has reformed and is in contact with the newly developed bone. The osseous defect typically is filled with bone tissue by 16 weeks after surgery. However, the cortical plate has not yet totally reformed. Maturation and remodeling of the osseous tissue continues for several more months.[223]

Local healing is also influenced systemically by the endocrine system and its three general categories of hormones: polypeptide regulators (parathyroid hormone, calcitonin, insulin, and growth hormone), steroid hormones (vitamin D_3, glucocorticoids, and the sex hormones), and thyroid hormones.[219]

Cementoblasts: Cementogenesis

During regeneration of the periradicular tissues, cementum forms over the surface of surgically resected root ends.[114] The exact spatial and temporal sequences of events leading to this formation of new cementum remains undefined; however, cementogenesis is important, because cementum is relatively resistant to resorption (osteoclasts have little affinity for attaching to cementum).

Cementogenesis begins 10 to 12 days after root-end resection. Cementoblasts develop at the root periphery and proceed centrally toward the root canal.[24] Considerable evidence indicates that the cells that regulate cementogenesis are derived from ectomesenchymal cells in the tooth germ proper rather than from bone or other surrounding tissues. The migration and attachment of precementoblasts to the root surface dentin is monitored by mediators from within the dentin itself.[140,210] Cementum covers the resected root end in approximately 28 days. Newly formed PDL fibers show a functional realignment that involves reorientation of fibers perpendicular to the plane of the resected root end, extending from the newly formed cementum to the woven bone trabeculae. This occurs about 8 weeks after surgery.[212,319,320]

SYSTEMIC MEDICATIONS AND WOUND HEALING

Bisphosphonates

Bisphosphonates are commonly used for the treatment of osteopenia, osteoporosis, Paget's disease of bone, multiple myeloma, and metastatic bone, breast, and prostate cancer. The potential association between bisphosphonate use and osteonecrosis of the jaw was first reported in 2003.[332,351] The current preferred term for this condition is antiresorptive agent-induced osteonecrosis of the jaw (ARONJ)[229] or medication-related osteonecrosis of the jaw (MRONJ). The change in terminology reflects the finding that, in addition to bisphosphonates, other antiresorptive agents can increase the risk for osteonecrosis of the jaw (e.g., denosumab). ARONJ can occur spontaneously but is more commonly associated with dental procedures that involve bone trauma. Patient variables that increase the risk for ARONJ include age (over 65 years old), chronic use of corticosteroids, use of bisphosphonates for more than 2 years, smoking, diabetes, and obesity.[278,334,340,583] It is important to note that the risk for ARONJ with commonly prescribed oral bisphosphonates appears to be very low, whereas the overall benefits of this drug class for reducing morbidity and mortality related to hip, vertebral, and other bone fractures are significant.[229] The estimated incidence for ARONJ in patients taking oral bisphosphonates ranges from zero to 1 in 2260 cases, although dental extractions may quadruple the risk of developing ARONJ.[7,340] A reasonable upper estimate of the risk of developing ARONJ in a patient who does not have cancer is about 0.1%.[229] One clinical study reported a much higher 4% risk for developing ARONJ in patients taking a specific oral bisphosphonate (alendronate sodium),[479] although this was a retrospective study using an electronic patient record at a dental school and may not have adequately controlled for other relevant variables. The majority of ARONJ cases have been reported in patients taking IV bisphosphonates (e.g., zoledronic acid and pamidronate). According to one report, approximately 20% of patients taking IV bisphosphonates may develop ARONJ.[7,340] A systematic review found that there was a strong association between cancer and risk of ARONJ, with the prevalence ranging from 0.7% to 13.3%.[352] Interestingly, this same review found that the higher-quality studies reported the highest prevalence of ARONJ in cancer patients.

Conservative and timely management of apical periodontitis is essential to reduce the risk of ARONJ in patients taking bisphosphonates. Because periapical pathosis may exacerbate or increase the risk for ARONJ, the "no treatment" option is not a viable choice. The potential risk for ARONJ should be thoroughly discussed with all patients that are taking bisphosphonates, as well as treatment options. Nonsurgical retreatment should usually be considered the first choice, especially for patients with a history of IV bisphosphonate use or other risk factors. Even so, surgical treatment may be indicated to manage chronic or acute apical periodontitis. When the only viable treatment options for the management of persistent periradicular inflammation are surgical root canal therapy or extraction, the question of which option is more or less likely to lead to ARONJ in at-risk patients remains unanswered. In general, the procedure that could most predictably eliminate the periradicular inflammation with the least amount of surgical trauma would be preferred. Conservative surgical technique, primary tissue closure, and use of chlorhexidine mouth rinses preoperatively and during the healing stage are recommended.[229] There is some limited evidence to support the use of prophylactic antibiotics and chlorhexidine mouth rinse to decrease the risk of ARONJ for patients undergoing surgical dental treatment.[229] Because bisphosphonates have a substantial half-life when

incorporated into bone, discontinuation of bisphosphonates prior to dental treatment is unlikely to provide any measurable benefit and may place the patient at greater risk for complications that the drug is intended to prevent.

The possibility of predicting which patients may be at greater risk for ARONJ based on serum levels of C-terminal cross-linking telopeptide of type I collagen (CTX) has been suggested based on clinical observations.[333] This observation may provide a useful clue for future risk assessment but requires additional refinement and validation prior to widespread acceptance. In fact, one study found that although serum CTX levels were lower in patients taking bisphosphonates (as expected), there was no association between lower CTX levels and increased risk of ARONJ.[208] This same study found that patients taking a once-a-year dose of 5 mg zoledronic acid were at no greater risk for ARONJ than a control group (1 case in 5903 patients). Once ARONJ develops, treatment options are limited. A possible treatment strategy proposed in a series of case reports is the use of teriparatide, an anabolic drug that stimulates osteoblast formation and is used for the management of osteoporosis (see also Chapter 3).[505]

Glucocorticoids

Glucocorticoid therapy has been shown to induce rapid bone loss within the first 3 months of treatment. Even inhaled steroids have been implicated as a cause of bone loss. Bone formation is inhibited partly through a decrease in osteoblast life span and function, a reduction in the mineral apposition rate, and a prolonged mineralization lag time. Biochemical markers of bone formation (i.e., osteocalcin and bone-specific alkaline phosphatase) are suppressed. In addition to this primary suppressive effect, glucocorticoids cause accelerated bone resorption. The number and activity of osteoclasts increase during early glucocorticoid exposure. With continued use of glucocorticoids, the rapid rate of osteoclast-mediated bone resorption slows, but suppression of bone formation continues as the overriding skeletal activity.[272] Bone loss therefore is progressive, because bone resorption chronically exceeds bone formation.

The adverse effects of glucocorticoids on bone are mediated by sex steroid deficiency and expression of locally produced growth factors and related proteins, such as reduced production of IGF-1 and alterations in IGF-binding proteins in osteoblasts. The direct effect on calcium metabolism through alteration of vitamin D metabolism leads to a state of secondary hyperparathyroidism.[447,581,582]

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

Bone homeostasis is regulated by many factors, including prostaglandins (PGs).[267] PGs are important to both normal and pathologic bone turnover. PGs modulate osteoblast proliferation and differentiated functions.[426,427] The levels of prostaglandins E (PGE) and F (PGF) are elevated in the early phase of fracture healing, and administration of PGE_2 has increased the rate of osseous repair in several animal studies.[272] NSAID inhibition of the enzyme cyclooxygenase (COX), which is involved in the synthesis of PGs, is the same mechanism by which NSAIDs control pain. By inhibiting the COX enzymes and the subsequent production of prostaglandins, NSAIDs accomplish the desired anti-inflammatory effects—but also prevent the increased production of PGs required for bone healing. In vitro studies using animal models have shown that NSAIDs inhibit osteoblast proliferation and stimulate protein synthesis.[235] These drugs also have been shown to delay fracture healing and to affect bone formation adversely in animals and humans.[15,192] In one study, the use of NSAIDs reduced the amount of bony ingrowth into an orthopedic implant.[220]

In other studies, NSAIDs reduced bone resorption associated with experimentally induced periapical lesions,[18,390] and systemic NSAIDs may play a positive role in maintaining bone height around endosseous titanium dental implants.[257] Additional research is needed to clarify the specific influence of NSAIDs on healing after periradicular surgery.

Cyclooxygenase-2 (COX-2) Inhibitors

Although both COX-1 and COX-2 have been identified in osteoblasts, the different roles of the two cyclooxygenases in bone formation remain unclear. A study using COX-1 and COX-2 knockout mice compared the roles of the two enzymes in fracture healing. COX-2 was shown to have an essential role in both endochondral and intramembranous bone formation during wound healing. COX-2 knockout mice showed a persistent delay in cartilage tissue ossification. No difference in fracture healing was observed between the COX-1 knockout mice and the wild-type control used in this study.[603] Additional studies have shown a persistent delay in healing with COX-2 NSAIDs[202,203]; however, this difference in effect was not apparent clinically in a study examining the healing of spinal fusion wounds.[182]

PREOPERATIVE EVALUATION OF MEDICALLY COMPLEX PATIENTS

The preoperative assessment must take into account both the type of procedure planned and the type of patient (i.e., physical health and psychological status). Healthy patients clearly can be expected to tolerate surgical procedures better than medically complex patients (see Chapters 3 and 26). Clinicians should anticipate and prepare for the inevitability of treating more medically complex patients as the population ages. It is beyond the scope of this brief section to cover all possible medical considerations; rather, the most common issues that may require modification of an endodontic surgical treatment plan are presented. Relatively few absolute contraindications to periradicular surgery exist for patients well enough to seek care in an ambulatory dental office. Nonetheless, if any question arises about a patient's ability to tolerate a surgical procedure, medical consultation is advised. A thorough medical history and assessment of vital signs are required parts of the presurgical evaluation.

The American Society of Anesthesiologists (ASA) has developed a widely used system for establishing surgical risk. Patients categorized as ASA 1 are healthy and usually require no modification of the surgical treatment plan. Patients classified as ASA 4 or ASA 5 are not treated in a dental office; these individuals have significant medical problems that take priority over dental considerations. Patients considered ASA 2 or ASA 3 are commonly seen on an outpatient basis and may require medical consultation and modification of the surgical treatment plan. Patients in the ASA 2 and ASA 3 categories have mild to moderate systemic disease and often are undergoing treatment with one or more prescription medications. The ASA

classification system should only be used as a general guide because, when used alone, the ASA system is not a reliable predictor of operative risk.[201] In addition, even experienced anesthesiologists exhibit differences of opinion when using the ASA system to classify patients.[227,395] The patient's psychological status and anticipated procedural stress should be considered in addition to the ASA classification of physical health. A stress reduction protocol may be helpful for patients who report moderate dental anxiety with concurrent mild to moderate systemic disease (see Chapter 28).

Surgical procedures typically require a larger amount of local anesthetic with a vasoconstrictor than nonsurgical root canal treatment. An essential part of the presurgical evaluation is an assessment of the patient's cardiovascular status and tolerance for local anesthetics that contain epinephrine. In particular, patients with advanced cardiovascular disease, geriatric patients, and patients taking certain medications may have a reduced tolerance for local anesthetics containing a vasoconstrictor (see Chapters 3 and 4). Treatment-induced stress associated with surgical procedures can cause a significant increase in heart rate and systolic blood pressure when compared to nonsurgical root canal therapy.[189] The use of local anesthetics with vasoconstrictors was addressed in the seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7).[231] An updated version of this report (JNC 8) was issued in 2013. In patients with cardiovascular disease, 0.036 to 0.054 mg of epinephrine (approximately two to three cartridges of local anesthetic with 1:100,000 epinephrine) should be safe for most patients except those with severe cardiovascular disease or other specific risk factors.[38,231,594] Local anesthetics with vasoconstrictors should be avoided or used with extreme caution in patients with the following cardiovascular conditions: severe or poorly controlled hypertension, arrhythmias that are refractory to treatment, myocardial infarction within the past month, stroke within the past 6 months, coronary artery bypass graft within the past 3 months, and uncontrolled congestive heart failure.[311] Patients unable to tolerate vasoconstrictors may not be good candidates for periradicular surgery, because a local anesthetic with a vasoconstrictor is essential for obtaining adequate hemostasis and visibility during this type of procedure. Surgery can be performed using only local anesthetics without vasoconstrictors, but this is not recommended.

The potential for multiple drug interactions is increasing because of the aging population and the introduction of many new drugs. Many elderly patients have diminished liver and kidney function and therefore cannot metabolize and excrete drugs as efficiently as younger, healthy patients. The potential for drug interactions and decreased metabolism and excretion of drugs should be considered even for commonly used agents such as local anesthetics and analgesics.

A transient bacteremia is a virtual certainty with periradicular surgery; therefore, patients at high risk for bacterial endocarditis should receive appropriate antibiotic prophylaxis as recommended by the American Heart Association. New guidelines for prevention of infective endocarditis were published in 2007 and represent a significant change from previous American Heart Association guidelines.[588] For example, antibiotic prophylaxis is no longer recommended for patients with a history of mitral valve prolapse (with or without regurgitation), rheumatic heart disease, bicuspid valve disease, aortic stenosis, and certain congenital heart conditions. Antibiotic prophylaxis is now only recommended for patients with valvular disease associated with the highest risk of adverse outcomes from infective endocarditis. For patients in the highest risk category, antibiotic prophylaxis is recommended for dental procedures that involve manipulation of gingival tissues or the periapical region of teeth or perforation of the oral mucosa. For all other patients with valvular disease, the risks associated with routine antibiotic prophylaxis are greater than the potential benefits.[588] Although these guidelines represent the best available current evidence, practitioners should be aware that a recent study from England found a significant increase in cases of infective endocarditis after widespread adoption of the new guidelines in 2008. However, the authors point out that their data do not establish a causal relationship and recommend adherence to the current guidelines at this time (Dayer MJ, et al. Lancet 2014).

New clinical practice guidelines for the management of patients with prosthetic joints were co-developed by the American Association of Orthopaedic Surgeons and the American Dental Association in December 2012.[578] The working group conducted a systematic review and presented three recommendations. Recommendation 1 states that "the practitioner might consider discontinuing the practice of routinely prescribing prophylactic antibiotics for patients with hip and knee prosthetic joint implants undergoing dental procedures." The level of evidence to support this recommendation was classified as "limited," but that was the highest level of evidence assigned to any of the three recommendations. Two case-control studies provide evidence for this recommendation.[51,498] In recommendation 2, the group was unable to recommend for or against the use of topical antimicrobial agents (grade of recommendation = inconclusive). Recommendation 3 was a consensus recommendation to support the maintenance of appropriate oral hygiene (grade of recommendation = consensus). A recent American Dental Association Council on Scientific Affairs report added further clarification by concluding that: "In general, for patients with prosthetic joint implants, prophylactic antibiotics are not recommended prior to dental procedures to prevent prosthetic joint infection." (Sollecito TP, et al. JADA 2015).

Management of patients undergoing anticoagulant therapy depends on the type of anticoagulant, the reason for anticoagulant therapy, and the type of oral surgery planned. Warfarin (Coumadin), a commonly prescribed anticoagulant used to treat or prevent thromboembolisms, blocks the formation of prothrombin and other clotting factors. The international normalized ratio (INR) value is the accepted standard for measuring prothrombin time (PT). The desired therapeutic range for the INR usually is 2 to 3.5, depending on the underlying medical indication for anticoagulant therapy. Limited oral surgery procedures, such as simple forceps extraction of one to three teeth, may be performed safely on patients with INR values within the normal therapeutic range.[8,89,255,478] Periradicular surgery, however, may present a greater challenge for hemostasis, even for patients well maintained within the therapeutic range. The clear field visibility normally required for proper surgical management of the root end may not be possible in patients undergoing anticoagulant therapy. The patient's physician must be consulted for assistance in developing an appropriate treatment plan. Some patients may be able to tolerate discontinuation of warfarin therapy 2 days before a planned surgical procedure, which allows the INR to drift downward.

In a prospective cohort study, Russo and colleagues[461] reported that suspension of warfarin 2 days before a surgical procedure resulted in no bleeding problems and no thromboembolic events. They found that the average time spent at an INR below 2 (critical value) was 28 hours and that 90% of the patients returned to the desired therapeutic INR value within 7 days. However, this strategy may place certain patients at greater risk for a thromboembolic event; therefore, discontinuation of anticoagulant therapy would not be recommended.

In general, patients undergoing anticoagulant therapy should present minimal risk for significant bleeding during or after oral surgery, and local measures to control bleeding should be adequate.[88,569] In a review prepared for the American Dental Association Council on Scientific Affairs and Division of Science, Jeske and Suchko[260] recommended against routine discontinuation of anticoagulant therapy before dental procedures, including surgical procedures. Regardless of the management approach selected, consultation with the patient's physician and an INR test on the day of surgery are strongly recommended. A retrospective study of an urban dental school population found that INR values for 43% of patients taking warfarin were not within the recommended therapeutic range.[266] To underscore the challenge of maintaining anticoagulation levels within an appropriate therapeutic range, warfarin has been implicated in more emergency hospital admissions than any other medication.[83]

Hospitalization and conversion to heparin therapy may be considered in special cases, but the patient, physician, and surgeon must carefully weigh the potential risks against the expected outcome and benefits. A new category of heparin anticoagulant, low-molecular-weight heparins (LMWHs), allows patient self-administration and may be an alternative for patients who need to maintain a high level of anticoagulation but want to reduce the cost and time required for traditional heparin conversion therapy.

Novel oral anticoagulant drugs (NOACs) have recently emerged as an alternative to warfarin for most indications (e.g., previous stroke, atrial fibrillation, and deep vein thrombosis) *except* mechanical heart valves. Examples include: apixaban (Eliquis), dabigratran (Pradaxa), edoxaban (Lixiana), and rivaroxaban (Xarelto). NOACs have fewer interactions with foods and other drugs, and there is no need for routine blood work monitoring. However, although NOACs are known to prolong prothrombin time (PT) by inhibiting factor X to Xa conversion, there is currently no reliable test to accurately measure level of anticoagulation. Medical consultation may be indicated to help evaluate the relative benefits and risks of discontinuing NOAC drugs for one or two days prior to endodontic surgery.

Low-dose aspirin therapy is known to increase bleeding time by irreversibly inhibiting platelet aggregation. A common practice has been to advise patients to discontinue aspirin therapy for 7 to 10 days before oral surgery.[28] At low-dose therapeutic levels (less than 100 mg per day), aspirin may increase bleeding time and complicate surgical procedures. However, Ardekian and colleagues[28] concluded that low-dose aspirin therapy should *not* be discontinued before surgical procedures and that bleeding could be controlled by local measures. Higher-dose therapy may create a greater risk of bleeding during or after surgery.

Although a patient undergoing aspirin therapy may not be at high risk for significant bleeding during or after surgery, a concern in periradicular surgery is the visibility problems created by oozing blood. The clinician should consult the patient's physician about the medical reason for aspirin therapy and should weigh the risks and benefits of discontinuing aspirin before the proposed surgery. It should be possible to perform periradicular surgery without discontinuing aspirin therapy if necessary, but visibility during the procedure may be compromised, which may adversely affect the prognosis.

Herbs, dietary supplements, and vitamins can contribute to bleeding problems during surgery, and patients often fail to report use of these substances in the preoperative evaluation.[385] In a survey of surgical patients, approximately one third reported using a nonprescription medication that might inhibit coagulation or interact with anesthetics.[384] In particular, ginkgo biloba, ginger, garlic, ginseng, feverfew, and vitamin E inhibit platelet aggregation and can increase the risk of bleeding.[96] Ingredients in over-the-counter (OTC) weight loss products can potentiate the effect of epinephrine and increase cardiac stress, although the most obvious example of this phenomenon, ephedra, has been removed from the U.S. market by a Food and Drug Administration (FDA) order.

Patients with inherited or acquired bleeding disorders are also at risk for excessive bleeding during and after periradicular surgery. Impaired liver function associated with past or current alcohol or drug abuse may also predispose a patient to excessive bleeding during surgery. A thorough medical history and patient interview should help identify these patients and, in consultation with the patient's physician, allow for any necessary treatment modifications.

Many other medical conditions, such as recent myocardial infarction, stroke, cardiac arrhythmias, diabetes, radiation therapy for head and neck cancer, immunocompromising conditions, seizure disorders, adrenal suppression, liver or kidney disease, and pregnancy may require modification of the treatment plan. However, these conditions usually present more general problems that are not unique to a surgical procedure. The value of a thorough medical history and patient interview cannot be overemphasized.

ANATOMIC CONSIDERATIONS

Evaluating the access to the surgical site is one of the most important steps in case selection for periradicular surgery. Anatomic studies can provide some guidance, but individual variation is great, and there is no substitute for a complete clinical examination. A small oral opening, active facial muscles, shallow vestibule, and thick buccal alveolar bone all can significantly increase the difficulty of the procedure, even in cases that appear straightforward on radiographic examination.

Posterior Mandible

The primary anatomic structure of concern for periradicular surgery in the posterior mandible is the neurovascular bundle that courses through the mandibular canal and exits through the mental foramen. The relationship among the mandibular canal, the mental foramen, and the root apices of mandibular teeth has been well studied; however, anthropometric averages have limited value in the treatment of individual patients. An understanding of the typical anatomic relationships is important, but even more important is an evaluation of the individual patient to develop a case-specific risk assessment.

The depth of the vestibular fornix generally is a good predictor of the possible difficulty involved in obtaining surgical

FIG. 9-5 Lateral view of the skull showing the anterior nasal spine and the proximity of the maxillary anterior root apices to the floor of the nose *(red arrow),* as well as the typical location of the mental foramen *(black arrow).*

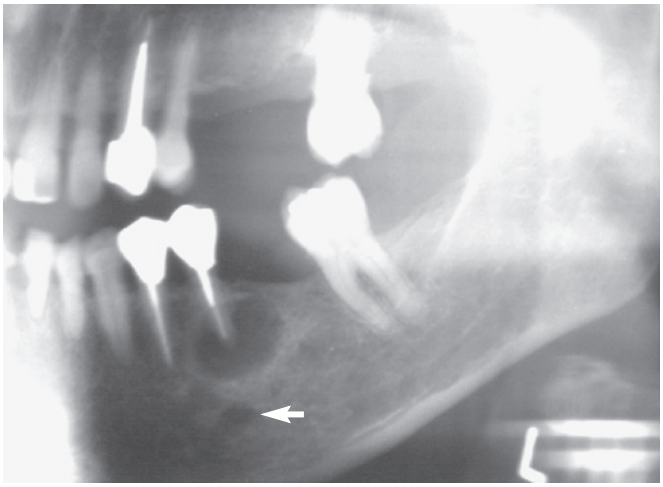

FIG. 9-6 Preoperative evaluation of a mandibular left second premolar included a panoramic radiograph to help locate the mental foramen *(white arrow),* which was not visible on a standard periapical radiograph.

access to the mandibular posterior teeth.[305] A shallow vestibule usually portends thicker alveolar bone and more difficult access to the root end.

The mental foramen, another key anatomic structure, usually is located between and apical to the mandibular first and second premolars[118,356]; however, this varies considerably, and the practitioner must examine each patient carefully to determine its location (Figs. 9-5 and 9-6). Vertical location of the mental foramen may vary even more than horizontal location. Moiseiwitsch[356] found that the average location was 16 mm inferior to the cementoenamel junction (CEJ) of the second premolar, although the range was 8 to 21 mm, which would place approximately 20% of the foramina at or coronal to the root apex. Fortunately, the mental foramen usually is easily visualized with standard periapical and panoramic radiographs. A vertically positioned periapical radiograph often may be more useful than a horizontally positioned one, especially in individuals with longer roots. Also, the mental foramen usually can be palpated.

When a vertical releasing incision is indicated, it typically is made at the mesial line angle of the mandibular canine. This location is always mesial to the mental foramen, because the foramen is located in the area ranging from the apex of the mandibular first premolar to slightly distal to the second premolar. The nerve bundle exits from the foramen in a distal direction. An alternative technique for gaining access to mandibular posterior teeth involves a distal releasing incision between the mandibular first and second molars.[355] This approach may be especially useful for access to the mandibular second premolar and first molar. Care must be taken to avoid the facial artery as it crosses the level of the inferior vestibular fornix near the mandibular first molar. Inadvertent contact with the facial artery is unlikely if the incision is not extended beyond the depth of the vestibule.

Regardless of the approach selected, it obviously is important to avoid making an incision in the immediate vicinity of the mental foramen. The mental nerve is encased in a relatively tough sheath, and permanent damage can be avoided if careful blunt dissection is used in the area. A misguided vertical releasing incision, however, may sever the nerve, causing permanent injury. Trauma to the nerve from blunt dissection in this area or from pressure from a misplaced retractor may cause temporary paresthesia but is much less likely to do permanent injury. (Documentation and management of nerve injuries are discussed later in the chapter.)

The borders of the mandibular canal often are more difficult to visualize with conventional radiographic techniques. A parallel periapical radiograph, either horizontally or vertically positioned, usually can provide a reasonably accurate image of the relationship between the superior border of the mandibular canal and the root apices. However, the mandibular canal sometimes cannot be readily visualized. Such cases should be approached with extreme caution, because an increased risk of paresthesia secondary to nerve injury may be an unacceptable risk for many patients. Cone-beam computed tomography (CBCT) imaging can be very useful for identifying the location of the mandibular canal and determining its relationship to the root apices (see Chapter 2).[68,285,556]

In the buccolingual dimension, the mandibular canal commonly follows a curving pathway from the buccal half of the mandible near the distal root of the second molar to the lingual half of the mandible near the first molar, then curving back to the buccal near the second premolar as it exits the mental foramen.[136] The average vertical distance from the superior border of the mandibular canal to the distal root apex of the mandibular second molar is approximately 3.5 mm; this increases gradually to approximately 6.2 mm for the mesial root of the mandibular first molar and to 4.7 mm for the second premolar.[136,312] This relationship typically provides a greater margin of safety for surgery on the mandibular first molar compared with the second premolar and especially the second molar. Surgery on the mandibular second molar may be further complicated by relatively thick overlying buccal bone, lingual inclination of the roots, and a more buccal location of the mandibular canal. This is not to say that periradicular surgery should not be performed on mandibular second molars; rather, it points out that the relative risks and benefits must be carefully considered. Often the most prudent choice for a mandibular second molar is an intentional replantation procedure or extraction and placement of an implant.

Posterior Maxilla

The primary anatomic structure of concern in the posterior maxilla is the maxillary sinus. CBCT allows for a more precise preoperative three-dimensional evaluation of the relationship between the roots of maxillary posterior teeth and the sinus.[69,79] Perforation of the sinus during surgery is fairly common, with a reported incidence of about 10% to 50% of cases.[157,177,456] Even without periradicular pathosis, the distance between the root apices of the maxillary posterior teeth and the maxillary sinus sometimes is less than 1 mm.[225] An inflammatory periradicular lesion often increases the likelihood of sinus exposure during surgery. Fortunately, perforation of the maxillary sinus rarely results in long-term postoperative problems.[225] In a report of 146 cases of sinus exposure during periradicular surgery, Watzek and colleagues[579] found no difference in healing compared with similar surgical procedures without sinus exposure. The sinus membrane usually regenerates, and a thin layer of new bone often forms over the root end, although osseous regeneration is less predictable.[50,157,579] The general rule of placing a vertical releasing incision at least one tooth mesial and distal to the surgical site is especially important when sinus perforation is possible, because the exposure site should be completely covered with the mucoperiosteal flap to provide primary closure.

If the maxillary sinus is entered during surgery, special care must be taken to prevent infected root fragments and debris from entering the sinus. The most commonly used root resection technique involves grinding the root apex with a high-speed drill for approximately 3 mm in an apical to coronal direction; therefore, an opening could allow infected debris into the sinus. A sinus opening can be temporarily occluded with a material such as Telfa gauze, although the gauze should be secured so as to prevent inadvertent displacement into the sinus. A suture can be placed through the packing material to prevent displacement and aid retrieval. Jerome and Hill[259] suggested securing the apical root segment by drilling a small hole in the root tip and threading a piece of suture material through the hole. The root is then resected at the appropriate level, and the root-end fragment is removed in one piece. If a root fragment or other foreign object is displaced into the sinus, it should be removed. An orascope or endoscope may be useful for visualizing the foreign object, but referral for evaluation and surgical removal may be indicated if the fragment cannot be located and removed.

The palatal roots of maxillary molars present a special challenge for surgical access. Palatal roots may be reached from either a buccal (transantral) or palatal approach. Wallace[572] described a transantral approach in which a buccal flap is reflected, the buccal roots are resected, the osteotomy access into the sinus is enlarged to approximately 1 by 1.5 cm, and the palatal root tip is resected, ultrasonically prepared, and filled. The sinus may be packed with moist gauze to catch debris, and it should be irrigated with sterile saline upon completion of the surgery. In some cases, careful reflection and retraction of the sinus membrane may be possible, allowing access to the palatal root end without direct invasion of the sinus.[16] Many who have tried this approach find it more challenging than it might initially seem. The enhanced illumination and magnification provided by a dental operating microscope, endoscope, or orascope are essential aids in this type of surgery.[40]

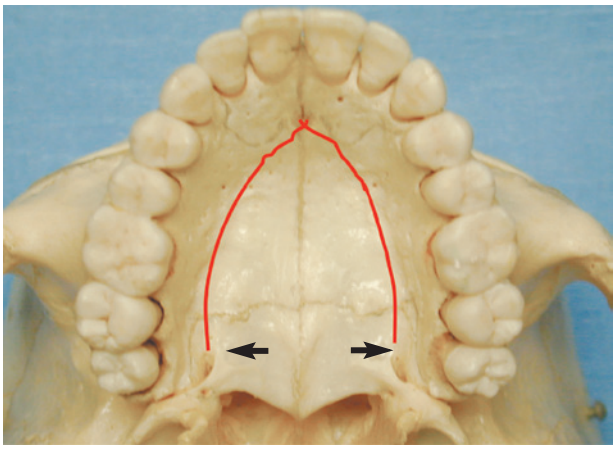

FIG. 9-7 Palatal view showing the position of the greater palatine foramen *(arrows)*. The approximate location of the anterior palatine artery is marked in red.

A palatal approach to the palatal root of maxillary molars may seem more direct than a transantral approach, but it can present certain difficulties. Visibility in the surgical field is reduced and manipulation of instruments is more difficult than with most routine buccal approaches. Patients with a deep, vertical palatal vault are better candidates for this approach than individuals with a wide, shallow palate. A sinus tract or a large lesion on the palatal root may allow easier access and better visualization of the palatal root, because only limited bone removal would be required. The position of the anterior palatine artery must be carefully considered when the incision is made and the flap reflected. This artery emerges from the greater palatine foramen distal to the maxillary second molar at the junction of the vertical section of the alveolar process and the flat portion of the palate and continues anteriorly (Fig. 9-7). A vertical releasing incision can be placed between the maxillary first premolar and canine, where the artery is relatively narrow and branches off into smaller arteries. If needed, a short distal vertical releasing incision may be made distal to the second molar, but it should not approach the junction of the alveolar process and roof of the palate. If the anterior palatine artery is severed, local clamping and pressure may not stop the hemorrhage, and ligation of the external carotid artery may be necessary. Because of the palatal vault's concave shape, repositioning the flap may be challenging. An acrylic surgical stent may be fabricated before surgery to assist repositioning of the flap and to help prevent pooling of blood under the flap.

Anterior Maxilla and Mandible

Periradicular surgery on anterior teeth generally involves fewer anatomic hazards and potential complications than in posterior teeth. Nonetheless, access to the root apex in some patients may be unexpectedly difficult because of long roots, a shallow vestibule, or lingual inclination of the roots. As shown in Figure 9-5, the root apices of maxillary central and lateral incisors can be quite close to the floor of the nose and the bony anterior nasal spine. Figure 9-8 demonstrates isolation and protection of the nasopalatine neurovascular bundle during maxillary anterior surgery. The average maxillary canine is about 26 mm long and usually presents no difficulty for surgical access; however, the combination of a shallow vestibule and

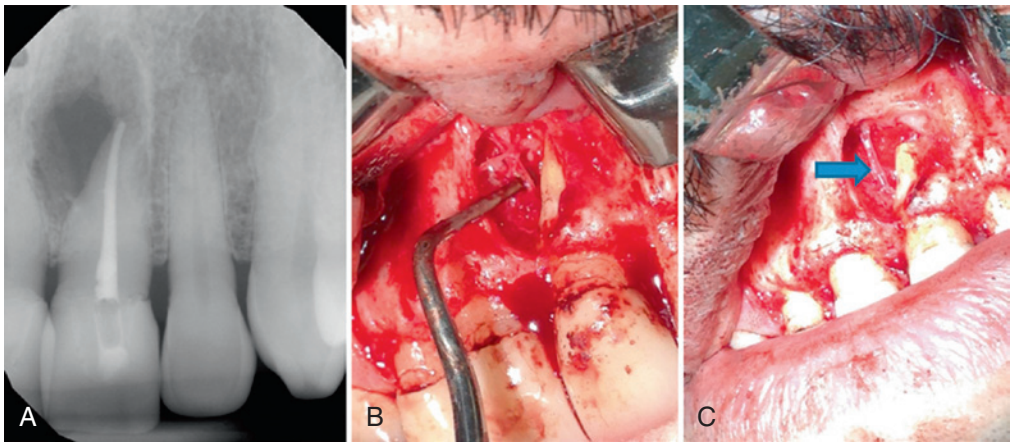

FIG. 9-8 **A**, Radiograph demonstrating periradicular radiolucency associated with previously treated tooth #9. **B-C**, After full thickness flap reflection, the nasopalatine neurovascular bundle was identified (**B**), protected, and isolated (*arrow* in **C**) during curettage of cystic lesion. (Courtesy Dr. Tim Rogers.)

a longer than average root length could complicate access to the root apex area. In such cases, the creation of an osteotomy apical to the root end may be impossible. An alternative approach for long-rooted teeth and root tips in the vicinity of critical anatomic structures is to enter the bone and resect the root at a level approximately 3 mm coronal to the apex. After the root tip is removed, the area apical to the root can be inspected and curetted as needed.

Periradicular surgery on mandibular incisors often is more challenging than expected. The combination of lingual root inclination, a shallow vestibule, and a prominent mental protuberance all can increase the degree of difficulty, as can proximity to adjacent roots and the need for perpendicular root-end resection and preparation to include a possible missed lingual canal.

CONE-BEAM COMPUTED TOMOGRAPHY

Radiographic examination is an essential component in all aspects of endodontic treatment from diagnosis and treatment planning to assessing outcome (see also Chapter 2). Information gained from conventional films and digital periapical radiographs is limited by the fact that the three-dimensional anatomy of the area is compressed into a two-dimensional image. As a result of superimposition, periapical radiographs reveal limited aspects of the three-dimensional anatomy. In addition, there may also be geometric distortion of the anatomic structures imaged. These problems may be overcome using small volume cone-beam computed tomography (CBCT) imaging techniques, which can produce three-dimensional images of individual teeth and the surrounding tissues. CBCT may be particularly useful in diagnosis and treatment planning for periradicular surgery[112,163,249,318] (Fig. 9-9). The term *cone-beam computed tomography* is often used interchangeably with *cone-beam volumetric tomography* (CBVT).

Differences Between CT and CBCT Imaging

The benefits of three-dimensional medical computer tomography (CT) imaging are already well established in certain dental specialties. Current CT scanners have a linear array of multiple detectors, allowing multiple slices to be taken simultaneously, resulting in faster scan times and often less radiation exposure to the patient.[507] The slices of data are then "stacked" and can be reformatted to obtain three-dimensional images. The high-radiation dose, cost, availability, poor resolution, and difficulty in interpretation have resulted in limited use of CT imaging in endodontics. These issues may be addressed by cone-beam innovations in CBCT technology.

In 2000, the Food and Drug Administration approved the first CBCT unit for dental use in the United States. Cone-beam technology uses a cone-shaped beam of radiation to acquire a volume in a single 360-degree rotation, similar to panoramic radiography. The volume of acquired images by a CBCT is composed of voxels. Essentially, a voxel is a 3D pixel. Because the data are captured in a volume as opposed to slices, all the voxels are isotropic, which enables objects within the volume to be accurately measured in different directions. Unlike the CBCT voxel, a medical CT voxel is not a perfect cube, and measurements made in multiple planes are not accurate. In addition to increased accuracy and higher resolution, CBCT offers significant scan-time reduction, radiation dose reduction, and reduced cost for the patient.[472,595,606] CBCT systems can be classified into two categories: limited (dental or regional) CBCT or full (ortho or facial) CBCT. The field of view (FOV) of limited CBCT ranges in diameter from 40 to 100 mm, whereas the FOV of full CBCT ranges from 100 to 200 mm.[112] Another difference between the limited CBCT and full CBCT is that a voxel is generally smaller for the limited version (0.1 to 0.2 mm versus 0.3 to 0.4 mm). Thus, limited CBCT systems offer higher resolution and are better suited for endodontic applications. Limited volume CBCT scanners capture small volumes of data that can include just two or three individual teeth. The most important and clinically useful feature of CBCT technology is the highly sophisticated software that allows the huge volume of data collected to be reconstructed. Tomographic slices, as thin as one voxel, may be displayed in a number of ways. One option, for example, is for the images to be displayed in the three orthogonal planes—axial, sagittal and coronal—simultaneously. The axial and proximal (sagittal in the anterior, coronal in the posterior) views are of particular value, because they are generally not seen with conventional periapical radiography. The ability to reduce or eliminate

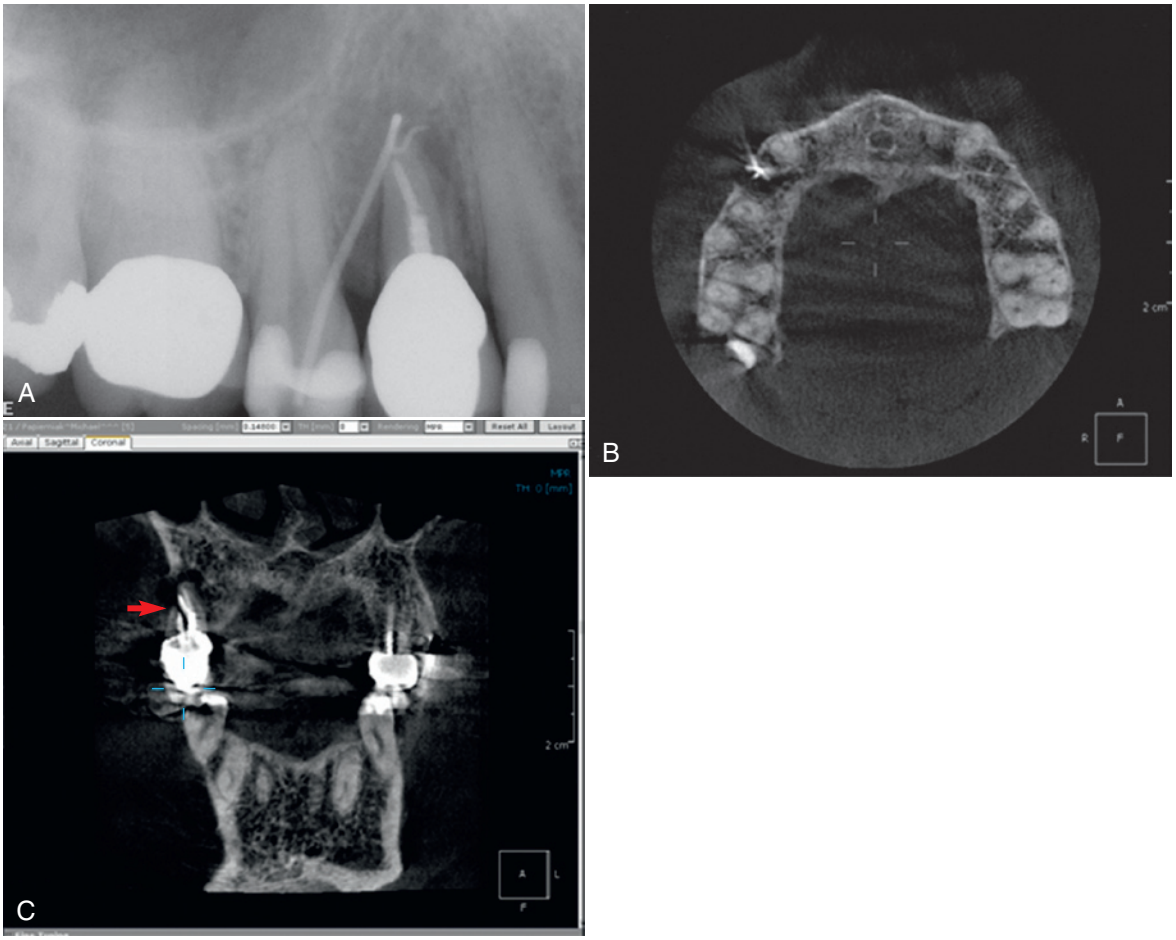

FIG. 9-9 A, Periapical radiograph with gutta percha tracing the sinus tract to tooth #5. Periodontal probings were WNL. This tooth was initially referred for exploratory surgery to rule out root fracture. CBCT confirmed root fracture and the treatment plan was changed to extraction with possible bone graft and guided tissue regeneration for ridge augmentation prior to implant placement. superimposition of the surrounding structures makes CBCT superior to conventional periapical radiography.[314]

Scan times are typically 10 to 40 s, although the actual exposure time is significantly less (2 to 5 s) as scans involve a number (up to 360) of separate, small, individual exposures rather than one continuous exposure. With medical CT scanners, the scanning and exposure times for the skull can be significantly longer. Most CBCT scanners are much smaller than medical CT scanners, taking up about the same space as a dental panoramic machine. They are also significantly less expensive than medical CT scanners. With the help of viewer software, the clinician is able to scroll through the entire volume and simultaneously view axial, coronal, and sagittal 2D sections that range from 0.125 to 2 mm thick. Comparing the radiation dose of different CBCT scanners with medical CT scanners may be confusing because different units of radiation dose are often used. There are three basic measurement units in radiation dosimetry: the radiation absorbed dose (D), the equivalent dose (H), and the effective dose (E). The *radiation absorbed dose* is defined as the measure of the amount of energy absorbed from the radiation beam per unit mass of tissue and is measured in joules per kilogram. The *equivalent dose* is defined as a measure that indicates the radiobiologic effectiveness of different types of radiation and thus provides a common unit. The *effective dose* is calculated by multiplying the equivalent dose by different tissue weighting factors, which converts all doses to an equivalent whole-body dose and allows doses from different investigations of different parts of the body to be compared. The unit remains as the Sievert (Sv) and can be used to estimate the damage from radiation to an exposed population. The reported effective doses from CBCT scanners vary but can be almost as low as those from panoramic dental x-ray units and considerably less than that from medical CT scanners.[398] The higher effective doses from particular models of CBCT scanners is in part due to the larger size of the field of view used as well as the type of image receptor employed. The small volume scanners capture information from a small region of the jaw, approximately the same area as a periapical radiograph. The effective dose has been reported to be in the same range as 2 to 3 standard periapical radiograph exposures, whereas the effective dose for a full mouth series of periapical radiographs has been reported to be similar to the effective dose of a large volume CBCT scan.[124,194] If multiple teeth in different quadrants require endodontic evaluation or

treatment, a large volume CBCT scan with a large field of view may be more appropriate. If endodontic information is required from multiple teeth in one jaw, a large volume CBCT scan with the field of view only limited to the jaw of interest could be the investigation of choice. This has the advantage of reducing the effective dosage from the full large volume CBCT scan by up to 65%.[321]

Potential Applications of CBCT in the Management of Endodontic Posttreatment Disease

Clinical radiographic examinations are usually limited to two-dimensional views captured using radiographic film or digital sensors. Crucial information related to the true three-dimensional anatomy of teeth and adjacent structures is obscured. Even with paralleling techniques, distortion and superimposition of dental structures in periapical views is unavoidable. A major reported advantage of CBCT is the accuracy of measurements in all dimensions.[331] The ability to view thin sagittal, coronal, and axial slices effectively eliminates the problem of superimposition of anatomic structures. For example, roots of maxillary posterior teeth and surrounding tissues can be viewed without superimposition of the zygomatic buttress, alveolar bone, maxillary sinus, and other roots (Fig. 9-10). CBCT enables clinicians to detect changes in apical bone density at an earlier stage when compared to conventional periapical radiographs and therefore has the potential to detect previously undiagnosed periradicular pathoses.[163,314,371] CBCT may also prove to be a useful tool for noninvasive differentiation of periapical cysts and granulomas,[489] a previously unattainable goal using conventional radiographic imaging.

Three-dimensional imaging allows for clear identification of the anatomic relationship of the root apices to important neighboring anatomic structures such as the mandibular canal, mental foramen, and maxillary sinus (Fig. 9-11). Velvart and colleagues reported that the relationship of the inferior alveolar canal to the root apices could be determined in every case when utilizing medical CT, but in less than 40% of cases when using conventional radiography.[556] It is likely that similar results could be achieved with CBCT using considerably less radiation. Rigolone and coworkers concluded that CBCT may play an important role in periapical microsurgery of palatal roots of maxillary first molars.[442] The distance between the cortical plate and the palatal root apex could be measured using CBCT and the presence of the maxillary sinus between the roots could be assessed. Additional information such as the thickness of the cortical plate, cancellous bone pattern, fenestrations, and inclination of the roots can be obtained prior to surgical entry.[371] Root morphology (shape, size, curvature, and number of canals) can be visualized in three dimensions. Unidentified (and untreated) canals in root-filled teeth can be routinely visualized in axial slices. CBCT has been used to determine the location and extent of invasive external root resorptive defects.[398]

One of the most useful potential applications of CBCT may be the assessment of endodontic treatment outcomes, both nonsurgical and surgical. When compared to two-dimensional film and digital images, CBCT is dimensionally precise and can detect smaller changes in bone density.[331]

It is worth remembering that CBCT still uses ionizing radiation and is not without risk. It is essential that patient exposure is kept as low as reasonably practical and that justifiable selection criteria for CBCT use are developed. CBCT may be indicated when it is determined that the additional information obtained is likely to result in a more accurate diagnosis and enhanced patient safety.

PATIENT PREPARATION FOR SURGERY

Informed-Consent Issues Specific to Surgery

The general principles of informed consent discussed in Chapter 29 form the basis for informed consent for periradicular surgery. The patient must be thoroughly advised of the benefits, risks, and other treatment options and must be given an opportunity to ask questions. The main consent issues specific to surgical procedures are closely related to the anatomic considerations discussed in the previous section. That is, major neurovascular bundles may be traumatized, and a sinus exposure may occur. Paresthesia after mandibular posterior surgery is uncommon but should be discussed with the patient because this potential complication is a risk some patients may be unwilling to assume. Postoperative swelling, bruising, bleeding, and infections are possible complications that typically are self-limiting or readily manageable. Although the incidence of serious complications related to surgical procedures is very low, patients should be advised of any risks unique to their situation. Prompt attention to any surgical complications and thorough follow-up are essential from a medical-legal standpoint.

Premedication: NSAIDs, Antibiotics, Chlorhexidine, and Conscious Sedation

Administration of an NSAID, either before or up to 30 minutes after surgery, enhances postoperative analgesia.[494] NSAIDs generally have proved more effective in the management of postoperative oral surgery pain than placebo or acetaminophen and codeine combinations.[9,41,143] The combination of preoperative administration of an NSAID and use of a long-acting local anesthetic may be particularly helpful for reducing postoperative pain.[144] Many types of NSAIDs are available, but ibuprofen remains the usual standard for comparison. Ibuprofen (400 mg) provides analgesia approximately equal to that obtained with morphine (10 mg) and significantly greater than that from codeine (60 mg), tramadol (100 mg), or acetaminophen (1000 mg).[346] The analgesic effectiveness of ibuprofen tends to level off at about the 400-mg level *(ceiling effect),* although a slight increase in analgesic potential may be expected in doses up to 800 mg. (See Chapter 4 for further discussion of analgesics.)

The value of antibiotic prophylaxis before or after oral surgery is controversial, and the current best available evidence does not support the routine use of prophylactic antibiotics for periradicular surgery.[11] For most patients, the risks of indiscriminate antibiotic therapy are believed to be greater than the potential benefits.[526] The incidence of infection after oral surgery in healthy patients is very low. Peterson reported that only 1% of patients developed infections after third molar extractions.[355] A systematic review of the use of antibiotics to prevent complications after placement of dental implants found that evidence was lacking either to recommend or discourage the use of antibiotics for this purpose.[162] However, the

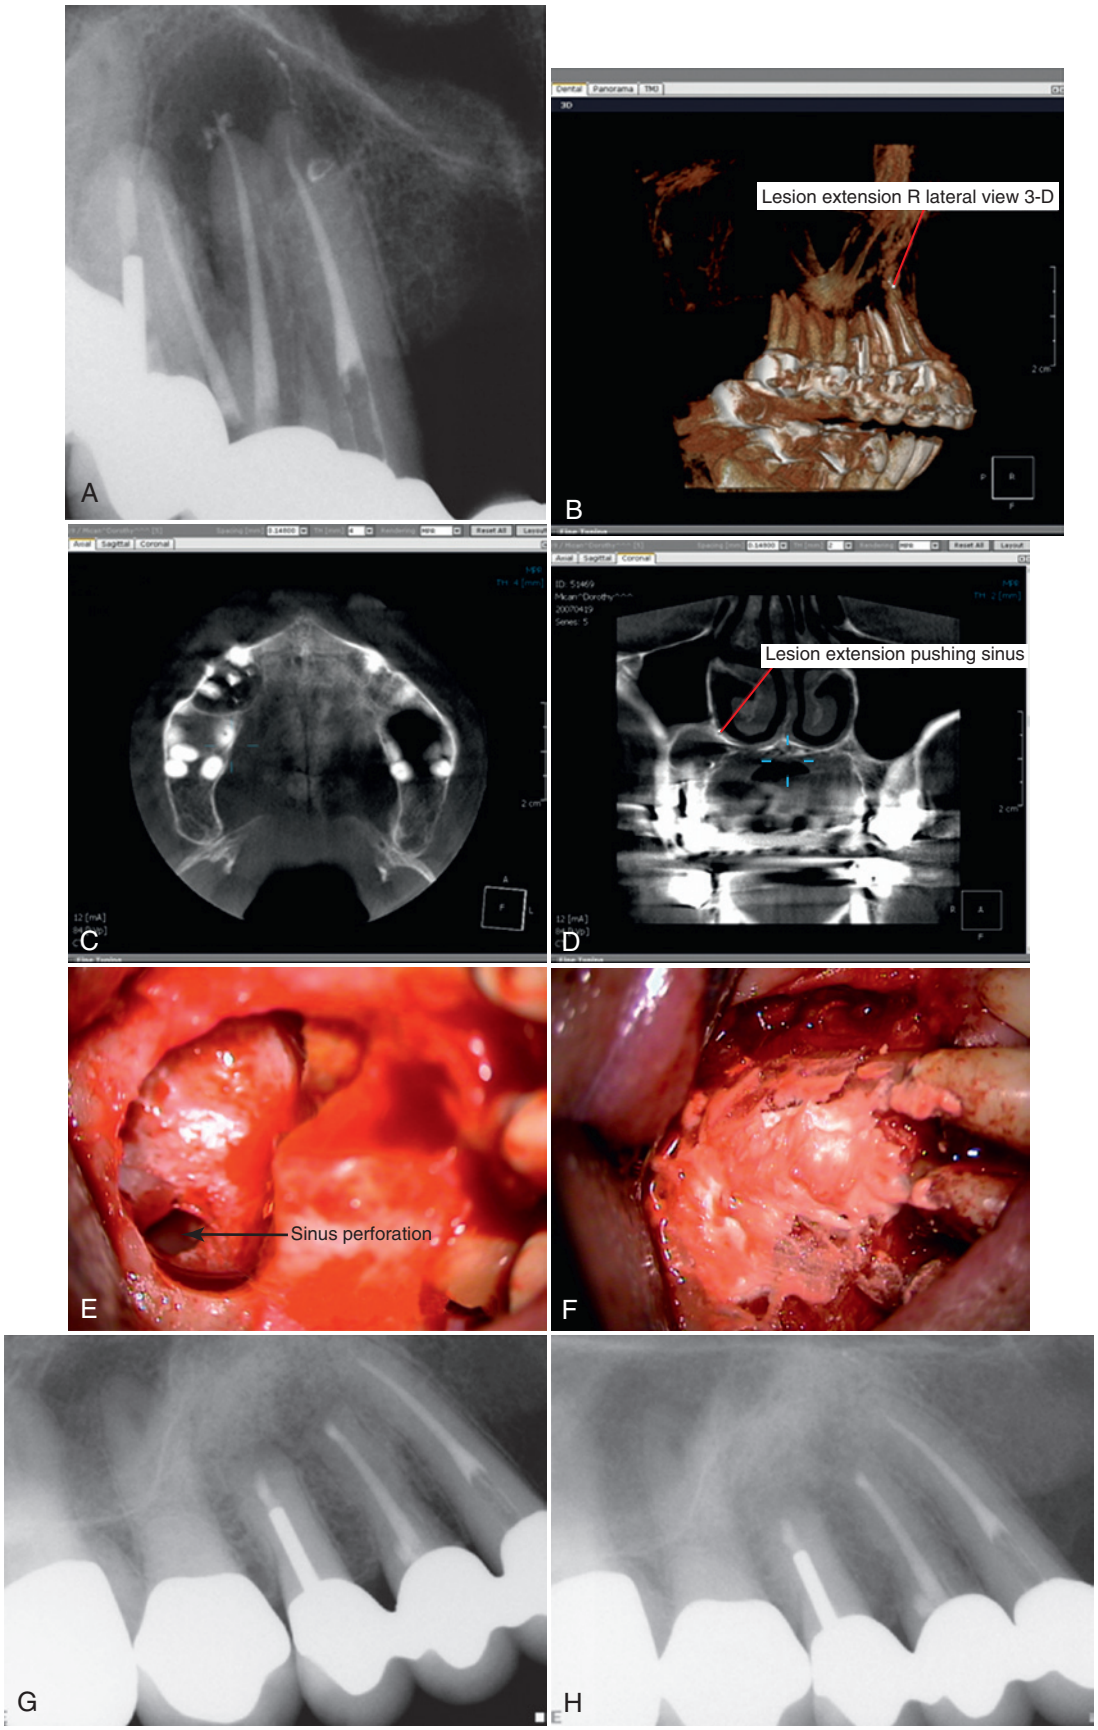

FIG. 9-10 **A**, Preoperative periapical radiograph showing large radiolucency associated with teeth #4, 5, and 6. **B**, CBCT reconstruction *(lateral view).* Rotation of the 3D volume on a computer monitor demonstrated that intact bone was present around the apex of tooth #6 and the lesion was associated only with #4 and 5 (this could not be detected with multiple angled periapical radiographs). **C**, Axial CBCT view demonstrating facial-palatal extent of the lesion. **D**, Coronal CBCT view showing displacement of the sinus membrane (a finding that suggests a sinus membrane perforation will be detected during surgery). **E**, Clinical image after surgical access removal of granulation tissue, and root-end resection (note sinus perforation [*arrow*]). **F**, Placement of bone graft and Capset. **G**, Immediate postoperative radiograph. **H**, Two-year follow-up radiograph demonstrating good healing.

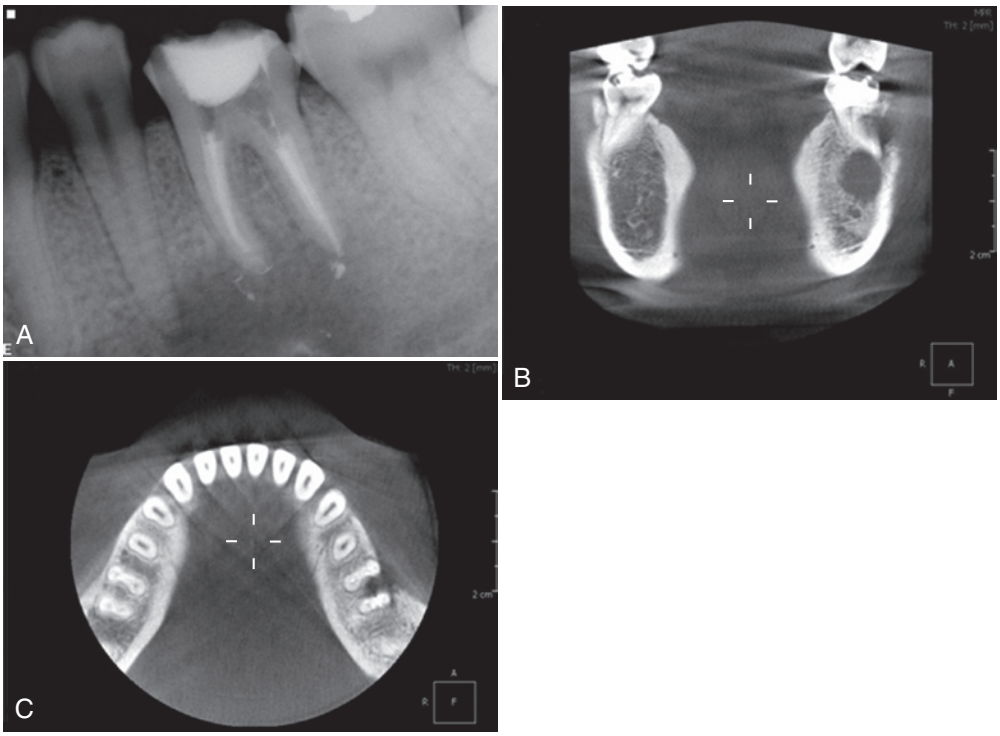

FIG. 9-11 A, Periapical radiograph demonstrating persistent periradicular pathosis following nonsurgical retreatment of tooth #19. The extension of the lesion in the vicinity of the mandibular canal and possible involvement of tooth #20 was uncertain based on interpretation of periapical and panoramic radiographs. Tooth #20 responded WNL to pulp vitality test. B, Coronal CBCT demonstrates that the periradicular lesion does not extend apical or lingual to the mandibular canal. C, Axial CBCT view demonstrating perforation of the buccal cortical plate and extension into, but not through, the furcation of #19 and presence of intact bone around #20.

use of prophylactic antibiotics for more invasive procedures, such as orthognathic surgery, has significantly reduced the risk of postoperative infection and complications.[146] Although routine use of prophylactic antibiotics for periradicular surgery is not currently recommended, clinical judgment is important in determining exceptions to the general rule. For example, immunocompromised patients may be good candidates for prophylactic antibiotic coverage. Certain categories of medically complex patients also may benefit from antibiotic coverage. Diabetic patients have shown impaired healing capacity after nonsurgical root canal treatment,[78,175] and a like pattern of delayed or impaired healing may emerge in studies of surgical outcomes. The global problems associated with overprescription of antibiotics are significant and should prompt due caution in the decision on whether to use these drugs prophylactically.

Chlorhexidine gluconate (0.12%) often is recommended as a mouth rinse to reduce the number of surface microorganisms in the surgical field, and its use may be continued during the postoperative healing stage.[7,281,545] Although no solid evidence supports this practice in periradicular surgery, the use of chlorhexidine follows from the general surgical principle of surface disinfection before incision and opening into a body cavity. In addition, chlorhexidine has proved to be a safe, effective adjunct in the treatment of periodontitis, and short-term use (i.e., several days) poses little or no risk. Chlorhexidine may be useful for reducing the risk of postoperative infection after oral surgery,[67,598] although the evidence in this area is conflicting. Postoperative use of chlorhexidine mouth rinse can reduce bacterial growth on sutures and wound margins,[389] but it may interfere with fibroblast reattachment to the root surface.[14] A useful empirical regimen is to have the patient rinse for 30 seconds twice a day beginning 1 or 2 days before surgery and continuing until the sutures are removed.

Conscious sedation, either by an orally administered sedative or by nitrous oxide/oxygen inhalation analgesia, may be useful for patients who are anxious about the surgical procedure or dental treatment in general. Benzodiazepines with a short half-life are particularly useful because they generally have a wide margin of safety, good absorption after oral administration, and limited residual sedative effects. When these drugs are used in sedative-hypnotic doses, the blood pressure, pulse, and respiration must be monitored, and states differ in their requirement for additional training or certification of staff members who do this monitoring. With oral conscious sedation, pulse oximetry should be used to monitor the pulse and blood oxygen saturation during the surgery.[84] As with all orally administered drugs, the dosage cannot be closely titrated; therefore, the effect of the agent varies somewhat. A typical protocol is a single dose at bedtime the evening before the procedure and a second dose 1 hour before the start of surgery. The patient should not drive to or from the office and should have a responsible adult for assistance as needed. In appropriate doses, benzodiazepines and similar drugs may allow for a more relaxed patient and thus a less stressful surgical experience for both patient and surgeon.

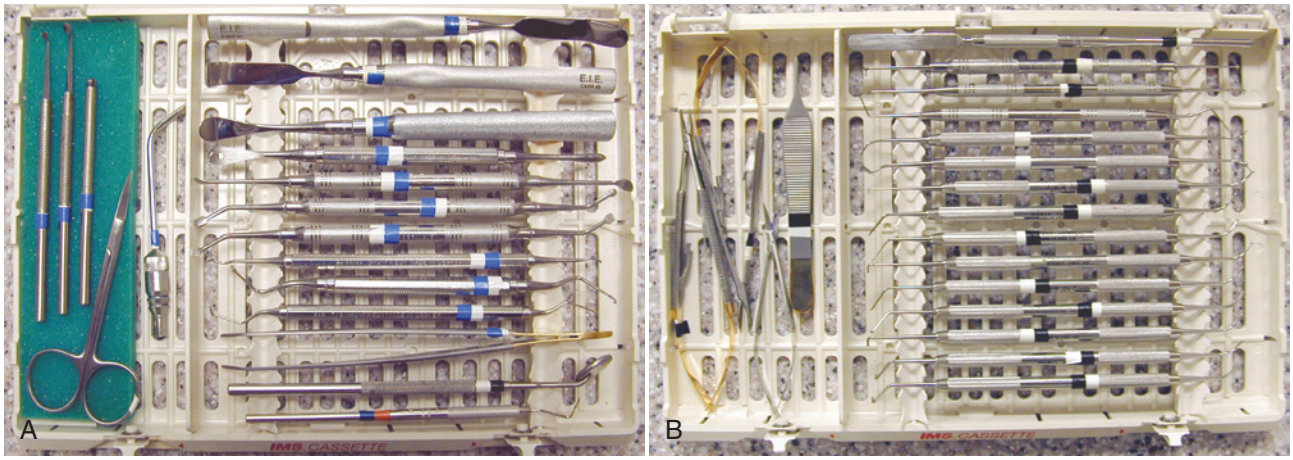

FIG. 9-12 A, Basic tray setup for initial surgical access. Surgical instruments shown are distributed by Hu-Friedy ([HF] Chicago), CK Dental Specialities ([CKDS] Orange, CA), EIE ([EIE]), and G. Hartzell & Son ([GHS]). *Left to right* (left section of tray): Small round micromirror (CKDS); medium oval micromirror (CKDS); handle for microscalpel (CKDS); scissors (S18 [HF]); surgical suction tip (GHS). *Top to bottom* (main section of tray): Carr #1 retractor (EIE); Carr #2 retractor (EIE); TRH-1 retractor (HF); periosteal elevator (HF); Ruddle R elevator (EIE); Ruddle L elevator (EIE); Jacquette curette (SJ 34/35 [HF]); spoon curette (CL 84 [HF]); scaler (7/8 [HF]); surgical forceps (TP 5061 [HF]); mouth mirror (HF); periodontal probe (HF). B, Instrument tray for root-end filling and suturing. *Left to right* (left section of tray): Two Castroviejo needle holders (Roydent Dental Products, Rochester Hills, MI); Castroviejo scissors (S31 [HF]); micro–tissue forceps (TP 5042 [HF]). *Top to bottom* (main section of tray): Cement spatula (HF); Feinstein super plugger (F1L); microexplorer (CX-1 [EIE]); endoexplorer (DG-16 [EIE]); right Super-EBA Placing & Plugging instrument (MRFR [HF]); left Super-EBA Placing & Plugging instrument (MRFL [HF]); small anterior microburnisher and plugger (HF); small left microburnisher and plugger (HF); small right microburnisher and plugger (HF); medium anterior microburnisher and plugger (HF); medium left microburnisher and plugger (HF); medium right microburnisher and plugger (HF); large anterior microburnisher and plugger (HF); large left microburnisher and plugger (HF); large right microburnisher and plugger (HF).

INSTRUMENTS AND OPERATORY SETUP

The development of microsurgical techniques and new materials has changed the typical surgical instrument tray dramatically. Instruments have been designed to take full advantage of the increased visibility obtained with dental operating microscopes, endoscopes, and orascopes. Better visualization of the surgical site would have limited value without microsurgical instruments, such as ultrasonic tips for root-end preparation and micromirrors for inspecting the root end. Figure 9-12 shows a typical basic surgery tray arrangement. This setup is not a definitive guide to surgical armamentarium but rather an adequate, efficient starting point for most periradicular surgical procedures. Although the number of instruments can easily be doubled or even tripled, the ease of locating a specific instrument is inversely proportional to the number of instruments on a tray. Specialized instruments can be kept readily available in separate sterilized bags or trays and opened as needed. A skilled surgeon can use a wide variety of instruments (Figs. 9-12 to 9-24) to achieve excellent results.

Periradicular surgery can be performed without the benefit of enhanced magnification and illumination; however, those who use microscopes, endoscopes, and orascopes report dramatically improved visualization and control of the surgical site.[39,92,280,350] Studies reporting the highest surgical success rates and those cited previously in this chapter all involved some form of enhanced magnification and illumination as part of the standard operating protocol. A systematic review and meta-analysis found that the outcome for endodontic surgery performed with high magnification and illumination (microscope or endoscope) was significantly higher than surgery performed with loupes only or no magnification.[482]

LOCAL ANESTHESIA FOR SURGERY

Local anesthesia for surgical root canal procedures differs from that for nonsurgical root canal treatment primarily in the need

for localized hemostasis in addition to profound local anesthesia. In fact, use of a local anesthetic with a vasoconstrictor may be the single most important local measure to help control hemorrhage and provide a clear surgical field. Otherwise, the same regional block and local infiltration techniques used for nonsurgical treatment (see Chapter 4) are used for surgical root canal procedures. Infiltration of the surgical site with a local anesthetic containing 1:50,000 epinephrine is the technique of choice to obtain vasoconstriction and hemostasis.[280] The local anesthetic is first slowly deposited in the buccal root apex

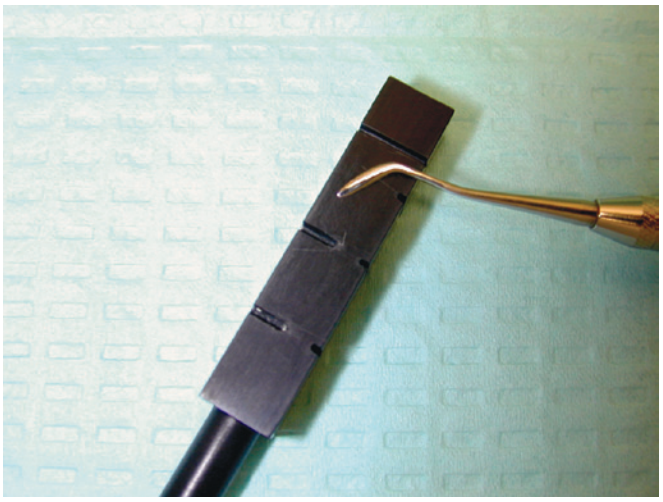

FIG. 9-22 Hard plastic block with notches of varying shapes and sizes (G. Hartzell & Son). MTA is mixed on a glass slab to the consistency of wet sand and then packed into a notch. The applicator instrument is used to transfer the preformed plug of MTA from the block to the root end.

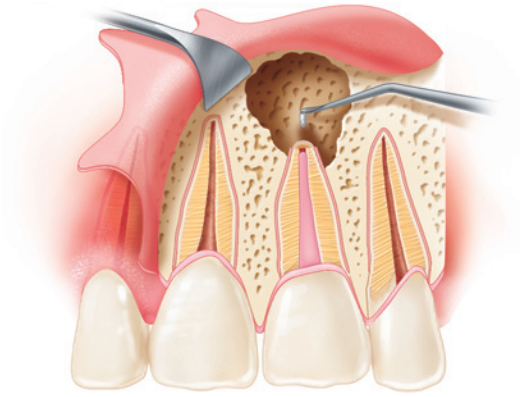

FIG. 9-23 Placement of a root-end filling.

FIG. 9-24 Surgeon, assistant, and patient positioned for initiation of surgery. The patient should be given tinted goggles or some other form of eye protection before the procedure begins.

area of the alveolar mucosa at the surgical site and extended two or three teeth on either side of the site. Usually palatal or lingual infiltration is also required, although this requires a much smaller amount of local anesthetic than the primary buccal infiltration. After the injections for anesthesia, the surgeon should wait at least 10 minutes before making the first incision.

Long-acting local anesthetics (e.g., 0.5% bupivacaine with 1:200,000 epinephrine) have been shown to reduce postoperative pain and analgesic use after surgical removal of impacted third molars.[125,204] However, use of a local anesthetic with 1:200,000 epinephrine may result in greater blood loss during surgery.[234,493] To maximize postoperative analgesia and minimize intraoperative bleeding, a local anesthetic can be used with higher epinephrine concentrations (1:100,000 or 1:50,000) for the primary surgical anesthesia and supplemented with one cartridge of long-acting local anesthetic immediately after surgery. Long-lasting local anesthetics are particularly beneficial in mandibular surgery but much less so for surgery in the maxillary arch.

Every effort must be made to ensure profound local anesthesia before surgery begins. Usually a minimum of 10 to 20 minutes is required from the time of injection to the start of surgery to ensure both profound local anesthesia and adequate vasoconstriction for hemostasis. The patient should be asked about the usual signs of soft-tissue anesthesia, and a sharp explorer can be used to test the surgical area for sensation. Even when the surgeon pays careful attention to local anesthetic technique, a patient sometimes has inadequate anesthesia or loss of anesthesia during the surgical procedure. Providing supplemental infiltration anesthesia is difficult after a full-thickness flap has been reflected. A supplemental block injection may be useful for mandibular teeth and maxillary posterior teeth. In the maxillary anterior area, a palatal approach to the anterior middle superior nerve may be helpful. The key to this approach is slow injection of approximately 1 mL of local anesthetic in the area of the first and second maxillary premolars midway between the gingival crest and the palatal midline. An intraosseous injection also may be used to regain lost anesthesia, but even when it is effective, the area of local anesthesia often is smaller than desired for a surgical procedure. As a last resort, the procedure can be terminated short of completion and the patient can be rescheduled for surgery under sedation or general anesthesia.

SURGICAL ACCESS

The goals of periradicular surgery are to access the affected area, remove the diseased tissue, evaluate the root circumference and root canal system, and place a biocompatible seal in the form of a root-end filling that can stimulate regeneration of the periodontium. The formation of new cementum on the surgically exposed root surface and on the root-end filling material is essential to regeneration of the periodontium.

Successful endodontic surgery requires the surgeon to use several conceptual elements in planning the procedure. A vision of the immediate postoperative surgical end point (i.e., replacement of the reflected tissues) is essential for designing each phase of the surgery. Visualization of a three-dimensional image of the surgical procedure allows the surgeon to anticipate and prepare for unusual circumstances. In surgical root canal treatment, once a procedure is started, it must be completed uninterrupted within a limited time; this is a paramount difference between nonsurgical and surgical root canal treatment. For this reason, it is absolutely essential that the surgeon plan the procedure thoroughly and include alternative plans of action that anticipate unusual findings during the process of discovery.

Several general principles are important for designing the access to a diseased region: (1) the surgeon must have a thorough knowledge of the anatomic structures in relation to each other, including tooth anatomy; (2) the surgeon must be able to visualize the three-dimensional nature of the structures in the soft and hard tissue (this reduces unnecessary tissue damage); (3) the trauma of the surgical procedure itself must be minimized, which includes the preservation of tooth and supporting structures; (4) the tissue and instruments must be manipulated within a limited space with the aim of removing diseased tissues and retaining healthy tissues.

Soft-Tissue Access

In designing the soft-tissue access window to the diseased tissue, the surgeon must take into consideration various anatomic features, such as frenum-muscle attachments, the width of attached gingiva, papillary height and width, bone eminence, and crown margins. The supraperiosteal blood vessels of the attached gingiva extend from the alveolar mucosa and run parallel to the long axis of the teeth, lying in the reticular layer superficial to the periosteum.[172] A vertical, rather than an angled, releasing incision severs fewer vessels,[325] reducing the possibility of hemorrhage. Also, the blood supply to the tissue coronal to the incision is not compromised,[477] which prevents localized ischemia and sloughing of these tissues. Ultimately, the result is less bleeding during the procedure and enhanced healing. For these reasons, an angled releasing incision is contraindicated in periradicular surgery.

Vertical Incision

The general principles for placement of a vertical relieving incision are as follows:

1. The incision should be made parallel to the supraperiosteal vessels in the attached gingiva and submucosa (Fig. 9-25).
2. No cuts should be made across frenum and muscle attachments.
3. Frenum and muscle attachments should not be located in the reflected tissue, if possible.
4. The incision should be placed directly over healthy bone.

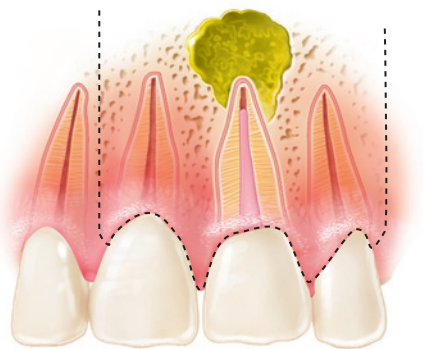

FIG. 9-25 Intrasulcular incision with two vertical releasing incisions (rectangular flap).

5. The incision should not be placed superior to a bony eminence.
6. The dental papilla should be included or excluded but not dissected.
7. The incision should extend from the depth of the vestibular sulcus to the midpoint between the dental papilla and the horizontal aspect of the buccal gingival sulcus.

Horizontal Incision

Three types of horizontal incisions can be used to gain access to a surgical site in hard tissue:

- *An intrasulcular incision that includes the dental papilla.* This incision extends from the gingival sulcus through the PDL fibers and terminates at the crestal bone of the alveolar bone proper. The incision then passes in a buccolingual direction adjacent to each tooth of the dental papilla and includes the midcol region of each dental papilla. Thus, the entire dental papilla is completely mobilized.
- *An intrasulcular incision that excludes the dental papilla (papillary-based incision, Fig. 9-26).* This technique consists of a shallow first incision at the base of the papilla and a second incision directed to the crestal bone.
- *An incision made in the attached gingiva (a submarginal or Ochsenbein-Luebke flap).*[322] With this technique, at least 2 mm of attached gingiva must be retained to prevent mucogingival degeneration.[296] Consequently, the incision must be placed at least 2 mm from the depth of the gingival sulcus. Extensive periodontal probing should be done to establish the depth of the gingival sulcus before the incision is made. The average width of the attached gingiva is 2.1 to 5.1 mm in the maxilla and 1.8 to 3.8 mm in the mandible.[10,199,341,563] It is widest over the central and lateral incisors, narrows over the canine and the first premolar, and then widens over the second premolar and the first molar. These variances were similar for both the maxilla and mandible.[317] Overall, this incision technique has a narrow margin of safety. It generally is recommended for use in the maxilla, especially where the aesthetics of existing crown margins are a concern.

Studies have compared the incision techniques that include and exclude the dental papilla in patients with healthy marginal periodontal conditions.[554,555,557] These researchers found that the papilla base incision resulted in rapid, recession-free healing. In contrast, complete mobilization of the papilla led to a marked loss of papilla height. The authors suggested that use of the papilla base incision in aesthetically sensitive regions could help prevent papilla recession and surgical cleft, or double papilla.

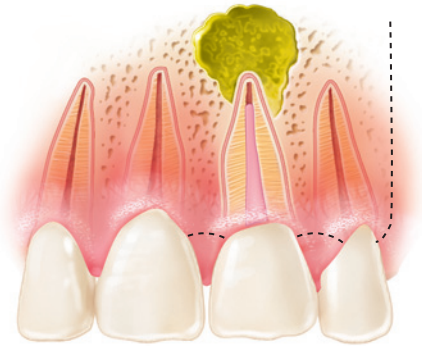

FIG. 9-26 Papillary-based incision with one vertical releasing incision.

Flap Design

Combinations of vertical and horizontal incisions are used to achieve various flap designs (Figs. 9-27 and 9-28). The full mucoperiosteal and limited mucoperiosteal are the two major categories of flap design used during periradicular surgery, the main differentiating feature being the position of the horizontal incision. In each case the entire body of soft tissue is reflected as one unit and includes the alveolar mucosa, the gingival tissues, and the periosteum. The number and position of the vertical relaxing incisions therefore governs the major variation in design:

1. Full mucoperiosteal (intrasulcular incision including the dental papilla or papillary based) (Figs 9-27 and 9-28):
   a. Triangular: one vertical relieving incision
   b. Rectangular: two vertical relieving incisions
   c. Trapezoidal: two angled vertical relieving incisions
   d. Horizontal: no vertical relieving incision
2. Limited mucoperiosteal (Figs 9-29 and 9-30):
   a. Curve submarginal (semilunar)
   b. Freeform rectilinear submarginal (Ochsenbein-Luebke)

Tissue Reflection

Elevation and reflection of the entire mucoperiosteal complex, maintaining the microvasculature in the body of the tissue flap, increases hemostatic control during surgery. Tissue reflection should begin from the vertical releasing incision at the junction

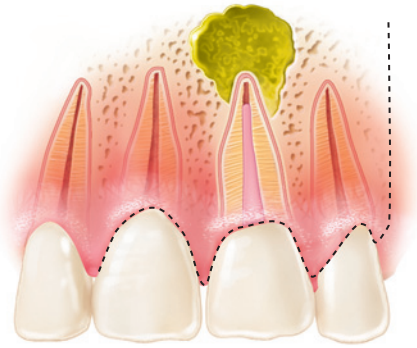

FIG. 9-27 Intrasulcular incision with one vertical releasing incision (triangular flap).

FIG. 9-28 Reflection of the triangular flap to expose the root-end area.

of the submucosa and the attached gingiva (Figs. 9-31 and 9-32). By initiating the reflection process at this point, damage to the delicate supracrestal root-attached fibers is avoided. Using a flap reflection technique that reduces reflective tissue forces in the intrasulcular incisional wound and avoids curettage of the root surface conserves the root-attached tissues and helps prevent apical down-growth of epithelium and loss of soft-tissue attachment.[222] Force should be applied such that the periosteum and superficial tissues are reflected as a complete unit. Using a gentle rocking motion, the surgeon initially should reflect the tissue in a horizontal direction.[213] The underlying bone of the cortical plate is irregular, and it is critical to avoid damaging the fragile tissues during elevation.

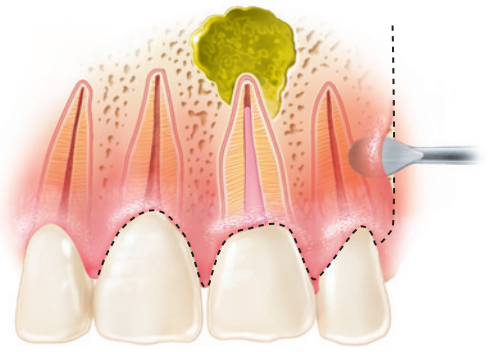

FIG. 9-31 Elevator placed in the vertical incision for the first step in undermining flap reflection.

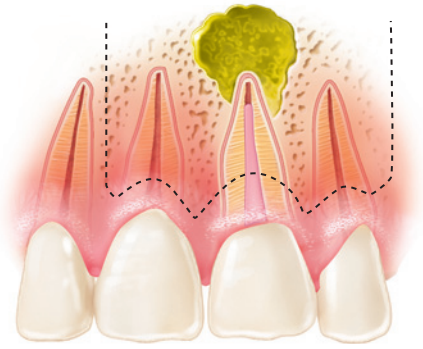

FIG. 9-29 Submarginal (Ochsenbein-Luebke) flap.

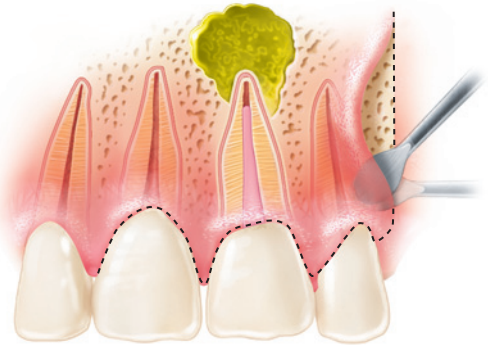

FIG. 9-32 Continuation of reflection of full-thickness flap.

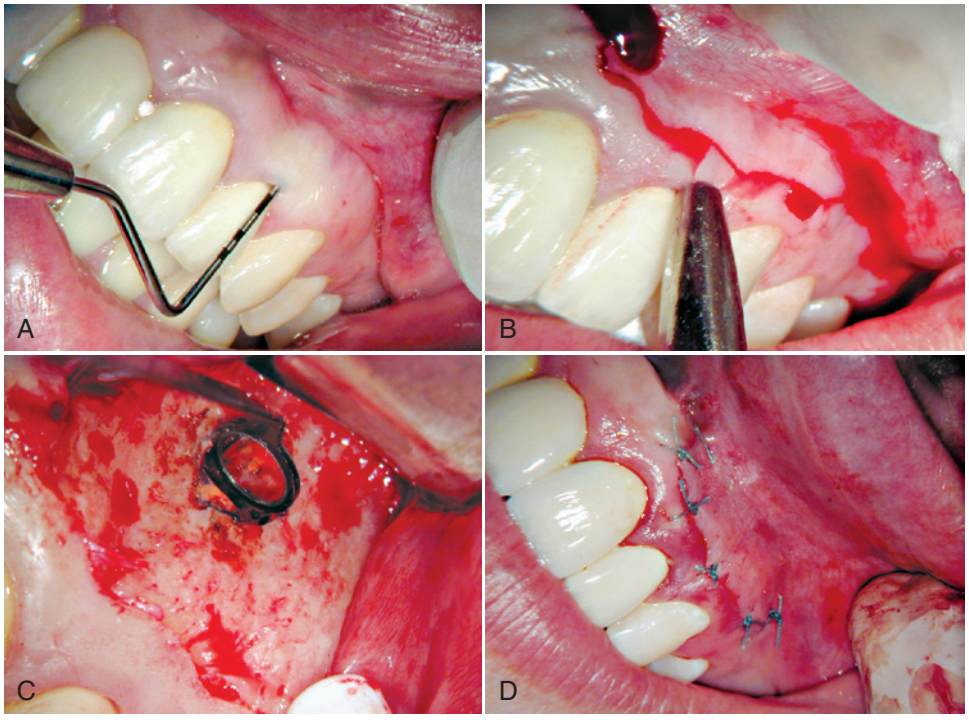

FIG. 9-30 Clinical case involving a submarginal incision and flap. **A,** Periodontal probing of the entire area was performed before this type of flap was selected and the incision started. A submarginal incision often is used in aesthetic anterior areas of the mouth where postoperative gingival recession might expose the crown margins. **B,** The incision should be at least 2 mm apical to the depth of the sulcus. **C,** With the flap reflected, osteotomy and root-end resection were performed. Methylene blue dye was placed to mark the outline of the root end and to help identify cracks or fractures before root-end cavity preparation and filling. **D,** The flap was repositioned and sutured with 5-0 Tevdek. (Courtesy Dr. Martin Rogers.)

The operator should take great care not to slip during the tissue reflection process by using an appropriate instrument stabilized with adequate finger support. Slipping can result not only in puncture of the immediate overlying tissue but also damage to the surrounding structures.

As space permits, the elevator should be directed coronally, undermining the attached gingiva. As the interdental papilla is approached, a narrower instrument may be required to undermine and gently elevate the tissue in this region, to avoid crushing the delicate free gingival tissues. This process should be continued gradually until the osseous tissues overlying the diseased tooth structure have been adequately exposed. Generally, elevation of the flap 0.75 cm apical to the estimated apex of the root should allow adequate space to perform the surgical procedure.

No single instrument is essential for the flap elevation procedure, because every instrument has both advantages and disadvantages. Surgeons should familiarize themselves with the various instruments available.

Tissue Retraction

After the tissue is reflected, it must be retracted to provide adequate access for bone removal and root-end procedures. The main goals of tissue retraction are to provide a clear view of the bony surgical site and to prevent further soft-tissue trauma. Accidental crushing of the soft tissues leads to more postoperative swelling and ecchymoses.[222,223]

The general principles of retraction are as follows: (1) retractors should rest on solid cortical bone; (2) firm but light pressure should be used; (3) tearing, puncturing, and crushing of the soft tissue should be avoided; (4) sterile physiologic saline should be used periodically to maintain hydration of the reflected tissue; and (5) the retractor should be large enough to protect the retracted soft tissue during surgical treatment (e.g., prevent it from becoming entangled in the bone bur). No one retractor suffices for all surgical procedures, therefore the surgeon should have a selection of retractors available for the various situations that arise during surgery. If difficulty is encountered in stabilizing the retractor, a small groove can be cut into the cortical plate to support it.

Hard-Tissue Access

Two biologic principles govern the removal of bone for hard-tissue access to diseased root ends: (1) healthy hard tissue must be preserved, and (2) heat generation during the process must be minimized.

Temperature increases above normal body temperature in osseous tissues are detrimental. Heating osseous tissue to 117° to 122°F (47° to 50°C) for 1 minute significantly reduces bone formation and is associated with irreversible cellular damage and fatty cell infiltration.[161,338] Two critical factors determine the degree of injury: how high the temperature increases and how long it remains elevated. As the temperature rises above 104°F (40°C), blood flow initially increases. It stagnates at 198°F (46°C) applied for 2 minutes. Heating osseous tissue to 133°F (56°C) deactivates alkaline phosphatase.[422,423] Studies using animal bone have shown that at temperatures above 109°F (42.5°C), for every 1°C elevation in temperature, the exposure time for the same biologic effect decreases by a factor of approximately 2.[158-161] Temperatures above 117°F (47°C) maintained for 1 minute produce effects similar to those at 118°F (48°C) applied for 30 seconds. This correlation means that the decisive exposure time declines quickly as the temperature increases. Temperatures above 127°F (53°C) applied for less than 1 second can adversely affect osteogenesis.[158-161]

Several factors determine the amount of heat generated during bone removal, including the shape and composition of the bur, the rotational speed, the use of coolant, and the pressure applied during cutting.

The round bur has the best shape for removing osseous tissue, and it should be used with a gentle brushstroke action.[519] This type of bur also readily allows access of coolant to the actual cutting surfaces. Studies comparing the heat generated with round and fissure burs found more favorable results with the round burs.[85,111,216,338,360] Cutting with round burs produced a wound site with less inflammation, which is more favorable for rapid wound healing. Although fissure-type burs cut efficiently on the sides, the tip of the bur is very inefficient because it allows no coolant access. The net result is increased inflammation and a reduced healing response.

Use of a diamond bur to remove osseous tissue is inefficient and retards ultimate wound healing. Because of its larger surface area, more of a diamond bur is in contact with the bone tissue. As a result, less coolant reaches the cutting surface, and the bur has a greater tendency to become clogged with residual bone fragments. The net effect is greater heat generation, increased inflammation, and reduced healing.[85,586]

Use of a coolant during bone cutting is essential. If an appropriate irrigant is not used, temperatures can exceed those known to impair bone healing[274]; histologically, healing can be delayed up to 3 weeks.[169] It also is critical that the coolant reach the cutting surface. Temperatures can rise above 212°F (100°C) when excess pressure is applied during cutting; this burrows the bur into the bone, where little or no irrigant can reach the cutting tip,[519] hence the recommendation for a gentle brushstroke technique.[213] Favorable results are obtained with these provided the surgeon follows the basic tenet of minimizing heat generation: using a round fluted bur with coolant and a brushstroke technique. A high-speed handpiece that exhausts air from the base rather than the cutting end is recommended to reduce the risk of air embolism (Fig. 9-33).

PERIRADICULAR CURETTAGE AND BIOPSY

Most periradicular lesions originate in the pulp and can be classified histopathologically as granulomas or

FIG. 9-33 Surgical handpiece with 45-degree angle head and rear air exhaust (Impact Air 45).

cysts.[53,58,292,295,297,359,367,382,488] Histologically, such lesions consist mainly of granulation tissue associated with angiogenesis, fibroblasts, connective tissue fibers, and inflammatory cells. Foreign material, cholesterol clefts,[365,370] and stimulated strands of epithelium also may be present. The stimulated epithelium can form into a stratified, squamous epithelium–lined cystic cavity.[366] These periradicular lesions (granulomas and cysts) are inflammatory lesions that develop in response to irritation caused by intraradicular and extraradicular microorganisms associated with the root canal system[363,368] or by foreign materials forced into the periradicular tissues.[600]

An important aspect of periradicular surgery is the removal of diseased tissue associated with the root apex. Because a large portion of this tissue is reactionary, the focus of surgical root canal treatment is removal of the irritant or diseased tissues. Histologically, an inflammatory periradicular lesion is similar to healing granulation tissue. If the irritant can be readily identified and successfully eliminated, it is not always necessary to completely curette all the inflamed periradicular tissues during surgery.[306] This is especially true when complete removal might result in injury to neural or vascular tissues. In addition to removing diseased tissue, periradicular curettage provides visibility and accessibility to facilitate treatment of the apical root canal system or removal of foreign materials in the periradicular tissues.

The need for a histopathologic assessment of all tissues removed from the body cannot be overstated. Although only a small percentage of periradicular lesions are associated with pathoses other than a periradicular cyst or granuloma, all lesions must be diagnosed definitively because of the potential gravity of the few rare diseases associated with periradicular lesions.[12,121,185,383,409]

The technical aspect of removing soft tissue from the bony crypt varies among surgeons and clinical settings. Various bone and periodontal curettes are available for this purpose, and no one instrument suffices for all cases. Regardless of the instrument selected, the basic principles are the same. A sharp instrument is always preferable to a blunt instrument. The soft-tissue lesion first should be peeled away from the osseous crypt, starting at the lateral borders. This can be accomplished efficiently by using the curette with the concave surface facing the internal wall of the osseous crypt. Once the soft-tissue lesion has been separated from the osseous crypt to the point where the crypt changes its convexity, the curette can be used in a scraping manner to remove the remainder of the lesion from the medial wall of the osseous defect.

LOCALIZED HEMOSTASIS

Localized hemostasis during periradicular surgery is essential to successful management of the resected root end. Appropriate hemostasis during surgery minimizes surgical time, surgical blood loss, and postoperative hemorrhage and swelling.[213] The hemostatic agents used during endodontic surgery are intended to control bleeding from small blood vessels or capillaries. Localized hemorrhage control not only enhances visibility and assessment of the root structure, but it also ensures the appropriate environment for placement of the current root-end filling materials and minimizes root-end filling contamination.

Many hemostatic agents have been advocated for use during surgery, and the action of these agents, their ability to control bleeding, and their effect on healing vary considerably. They generally aid coagulation by inducing rapid development of an occlusive clot, either by exerting a physical tamponade action or by enhancing the clotting mechanism and vasoconstriction (or both). No one local hemostatic agent is ideal; each has disadvantages. Therefore, further investigation is indicated to find the ideal local hemostatic agent.

Preoperative Considerations

A thorough review of the patient's body systems and medical history increases the likelihood of detecting an undiagnosed condition that might affect hemostasis during periradicular surgery. Review of the patient's medications, both prescribed and over-the-counter (OTC) drugs, is essential. Many OTC drugs can affect the clotting mechanism. The patient's vital signs (i.e., blood pressure, heart rate, and respiratory rate) should be assessed. Vital signs also can be used to monitor anxious patients. An increase in blood pressure and heart rate above a patient's known normal values indicates increased stress or poorly controlled hypertension. Easing the patient's anxiety before surgery reduces the possible hemostatic-potentiating effect of elevated cardiac output during surgery.[156] Anxiety and stress can be alleviated with planning, sedation, and profound local anesthesia.

Local Hemostatic Agents

Collagen-Based Materials

Various collagen-based hemostatic agents are available for use as local hemostatic agents. The principal differences are in the microstructure and density of the collagen. Collagen can act as a mild allergen, but the problem of allergenization and unwanted tissue reaction does not occur when highly purified animal collagen is used.[49] The mechanisms by which collagen products help achieve hemostasis involves stimulation of platelet adhesion, platelet aggregation and release reaction,[270,271] activation of factor XII (Hageman factor),[335,336] and mechanical tamponade by the structure that forms at the collagen-blood wound interface. Collagen shows minimal interference in the wound healing process, with a limited foreign body reaction.[215] It does not increase the incidence of infection and only slightly delays early bone repair.[246] Osseous regeneration in the presence of collagen typically proceeds uneventfully, without a foreign body reaction.[168]

Collagen-based materials can be difficult to apply to the bony crypt because they adhere to wet surfaces, particularly instruments and gloves.[466] Several collagen-based products are commercially available. They include CollaCote (Integra Life Sciences, Plainsboro, NJ) (Fig. 9-34, *A*), CollaStat (American Medical Products Corp, Eatontown, NJ), Hemocollagene (Septodont, United Kingdom) and Instat (Ethicon, Somerville, NJ). These materials act in essentially similar ways, and the surgical area undergoes a similar healing pattern.[485,504] Overall, studies of wound healing with collagen-based hemostatic agents have shown favorable results.

Surgicel

Surgicel (Ethicon) is a chemically sterilized material prepared through oxidation of regenerated alpha cellulose (oxycellulose). The basic element of Surgicel is polyanhydroglucuronic acid, which is spun into threads and then woven into gauze. Surgicel has a pH of 3. If the material is maintained in the wound for up to 120 days, a pH this low could retard healing.[408]

FIG. 9-34 A, Absorbable collagen (CollaCote) is a convenient, biocompatible packing material for localized hemostasis. B, Cotton pellets impregnated with racemic epinephrine (Racellet) also may be used for localized hemostasis.

It is primarily a physical hemostatic agent, which acts as a barrier to blood and then becomes a sticky mass that serves as an artificial coagulum. It does not enhance the clotting cascade through adhesion or aggregation of platelets. Surgicel is retained in the surgical wound,[373] and healing is retarded, with little evidence of resorption of the material at 120 days.[57] Use of Surgicel in extraction sockets resulted in greater postoperative pain compared with a control in a split mouth–designed study.[408]

Gelfoam

Gelfoam (Pharmacia, Peapack, NJ) is a gelatin-based sponge that is water insoluble and biologically resorbable. It stimulates the intrinsic clotting pathway by promoting platelet disintegration and the subsequent release of thromboplastin and thrombin.[164] The initial reaction to Gelfoam in the surgical site is a decrease in the rate of healing. Extraction sockets containing Gelfoam showed a greater inflammatory cell infiltrate, marked reduction in bone ingrowth, and a foreign body reaction at 8 days.[74] However, these effects were transitory and did not impair long-term bone healing.[392]

Bone Wax

Historically, bone wax has been advocated for controlling both hemostasis and debris in the bony crypt during periradicular surgery.[480] It is a nonabsorbable product composed of 88% beeswax and 12% isopropyl palmitate. Healing with bone wax is best described as poor. The bony crypt typically contains fibrous connective tissue and has no bony or hematopoietic tissue. Bone wax retards bone healing and predisposes the surgical site to infection[117,378] by producing a chronic inflammatory foreign body reaction[35] and impairing the clearance of bacteria.[263] The use of bone wax can no longer be recommended because it impairs healing and several good alternatives are available.[589]

Ferric Sulfate

Ferric sulfate (Cut-Trol, Ichthys Enterprises, Mobile, AL), a necrotizing agent with an extremely low pH, is one of the few products investigated for use in periradicular surgery. In studies using a rabbit model, Lemon and colleagues[301] and Jeansonne and colleagues[256] reported hemostatic control for 5 minutes and near normal healing with only a mild foreign body reaction, provided the surgical wound was adequately curetted and irrigated with saline. Failure to remove ferric sulfate from the surgical wound site resulted in severely impaired healing, a foreign body–type reaction, and, in some cases, abscess formation. The possibility of acute inflammation and necrosis of the surrounding soft tissue with careless use of this solution should not be underestimated.[298] A similar product, Monsel's solution (ferric subsulfate), has been used to control local hemostasis in dermatologic procedures. However, the popularity of this solution has declined because application to wound sites has resulted in tissue necrosis for up to 2 weeks,[130] differences in the degree of epidermal maturation, and tattoo formation.[536]

Calcium Sulfate

Calcium sulfate has been used as a substitute bone graft material to fill bone defects since the late 1800s. The presence of calcium sulfate in an osseous wound does not inhibit bone formation.[574] It is gradually removed from the site of implantation regardless of whether new bone has formed.[110] Use of calcium sulfate during periradicular surgery does not significantly affect healing, and deposition of cementum and osseous healing proceed normally.[27] As a hemostatic agent, calcium sulfate acts as a physical barrier. The material is placed in the bony crypt, allowed to set, and then partly carved away to allow access to the root end.[283] The remaining material lines the crypt walls, preventing bleeding. When the root-end filling has been placed and all extraneous root-end filling material removed, the residual calcium sulfate can be removed or left in situ.

Epinephrine Pellets

Epinephrine, a sympathomimetic-amine vasoconstrictor, is frequently used to control hemorrhage during oral surgery.[82,283] All granulation tissue should be removed from the root apex area prior to placement of the epinephrine pellet to assure direct contact with bone.[282] Vasoconstrictive amines exert their effects by binding to and interacting with adrenergic receptors in various body tissues. When epinephrine is bound to alpha$_1$- and alpha$_2$-adrenergic receptors, a powerful vasoconstricting effect results. Racemic epinephrine cotton pellets (Racellet #3; Pascal Co., Bellevue, WA) contain an average of 0.55 mg of racemic epinephrine hydrochloride per pellet, half of which is the pharmacologically active L-form. Racellets (see Fig. 9-31, *B*) provide good localized hemostasis in periradicular surgery.[558]

Two concerns arise with the use of Racellets in the surgical site: the cardiovascular impact of the additional epinephrine and the retention of cotton fibers in the wound, resulting in impaired wound healing.[213,265] A study by Vickers and coworkers[558] examined the cardiovascular effects of epinephrine pellets and concluded that no evidence existed of cardiovascular changes (blood pressure and pulse) compared with saline-saturated pellet controls. These authors hypothesized that the vasoconstrictive effect on the capillaries is localized and immediate and that little or no systemic uptake of epinephrine occurred.

Although the cardiovascular effect appears to be of little concern, retention of cotton fibers in the surgical site could result in inflammation and impaired wound healing. Therefore,

due diligence on the part of the surgeon is paramount when epinephrine pellets are used. Each pellet applied during surgery must be accounted for, and the bony crypt should be lightly curetted to remove any embedded cotton fibers before the wound is closed. The retention of cotton fibers in the crypt can be eliminated by substituting CollaCote saturated with 10 drops of 2.25% racepinephrine inhalation solution.[567] As previously noted, CollaCote is biocompatible and does not interfere with wound healing.

Cautery/Electrosurgery

Cautery stops the flow of blood through coagulation of blood and tissue protein, leaving an eschar that the body attempts to slough.[537] The effect of cautery in the bony crypt during periradicular surgery has not been studied to date. However, the effect of electrosurgery on alveolar bone has been studied in periodontal surgery. Tissue destruction was greater in areas exposed to electrosurgery and healing was delayed compared with surgical sites not exposed to electrosurgery. Twelve hours after surgery, a more extensive inflammatory reaction and greater destruction of periosteum were noted with electrosurgery.[36] At 24 hours, many empty lacunae were observed in the bone associated with electrosurgery, and this necrosis was even more extensive by 48 hours. At 96 hours the electrosurgical connective tissue wounds were still lined by coagulum, whereas the scalpel wound was beginning to repair.[381] The detrimental effect of applying heat to bone is proportional to both temperature and the duration of application.

MANAGEMENT OF THE ROOT END

Management of the resected root end during periradicular surgery is critical to the overall success of a case. The aim of surgery should be to create an environment conducive to regeneration of the periodontium—that is, healing and regeneration of the alveolar bone, periodontal ligament, and cementum overlying the root end and root-end filling material. The key to regeneration is the presence of appropriate inducible cell types, growth factors, and specific substances necessary for mineralization. Failure to create an environment conducive to this process results in tissue repair rather than regeneration and possibly less than ideal healing.

Determination of the Need for Root-End Resection and Filling

The basis for periradicular surgery is twofold. The first objective is to remove the etiologic factor; the second is to prevent recontamination of the periradicular tissues once the etiologic agent has been removed.

Etiologic factors typically can be categorized as intraradicular or extraradicular bacteria,[254,287,367,491,540,541,559,580] intraradicular or extraradicular chemical substances, or extraradicular physical factors.[370,496,497] The etiology cannot always be determined with complete certainty; frequently, a number of factors are involved.[98] However, most cases involve some form of bacterial participation (e.g., bacteria within apical ramifications). The only definitive means of eradicating such an irritant is physical removal through root-end resection. The rationale for root-end resection in such cases is to establish access to and remove the diseased tissues. This ensures that the optimum environment for wound healing is established.

As mentioned, the second objective of periradicular surgery is to prevent recontamination of the tissues after removal of the etiologic agent. It follows, then, that if the remainder of the canal system cannot be verified to be irritant free, a root-end filling should be placed to seal any remaining irritants within the canal system, thus preventing recontamination of the periradicular tissues.

Root-End Resection

Two main principles dictate the extent of the root-end resection. First, the cause (or causes) of an ongoing disease process must be removed; this includes removal of the diseased tissue and, when indicated, reduction of an apically fenestrated root. Second, adequate room must be provided for inspection and management of the root end.

The anatomy of each tooth root is complex (see Chapter 5). The surgeon must understand the anatomy of the apical third of the root to determine the extent of a root-end resection. Approximately 75% of teeth have canal aberrations (e.g., accessory or lateral canals) in the apical 3 mm of the tooth.[131,481] An apical resection of approximately 3 mm should include most accessory and lateral canals and thus eliminate most residual microorganisms and irritants (Fig. 9-35). When roots with more than one main canal are resected, isthmus tissue may be present, and the preparation should be modified to include the isthmus area (Fig. 9-36).

If the root apex is close to the buccal cortical plate, apical fenestration can occur, leading to persistent symptoms, especially tenderness to palpation over the root apex.[72] Reduction of an apically fenestrated root apex below the level of the surrounding cortical bone allows remodeling of the bone over the tooth structure. The buccal root of the maxillary first premolar often is closest to the buccal cortical plate.

The surgeon's convenience as a rationale for root-end resection depends on the individual case and the surgeon's abilities. The basic principle of the dental surgeon's convenience should be modified by the desire to minimize the trauma of the surgical procedure itself, including the preservation of tooth and supporting structures. Access to and visibility of the periradicular root structures historically has determined the extent of root-end resection. The surgeon must be able to inspect the

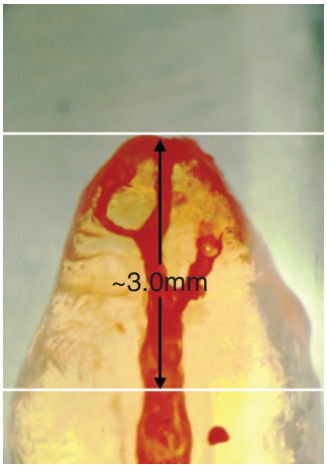

FIG. 9-35 Cleared section of a typical single-canal root that was injected with dye to demonstrate apical accessory canals. Most of the apical ramifications can be eliminated with a 3-mm resection.

resected root end, prepare a root-end cavity, and place a root-end filling. Enhanced visualization equipment (e.g., microscopes, endoscopes, and orascopes) have reduced the need to resect large amounts of the root to gain adequate visualization and access.[91,94,228,280,440,441,448,486] In some cases part of the root must be resected to gain access to the entire soft-tissue lesion, an additional palatally positioned root (e.g., maxillary premolars), or foreign material in the periradicular tissues.

A major consideration in determining the extent of root-end resection is the presence of anatomic structures such as the mental foramen or mandibular canal.[355,410-412] The surgeon should position the resection of the root to avoid possible damage to these structures.

Angle of Resection

Enhanced magnification and illumination techniques have eliminated the need to create a beveled root surface in most cases.[94,441] From a biologic perspective, the most appropriate angle of root-end resection is perpendicular to the long axis of the tooth (Figs. 9-37 and 9-38). The rationale for a perpendicular root-end resection is based on several anatomic parameters. First, a perpendicular resection approximately 3 mm from the anatomic apex is more likely to include all the apical ramifications in that region of the tooth.[339] Second, as the angle of resection increases, the number of dentinal tubules that communicate with the periradicular region and the root canal system increases significantly; therefore, the probability that irritants from within the canal system will gain access to the healing tissues also rises as the resection angle increases.[181,523] Third, extending the root-end cavity preparation beyond the coronal extent of the root surface is simpler if the root-end resection is perpendicular to the long axis of the tooth.[195] Finally, with a perpendicular root-end resection, the stress forces exerted in the apical region are more evenly distributed; this may reduce the propagation of apical fractures and provide a better environment for apical healing.[470]

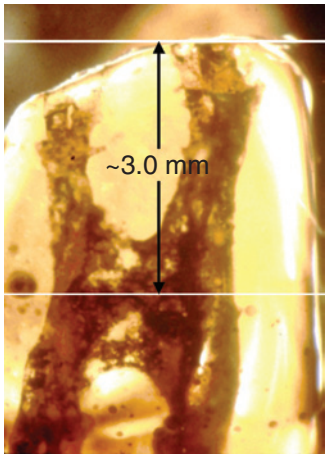

FIG. 9-36 Cleared section of a mesiobuccal (MB) root in a maxillary first molar. Root resection at the recommended 3-mm level exposes isthmus tissue connecting the MB-1 and MB-2 canals.

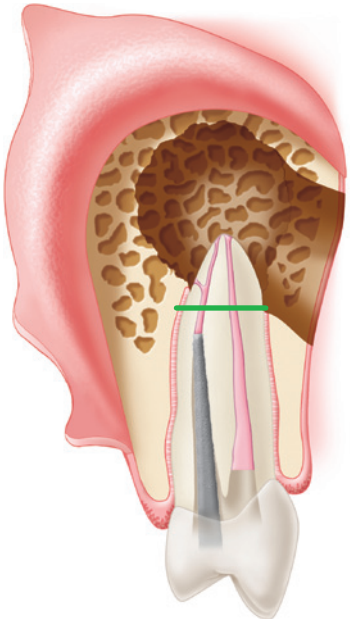

FIG. 9-38 Perpendicular or near perpendicular root-end resection *(green line)* can be achieved with the use of microsurgical instruments and enhanced magnification and illumination.

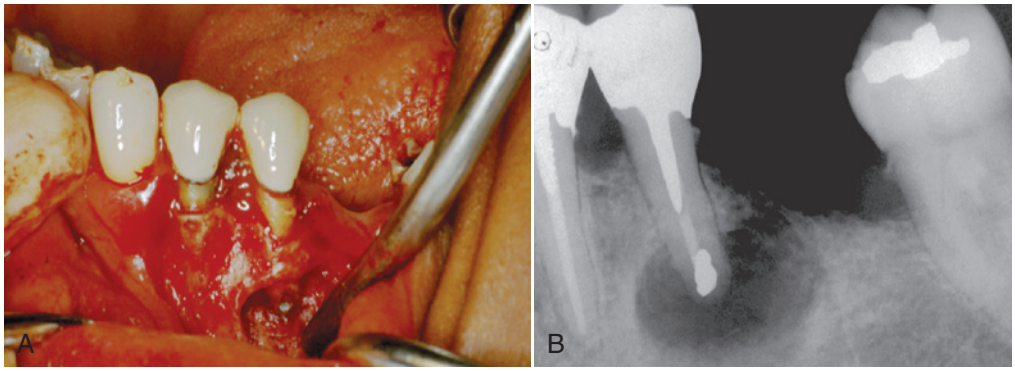

FIG. 9-37 Periradicular surgery circa 1990. **A**, The root end was prepared with a 45-degree bevel and rotary bur microhandpiece. Amalgam was a commonly used root-end filling material at this time. **B**, Immediate postoperative radiograph of a mandibular second premolar with amalgam root-end filling. Although many teeth treated this way healed successfully, newer materials and techniques described in this chapter are currently recommended.

Root-End Surface Preparation

As with all phases of endodontic surgery, the goal is to produce a resected root end with optimum conditions for the growth of cementum and subsequent regeneration of the periodontal ligament across the resected root end. Two important aspects of this process are the surface topography of the resected root end and chemical treatment of the resected root end. Healthy cementum on the root end is required for successful regeneration of periodontal tissues.[22] A number of substances found in cementum stimulate the migration, growth, and attachment of periodontal fibroblasts. Cementum extracts also activate fibroblast, protein, and collagen synthesis, which is necessary to reestablish a functional periodontal ligament.[52,471,562]

Resected Root-End Surface Topography

The conventional axiom for surface preparation of the resected root end has been to produce a smooth, flat root surface without sharp edges or spurs of root structure that might serve as irritants during the healing process. However, little information exists on whether smooth root ends heal differently or more quickly than rough root ends after root-end resection. A study investigating the effect of the surface topography of resected root ends on human PDL fibroblast attachment found no significant difference in fibroblast attachment to the root ends prepared with various instruments.[584] However, with a smooth resected root-end surface, the surgeon is better able to detect surface cracks and anatomic variations.[357] Given that human PDL fibroblast attachment to a smooth surface was not impaired, it would seem appropriate to produce as smooth a surface as possible to facilitate inspection of the resected root end. A smooth root end therefore should be considered advantageous.

Different types of burs tend to produce different patterns on the resected root surface.[212] Several studies have compared the root-end surface after resection.[357,377,585] Generally, crosscut fissure burs in both high-speed and low-speed handpieces produced the roughest and most irregular surfaces. Morgan and Marshall[357] compared the surface topography of root-end resection with a #57 straight fissure bur (Midwest Dental Products, Des Plains, IL), a Lindeman bone bur (Brasseler USA, Savannah, GA), and the Multi-Purpose bur (Dentsply Maillefer, Ballaigues, Switzerland), then finished with a either a multifluted carbide finishing bur (Brasseler USA) or an ultrafine diamond finishing bur (Brasseler). The Multi-Purpose bur produced the smoothest, most uniplanar resected root-end surface with the least amount of shattering. Regardless of the type of bur used, smearing and shredding of the gutta-percha across the root face occurred only when the handpiece was moved across the root face in reverse direction in relation to the bur's direction of rotation.[585] Burs that produce a smooth surface also tend to cut with less vibration and chatter, resulting in greater patient comfort.

Root-End Conditioning

Root surface conditioning removes the smear layer and provides a surface conducive to mechanical adhesion and cellular mechanisms for growth and attachment. It exposes the collagenous matrix of dentin and retains biologically active substances, such as growth factors, in the dentin proper. Experimental studies have shown that demineralized dentin can induce the development of bonelike mineralized tissue.[42,43,241,550,597] Some contend that root surface conditioning produces a biocompatible surface conducive to periodontal cell colonization without compromising the vitality of the adjacent periodontium.

Three solutions have been advocated for root surface modification: citric acid, tetracycline, and ethylenediamine tetraacetic acid (EDTA). All three solutions have enhanced fibroblast attachment to the root surface in vitro. However, citric acid is the only solution tested in an endodontic surgical application.

Citric acid traditionally has been the solution of choice. Periodontists have used an aqueous solution of citric acid (pH 1) for 2 to 3 minutes to etch diseased root surfaces to facilitate formation, new attachment, and cementogenesis.[434-438] Craig and Harrison[114] examined the effect of citric acid demineralization of resected root ends on periradicular healing. They found that 1- or 2-minute applications of 50% citric acid (pH 1) resulted in demineralized root ends and earlier complete healing than in the nondemineralized root ends. However, the periodontal literature has questioned the benefit of etching dentin surfaces with low pH agents. At a low pH, adjacent vital periodontal tissues may be compromised. Also, extended application (3 minutes) has been shown to discourage alveolar bone growth.[60,62]

EDTA, a solution with a neutral pH that endodontists have used as a canal irrigant, has been shown to be equally effective at exposing collagen fibers on dentin surfaces.[64] Unlike the lower pH solution, EDTA does not adversely affect the surrounding tissues.[63]

A series of studies that examined the effect of EDTA and citric and phosphoric acids in a periodontal application showed that application of 15% to 24% EDTA for approximately 2 minutes produces the optimum root surface.[59,61,64] These researchers concluded that EDTA, at neutral pH, was able to selectively remove mineral from a dentin surface, exposing a collagenous matrix. Citric and phosphoric acids, which have a low pH, appeared not only to remove the mineral component but also to denature the collagenous matrix.

Tetracycline has been shown to remove the dentin smear layer, leaving clean, open tubules, with application times as short as 30 seconds.[327] A histologic evaluation of new attachment in periodontally diseased human roots treated with tetracycline hydrochloride showed a trend for greater connective tissue attachment after tetracycline treatment of roots.[13] Studies comparing the effect of a 3-minute application of either EDTA (pH 7.3) or tetracycline HCl (pH 1.8) showed no significant difference in the treated tooth surfaces.[37] However, EDTA has been shown to be more favorable to human PDL cell attachment.[601]

Although the root surface conditioning effects of citric acid, EDTA, and tetracycline are well documented in the periodontal literature, this treatment has not translated into significant gains in periodontal attachment in periodontally diseased teeth.[330] Currently only citric acid has been assessed as a root-end conditioning agent. In an animal model, citric acid was shown to enhance periradicular healing. Nonetheless, its effect and the effect of other root-end conditioning agents on the outcome of human periradicular surgery have not been established. Based on periodontal research, it would appear that if a root surface conditioning agent were to be used during periradicular surgery, EDTA might be the most appropriate solution. However, the manufacturer (personnel communication, Dr. Torabinejad) has advised against the use of EDTA when mineral trioxide aggregate (MTA) is used as a root-end filling material, because it may interfere with the hard tissue–producing effect of MTA.

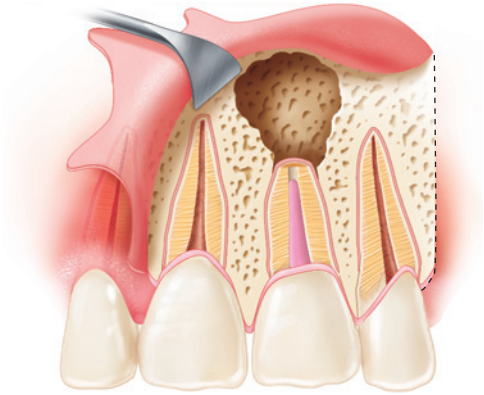

FIG. 9-39 Diagram of a perpendicular root-end preparation and 3-mm deep cavity preparation along the long axis of the root.

FIG. 9-40 Error in root-end cavity preparation: ultrasonic preparation did not follow the long axis of the mesial root and therefore did not allow for proper sealing of this root. Healing is unlikely.

ROOT-END CAVITY PREPARATION
