In 2002, results of a larger comparative study were published[219] with a sample comprising 133 pulpotomy-treated molars of 90 children from 3 to 10 years old with a mean age of 6.2 years. Sixty teeth (45%) were treated with formocresol and 73 (55%) with ferric sulfate. The number of teeth restored with either a stainless steel crown or a composite resin material was almost equal within each group. After 36 months, the clinical success rate was 97.3% for formocresol and 90.3% for ferric sulfate, but the difference in success rate between the two groups was reported to be statistically insignificant. The radiographic success rate was 78.3% for formocresol and 74% for ferric sulfate, again with no statistically significant difference between them. This success rate seems to be the lowest recorded compared with the previously mentioned comparative studies. The author feels that this finding could be due to three reasons: the larger sample size and the very good recall rate, which increased the possibility to observe and locate more failures, and the very strict radiographic assessment. Internal resorption was the most common radiographic finding for both treatments, with no statistically significant difference between ferric sulfate and formocresol. However, most cases classified initially as failures because of internal resorption remained stable throughout the 36-month observation period, and in two cases the respective areas were self-filled with reparative hard tissue. Based on this observation, the data were reevaluated, with only those cases of internal resorption that were either extensive in size or progressing with time considered as failures. After the reevaluation, the overall success rate became 78.7% for ferric sulfate and 85% for formocresol, with no statistically significant difference between them. The survival rate of the treated teeth after 6 months was 98% for both treatments and then 97% for ferric sulfate and 94% for formocresol after 1 year. These figures decreased with time for both groups, and the survival rate dropped to 81% for ferric sulfate and 78% for formocresol from 25 to 36 months.

Retrospective Studies

In a retrospective study published in 2000,[276] ferric sulfate pulpotomies performed over a period of 5 years by a private pediatric dentist were evaluated. The clinical success rate was very high: 99% up to 36 months and no further failures after 36 months. The radiographic success varied from 80% for the 4- to 12-month period, 74% for the 13- to 24-month period, 81% for the 25- to 36-month period, and 74% for the over 36-month period. The estimated tooth survival time was very high, starting with 99% up to 10 months and dropping to 80% after 43 months. The two most common radiographic findings in this study were calcific metamorphosis and internal resorption. The records in this study showed that 13 teeth that presented with internal resorption did not develop osseous lesions for the period of 43 months.

A second retrospective study, published 2 years later in 2002, reported results comparing different pulpotomy treatments; 83 formocresol pulpotomies, 45 ferric sulfate pulpotomies, and 74 pulpotomies treated with a combination of ferric sulfate and formocresol were selected from the records of children treated in a public clinic at different times and by different clinicians.[30] The initial results showed that the total success rate was similar in the three groups, but after a 36-month follow-up, the success rate was better for formocresol than for ferric sulfate, and the combination of the two agents was the worst. The last finding is not surprising because the teeth were treated initially with ferric sulfate for hemostasis and then with formocresol, and they had a poor prognosis (i.e., hyperemic and/or symptomatic). As pointed out by the authors, this study had several shortcomings, the most serious being that the pulpotomies were performed by many clinicians of different levels of experience and expertise; that the criteria for selection of cases were not strictly defined; and that the radiographs were not always satisfactory, compromising accurate evaluation of the periradicular and furcal areas of the treated teeth.

The studies described demonstrate a higher success rate for both ferric sulfate and formocresol in those with shorter observation times and smaller sample sizes. As the sample size increases and the observation period becomes longer, the success rate drops; this holds true for both ferric sulfate and formocresol pulpotomies. The most important finding is that no statistically significant differences in the success rates between ferric sulfate and formocresol existed, with the exception of one short-term study[75] in which a statistically significant difference was observed in favor of ferric sulfate at the 1-year period. In all the reviewed studies (prospective and retrospective), both ferric sulfate and formocresol treatments gave very good results with high tooth survival rates. Moreover, the type of restoration (stainless steel crown or composite resin) was not reported to influence the success rate for either pulpotomy agent.[219]

Clinical Outcome

In one study, the cases of internal resorption that remained unchanged throughout the 36-month observation period were not considered as failures in the final examination of the results.[219] Others proposed that internal resorption should not be considered as pulpotomy failure and based this proposal on the fact that none of the teeth with internal resorption in their sample developed an osseous lesion.[276] This proposal may be accepted only in cases of minimal or unchanged internal resorption but not for severe or progressive resorption. Internal resorption may indicate pulp inflammation that is expected at the amputation site after pulpotomy. However, if the inflammation can be restricted and confined to a very small part of the pulp while the rest is healthy, the resorption process will cease or even self-heal by the apposition of hard tissue and therefore will not be a failure. In all the other cases, internal resorption indicates irreversible or extensive inflammation and should be considered a failure.

It can be seen from these studies and the results of a recent meta-analysis[163] that for human carious primary molars with reversible coronal pulpitis, both ferric sulfate and formocresol pulpotomies similarly give good clinical and radiographic results, with high tooth survival rates and no statistically significant differences in success rates. These findings agreed with

an earlier Cochrane Review of pulp treatment for extensive decay in primary teeth.[199]

Based on these studies, ferric sulfate can be used instead of formocresol for treatment periods up to 36 months.

Mineral Trioxide Aggregate Pulpotomy

Technique

1. After completion of coronal pulp amputation and achievement of hemostasis with moist cotton pellets, MTA powder is mixed with sterile water until the powder is adherent. Excess moisture is removed from the powder by placing a dry paper point into the mixture to act as a moisture wick.
2. The MTA may be applied to the pulp tissue using an excavator or retrograde amalgam carrier, ensuring enough material to completely cover the exposed pulp tissue to a depth of 3 to 4 mm (see Fig. 23-15, *G*).
3. The MTA mixture is gently packed over the pulp tissue using the blunt end of a large paper point and a broad-ended amalgam compactor. This layer of MTA is a permanent wound dressing.
4. A cement base of ZOE or glass ionomer cement is placed gently over the MTA and allowed to set. The MTA will take several hours to reach its optimum physical strength, so care must be taken to ensure an intact layer of MTA is in contact with the pulp tissue.
5. The tooth may then be restored permanently as described for the formocresol pulpotomy.

MTA used as a pulp capping agent in monkey teeth showed the pulp tissue responses to MTA to be superior to those produced using $Ca(OH)_2$.[228] Similar results were found when human intact third molars were used to compare the effect of pulp capping with MTA and $Ca(OH)_2$.[2] MTA was found to maintain pulp integrity after pulp capping and pulpotomy in animal studies[59,255] and to have a dentinogenic effect on the pulp expressed by the induction of dentin bridge formation (see Fig. 23-15, *H*) where it touches the pulp tissue.[255,257,310]

Clinical Studies

One of the first preliminary studies published comparing MTA with formocresol in humans[63] involved 45 pulpotomy-treated primary molars in 26 children with a mean age of 6 years, 5 months. Clinical and radiographic follow-up ranged between 6 and 30 months, involving 18 children with 32 teeth. Internal resorption was seen in one molar treated with formocresol (17 months post treatment). None of the teeth from the MTA group presented any clinical or radiographic pathosis. Pulp canal obliteration was observed in 9 of 32 (28%) molars evaluated.

Preliminary results of a 3-year prospective follow-up study comparing MTA with formocresol were reported at a scientific congress.[245] Pulpotomies were undertaken on 60 primary molars in 22 children aged 2 to 8 years, each needing at least two pulpotomies. Each child received at least one MTA and one formocresol pulpotomy followed by preformed metal (stainless steel) crown. Six months after treatment, seven teeth of the formocresol group and two of the MTA group presented abnormal radiographic findings, but these differences were not statistically significant.

More promising results were observed[122] in a more extensive study that included part of the material presented by Eidelman et al.[63] and a longer follow-up time. These authors assessed the long-term success rate of pulpotomy in primary molars with carious pulp exposure using MTA or formocresol as pulp dressing agents. Sixty-four primary molars of 35 children were treated by a conventional pulpotomy technique. Following removal of the coronal pulp and hemostasis, the pulp stumps were covered with MTA in the experimental group. In the control group, formocresol was placed with a cotton pellet over the pulp stumps for 5 minutes and then removed; the pulp stumps were then covered by ZOE paste. Eight teeth from each group were restored with an amalgam restoration, and all others were covered with a preformed metal (stainless steel) crown. Thirty-three children with 62 teeth (29 treated with formocresol and 33 with MTA) were available for long-term clinical and radiographic evaluation. Follow-up ranged between 4 and 74 months, with a mean follow-up time of 38 months and with no difference between the groups. Twenty-nine teeth were followed until natural exfoliation (mean 33 months). Failures were detected after a mean period of 16 months (range 4 to 30 months). The success rate of pulpotomy was 97% for MTA (one failure) and 83% for formocresol (five failures). Eight teeth presented internal resorption. In four (two from each group), progress of the resorption process stopped, and the pulp tissue was replaced by a radiopaque calcified tissue. Pulp canal obliteration was observed in 55% (34 of 62) of the evaluated molars. This finding, which was not considered a failure, was detected in 58% (19 of 33) of the MTA and in 52% (15 of 29) of the formocresol group. The authors concluded that MTA showed a higher long-term clinical and radiographic success rate than formocresol as a dressing material following pulpotomy in primary molars and recommended it as a suitable replacement for formocresol.

The clinical, radiographic, and histologic effects of gray MTA, white MTA, and formocresol as pulp dressings in pulpotomy-treated primary teeth have been reported.[107] This involved 24 children with a mean age of 6 years (range 4 to 8 years), each with at least three primary molars requiring pulpotomy, for the clinical and radiographic part of the study. An additional 15 carious primary teeth planned for serial extractions were selected for the histologic part of the study. All the teeth were evaluated periodically for 12 months except those selected for histologic evaluation; these were extracted 6 months post treatment. Sixty pulpotomy-treated teeth in 20 children were reviewed; of these, one tooth (gray MTA) exfoliated normally, and six teeth (four white MTA and two formocresol) failed because of abscesses. All the remaining 53 teeth showed success clinically and on radiographs. Pulp canal obliteration was found in 11 teeth treated with gray MTA and one treated with white MTA. The histologic evaluation demonstrated that both types of MTA induced thick dentin bridges, whereas in the formocresol group these were thin and poorly calcified. The pulpal architecture observed with the gray MTA was closer to normal than the white MTA, which presented a dense fibrotic pattern with isolated pulp calcification. These authors concluded that gray MTA was better than both white MTA and formocresol as a pulp dressing for pulpotomy-treated primary teeth.

MTA is commercially available in the United States as ProRoot MTA (DENTSPLY Tulsa Dental, Tulsa, OK), and Angelus MTA (Angelus, Londrina, Brazil) is also available in Latin America and Europe. ProRoot MTA is considered

expensive, particularly because it is retailed in cartons containing a number of sealed 1-gram packets. The composition of MTA is similar to cement used in the building industry, and such material should be kept dry during storage, because contact of the powder with moist air will lead to "air-setting," affecting its physical properties. The same could be applied to the "clinical-grade" cement, and the manufacturer of ProRoot MTA recommends the 1-gram sachet as a single-use, which would be expensive. The unused MTA remaining in a sachet may actually be stored for up to a further 4 weeks in a watertight, air-tight container such as an Eppendorf tube (Eppendorf UK Ltd, Cambridge, UK), reducing its cost.[283] Alternatively, it has been suggested that the MTA powder can be stored indefinitely if the corner of the packet is folded firmly and the packet is stored in a sealable plastic bag. Angelus MTA is presented in a sealable glass vial, with the recommendation that 1 gram may provide up to seven treatments. Care must be taken not to contaminate the MTA powder when it is dispensed.

Electrosurgical Pulpotomy

Technique

The steps in the electrosurgical pulpotomy technique are basically the same as those for the formocresol technique through the removal of the coronal pulp tissue.

1. Large sterile cotton pellets are placed in contact with the pulp, and pressure is applied to obtain hemostasis.
2. The Hyfrecator Plus 7-797 (Birtcher Medical Systems, Irvine, CA) is set at 40% power (high at 12 W), and the 705-A dental electrode is used to deliver the electric arc. The cotton pellets are quickly removed, and the electrode is placed 1 to 2 mm above the pulpal stump.
3. The electric arc is allowed to bridge the gap to the pulpal stump for 1 second, followed by a cool-down period of 5 seconds. Heat and electrical transfer are minimized by keeping the electrode as far away from the pulpal stump and tooth structure as possible while still allowing electric arcing to occur.
4. If necessary, this procedure may be repeated up to a maximum of three times. The procedure is then repeated for the next pulpal stump.
5. When the procedure is properly performed, the pulpal stumps appear dry and completely blackened.
6. The chamber is filled with ZOE placed directly against the pulpal stumps. Research[80] has shown no difference between ZOE and $Ca(OH)_2$ as the dressing. The tooth should then be restored with a preformed metal (stainless steel) crown.

Although electrocoagulation on the pulps of teeth was reported in 1957,[157] it was a decade later that Mack[168] became the first U.S. clinician to routinely perform electrosurgical pulpotomies. Oringer[216] also strongly advocated this technique in his 1975 text on electrosurgery.

Electrosurgery is a nonpharmacologic, hemostatic pulpotomy technique used directly on the radicular pulp stumps following coronal pulp amputation. Depending on the currents used and thus the heat generated, incision, coagulation, or electrofulguration can occur. Electrosurgical pulpotomy carbonizes and denatures pulp tissue, producing a layer of coagulative necrosis. This acts as a barrier between the lining material and healthy pulp tissue below.[278]

Several clinical studies[253,270] have produced results comparable to those found with the use of formocresol. Conflicting results have been reported from histologic studies, ranging from comparable results to formocresol pulpotomy[269] to pathologic root resorption with periapical and furcal involvement.[271] A retrospective human study[169] in 1993 showed a success rate of 99% for primary molars undergoing electrosurgical pulpotomies. Compared with a formocresol pulpotomy study of similar design, the success rate of the electrosurgery technique was shown to be significantly higher.

Laser Pulpotomy

Several reports have appeared in the literature on the use of the carbon dioxide laser for performing vital pulpotomies on primary teeth.[64,161] Investigators[64] compared the use of the laser with formocresol in caries-free, primary cuspid teeth that were scheduled for extraction in children between 6 and 10 years of age. Thirty teeth were included in the study. No significant differences were found between the formocresol and laser-treated groups. Areas of isolated internal resorption were identified in one of the formocresol-treated teeth and two of the laser-treated teeth. They concluded that on the basis of symptomatic, clinical, and histologic findings, the carbon dioxide laser appeared to compare favorably with formocresol treatment. It was suggested that additional studies should be conducted to establish the ideal applied laser energy to maximize optimum residual pulpal response, and to explore the effects of laser pulpotomy upon pulps previously exposed by carious lesions.

Other researchers[161] reported the use of the laser on primary teeth with vital carious pulpal exposures. Thirty-three teeth, 21 primary molars and 12 primary canines, were treated and observed for 12 to 27 months. All were clinically successful, and only one showed evidence of internal resorption at the 6-month follow-up visit. The authors observed complete calcification on radiographs after 9 months in approximately half of the treated teeth.

On the basis of these initial studies, the use of the carbon dioxide laser could be considered a viable alternative to formocresol. More randomized controlled human clinical trials are recommended.

In summary, the search for alternatives to the formocresol pulpotomy in cariously exposed vital primary teeth has yet to reveal an agent, instrument, or technique that has unequivocal long-term clinical success rates better than those of formocresol. Until such an agent, instrument, or technique is found, ferric sulfate, MTA, or formocresol (one-fifth dilution) can be used with equal confidence in primary tooth pulpotomies.[84,250,278]

NONVITAL PULP THERAPY ON PRIMARY TEETH

Pulpectomy in Primary Teeth

The anatomic and normal physiologic features of primary teeth can present challenges to the clinician wishing to undertake pulpectomy procedures. However, with knowledge of these features and how they may impact upon clinical technique, pulpectomy and root canal obturation of primary teeth with irreversibly inflamed or necrotic pulp can be a clinically successful option.

In brief, these features are:

- Root anatomy: apical positions, lateral and accessory canals.
- Root physiology: the effect of exfoliation upon root anatomy and choice of root canal filling material.
- The permanent tooth bud: its proximity to the primary root apex.

Effect of Resorption on Canal Anatomy and Apical Foramina

In the newly completed roots of the primary teeth, the apical foramina are located near the anatomic apices of the roots. After the deposition of additional dentin and cementum, there are multiple apical ramifications of the pulp as it exits the root, just as in the mature permanent tooth.

The physiologic resorption of the roots of the primary incisors and canines starts on the lingual surfaces in the apical third because of the position of the permanent tooth bud. In primary molars, resorption usually begins on the inner surfaces of the roots near the interradicular septum (Box 23-7).

As resorption progresses, the apical foramen may not correspond to the anatomic apex of the root but be coronal to it. Subsequently, radiographic establishment of the root canal length may be challenging (Fig. 23-19). Resorption may extend through the roots and into the root canals, creating additional communications with the periapical tissues other than through the apical foramina or lateral and accessory canals. This has been shown to occur at all levels of the root.[244] Because of these factors, use of an apex locator is not reliable to establish canal length.

Permanent Tooth Bud

The effects of primary endodontic therapy on the developing permanent tooth bud should be of paramount concern to the clinician. Manipulation through the root apex of a primary tooth and overextension of root canal instruments and filling materials are to be avoided because the permanent tooth bud lies in close proximity. If radiographic signs of resorption are visible, canal length is usually established by measurement of the diagnostic radiograph, ensuring the working length of endodontic instruments are 2 or 3 mm short of the radiographic apex. The use of the long-cone radiographic paralleling technique for maximal accuracy is recommended. Hemorrhage after pulp removal may indicate overextension into the periapical tissues.

Anesthesia is usually necessary for pulp extirpation and cleaning of the canals but may be unnecessary when primary teeth are filled at a subsequent appointment. The response of the patient can sometimes be used as a guide to the proximity of the apex and as a check of the length of the canal. However, this can only be done in cooperative patients, because the discomfort caused by placing the rubber dam clamp or by the approach of the instrument to the apex might create disruptive behavior in some children.

The material used to obturate root canals in primary teeth must be resorbable, so that as the tooth resorbs it offers no resistance or deflection to the eruption of the permanent tooth. *Permanent obturating materials, such as gutta-percha, are contraindicated in root canal therapy for primary teeth that have permanent successors.*

Pulpectomy

Pulpectomy and root canal filling procedures on primary teeth have been the subject of much controversy. Fear of damage to developing permanent tooth buds and a belief that the tortuous root canals of primary teeth could not be adequately negotiated, cleaned, shaped, and filled have led to the needless sacrifice of many pulpally involved primary teeth. Much has been written regarding potential damage to the developing permanent tooth bud from root canal fillings. The extraction of pulpally involved primary teeth and placement of space maintainers is an alternative to pulpectomy. However, there is no better space maintainer than the primary tooth. If a space maintainer is placed but adequate monitoring and preventive care is not achieved, further problems often occur.

For example, with a "band and loop" design of space maintainer, loose bands and poor oral hygiene increase the risk of dental caries and gingival inflammation. Prolonged retention of the appliance may cause deflection of the erupting permanent tooth, and premature loss of the band can result in loss of space, particularly if the patient delays returning for treatment.

It has been reported[126] that minor hypoplasia is increased in permanent successor teeth after root canal treatment of the primary precursors. Others[39] have reported no such increased effect and concluded that defects result from the infection existing before the pulpectomy and not the procedure itself. It

BOX 23-7

Physiologic Root Resorption in Primary Teeth

Physiologic root resorption begins:
- Soon after root-length completion.
- In primary incisors and canines on the lingual aspect of the apical third of the roots.
- In primary molars on the inner surfaces of the roots next to the interradicular septum.

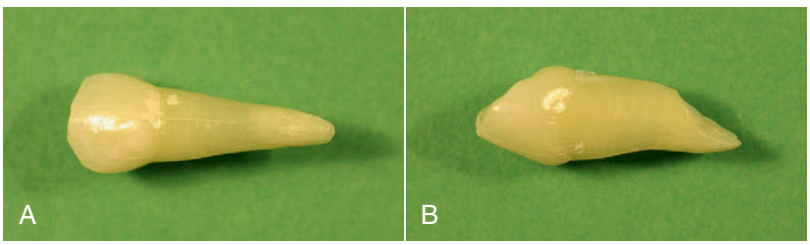

FIG. 23-19 Primary maxillary canine. **A,** Facial view, where apical foramen appears to be at the apex of the root. **B,** Physiologic root resorption has occurred at the palatal aspect of the root; apical foramen is positioned more coronally and will not be coincident with the perceived radiographic apex of the tooth.

is noteworthy that these studies are retrospective, involving erupted permanent teeth; findings should be viewed with caution.

Economics has been advanced as an argument against endodontic treatment of primary teeth, but it is not a reasonable argument when compared with the cost of space maintainers, including the required follow-up treatment. In fact, endodontic treatment is probably the less expensive alternative when the entire treatment sequence is considered.

Success of endodontic treatment on primary teeth is judged by the same criteria that are used for permanent teeth. The treated primary tooth must remain firmly attached and function without pain or infection. Radiographic signs of furcal and periapical infection should be resolved with a normal periodontal attachment. The primary tooth should resorb normally and in no way interfere with the formation or eruption of the permanent tooth.

Success rates ranging from 75% to 96% have been reported.[13,123,155,327] The usual means of studying root canal filling on primary teeth have been clinical and radiographic. There exists a great need for histologic study in this area.

Early reports of endodontic treatment on primary teeth usually involved devitalization with arsenic in vital teeth and the use of creosote, formocresol, or paraformaldehyde pastes in nonvital teeth. The canals were filled with a variety of materials, usually consisting of zinc oxide and numerous additives.[62,98,138,281]

Rabinowitch[234] published the first well-documented scientific report of endodontic procedures on primary teeth in 1953. A 13-year study of 1363 cases of partially or totally nonvital primary molars was reported. Only seven cases were failures; most patients were followed for 1 or 2 years clinically and with radiographs. Patients underwent multiple visits to achieve root canal fillings of ZOE and silver nitrate. Periapically involved teeth required an average of 7.7 visits to complete treatment, and teeth with no periapical involvement required an average of 5.5 visits. Rabinowitch listed internal resorption and gross pathologic external resorption as contraindications to primary root canal fillings.

Another well-documented study reported a success rate of 95% in vital and infected teeth using a filling material of thymol, cresol, iodoform, and zinc oxide.[13] (See Bennett[21] for a review of the techniques of partial and total pulpectomy.)

In a well-controlled clinical study of primary root canals using Oxpara paste as the filling material,[155] five preexisting factors were reported to render the prognosis less favorable:

1. Perforation of the furcation
2. Excessive external resorption of roots
3. Internal resorption
4. Extensive bone loss
5. Periodontal involvement of the furcation

When teeth with these factors were eliminated, a clinical success rate of 96% was achieved. When all symptoms of residual infection were resolved before filling of the canals, the success rate improved.

Contraindications for Primary Root Canal Fillings

Many primary teeth with pulpal involvement that has spread beyond the coronal pulp are candidates for root canal fillings, whether they are vital or nonvital. Box 23-8 lists the categories of teeth that are not good candidates for pulpectomy.

BOX 23-8

Contraindications for Pulpectomy in the Primary Dentition

- An unrestorable tooth
- Internal resorption in the roots visible on radiographs
- Teeth with mechanical or carious perforations of the floor of the pulp chamber
- Excessive pathologic root resorption involving more than a third of the root
- Excessive pathologic loss of bone support, with loss of the normal periodontal attachment
- Presence of a dentigerous or follicular cyst
- Periapical or interradicular lesion involving the crypt of the developing permanent successor

Internal resorption usually begins just inside the root canals near the furcation area. Because of the thinness of the roots of the primary teeth, once internal resorption has become visible on radiographs, there is invariably a perforation of the root by the resorption (see Fig. 23-13). The short furcal surface area of the primary teeth leads to rapid communication between the inflammatory process and the oral cavity through the periodontal attachment. The end result is loss of the periodontal attachment of the tooth and, ultimately, further resorption and loss of the tooth. Mechanical or carious perforations of the floor of the pulp chamber fail for the same reasons. It has been shown that root length is the most reliable criterion of root integrity, and at least 4 mm of root length is necessary for the primary tooth to be treatable.[244]

Access Openings for Pulpectomy

Anterior Primary Teeth

Access openings for endodontic treatment on primary or permanent anterior teeth have traditionally been through the lingual surface. This continues to be the surface of choice except for discolored maxillary primary incisors, in which it is recommended that the clinician use a facial approach followed by an acid-etched composite restoration to improve aesthetics (Fig. 23-20).[170]

Posterior Primary Teeth

Access openings into the posterior primary root canals are essentially the same as those for the permanent teeth. Important differences between the primary and permanent teeth are the length of the crowns, the bulbous shape of the crowns, and the very thin dentinal walls of the pulpal floors and roots. The depth necessary to penetrate into the pulpal chamber is much less than that in the permanent teeth. Likewise, the distance from the occlusal surface to the pulpal floor of the pulp chamber is much less than in permanent teeth. In primary molars, care must be taken not to overinstrument the relatively thin pulpal floor, owing to the high risk of perforation (Fig. 23-21).

When the roof of the pulp chamber is breached and the pulp chamber identified, the entire roof should be removed. Because the crowns of the primary teeth are more bulbous, less extension toward the exterior of the tooth is necessary to uncover the openings of the root canals than in the permanent teeth.

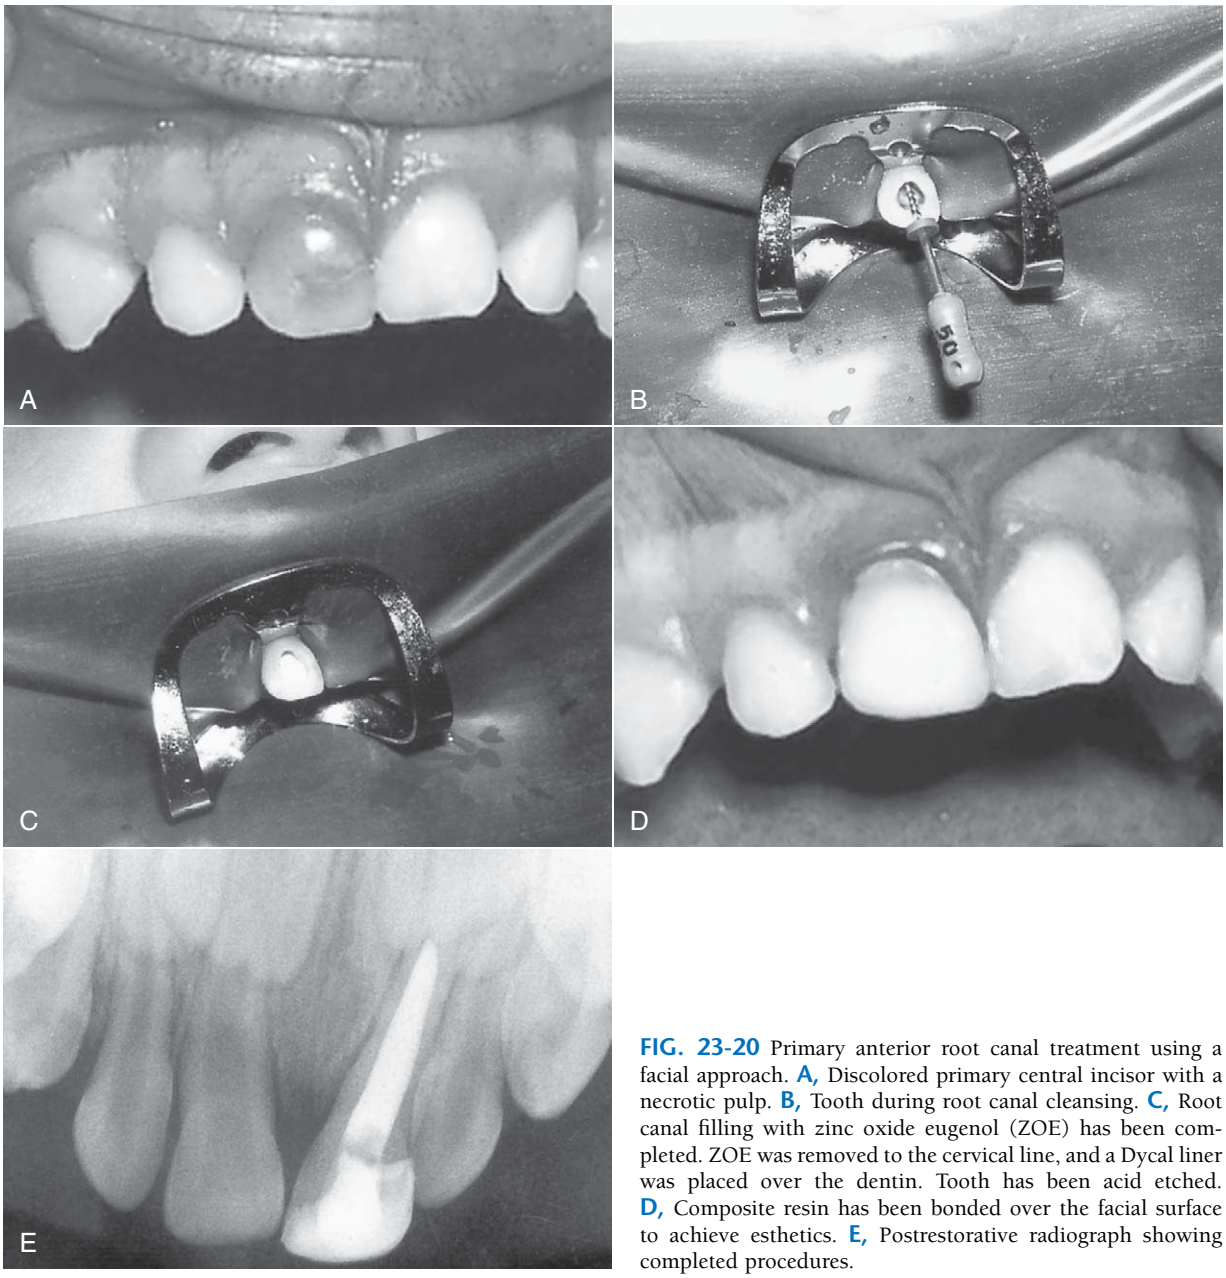

FIG. 23-20 Primary anterior root canal treatment using a facial approach. **A,** Discolored primary central incisor with a necrotic pulp. **B,** Tooth during root canal cleansing. **C,** Root canal filling with zinc oxide eugenol (ZOE) has been completed. ZOE was removed to the cervical line, and a Dycal liner was placed over the dentin. Tooth has been acid etched. **D,** Composite resin has been bonded over the facial surface to achieve esthetics. **E,** Postrestorative radiograph showing completed procedures.

Technique

As in permanent endodontic therapy, the main objective of the chemical and mechanical preparation of the primary tooth is débridement of the canals. Although an apical taper is desirable, it is not necessary to have an exact shape to the canals because obturation is achieved using a resorbable paste. Fig. 23-22 provides a schematic overview of the procedure.

Canal Preparation

1. A preliminary working length is determined by measurement of a radiograph taken with a paralleling technique.
2. Local anesthesia is advisable.
3. The placement of a rubber dam is mandatory.
4. The working length is determined from a radiograph with an endodontic file in the canal. The use of apex locators is unreliable because root resorption may create lateral openings into the periodontal tissues at any level.[244]
5. To prevent overextension through the apical foramen, it is advisable that the working length be shortened to 2 to 3 mm short of the radiographic length, especially in teeth exhibiting signs of apical root resorption (see Fig. 23-22, *B*).
6. After establishment of the working length, the canal is cleaned and gently shaped (as described in Chapter 9). *Because of the thin root walls, sonic and ultrasonic cleaning devices should not be used to prepare the canals. Also, the use of Gates-Glidden (GG) or Peeso drills (Pulpdent Corp, Watertown, MA) is contraindicated because of the danger of perforation or stripping of the roots.*

FIG. 23-21 Illustration to show the safe removal of the roof of a pulp chamber in a primary molar. A non-end cutting bur ensures that the relatively thin floor to the pulp chamber is not perforated inadvertently by rotary cutting instruments.

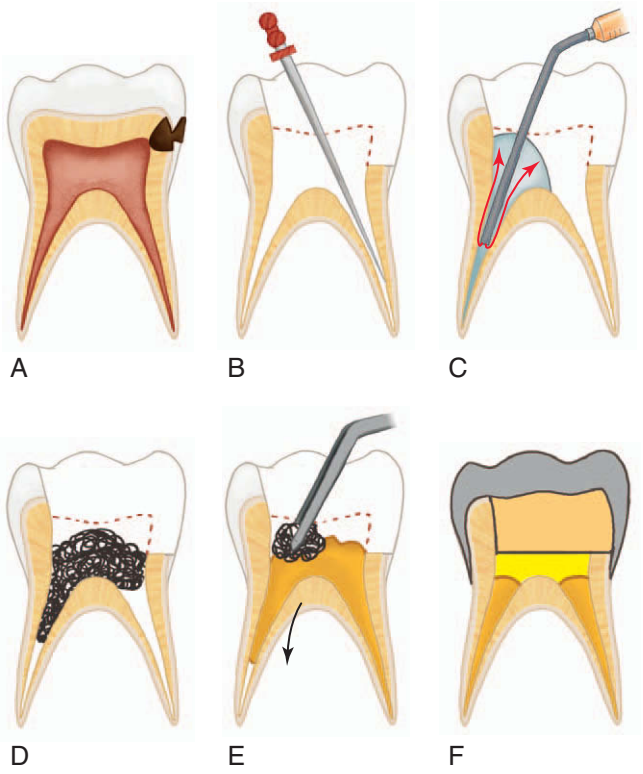

FIG. 23-22 Illustration to show the stages of pulpectomy and root canal filling in a mandibular second primary molar. **A,** Extensive approximal caries. Note the irreversible inflammation present in coronal and radicular pulp. **B,** Following caries removal and unroofing of the pulp chamber, the coronal pulp is amputated. Irreversibly inflamed tissue will bleed profusely. A premeasured hand file is placed approximately 2 mm from the radiographic apex; canals are gently cleaned with minimal shaping. **C,** Irrigation with sodium hypochlorite or chlorhexidine digluconate solution should be undertaken during the cleaning phase. **D,** If root canals are not to be obturated at the same visit, they may be dressed with nonsetting calcium hydroxide, or canals can be left empty and the tooth restored with a small cotton wool pledget and an interim intracoronal restoration. **E,** At the subsequent visit, root canals can be obturated with a resorbable root-filling material such as zinc oxide eugenol (ZOE). This can be applied using various methods; shown here is the ZOE being tamped down the canal by the piston action of a cotton pledget held in tweezers. **F,** Following root canal filling, the tooth is restored definitively using a preformed metal (stainless steel) crown.

7. The more flexible nickel-titanium (NiTi) instruments are recommended rather than stainless steel (SS). Hand or rotary techniques are ideal for primary teeth. If SS files are used, the instruments must be gently precurved to help negotiate the canals.
8. Care must be taken not to perforate the thin roots during cleaning and shaping procedures. The canals are enlarged several sizes past the first file that fits snugly in the canal, with a minimum size of 30 to 35.

Importance of Irrigation During Treatment

Because many of the pulpal ramifications cannot be reached mechanically, copious irrigation during cleaning and shaping must be maintained (see Chapter 9). Débridement of the primary root canal is more often accomplished by chemical means than by mechanical means.[130] This statement should not be misinterpreted as a de-emphasis on the importance of thorough débridement and disinfection of the canal. Initially, RC-Prep (Premier Dental Products, Norristown, PA) may be used as the canals are negotiated. It will digest and emulsify pulp tissue and is an effective lubricant. Once a working length has been established, the use of NaOCl solution to dissolve organic debris can play an important part in removal of tissue from inaccessible areas of the root canal system (see Fig. 23-22, *C*).

The Nonvital Discolored Primary Incisor

If a primary incisor is intrinsically discolored following loss of pulp vitality, there may be an esthetic need to improve the tooth's color. Bleaching is not advised in the primary dentition. The anatomy of the maxillary primary incisors is such that access may successfully be made from the facial surface. The only variation to the opening is more extension to the incisal edge than with the normal lingual access to give as straight an approach as possible into the root canal.

The root canal is filled with ZOE (see the following section); then the ZOE is carefully removed to near the cervical line. A liner of Dycal or Life is placed over the ZOE to serve as a barrier between the composite resin and the root canal filling. The liner is extended over the darkly stained lingual dentin to serve as an opaquer. The access opening and entire facial surface are acid etched and restored with composite resin (see Fig. 23-20, *C-D*).

The Decision to Obturate

After canal débridement, the canals are again copiously flushed with NaOCl and are then dried with sterile premeasured paper

points. If the canals are dry and there is no exudate, obturation is performed in the same session. If the obturation cannot be done in the first appointment, a slurry paste of nonsetting $Ca(OH)_2$ can be injected into the canals and the tooth restored with a well-sealing temporary restoration.

At a subsequent appointment, the rubber dam is placed and the canals reentered. As long as the patient is free of all signs and symptoms of inflammation, the canals are irrigated with NaOCl to remove the intracanal dressing and dried before obturation. If signs or symptoms of inflammation are present, the canals are recleaned and remedicated and the canal obturation delayed until a later time.

Root-Filling Materials for the Primary Root Canals

The ideal root canal filling material for primary teeth should:

- Resorb at a similar rate as the primary root.
- Be harmless to the periapical tissues and the permanent tooth germ.
- Resorb readily if pressed beyond the apex.
- Be antiseptic.
- Fill the root canals easily.
- Adhere to the walls of the root canal.
- Not shrink.
- Be easily removed if necessary.
- Be radiopaque.
- Not discolor the tooth.[167]

No material currently available meets all these criteria. The filling materials most commonly used for primary pulp canals are ZOE paste, iodoform paste, and $Ca(OH)_2$. These will be discussed briefly in the following section.

Zinc Oxide Eugenol Paste

Most reports in the U.S. literature have advocated the use of ZOE as the filler, whereas other parts of the world have used iodoform-containing pastes.[124,151] The antibacterial activity of ZOE has been shown to be greater than that of an iodoform-containing paste (KRI paste, Pharmachemic AG, Zurich, Switzerland), whereas its cytotoxicity in direct and indirect contact with cells is equal to and less than (respectively) than that of KRI paste. *The filling material of choice in the United States is ZOE without a catalyst.* The lack of a catalyst is necessary to allow adequate working time for filling the canals.

Iodoform Paste

Several authors have reported the use of KRI paste, which is a mixture of iodoform, camphor, parachlorophenol, and menthol.[243] It resorbs rapidly and has no undesirable effects on successor teeth when used as a pulp canal medicament in abscessed primary teeth. Further, KRI paste that extrudes into periapical tissue is rapidly replaced with normal tissue.[124] Sometimes the material is also resorbed inside the root canal. A paste developed by Maisto has been used clinically for many years, and good results have been reported with its use.[174,289] This paste has the same components as the KRI paste, with the addition of zinc oxide, thymol, and lanolin.

Calcium Hydroxide

Several clinical and histopathologic investigations of $Ca(OH)_2$ and iodoform mixture (Vitapex, Neo Dental Chemical Products Co, Tokyo) have been published.[83,207] These authors found that this material is easy to apply, absorbs at a slightly faster rate than that of the roots, has no toxic effects on the permanent successor, and is radiopaque. For these reasons, one researcher[167] considers the calcium hydroxide–iodoform mixture to be a nearly ideal primary tooth root canal obtundant. Another preparation with similar composition, Endoflas, is available in the United States (Sanlor Laboratories, A.A. 7523 Cali, Colombia, South America). The results of root canal treatments using Endoflas in a students' clinic were similar to those observed with KRI paste.[87]

Obturation of the primary root canal is usually performed without a local anesthetic. This is preferable, if possible, so the patient's response can be used to indicate proximity to the apical foramen. It is, however, sometimes necessary to anesthetize the gingiva with a drop of anesthetic solution to place the rubber dam clamp without pain.

Obturation of the Root Canal

The chosen obturation technique depends upon the material employed and accessibility of the canal to relevant instruments.

If using ZOE, it is mixed to a thick consistency and carried into the pulp chamber with a plastic instrument or on a Lentulo spiral. The material may be packed into the canals with pluggers or the Lentulo spiral. A cotton pellet held in cotton pliers and acting as a piston within the pulp chambers is quite effective in forcing the ZOE into the canals (see Fig. 23-22, *E*). The endodontic pressure syringe[23,103] is also effective for placing the ZOE in root canals. However, in a study of apical seal and quality of filling evaluated on radiographs, no statistically significant differences were reported between the Lentulo spiral, pressure syringe, or plugger.[56]

When the root canal is filled with a resorbable paste such as KRI, Maisto, or Endoflas, a Lentulo spiral mounted in a low-speed handpiece can be used to introduce the material into the canal. When the canal is completely filled, the material is compressed with a cotton pellet. Excessive material is rapidly resorbed.

Vitapex is packed in a convenient sterile syringe and the paste injected into the canal with disposable plastic needles. This technique is particularly easy to use for primary incisors but less practical for the narrow canals of primary molars.[210]

Regardless of the method used to fill the canals, care should be taken to prevent extrusion of the material into the periapical tissues. It is reported that a significantly greater failure rate occurs with overfilling of ZOE than with filling just to the apex or slightly underfilling.[39,123] The adequacy of the obturation is checked by radiographs (see Fig. 23-20, *E*; Fig. 23-23, *A*; Fig. 23-24, *C*).

In the event a small amount of the ZOE is inadvertently forced through the apical foramen, it is left alone (because the material is absorbable). It has been reported that defects on successor teeth have no relationship to length of the ZOE filling.[39]

When the canals are satisfactorily obturated, a fast-setting temporary cement is placed in the pulp chamber to seal over the root canal filling. The tooth may then be restored permanently. In primary molars, it is advisable to place a preformed (stainless steel) crown as the permanent restoration to ensure good coronal seal and prevent possible fracture of the tooth (see Fig. 23-22, *F*).

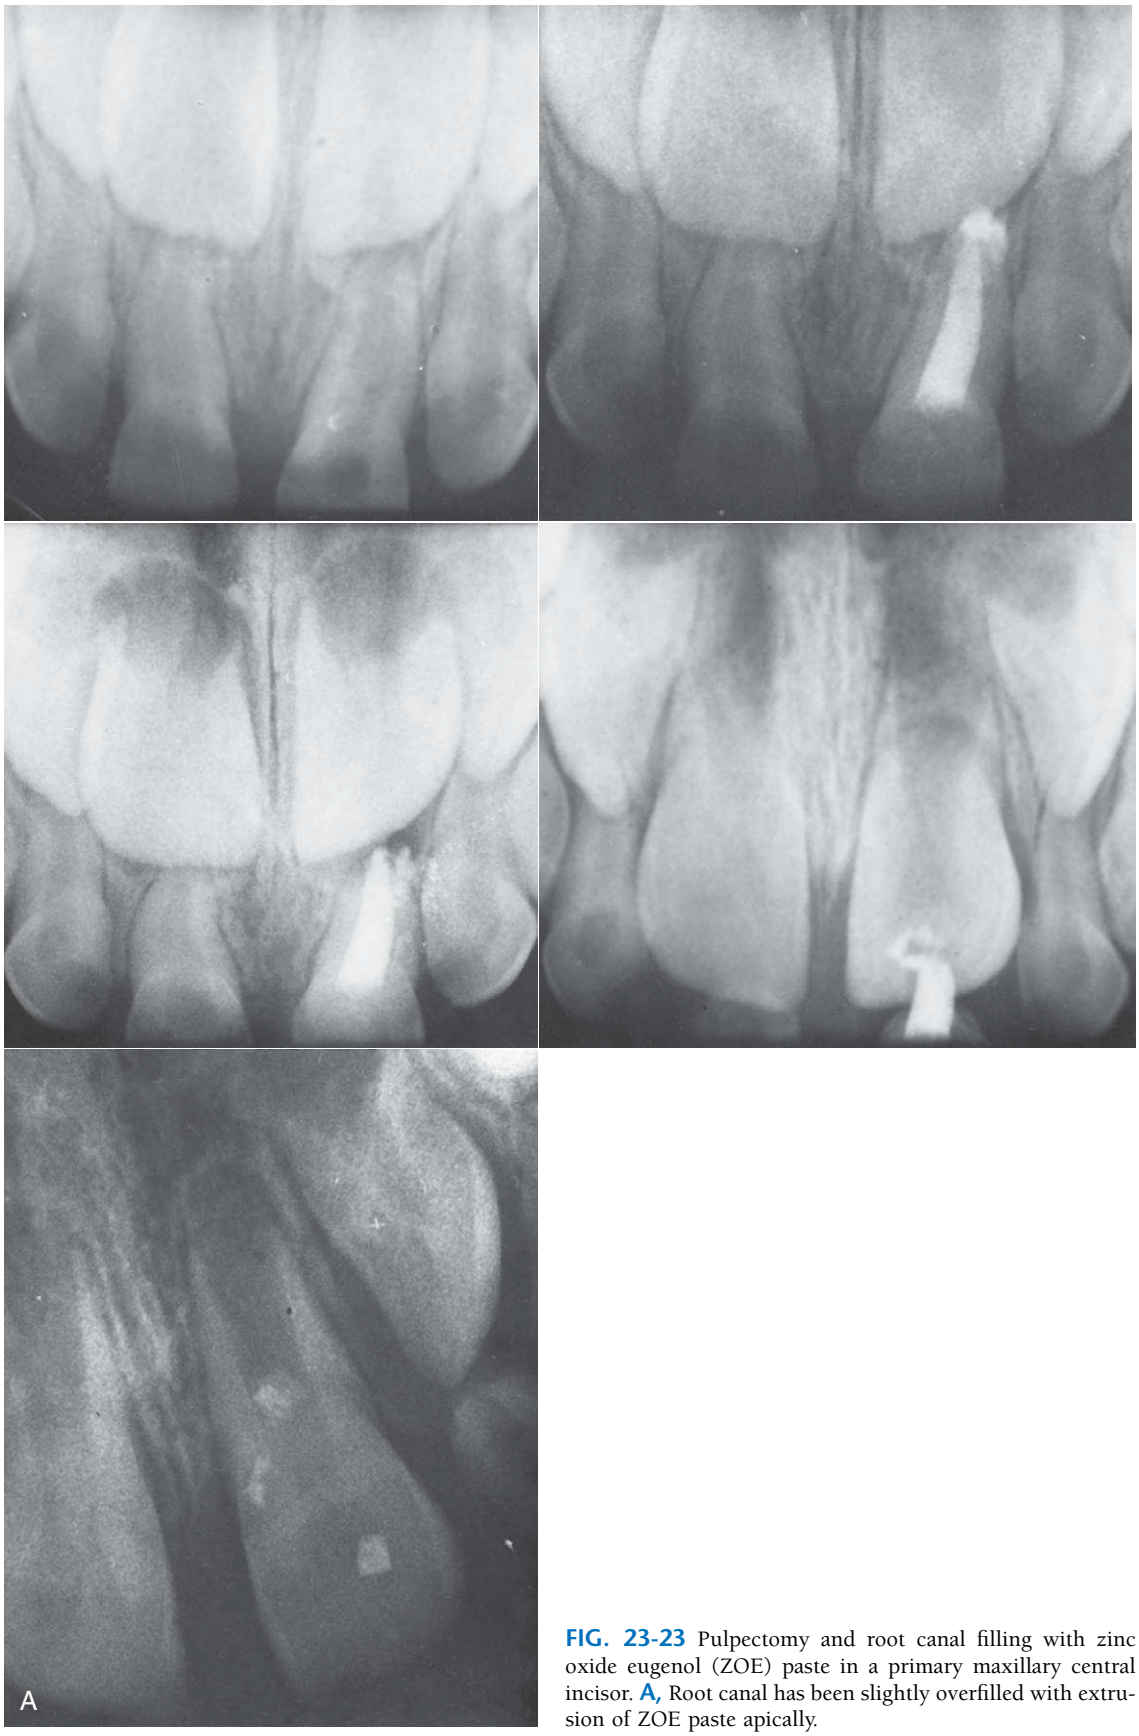

FIG. 23-23 Pulpectomy and root canal filling with zinc oxide eugenol (ZOE) paste in a primary maxillary central incisor. **A,** Root canal has been slightly overfilled with extrusion of ZOE paste apically.

Continued

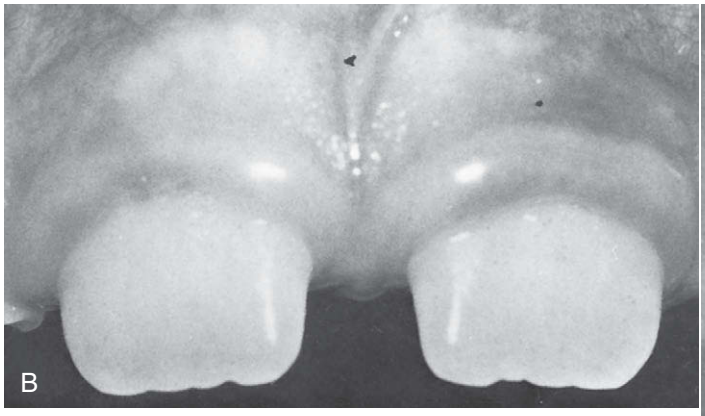

FIG. 23-23, cont'd B, Same patient showing newly erupted permanent incisors. Note there are no enamel defects present on the crown, despite overfill of the root canal of the predecessor. **C,** Radiograph almost 5 years after pulpectomy and root canal filling of predecessor. Note normal apical development and almost total absorption of ZOE remnants.

If a primary tooth requires pulpectomy and the permanent successor tooth is absent, the primary root canals are filled with gutta-percha and sealer in an attempt to retain the primary tooth long term (Fig. 23-25).

Follow-Up After Pulpectomy in the Primary Dentition

As previously stated, the rate of success after primary pulpectomy is high. However, these teeth should be periodically recalled to check for success of the treatment and intercept any problem associated with a failure. It has been reported[39,283] that pulpectomized primary teeth may show delayed exfoliation. One study[39] described a 20% incidence of crossbites or palatal eruption of permanent incisors after pulpectomy on primary incisors. In the posterior teeth, extraction was required in 22% of cases because of ectopic eruption of the premolars or difficulty in exfoliation of the treated primary molar.[39] After normal physiologic resorption of the roots reaches the pulp chamber, the large amount of ZOE present may impair the resorptive process and lead to prolonged retention of the crown. Treatment usually consists of simply removing the crown and allowing the permanent tooth to complete its eruption.

Retention of ZOE in the tissues is a common sequela to primary pulpectomy. One long-term study reported that after loss of the tooth, 50% of cases had retained ZOE. Teeth filled short of the apices had significantly less retained filler, and in time, most showed complete absorption or reducing amounts. Retention of filler was not related to success and caused no pathosis.[254] Therefore no attempt is made to remove retained filler from the tissues (see Fig. 23-23, *A*; Fig. 23-24, *C*).

While resorbing normally without interference from the eruption of the permanent tooth, the primary tooth should remain asymptomatic, firm in the alveolus, and free of pathosis. Traditionally, root treatments were considered successful when no pathologic resorption associated with bone rarefaction was present.[95,124] If evidence of pathosis is detected, extraction and conventional space maintenance are recommended.

Investigators[223] claim that most clinicians are prepared to accept pulp-treated primary teeth that have a limited degree of radiolucency or pathologic root resorption in the absence of clinical signs and symptoms. This is contingent on the assurance that the parent will contact the clinician if there is an acute problem, and the patient will return for review in 6 months. These criteria seem to be more suitable for pediatric dental practices and have been adopted clinically by Fuks et al[87]; they consider such teeth to be "successfully treated."

PULPAL THERAPY FOR THE YOUNG PERMANENT DENTITION

It could be argued that mature permanent teeth can survive for a lifetime without the support of a vital pulp. For the immature permanent tooth, the future is less secure. Premature loss of a functioning pulp results in a fragile tooth with a compromised crown/root ratio, thin dentin walls, and a wide and often apically diverging root that presents significant endodontic and restorative challenges (Fig. 23-26). A central responsibility of all clinicians is therefore to safeguard pulp survival until dental development is complete.

The procedures described in this section have much in common with those for primary teeth and focus on preserving all or part of the pulp in a functional condition. In addition to aspects of pulp protection, indirect pulp therapy, direct pulp capping and pulpotomy, attention will be given to the root canal treatment and restoration of nonvital, immature permanent teeth. The emerging potential of pulp regeneration and bioroot engineering will also be considered.

Indirect Pulp Therapy: Avoiding Pulp Exposure

The pulps of young permanent teeth are at risk of breakdown following traumatic injuries (considered fully in Chapter 17), dental caries, and restorative dentistry. There is good evidence that residual dentin thickness is a key determinant of pulp survival after cavity preparation,[190] and avoiding pulp exposure

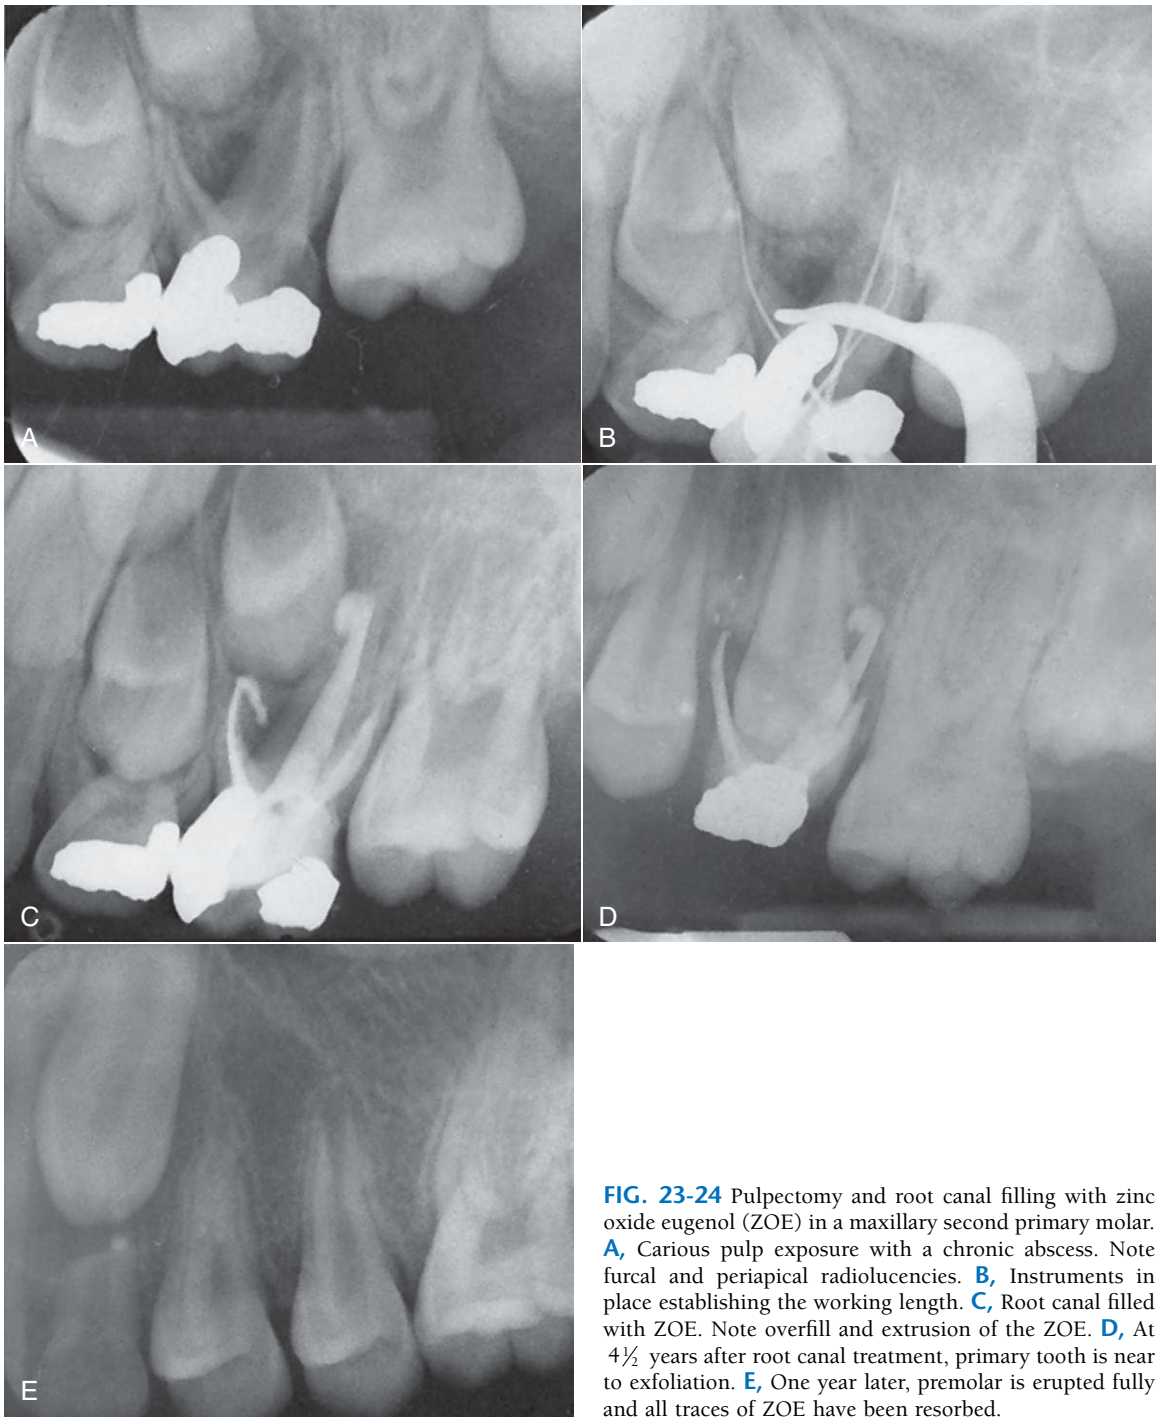

FIG. 23-24 Pulpectomy and root canal filling with zinc oxide eugenol (ZOE) in a maxillary second primary molar. **A,** Carious pulp exposure with a chronic abscess. Note furcal and periapical radiolucencies. **B,** Instruments in place establishing the working length. **C,** Root canal filled with ZOE. Note overfill and extrusion of the ZOE. **D,** At 4½ years after root canal treatment, primary tooth is near to exfoliation. **E,** One year later, premolar is erupted fully and all traces of ZOE have been resorbed.

has been considered advantageous. The management of deep caries by partial and serial excavation has gained considerable support in recent years, reducing the risks of pulp exposure and harnessing the natural defenses of the pulp in laying down protective tertiary (reactionary) dentin.[25] In the case of serial excavation, the need for a secondary excavation has recently been brought into question, while acknowledging the need for a tightly-sealing coronal restoration.[241] Researchers continue to investigate the role of antimicrobial treatments, including ozone fumigation,[229] photo-activated disinfection (PAD), and antimicrobial resins in sterilizing deep layers of affected dentin[307] and creating the conditions for arrest and remineralization. Considerable interest has also focused on the active upregulation of reactionary dentinogenesis by applying bioactive agents such as the TGF-β family of molecules to the depths of cavity preparations.[306] Therapeutic approaches present a hopeful future for pulp protection after deep caries, but significant challenges remain, not least in defining optimal agents and predictably delivering them to the pulp through the fluid-filled dentinal tubules of vital teeth.[232] More basic and clinical

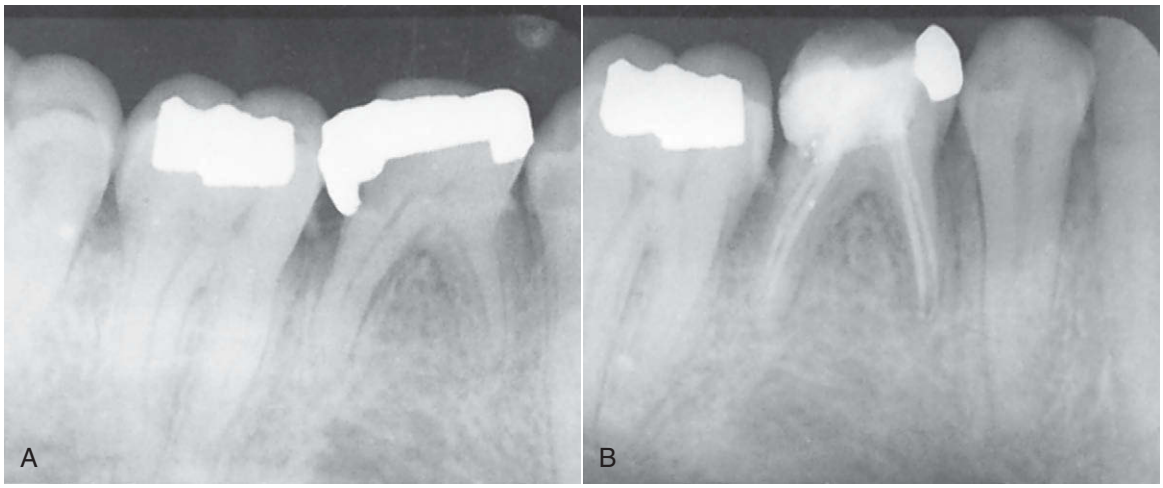

FIG. 23-25 Pulpectomy and root canal filling with gutta-percha in a retained mandibular primary second molar with no succedaneous permanent tooth. **A,** Carious exposure of the pulp. **B,** Because the permanent premolar is absent, root canals were filled with gutta-percha and sealer rather than just zinc oxide eugenol.

FIG. 23-26 Premature loss of vital pulp functions in an immature maxillary permanent incisor. Development is arrested, leaving a fragile tooth with a compromised crown-root ratio, thin dentin walls, and a wide-open root end which presents endodontic and restorative challenges.

research is needed before such agents can be widely adopted in practice.

There is, however, a substantial body of evidence to support the view that complete excavation is not necessary for the successful management of deep caries,[299] and that indirect pulp therapy may be the most effective means of securing pulp health in asymptomatic teeth.

Managing Pulp Exposure

Even with the greatest clinical judgment and restorative skill, pulps are sometimes exposed during deep caries excavation. A recent survey has also shown that 62% of clinicians would remove all caries when presented with a case in which one would expect pulp exposure, whereas only 18% would partially excavate caries, and 21% would initiate root canal treatment.[211] Direct pulp capping has generally not enjoyed predictable success in cariously exposed teeth. One study showed a 44.5% failure at 5 years and a disappointing 79.7% failure at 10 years.[20] Attitudes may be changing, especially for the management of immature permanent teeth, where pulp diagnosis is notoriously difficult and the stakes for pulp preservation are high. Though much of the evidence is relatively short term and involves previously uninflamed pulps, MTA has established a strong track record for promoting reparative tertiary dentin bridge formation after direct pulp capping[200] (see Fig. 23-5).

In a radically different approach to the management of deep caries, one of the authors (JC) has advocated complete caries excavation and direct capping of the exposure in the immature teeth of children (Fig. 23-27). Teeth with percussion sensitivity, swelling, or other obvious signs of pulpal necrosis are not considered good candidates, and the pulp tissue exposed during caries excavation must appear vital with no signs of degeneration or suppuration. In this procedure, the tooth is anesthetized and isolated with the rubber dam. All decay is removed with round carbide burs and copious water spray. No further pulpal tissue is removed except that occurring with the caries removal. The often profuse bleeding that occurs is controlled by lavaging the pulp with NaOCl, which is not only antimicrobial but appears to have no adverse effects on pulpal healing, odontoblastic cell formation, or dentinal bridging.[3,43] The solution may be left in contact with the exposed pulp tissue for 10 to 15 minutes, refreshing with new solution every 3 to 4 minutes. Care must be taken in aspirating the excess NaOCl to prevent further hemorrhage, the aspirator tip being placed lateral to and never directly above the crown.

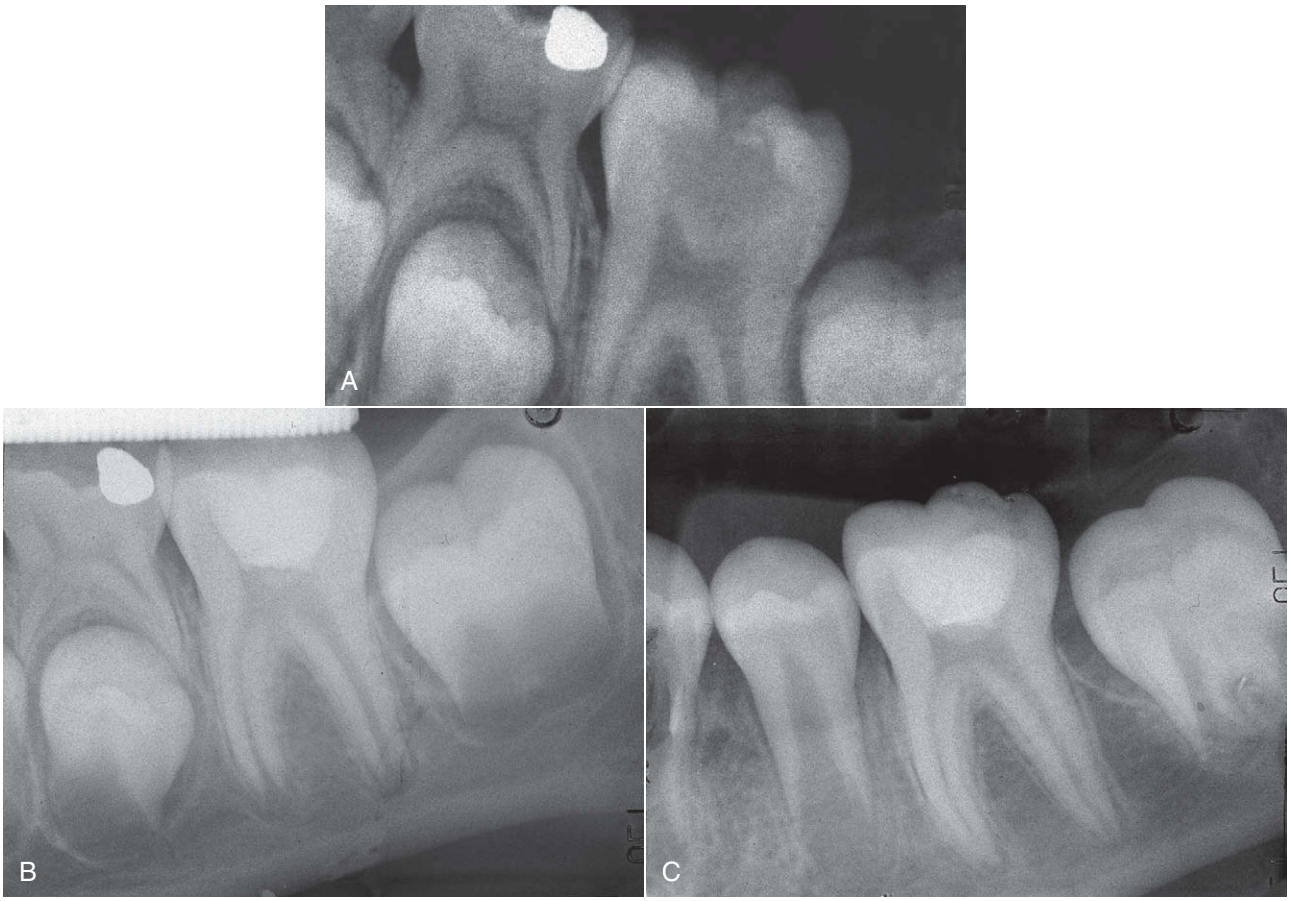

FIG. 23-27 Direct pulp capping in a symptomatic young permanent mandibular molar with an open apex. **A,** Extensive carious exposure in an immature molar with a history of spontaneous pain. **B,** After complete caries excavation and hemostasis, the pulp is overlaid with mineral trioxide aggregate and the tooth sealed with composite resin. **C,** Three-year recall shows completed root formation. Note lack of calcification within pulp chamber and canals.

Once hemorrhage is controlled, the tooth structure is cleansed with cotton pellets moistened with NaOCl, once again avoiding further pulp hemorrhage.

The exposed pulp is then covered with a 0.5- to 1-mm thickness of MTA, which is gently teased against the exposed pulp tissue with a damp cotton pellet. Wisps of cotton are wet with sterile water and placed over the MTA so it is completely covered. The tooth is then provisionally sealed with a temporary cement such as Cavit to allow hardening of the MTA.

The patient is seen again within 12 to 48 hours, and the tooth is anesthetized and isolated with a rubber dam. Following removal of the Cavit and cotton, the MTA is examined to ensure that it is set hard, and the tooth is restored with a bonded composite restoration. If the MTA has failed to harden, the author has advocated washing out the uncured material and repeating the procedure after removing pulp tissue to canal orifice level. This approach has received further support from two studies. In the first,[73] 30 asymptomatic permanent molars were reviewed clinically and radiographically after caries excavation and direct pulp capping with MTA; 93% were successful at 24 months, with continued root development. In the second report, Bogen et al. (2008)[27] described a series of 53 teeth diagnosed at the outset with deep caries and reversible pulpitis but with no periapical involvement. Caries was completely eliminated with the help of a caries-detector dye and magnification (Fig. 23-28, *A-B*), often resulting in multiple, large pulp exposures. Hemostasis was secured by bathing the pulp with 5.25% to 6% NaOCl for between 1 and 10 minutes (Fig. 23-28, *B-D*). One pulp which continued to bleed after this time was considered unsuitable for direct capping. After the application of 1.5 to 3 mm gray or white MTA (Fig. 23-28, *E*) and permanent bonded restorations at 5 to 10 days, teeth were reviewed for between 1 and 9 years (mean 3.94 years). The recall rate was 92.5%, and 97.96% of teeth were found to have favorable outcomes on the basis of radiographic appearances, subjective symptoms, and cold testing (Fig. 23-28, *F*). Of the 15 teeth which were immature at the time of treatment, 100% went on to complete root formation.[27]

At the time of writing, a conservative general consensus probably holds with partial and serial caries excavation, avoiding pulp exposure and attempting to create an environment which will upregulate reactionary tertiary dentin responses.[25,241] But evidence is growing that in correctly chosen cases with no indication of irreversible pulpitis or periapical change and where radical caries excavation is followed by confirmation of hemostasis, direct capping with MTA can enjoy remarkable levels of success in teeth with incomplete apices. Although

generally restricted to asymptomatic teeth, one of the authors (JC) has noted success in both asymptomatic and symptomatic teeth, with resolution of pain and continued root development. This procedure may in effect be considered a very superficial form of mechanical and chemical pulpotomy. *Because the loss of vital pulp function is so devastating in teeth with immature apices, it seems advisable to attempt conservative pulp-preserving procedures in deeply carious permanent teeth. If failure occurs, apexification or regenerative techniques can always be considered.*

PULPOTOMY

The pulpotomy procedure involves removing only part of the pulp, eliminating tissue that has inflammatory or degenerative changes and leaving intact the underlying healthy pulp tissue.[15] This is then covered with a wound-dressing agent in an effort to promote healing at the amputation site. Traditionally, the term *pulpotomy* has implied removal of pulp tissue to the cervical line. However, the depth to which tissue is removed is determined by clinical judgment of how deeply the pulp is affected. Superficial amputation (partial pulpotomy) may allow better visualization of the working area but risks leaving damaged tissue that may go on to break down. In multirooted teeth, the procedure may be simplified by removing tissue to the orifices of the root canals.

The Cvek Pulpotomy on Immature Permanent Teeth

Pulpotomy is an established technique for preserving vital pulp functions in immature teeth which have been subject to pulp-exposing trauma. A full account of the Cvek pulpotomy is

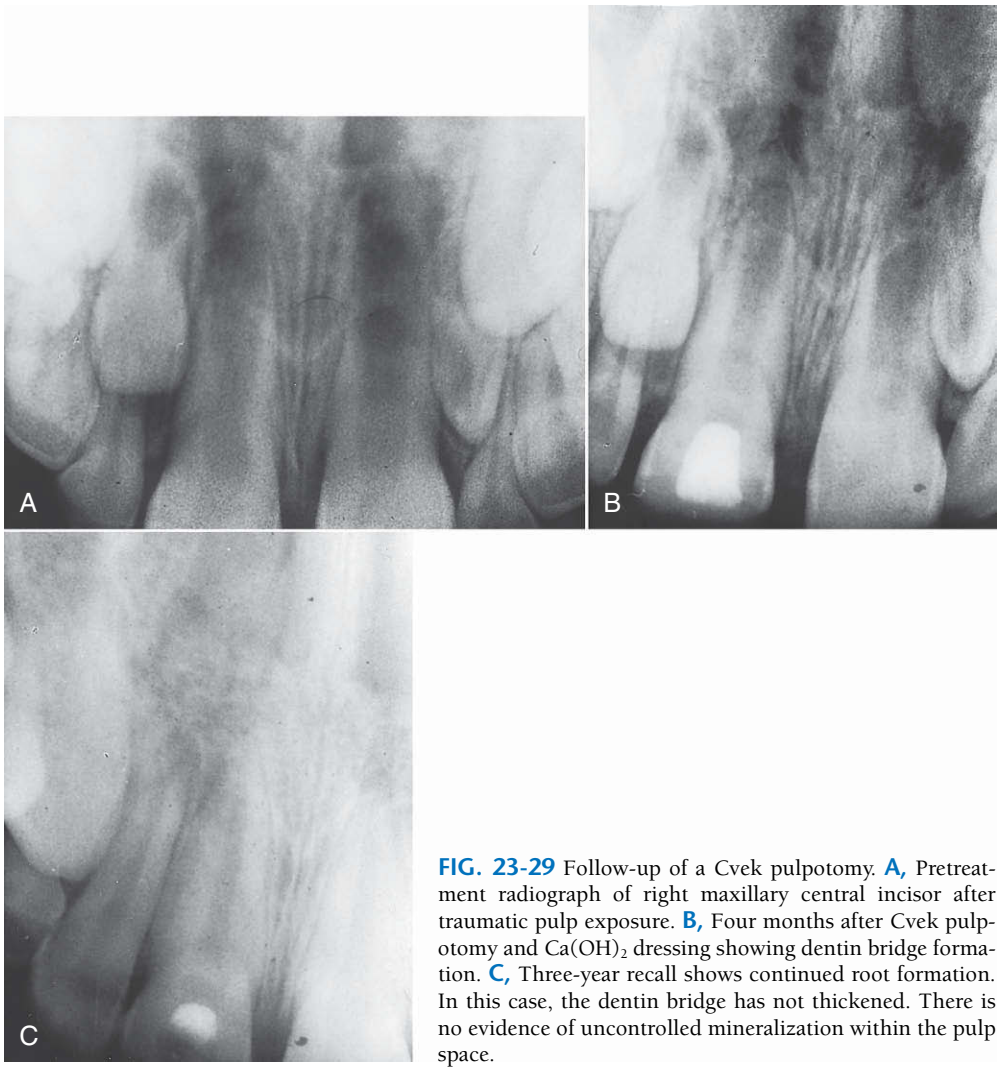

FIG. 23-29 Follow-up of a Cvek pulpotomy. **A,** Pretreatment radiograph of right maxillary central incisor after traumatic pulp exposure. **B,** Four months after Cvek pulpotomy and $Ca(OH)_2$ dressing showing dentin bridge formation. **C,** Three-year recall shows continued root formation. In this case, the dentin bridge has not thickened. There is no evidence of uncontrolled mineralization within the pulp space.

provided in Chapter 17 (see Fig. 17-11). Briefly, studies[55,113,114] have shown that inflammation is confined to the surface 2 to 3 mm of the pulp when traumatically exposed and left untreated for up to 168 hours. In experimental animals, the results were the same whether the crowns were fractured or ground off.[55] Direct invasion of vital pulp tissue by bacteria did not occur, although the pulps were left exposed to saliva.

In their classic report, Cvek[50] described a pulpotomy technique where only the superficial 2 to 3 mm of hyperplastic inflamed tissue was removed with a water-cooled high-speed diamond bur[102] to place the wound in a healthy site. Hemostasis was then secured before capping with an appropriate material. If hemostasis could not be secured after several minutes of saline-moistened cotton pellet application, the preparation was checked carefully for residual superficial tags of bleeding tissue which had not been fully removed, or questions were asked about the condition of the underlying pulp. Persistent bleeding from an inflamed pulp usually indicates that the tissue should be resected at a deeper level to preserve a vital apical pulp stump (see Apexogenesis).

Following hemostasis with saline and a pulp cap of calcium hydroxide overlaid with a sealing coronal restoration, Cvek reported success in an impressive 94% to 96% of cases (Fig. 23-29). However, histologically better results have been shown more recently with MTA as the pulp-capping agent.[1,140,198,200,228] MTA is thus recommended as the pulp-capping agent of choice in cases that do not extend deeply into the roots, where subsequent retrieval may present considerable challenge. Preference should be given to nonstaining white MTA products.

The question then is whether such techniques can be applied to posterior teeth, and especially to those with symptomatic cariously-affected pulps. The answer has historically been no, except as a short-term, pain-relieving exercise. Studies involving cavity preparations into teeth that left areas of impacted food, debris, and bacteria in contact with pulp tissue resulted in inflammation extending from 1 to 9 mm into the pulp, with abscess and pus formation.[55,113] The extent of inflammation in the pulp of a cariously exposed pulp is therefore difficult to judge, with the expectation that pulpotomy may be less predictable than posttraumatic exposure.

Partial Pulpotomy on Asymptomatic Young Permanent Posterior Teeth

A technique termed *partial pulpotomy for the management of vital carious pulp exposure on young permanent molars* has been reported by several researchers.[175,176,179,209] This approach has usually been reserved for teeth with little or no history of pain and in the absence of radiographic signs, percussion sensitivity, swelling, or mobility.

The procedure usually involves a 1- to 3-mm cutback of pulp tissue judged to be inflamed beneath the exposure site to reach underlying healthy tissue. After hemostasis, the exposure site has traditionally been covered with $Ca(OH)_2$ and the tooth sealed with ZOE and a permanent restoration. Mejàre and Cvek[179] followed 31 initially symptom-free teeth for a mean of 56 months (range 24 to 140 months) and found 93.5% healing. Others[175] reported 91.4% success in 35 cases followed between 12 and 48 months. Exposures exceeding 2 mm and those in which bleeding could not be controlled within 1 to 2 minutes were excluded from this study.

The use of MTA as the capping agent has again met with success in the hands of the authors and others.[261]

Pulpotomy on Symptomatic Young Permanent Teeth

Although some success has been reported,[179] vital pulp therapy in permanent teeth with a history of pain has generally been contraindicated. Reports do, however, support this pulp-preserving approach even to symptomatic teeth.[261] Of the six teeth with temporary pain, widened periodontal ligament space, and/or condensing osteitis managed in Mejàre and Cvek's study,[179] by $Ca(OH)_2$ pulpotomy, 66.7% healed. More recently, one study[33] undertook a similar $Ca(OH)_2$ pulpotomy procedure on 26 permanent vital molars with carious pulp exposures and apical periodontitis. Observation between 16 and 72 months revealed that 24 (92.3%) were free from clinical symptoms, responded to sensitivity testing, showed evidence of hard-tissue barrier formation, resolution of periapical involvement, and the absence of intraradicular pathosis radiographically.

Partial pulpotomy was also found to be successful in a randomized controlled trial[233] that compared $Ca(OH)_2$ and MTA pulpotomies in the permanent molars (n = 64) of children. Mean follow-up was 34.8 months (range 25.5 to 45.6 months), and success was comparably favorable in both $Ca(OH)_2$ (91%) and MTA (93%) groups.

A full coronal pulpotomy may be more predictable in the symptomatic case in which the depth of pulp inflammation is difficult to predict. Follow-up of MTA pulpotomies in 15 children with immature molars revealed no clinical or radiographic failures at 12 months, though four pulps had undergone calcific metamorphosis.[65] In a 2006 clinical report,[326] investigators described a series of 23 irreversibly pulpitic anterior and posterior teeth in children and adolescents, treated by full coronal pulpotomy, hemostasis for 1 minute with 6% NaOCl, and wound dressing with MTA. Follow-up between 6 and 53 months (mean 19.7 months) revealed that 79% had healed, 16% were healing, and only 5% had evidence of persistent disease. More research is needed, but the MTA pulpotomy seems to be gaining an evidence base as a reliable technique for preserving vital pulp functions in both asymptomatic and symptomatic teeth in children.[326]

This body of evidence suggests that young teeth, with their rich vascular supply, are good candidates for conservative pulp-preserving treatments. Again, the stakes are high, and efforts to secure vital pulp functions are to be promoted. Outcomes are probably more predictable in asymptomatic cases than symptomatic, and care should be taken preoperatively to distinguish between cases with symptoms of reversible and irreversible pulpitis. The correlation of clinical symptoms with histologic state is, however, poor.[60]

Follow-Up After Pulp Capping and Pulpotomy

After pulp capping and pulpotomy, the patient should be seen periodically for 2 to 4 years to determine success. Although normal vitality tests (e.g., electrical and thermal sensitivity tests) are reliable after pulp capping, they are not usually helpful in the pulpotomy-treated tooth. Since histologic success cannot be determined, clinical success is judged by the absence of any clinical or radiographic signs of pathosis and the presence of continued root development in teeth with incompletely formed roots.

Controversy exists as to whether the pulp should be reentered after the completion of root development in the pulpotomy-treated tooth. Some researchers[110,154] believe that pulp capping and pulpotomy procedures invariably lead to progressive calcification of the root canals. After successful root development, they advocate pulpectomy and root canal treatment before canals become obliterated and challenging to manage in the event of future endodontic infection. However, it has been the experience of the authors and others[53,90,114] that with good case selection, a gentle technique in removing infected tissue and dentin chips, and care in avoiding the compaction of pulp dressing into underlying pulp tissue, calcification of the pulp is an infrequent sequela of pulpotomy (see Fig. 23-29, *C*; Fig. 23-30).

In a follow-up study of clinically successful pulpotomies,[50] researchers removed the pulps 1 to 5 years later for restorative reasons and found the tissue to be histologically normal.[53] They concluded that changes seen in the pulps do not present sufficient histologic evidence to support routine pulpectomy after pulpotomy in accidentally fractured teeth with pulp exposures. Thus, routine reentry to remove the pulp and place a root canal filling after completion of root development is contraindicated unless dictated by restorative considerations such as the necessity for a retentive post. Nevertheless, calcific obliteration, internal resorption, and pulp necrosis are potential sequelae of pulp-capping and pulpotomy procedures which should be screened for during recall appointments. Although unlikely, they are possible, and the patient should be clearly informed.

In posterior teeth, where surgical endodontics is difficult, the observation of continued calcification after root closure may justify reentry of the tooth for root canal treatment. In anterior teeth, if calcification of the canal has made conventional endodontics impossible, surgical endodontics may be performed with relative ease. Therefore in anterior teeth, routine endodontic therapy after completion of root development is contraindicated unless clinical signs and symptoms of pathosis are present or unless such therapy is necessary for restorative procedures (e.g., placement of a post for retention of a crown because of missing tooth structure).

FIG. 23-30 Deep pulpotomy for apexogenesis. **A,** Immature maxillary central incisor 10 weeks after traumatic pulp exposure and a deep pulpotomy dressed with $Ca(OH)_2$. Note early formation of a dentin bridge. **B,** Three-year recall showing the dentin bridge to have thickened and root formation to be complete; tooth remained asymptomatic and required no further treatment at that time. Note absence of uncontrolled mineralization within apical pulp space.

Formocresol Pulpotomy on Young Permanent Teeth

Because of the historical track record of formocresol pulpotomy in primary teeth, interest developed in this technique for the management of young permanent teeth. Reports have demonstrated the potential for continued apical development after formocresol pulpotomy in young permanent teeth,[77,191,256,315] and several authors have reported better results with the diluted rather than the full-strength form. However, they reported a high incidence of internal resorption, which increased in severity with longer periods of time.[86,224]

The formocresol procedure had appeal because there was a lower risk of pulp calcification, a recognized complication of $Ca(OH)_2$ pulpotomy. After root completion, the tooth could easily be reentered, the pulp extirpated, and routine endodontic therapy performed. Contrary to these findings, one group of researchers[14] has shown calcification of the canals by continuous apposition of dentin on the lateral walls, with equal frequency whether using $Ca(OH)_2$ or formocresol. The only common denominator to this reaction was the presence of dentin chips that had accidentally been pushed into the radicular pulp tissue.

Although this treatment has been reported to be partly successful, it cannot be routinely recommended in an era of effective alternatives such as MTA.

Formocresol pulpotomy procedures can only be recommended as temporary treatments on permanent teeth with necrotic pulps, where clinical success after 3 years has been reported.[301] The formocresol pulpotomy has particularly been performed in preference to extraction when routine endodontic treatment was not economically viable. This procedure may buy symptom-free time until funds become available to complete root canal treatment.

APEXOGENESIS

Apexogenesis is treatment designed to preserve vital pulp tissue in the apical part of a root canal in order to complete formation of the root apex (Fig. 23-31).[111]

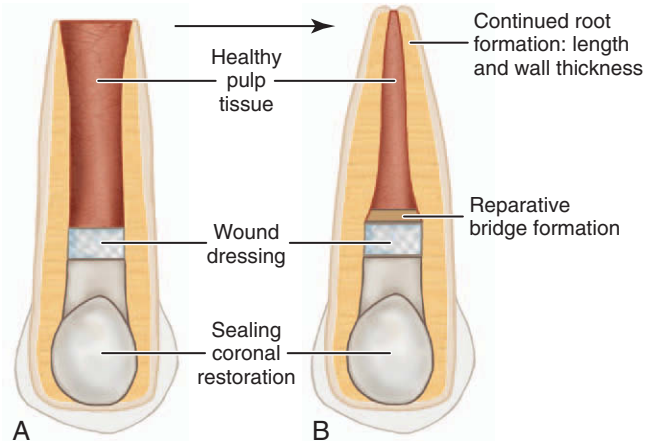

FIG. 23-31 Schematic representation of apexogenesis, a treatment designed to preserve at least the apical portion of pulp tissue in a healthy condition in order to complete root formation. **A,** Following a deep pulpotomy and hemostasis, the radicular pulp is dressed and a sealing coronal restoration applied. **B,** Success is evidenced by continued root development (length and wall thickness) and formation of a calcific barrier in response to the wound dressing.

The clinical procedure is essentially a deep pulpotomy undertaken to preserve the formative capacity of the radicular pulp in immature teeth that have deep pulpal inflammation. Examples include carious exposures and some trauma cases in which treatment of the exposed pulp is delayed, and it becomes necessary to extend further into the canal to reach healthy tissue.

Deep resection of pulp tissue is usually undertaken in single-rooted anterior teeth, with a small endodontic spoon excavator or round, abrasive diamond bur (see Fig. 23-30). In posterior teeth, the use of endodontic files or reamers may be necessary if tissue is being amputated within the canals. Extension of the amputation site into the root canals is undertaken

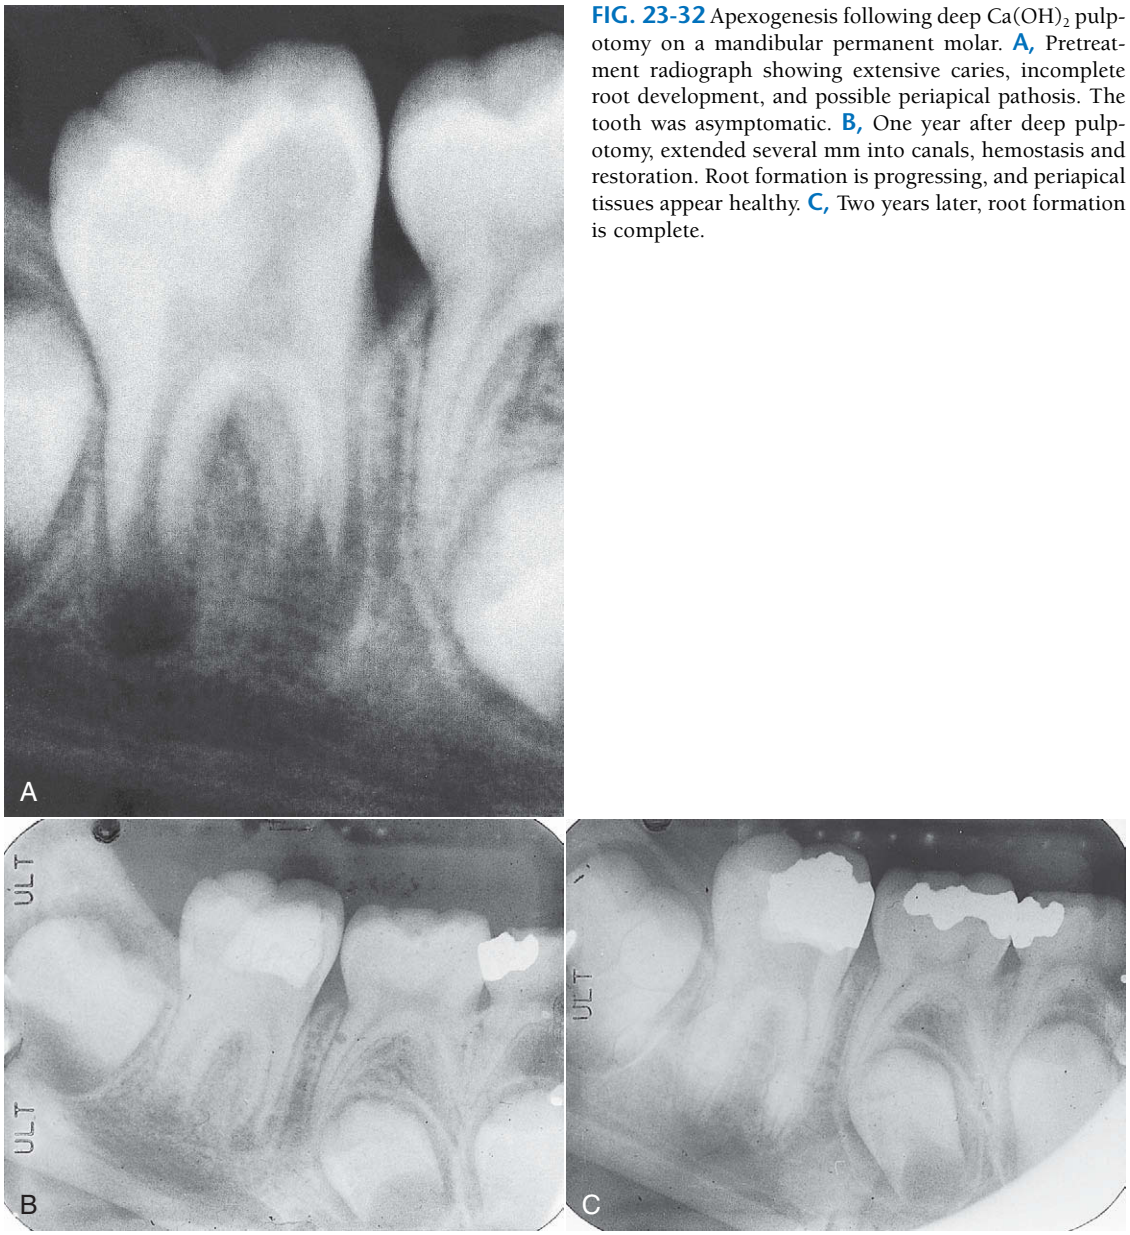

FIG. 23-32 Apexogenesis following deep $Ca(OH)_2$ pulpotomy on a mandibular permanent molar. **A,** Pretreatment radiograph showing extensive caries, incomplete root development, and possible periapical pathosis. The tooth was asymptomatic. **B,** One year after deep pulpotomy, extended several mm into canals, hemostasis and restoration. Root formation is progressing, and periapical tissues appear healthy. **C,** Two years later, root formation is complete.

only when there is little confidence that more superficial pulp capping or pulpotomy will be successful and where there is a desperate desire to preserve pulp functions in teeth with wide-open, blunderbuss apices (Fig. 23-32).

Bleeding is usually controlled with saline-soaked cotton pellets or NaOCl. If hemostasis cannot be secured by conventional means, this may indicate that even the deep pulp is inflamed, and treatment will be compromised. Despite the risks, it is legitimate to attempt pulp-preserving treatment after controlling the hemorrhage with hemostatic chemicals such as aluminum chloride or ferric sulfate.

The pulp wound is then covered with a dressing material before securely restoring the crown. It is challenging to determine the status of pulp tissue residing deep in the root canal, and its capacity for survival is difficult to predict. Radiographic and clinical follow-up is mandatory, and if there is no evidence of continued root formation and calcific barrier formation in response to the dressing, apexification or a regenerative technique may be considered.

Because of the depth at which this procedure is performed, preference has usually been given to the use of $Ca(OH)_2$ rather than MTA because, in the event of failure, this may facilitate reentry to the root canal to perform apexification or pulp regeneration. Also, if apexogenesis is successful and root-end formation is complete, the tooth could be reentered if desired for conventional root canal treatment. It is unclear if these concerns hold true in an era of microscopy and ultrasonic instrumentation.

Calcium hydroxide powder has usually been preferred over hard-setting products, carried into the canal with an amalgam carrier or gun system employed for MTA application. Small increments of $Ca(OH)_2$ powder are carefully teased against the entire surface of the pulp stump with a rounded-end, plastic instrument, ideally with microscope control. Care must be taken not to pack the $Ca(OH)_2$ into the pulp tissue because this causes greater inflammation and increases the chances of failure. Even if pulpotomy is successful, there is an increased risk that the remaining pulp tissue will mineralize around impacted particles of $Ca(OH)_2$.[308]

Commercial nonsetting calcium hydroxide pastes may also be spun or injected to flow lightly over the pulp stump. Care must be taken to avoid trapping air bubbles when applying such products, and it is recommended that they be overlaid with a hard-setting calcium hydroxide or glass ionomer cement[52] before meticulous cleaning of the cavity walls and restoration with a bonded composite resin restoration. Though little has been published on this topic, MTA probably does represent a viable alternative to calcium hydroxide, provided the challenges in its retrieval are recognized.

APEXIFICATION

Apexification, or root-end closure, is the process whereby a nonvital, immature, permanent tooth which has lost the capacity for further root development is induced to form a calcified barrier at the root terminus (Fig. 23-33). This barrier forms a matrix against which root canal filling or restorative material can be compacted with length control.

Unlike the pulp capping, pulpotomy, and apexogenesis procedures described previously, apexification will at best result in closure of the root end and cannot be expected to cause further root development in terms of length or wall thickness. Apexification is thus regarded as a treatment of last resort in immature teeth which have lost pulp vitality. The growing body of recent evidence on pulp regeneration, even in infected, nonvital immature teeth, may also relegate this approach to history archives in the years to come.

For now, root-end closure techniques, both those involving the generation of a biologic calcific barrier and those involving artificial root-end closure with a material such as MTA, still have a place in practice and will be considered.

Before the introduction of conservative apical closure techniques, the usual approach to this problem was surgical. Although this could be successful, psychological and patient-management issues in patients who were usually young children offered many contraindications. Local dental considerations presented a further disincentive, including worsening the crown/root ratio if further root reduction was required to achieve a seal, and the intrinsic difficulties of sealing a fragile, incompletely formed apex with traditional materials. A more predictable and less traumatic approach was desirable.

Until recently, the most widely accepted technique has involved cleaning and filling the canal with a temporary paste, most commonly $Ca(OH)_2$, which was replaced at intervals over several months, to stimulate the formation of an apical calcified barrier (see Fig. 23-33, *A-B*; Fig. 23-34).[284]

Diagnosis of pulpal necrosis in a tooth with an incompletely formed apex is often difficult, with the electronic pulp tester rarely providing meaningful data,[95] and thermal tests often giving equivocal or false results in young children and traumatized teeth. The presence of acute or chronic pain, percussion sensitivity, mobility, coronal discoloration, or a discharging sinus may be helpful guides, whereas radiographic diagnosis can be complicated by the normal radiolucencies appearing at the apices of developing teeth. Comparison of root formation with contralateral teeth should always be considered.

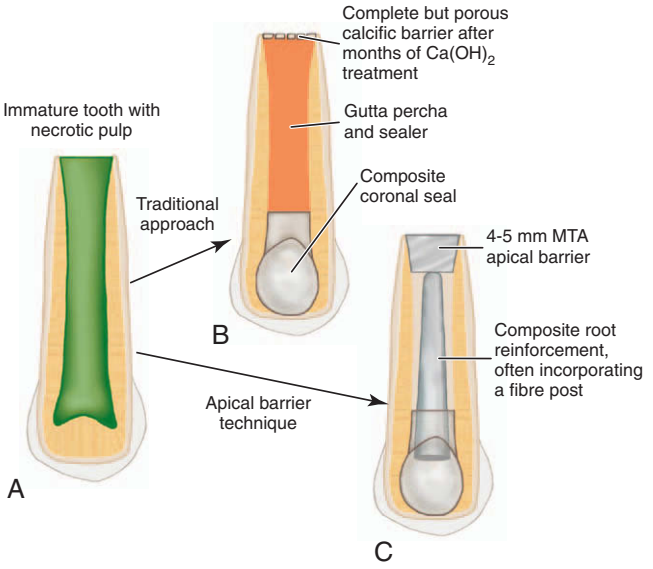

FIG. 23-33 Schematic representation of apexification, a treatment to develop a hard barrier at an open root end. **A,** Immature permanent tooth with a nonvital pulp. **B,** Traditional approach, with the formation of a "calcified barrier" at the root end following repeated dressing over many months with $Ca(OH)_2$. Canal is subsequently filled with gutta-percha and sealer before coronal restoration. **C,** Artificial apical barrier technique, where a 4- to 5-mm plug of mineral trioxide aggregate is placed at the root end. Canal space is subsequently restored with dual-curing composite resin, often accompanied by a fiber post to provide mechanical support.

If any doubt persists, it is usually wise to adopt a watch-and-wait approach before entering the immature tooth endodontically. Only when there is convincing evidence of pulp breakdown should the tooth be entered, and exposed dentin should in the interim be covered to reduce the risks of microbial entry to a potentially compromised pulp.

The extent of apical closure may be difficult to ascertain with plain radiographs. Three-dimensional imaging offers new opportunities to understand the complexity of root ends which may have different conformation in mesiodistal and faciolingual dimensions (see Fig. 23-14). In practical terms, the precise limit of apical opening that can be filled by conventional means is unclear.

Many materials have been reported to successfully stimulate apexification. The use of nonsetting $Ca(OH)_2$ was first reported by Kaiser in 1964.[141] The technique was popularized by the work of Frank,[81] and since that time, $Ca(OH)_2$ alone or in combination with other drugs became the most widely accepted material to promote apexification until the

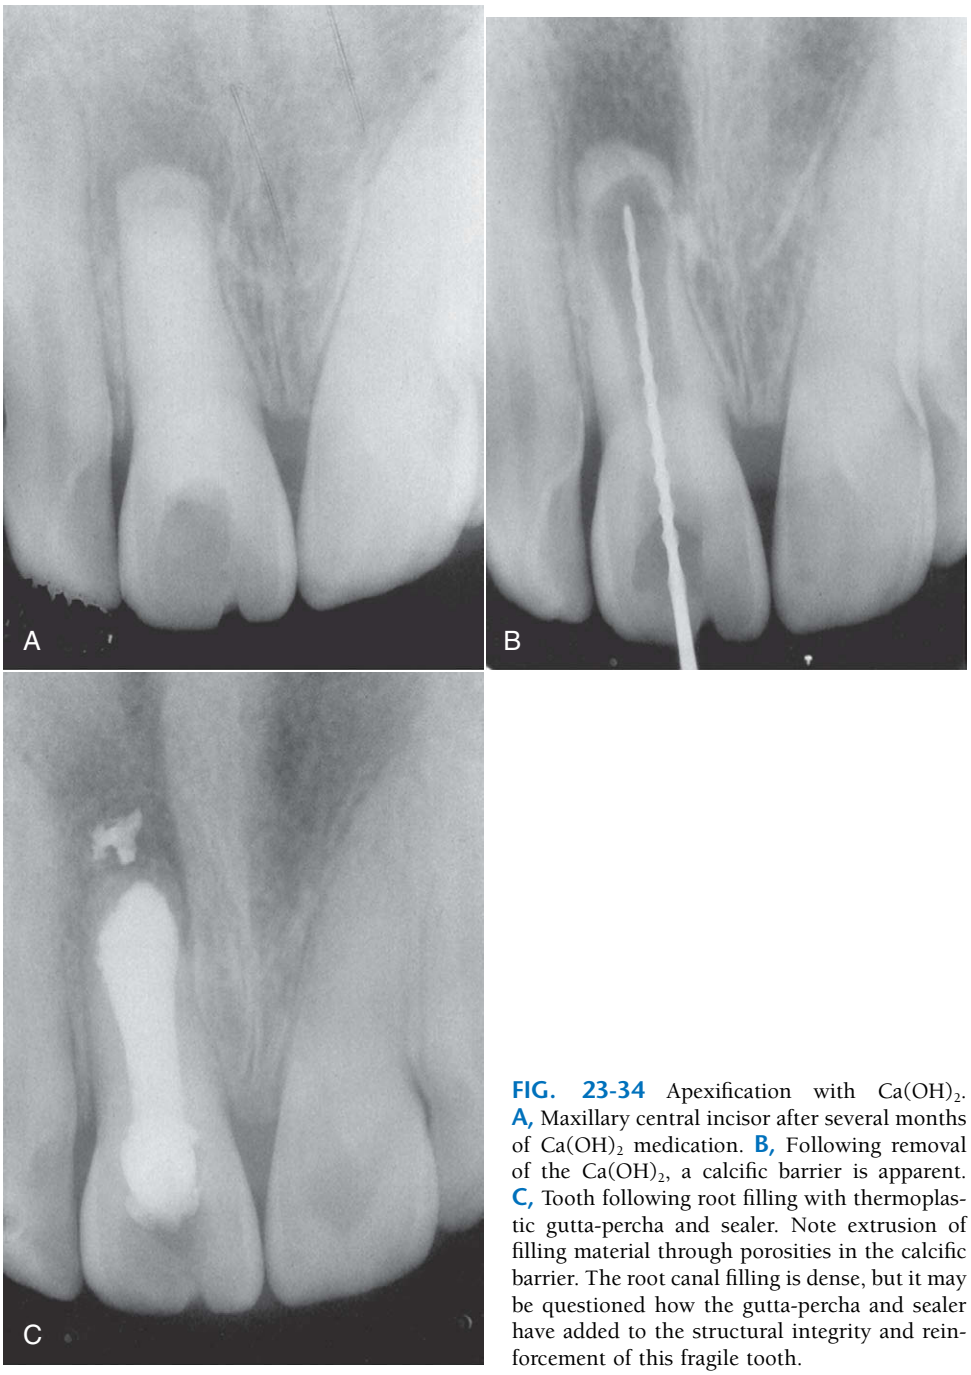

FIG. 23-34 Apexification with $Ca(OH)_2$. **A,** Maxillary central incisor after several months of $Ca(OH)_2$ medication. **B,** Following removal of the $Ca(OH)_2$, a calcific barrier is apparent. **C,** Tooth following root filling with thermoplastic gutta-percha and sealer. Note extrusion of filling material through porosities in the calcific barrier. The root canal filling is dense, but it may be questioned how the gutta-percha and sealer have added to the structural integrity and reinforcement of this fragile tooth.

development of MTA and the potential for rapid, artificial barrier formation.

For historical perspective, $Ca(OH)_2$ powder has been mixed with CMCP, metacresyl acetate, Cresanol (i.e., a mixture of CMCP and metacresyl acetate), physiologic saline, Ringer's solution, distilled water, and anesthetic solution. All have been reported to stimulate apexification, but most reports in the U.S. literature[34,108,285] have advocated mixing $Ca(OH)_2$ with CMCP or Cresanol, whereas reports from other parts of the world[52,178] showed the same success using distilled water or physiologic saline as the vehicle. The addition of 1:8 barium sulfate to $Ca(OH)_2$ enhanced radiopacity with no apparent adverse effects on apexification.[320] Comparable outcomes have been noted in humans and animals with tricalcium phosphate,[41,149,246] collagen calcium phosphate,[206] osteogenic protein-1,[267] bone growth factors,[300] and a number of other materials.[320]

The most important factors in achieving apexification seem to be thorough débridement of the root canal (to remove all necrotic pulp tissue and microbial infection) and sealing of the tooth (to prevent the ingress of bacteria and substrate[67]). *Apexification does not occur when the apex of the tooth penetrates the cortical plate. To be successful, the apex must be completely within the confines of the cortical plates.*

Apexification Technique

In the apexification technique, the canal is cleaned and disinfected in line with the principles defined in Chapter 9. The use of a rubber dam is mandatory, and resourcefulness may be needed to isolate partially erupted or damaged teeth in children.

The access opening may require some extension, especially in the anterior teeth, to accommodate the larger instruments necessary to clean the root canals, but care should be taken not to heavily instrument the already thin and relatively fragile walls of the root. Neither should operators deceive themselves that they are able to steer instruments against all walls of the canal system for complete débridement, particularly in apically diverging canals.

The length of the canal is established by radiographs, since the absence of an apical constriction may make electronic methods unreliable.[128] A constant drying point, determined with paper points, may provide helpful additional information on length.[18] Irrigation is central to the débridement of immature teeth, and with proper precautions, operators should not hesitate to benefit from the antimicrobial and tissue-solvent properties of NaOCl. Sonic, ultrasonic, and other vibratory devices capable of activating the irrigant within the canal may be advantageous,[313] and benefit may also come from the use of small brushes of the sort that are designed for interproximal tooth brushing or the application of etchants to post channels. After thorough débridement, the canal is dried and medicated with a fluid $Ca(OH)_2$ paste, carried into the canal with a Lentulo spiral or injected from a proprietary paste syringe. There is little evidence to commend any commercial $Ca(OH)_2$ paste over another in this application. The tooth is then sealed coronally, and the patient is recalled at 3-monthly intervals to wash out the $Ca(OH)_2$ paste and inspect clinically (with the aid of a gutta-percha or paper point or by direct visual inspection through the microscope) and radiographically for the development of a calcified barrier (see Fig. 23-34, *B*). Treatment typically extends over 9 to 24 months, with obvious demands on patient and parent compliance, while risking tooth embrittlement and cervical root fracture following long-term medication with calcium hydroxide.[10,51,252]

Histologic studies consistently report the absence of Hertwig's epithelial root sheath, and normal root formation should never be anticipated. Instead, there appears to be a differentiation of adjacent connective tissue cells into specialized cells; there is also deposition of calcified tissue adjacent to the filling material. The calcified material that formed over the apical foramen was histologically identified as an osteoid (i.e., bonelike) or cementoid (i.e., cementum-like) material (Fig. 23-35).[34,108,284] In a primate study, bridging of the root end with osteodentin was reported after vital pulpectomy and canal medication with $Ca(OH)_2$/parachlorophenol paste. The material appeared to be distinct from but continuous with the cementum, dentin, and predentin at the root apex.[61] The closure of the apex may be partial or complete but consistently has minute communications with the periapical tissues (see Fig. 23-33, *B*; Fig. 23-34, *C*; Fig. 23-35). For this reason, apexification stimulated by pastes must always be followed by

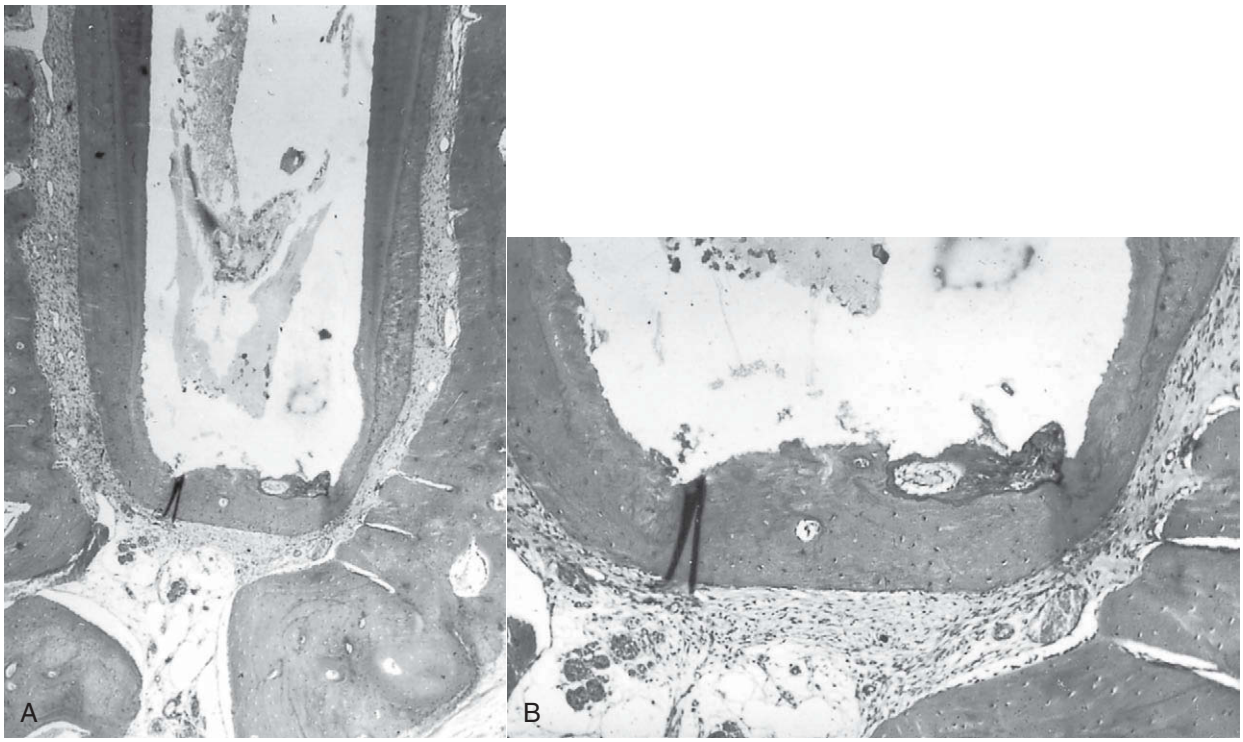

FIG. 23-35 Histologic section of a dog's tooth after $Ca(OH)_2$ apexification. **A,** Cementum-like mineralized tissue is closing the wide-open root end. Debris is apparent within the canal because of inadequate débridement before filling. **B,** Higher magnification showing cellular detail; periodontal ligament is free of inflammation. Root canal filling material was lost in histologic preparation. Note presence of tissue communication through the apical barrier (stain H&E).

obturation of the canal with a permanent root canal filling, traditionally of thermoplastic gutta-percha and sealer, though MTA would be a good contemporary alternative.

Although the apexification technique with $Ca(OH)_2$ has enjoyed considerable tooth-preserving success, the many disadvantages of this protracted treatment have justified a search for alternatives, such as artificial barrier techniques, with their potential for more rapid treatment, and regeneration techniques, with their potential for continued tooth development.

Artificial Apical Barrier Techniques (see Fig. 23-33, C)

Investigators[41] reported the use of tricalcium phosphate as an apical barrier in 1979. The material was packed into the apical 2 mm of the canal, against which gutta-percha was compacted. The treatment was completed in one appointment, and radiographic assessment confirmed successful apexification comparable to that achieved with $Ca(OH)_2$. Calcium hydroxide powder has also been used successfully as an apical barrier against which to pack gutta-percha.[264]

The use of MTA as an apical barrier was first reported in 1996,[300] and subsequent clinical investigations in animals[267] and humans[230,258,274] have established this as the standard, with biologic outcomes in terms of periapical healing and root-end closure at least comparable to those treated with $Ca(OH)_2$.[230] Simon et al. (2007)[274] treated 57 teeth in patients with a mean age of 18 years (standard deviation 12 years). Of the 43 teeth with at least 12-month follow-up, healing had occurred in 81%. More recently, a series of 17 nonvital immature incisors in children with a mean age of 11.7 years was followed up for a mean of 12.5 months. This study reported 94.1% clinical success, with radiographic healing in 76.5% and a further 17.6% uncertain.[258] This approach to the problem of root-end closure allows treatment to be completed on a short time scale, with advantages including improved patient compliance, reduced cost of clinical time, and the ability to securely restore the tooth at an earlier stage. The risk of tooth fracture after long-term $Ca(OH)_2$ medication[10,252] is also eliminated.

MTA Barrier Technique (see Figs 23-33, 23-36 and 23-37)

In the apexification technique, the canal is cleaned and disinfected as described for $Ca(OH)_2$ apexification. Research[158] has suggested that tissue pH may affect the hydration reaction and final physical properties of MTA, and it has become standard

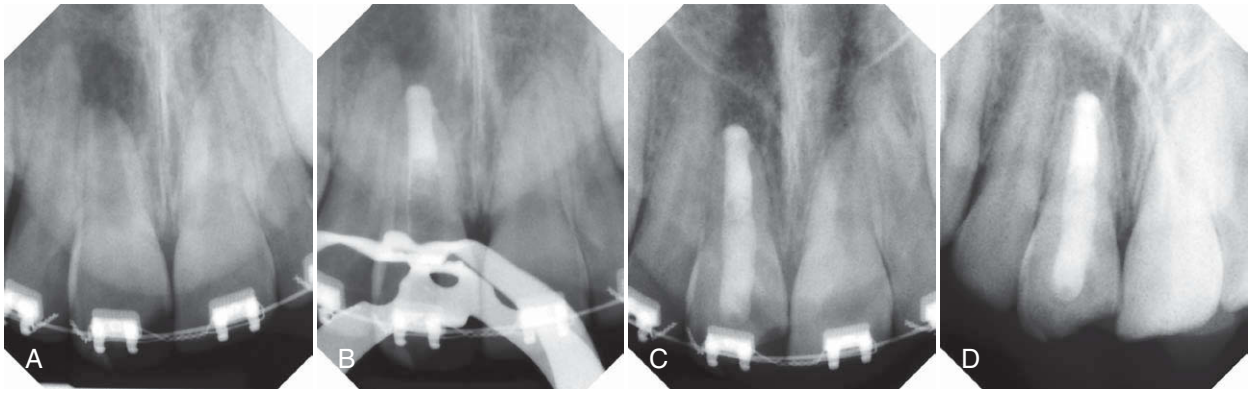

FIG. 23-36 Mineral trioxide aggregate (MTA) apical barrier apexification procedure and restoration with bonded composite. **A,** Maxillary right central incisor with a large periapical lesion. Patient is undergoing orthodontic treatment. **B,** Following placement of MTA in the apical 4 mm of the canal. **C,** Six months later. The entire canal coronal to the MTA apical barrier is filled with bonded composite resin. Note that calcification has occurred periapically as orthodontic treatment has continued. **D,** Thirty months after treatment. The periapical lesion has healed.

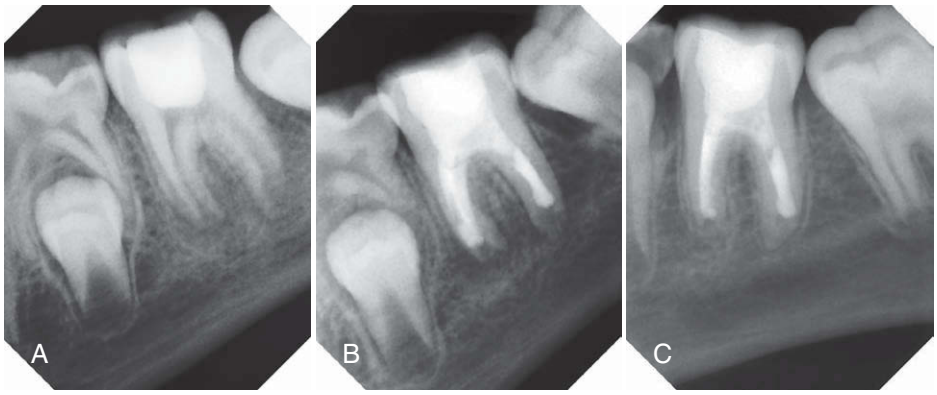

FIG. 23-37 Apexification with mineral trioxide aggregate (MTA) barriers in a mandibular permanent molar. **A,** Periapical lesion reveals open apices in this pulpless molar. **B,** Apical plugs of MTA and remainder of the pulp space restored with bonded composite resin. **C,** Two years later, showing closure of the root ends with cementum.

practice to medicate canals for at least 1 week with $Ca(OH)_2$ to raise the acidic pH of the inflamed periapical tissues before permanently sealing.

When the tooth is free of signs and symptoms of infection, it is reisolated with a rubber dam and the $Ca(OH)_2$ washed free, often with the help of ultrasonics and small brushes. After drying the canal with large, sometimes inverted, premeasured paper points, the canal is filled incrementally with MTA, delivered to the canal with a dedicated MTA carrier or deposited in small pellets from an amalgam gun. The material can then be worked up the canal with premeasured pluggers and set some 1 to 3 mm short of the root end, often with the help of sonic or ultrasonic energy to settle the material.[329] Apical matrices have not generally been considered necessary to limit the flow of MTA, though impressive-looking results may be obtained (see Fig. 17-17) by packing the apical region with calcium sulphate prior to MTA application.[304] An apical plug of 4- to 5-mm thickness is usually considered optimal (see Fig. 23-36, *B*).[311] The adequacy of the apical plug is verified radiographically.

All excess MTA is removed from the canal walls by scrubbing with large, moistened paper points or brushes. Meticulous cleanup is important to allow optimal bonding of the subsequent composite resin restoration, which will extend deeply into the canal and offer internal reinforcement of the fragile root.

A very wet cotton pellet is placed in the canal to provide moisture for the setting reaction. The pellet should not be in contact with the MTA because fibers of the cotton will become impregnated into the material. Excess water in the access preparation is dried with cotton pellets and the opening sealed with a provisional restorative material such as Cavit. At a subsequent appointment, the tooth is reisolated and the hard set of the MTA verified with an endodontic file or probe. If for some reason the MTA has not hardened, the canal can be recleansed and the procedure repeated before final bonded restoration.

Restoration After Apexification

Immature teeth, and particularly those which are pulpless and have undergone apexification, are at high risk of fracture. Within 3 years of long-term $Ca(OH)_2$ medication and root filling with gutta-percha, it has been reported[51] that 28% to 77% of immature teeth suffered a cervical root fracture. The degree of dental development appeared to be a key variable. Clinically, it is the impression of the authors that rapid MTA plug techniques in combination with the internal placement of bonded composite resin appears to have virtually eliminated cervical root fractures. Many of the studies are laboratory based, using simulated rather than real immature teeth, but the use of contemporary dentinal bonding techniques has been shown to strengthen endodontically treated teeth to levels close to those of intact teeth.[104,116,144] A 2004 study[156] demonstrated significantly greater resistance to root fracture after placement of a 4-mm thick apical plug of MTA followed by an intracanal composite resin when compared with MTA followed by gutta-percha and sealer. Root reinforcement has also been reported to improve by the cementation of a metal post within the channel created by removal of a light-transmitting composite curing post.[36] The potential of fiber-reinforced posts would also appear great,[28] though little clinical evidence has yet been published on the treatment of immature teeth.

Alternative materials which have been suggested to bond and reinforce fragile roots include resin-modified glass ionomer cements[100] and most recently, Resilon.[294] The evidence on Resilon however, remains highly contentious,[325] and the ideal of predictable bonding and tooth reinforcement throughout the length of the root canal system remains some way off.[293]

Bonding dual- or light-curing composite resin directly over the MTA plug, with no interposing layer of gutta-percha, has become an established clinical method (see Fig. 23-33, *C*; Fig. 23-36, *C*). Care should be taken to etch and bond the canal according to the manufacturer's instructions, with proper wash-out of etchant and avoiding gross pooling of unfilled resin. Complete resin infiltration of dentin cannot be guaranteed in the depths of a root canal, and the potential exists that host-derived metalloproteinases liberated by acid etching may degrade resin-dentin bonds with time. Flushing the preparation after etching with a synthetic protease inhibitor such as 2% chlorhexidine may help to counter some of these adverse events.[35]

Clear light-transmitting posts (e.g., Luminex System, Dentatus USA, New York) have been developed to ensure complete bonding of deep increments of light-activated composite. This may be less of an issue with dual-curing materials.

In the Luminex technique, a light-curing composite resin is placed in the canal, building up 2 mm increments with care to avoid trapping air bubbles. The Luminex post is placed to the depth of the preparation and the composite cured by transmitting light through the post. After curing, the plastic post is trimmed to the cervical line, and the incisal opening is restored.

If a core is needed for crown placement, a Luminex post without serrations is used for curing the composite. Because the composite does not bond to the smooth post, it can be gently removed and a corresponding metal Dentatus post cemented into the space with a resin cement. A composite buildup for crown retention may then be completed.

A variety of commercial quartz and glass fiber post systems are available for use in such applications, ensuring the delivery of light deep into the canal system and offering the potential for internal reinforcement (see Fig. 23-33, *C*). The heads of fiber posts should always be covered with composite resin to prevent them from absorbing oral fluids and delaminating.

NEW HORIZONS FOR PULP REGENERATION

Until recently, there have been few treatment options for the nonvital, permanent immature tooth. On confirming pulp necrosis, efforts could be made to preserve the tooth by apexification, or it could be extracted within a broader orthodontic treatment plan. This view has recently been challenged by a number of ground-breaking reports in which nonvital immature teeth with clear evidence of pulp breakdown and periapical suppuration were encouraged to grow new pulps and complete root formation (length and wall thickness; see also Chapter 16).[19,37,135,139,297] Success is dependent on the activity of a newly identified population of stem cells, the so-called stem cells from apical papilla (SCAP) (Fig. 23-38, *A*), a hidden treasure with enormous potential for tissue regeneration and bioroot engineering.[127]

All immature teeth with open apices may be considered candidates for regenerative treatment, even if they have frank pulp-space infection, a discharging sinus, or have been previously root canal treated.

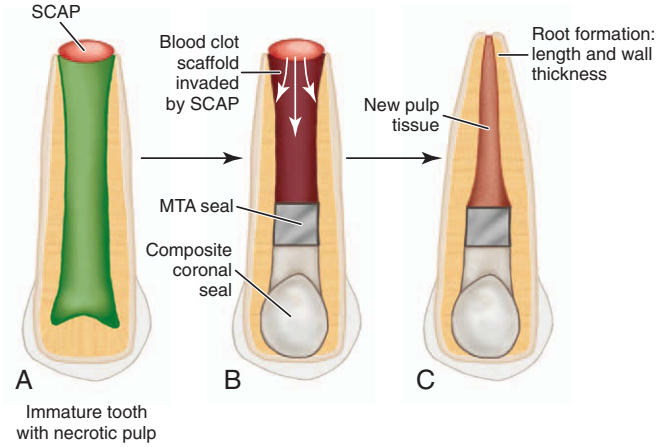

FIG. 23-38 Schematic representation of pulp regeneration. **A,** Immature, nonvital permanent tooth, showing the location of the apical papilla with its rich collection of stem cells. **B,** Following medication of the canal with triantibiotic paste, the canal is overinstrumented to encourage bleeding up to the cervical level. Subsequent blood clot is overlaid with MTA and a sealing restoration and forms a scaffold for invasion by SCAP cells. **C,** Pulp regeneration is expected to allow continued root formation in a previously pulpless tooth. *SCAP,* Stem cells from apical papilla.

The currently recommended protocol (see Fig. 23-38)[139,303] involves disinfecting the isolated canal system with little or no mechanical instrumentation and copious irrigation for 10 to 15 minutes with 5.25% NaOCl. The carefully dried canal is then medicated with a freshly mixed paste of ciprofloxacin, metronidazole, and minocycline in a macrogol ointment/propylene glycol base, which is sealed in place with a well-sealing provisional restoration. After 1 week, the tooth is carefully reopened under strict asepsis, and after washing out the antibiotic paste with NaOCl, the periapical tissues are gently instrumented to encourage bleeding into the canal. A blood clot is produced to the cemento-enamel junction, which will form a scaffold for pulp regeneration. The tooth is then sealed with several millimeters thickness of MTA before closing the crown with a provisional and later a resin-bonded composite restoration (see Fig. 23-38, *B-C*). Details of protocol vary from report to report, with some researchers demonstrating success with simpler protocols involving formocresol rather than antibiotic disinfection, and closure of the crown with glass ionomer cement.[268] Procedures are likely to evolve rapidly in this most exciting area of practice. Teeth are kept under periodic clinical and radiographic review, with the suggestion[303] that more traditional treatment may be considered if there are no signs of regeneration within 3 months. Clinical reports to date offer much promise, since there is little to be lost in attempting a treatment that could transform the prospects of a tooth which would otherwise require apexification. It is conceivable that $Ca(OH)_2$ and even MTA apexification techniques may in the foreseeable future be consigned to the history books. Readers are cross-referred to Chapter 16, which discusses broader aspects of regenerative endodontics, and to the clinical Figures 16-5 to 16-8 which illustrate immature teeth managed in this way.

The potential of bioengineering is huge, and work continues to optimize scaffolds that may encourage revascularization of the pulp space, and to explore the options of seeding cell populations into the properly sterilized pulp spaces of immature teeth.[189] Our call for action has never been louder as we seek effective, biologically based treatments for our pediatric patients.

CHAPTER 24

Effects of Age and Systemic Health on Endodontics

CARL W. NEWTON and JEFFREY M. COIL

CHAPTER OUTLINE

AN AGING SOCIETY
MEDICAL HISTORY
- Chief Complaint

DENTAL HISTORY
- Subjective Symptoms
- Objective Signs

DIAGNOSIS AND TREATMENT PLAN
- Consultation and Consent

TREATMENT
- Isolation
- Access
- Preparation
- Obturation
- Success and Failure

ENDODONTIC SURGERY
RESTORATION

Dental service requirements are determined by four demographic and epidemiologic factors:

1. The population at risk
2. The incidence and prevalence of dental diseases
3. The accepted standards of care
4. The perceived need and expectations toward dental health by the public[17]

These factors are changing as a result of the aging of the population.

AN AGING SOCIETY

According to the U.S. Census Bureau, America's population aged 65 years or older grew by 82% between 1965 and 1995.[75] Between 1980 and 1995, this same population grew by 28% to a historic high of 33.5 million people. The *oldest old* are defined as those who are at least 85 years of age. This group is the fastest-growing segment of America's senior citizen population. The number of persons 85 years and older has more than doubled since 1965 and has grown by 40% since 1980.

The 75 million people born in the United States between 1946 and 1964 constitute the baby boom generation. In 1994, baby boomers represented nearly one third of the U.S. population. Soon these people will enter the 65-years-and-older category. As the baby boomers begin to age, the United States will see an unparalleled increase in the absolute number of older persons.[12] Although one in eight Americans was 65 years of age or older in 1994, in a little more than 30 years, about one in five is expected to be in this group (Fig. 24-1).[3]

Information available from the U.S. Census Bureau and the National Institute on Aging indicates that America's older population is unevenly distributed among geographic locations. The most populous states have the largest number of older adults; Florida and Midwestern states currently have the highest proportions of older adults. Florida was the only state where the population of older adults was greater than 16% of its population in 1993; however, it is predicted that 32 states will fall in this category by 2020.[51]

Increased longevity of the dentition with expanding fields of advanced restorative procedures and periodontology lends support that dentistry will see a substantial growth in the number of older patients.[16] Until 1983, persons aged 65 years and older made an average of 1.5 dental visits annually, a lower utilization rate than that of any other age group.[78] Between 1983 and 1986, a 29% increase in visits by those 65 years and older was noted by the National Health Survey.[77] According to this survey, older adults currently make more visits per year on average than those in the "all ages combined" category. The percentage of office visits, services provided, and patient expenditures attributed to patients 65 years of age or older exceeded the percentage of the population in that age group.[44] In the future, clinicians will routinely serve a growing number of older persons, who will account for one third to two thirds of their workload.[42,43,45]

The growth of the population aged 65 years and older has affected every aspect of U.S. society, presenting challenges as well as opportunities to policymakers, families, businesses, and health care providers.[51] Future dental services (including root

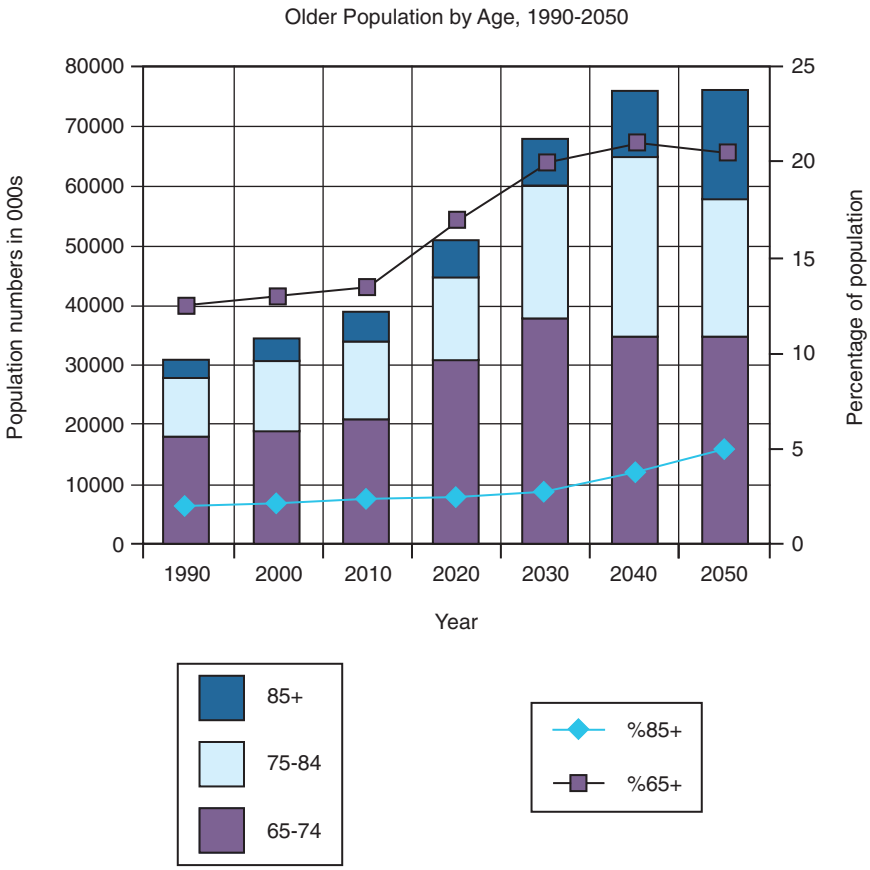

FIG. 24-1 Projected percentage growth rates of U.S. adults age 65+ years and 85+ years from 1990 to 2050. *(From U.S. Bureau of the Census, Population Division Population Projections Program. Available at: http://www.census.gov/ Accessed August 2009.)*

canal procedures) for older patients are anticipated to be of two general types:

1. Services for relatively healthy older adults who are functionally independent
2. Services for older patients with complex conditions and problems who are functionally dependent[49]

The latter group will require care from clinicians who have advanced training in geriatric dentistry. This age group is being targeted in dental education programs and advanced training through improved curriculum, research, and publications on aging. The National Institute on Aging stated that all dental professionals should receive education concerning treatment of older adults as part of basic professional education.[14,49]

This chapter discusses the effect of aging on the diagnosis of pulpal and periapical disease and successful root canal treatment. The quality of life for older patients can be significantly improved by saving teeth through endodontic treatment and can have a large and impressive value to overall dental, physical, and mental health.

With age, the simple pleasure of being able to eat what one wishes often becomes an issue, as does the increased need for proper diet and nourishment. Every tooth may be strategic, and old age is no time to be forced to replace sound teeth with removable appliances or dentures. Age is a factor in reduced stability and retention of removable partial dentures.[30] Consultation with older patients should help them overcome what may be a very limited knowledge of root canal treatment and lack of appreciation for regular dental care. Well-meaning friends and spouses who contend that their dentures are as good or better than their natural teeth may have had a lifetime of poor dental experiences or have forgotten what it is like to enjoy natural dentition.

Negative social attitudes toward older adults tend to carry over into their care. Older patients are in danger of being dismissed as hopeless or not worth the effort. At times, clinicians shy away from providing care for seniors because of the perceived difficulty or cost of certain treatment procedures or because of complicated medical conditions. Clinicians sometimes consider older patients less able to pay for treatment because of their age and appearance. However, most older adults engage in normal activities and can recognize and afford the value of good dentistry.[7]

Most older patients have had active, productive lives; they are very interested in maintaining their dignity and do not consider themselves a bad investment. Tooth loss is often associated with the prospect of aging and loss of vitality.[21] As with any age group, older patients must be considered as individuals. This may prove difficult in the face of the tendency of many health care professionals to assign any person older than 65 years to the classification *geriatric* and to stereotype patients (e.g., confusion, dementia, poor treatment response). Each older adult patient comes with a unique psychologic and social life history and with a set of values, needs, and resources unlike those of any other patient the provider will see. Most seniors are more concerned with maintaining control of their lives than they are about being old.[58] Clinicians' perception of the

effects of aging on diagnosis and treatment of pulp and periradicular disease is also improving along with the rate at which older patients need and seek specialty care.[27]

Because the primary function of teeth is mastication, it is presumed that loss of teeth leads to detrimental food changes and reduction in health.[31] However, this may not be the driving force when seniors are seeking treatment. Many times, social issues are the motivation for a senior to visit a clinician. After suggesting a mandibular anterior tooth extraction to a 93-year-old man, one clinician was told, "I can't, Doctor. You see, I go dancing every Saturday night, and I need that tooth. I can't look like that." The majority of people older than 60 years who still have their own natural anterior teeth would not wish for a change in appearance if they needed prosthodontic reconstruction.[28]

Clinicians should not presume that they know what is best for senior patients or what they can afford without the patient's full awareness. The needs, expectations, desires, and demands of older people may exceed those of any age group, and the gratitude shown by older patients is among the most satisfying of professional experiences.

The desire for root canal treatment among aging patients has increased considerably in recent years. Older patients are aware that treatment can be performed comfortably and that age is *not* a factor in predicting success.[5,69,71] Obtaining informed consent also requires that root canal treatment be offered as a favorable alternative to the trauma of extraction and the cost of replacement. The distribution of specialists and the improved endodontic training of all clinicians have broadened the availability of most endodontic procedures to everyone, regardless of age. Expanded dental insurance benefits for retirees and a heightened awareness of the benefits of saving teeth have encouraged many older patients to seek endodontia rather than extraction.[80] People with private dental insurance are more likely to visit a clinician. There is a trend toward less insurance in most demographic groups except the elderly, who also enjoyed benefits during their working years.[82]

This chapter compares the typical geriatric patient's endodontic needs with those of the general population. (Pulp changes attributed to age are discussed in Chapters 12 and 13; their effects on clinical treatment are also discussed in this chapter.)

MEDICAL HISTORY

It is important to focus on those factors that will truly indicate the risks undertaken in treating the older patient. Clinicians must recognize that the biologic or functional age of an individual is far more important than chronologic age. A medical history should be taken before the patient is brought into the treatment room, and a standardized form (see Chapter 1, Fig. 1-2) should be used to identify any disease or therapy that would alter treatment or its outcome. In general, aging causes dramatic changes to the cardiovascular, respiratory, and central nervous systems that result in most drug therapy needs. However, the decline in renal and liver function in older patients should also be considered when predicting behavior and interaction of drugs (e.g., anesthetics, analgesics, antibiotics) that may be used in dental treatment.

The review of the patient's medical history is the first opportunity for the clinician to talk with the patient. The time and consideration taken at the outset will set the tone for the entire treatment process. This first impression should reflect a warm, caring clinician who is highly trained and able to help patients with complex treatments. Some older patients may need assistance in filling out the forms and may not be fully aware of their conditions or history. Some patients may withhold their date of birth to conceal their age for reasons of vanity or even fear of ageism. Some may not fill out current medications because they think it would be unnecessary information for the clinician to know. Vision deficits caused by outdated glasses or cataracts can adversely affect a patient's ability to read the small print on many history forms. Consultation with the patient's family, guardian, or physician may be necessary to complete the history; however, the clinician is ultimately responsible for the treatment.

An updated history, including information on compliance with any prescribed treatment and sensitivity to medications, must be obtained at each visit and reviewed. The elderly usually take more drugs, prescription and nonprescription, than the general adult population, and drug interactions and adverse drug reactions are more likely to result from polypharmacy.[29] It is very important that the clinician take a careful history and update it at every visit.[46] *The Physicians' Desk Reference* should be consulted and any precaution or side effect of medication noted. It is available online at http://www.pdr.net/ and several other websites have been developed specifically for drug interactions.

Although geriatric patients are usually knowledgeable about their medical history, some may not understand the implications of their medical conditions in relation to dentistry or may be reluctant to let the clinician into their confidence. Their perceptions of their illnesses may not be accurate, so any clue to a patient's conditions should be investigated.

Symptoms of undiagnosed illnesses may present the clinician with a screening opportunity that can disclose a condition that might otherwise go untreated or lead to an emergency. Management of medical emergencies in the dental office is best directed toward prevention rather than treatment. Oral and pharyngeal cancers are primarily diagnosed in the elderly, and the prognosis is poor.[76]

Few families are without at least one member whose life has been extended as a result of medical progress. A great number have had diseases or disabilities controlled with therapies that may alter the clinician's case selection. Root canal treatment is certainly far less traumatic in the extremes of age or health than is extraction.

Chief Complaint

Most patients who are experiencing dental pain have a pulpal or periapical problem that requires root canal treatment or extraction. Dental needs are often manifested initially in the form of a complaint, which usually contains the information necessary to make a diagnosis. The diagnostic process is directed toward determining the vitality of the pulp, whether pulpal or periapical disease is present, and which tooth is the source (see Chapter 1).

The clinician should, without leading, allow the patient to explain the problem in his or her own way. This gives the examiner an opportunity to observe the patient's level of dental knowledge and ability to communicate. Visual and auditory handicaps may become evident at this time.

Patiently encouraging the patient to talk about problems may lead into areas of only peripheral interest to the clinician, but it establishes a needed rapport and demonstrates sincere interest. A patient may exhibit some feelings of distrust if there is a history of failed treatments or if well-meaning, denture-wearing friends or relatives have claimed normal function and freedom from the need for dental treatment. The effect of the "focal infection" theory is still evident when other aches and pains cannot be adequately explained and loss of teeth is accepted as inevitable. The best patients are those who have already had successful endodontic treatment. Older patients are more likely to have already had root canal treatment and have a more realistic perception about treatment comfort.

Most geriatric patients do not complain readily about signs or symptoms of pulpal and periapical disease and may consider them to be minor compared with other health concerns and discomfort. A disease process usually arises as an acute problem in children but assumes a more chronic or less dramatic form in the older adult. The *mere presence* of teeth indicates proper maintenance or resistance to disease. A lifetime of experiencing pains puts a different perspective on interpreting dental pain.

Pain associated with vital pulps (i.e., referred pain; pain caused by heat, cold, or sweets) seems to be reduced with age, and severity seems to diminish over time. Heat sensitivity that occurs as the only symptom suggests a reduced pulp volume, such as that occurring in older pulps.[33] Pulpal healing capacity is also reduced, and necrosis may occur quickly after microbial invasion, again with reduced symptoms.

Although complaints are fewer, they are usually more conclusive evidence of disease. The complaint should isolate the problem sufficiently to allow the clinician to take a periapical radiograph before proceeding. Studying radiographs before an examination can prejudice rather than focus attention; accordingly, they should be reviewed *after* the clinical examination has been completed.

DENTAL HISTORY

The clinician should search patients' records and explore their memories to determine the history of involved teeth or surrounding areas. The history may be as obvious as a recent pulp exposure and restoration, or it may be as subtle as a routine crown preparation 15 or 20 years ago. Any history of pain before or after treatments may establish the beginning of a degenerative process. Subclinical injuries caused by repeated episodes of decay and its treatment may accumulate and approach a clinically significant threshold that can be later exceeded after additional routine procedures. Multiple restorations on the same tooth are common (Fig. 24-2).

Recording information at the time of treatment may seem to be unnecessary "busy work," but it could prove to be helpful in identifying the source of a complaint or disease many years later. A patient's recall of dental treatments is usually limited to a few years, but the presence of certain materials or appliances, such as silver points, can sometimes date a procedure. Aging patients' dental histories are rarely complete and may indicate treatment by several clinicians at different locations. These patients are likely to have outlived at least one clinician and been forced to establish a relationship with a new, younger clinician. This new clinician may find dental needs that require an updated treatment plan.

FIG. 24-2 Multiple restorations on this 74-year-old patient suggest repeated episodes of caries and restorative procedures with pulpal effects that accumulated in the form of subclinical inflammation and calcification.

Subjective Symptoms

The examiner can pursue responses to questions about the patient's complaint, the stimulus or irritant that causes pain, the nature of the pain, and its relationship to the stimulus or irritant. This information is most useful in determining whether the source of the pain is pulpal in origin, if the problem is reversible, and whether inflammation or infection has extended to the apical tissues. Thus the clinician can determine what types of tests are necessary to confirm findings or suspicions. (Chapter 1 gives further information.)

Diagnostic Procedures

It is important to remember that pulpal symptoms are usually chronic in older patients, and other sources of orofacial pain should be ruled out when pain is not soon localized. Much information obtained from the complaint, history, and description of subjective symptoms can be gathered in a screening interview by the clinician's assistant or over the phone by the receptionist. The need for treatment can be established and can provide a focus for the examination.

Objective Signs

The intraoral and extraoral clinical examination provides valuable firsthand information about disease and previous treatment. The overall oral condition should not be overlooked while centering on the patient's chief complaint, and all abnormal conditions should be recorded and investigated. Exposures to factors that contribute to oral cancers accumulate with age. Oral premalignant and malignant mucosal lesions require

state-of-the-art diagnostic tools to ensure early diagnosis of these lesions.[63] Furthermore, many systemic diseases may initially manifest with prodromal oral signs or symptoms.[14]

Missing teeth contribute to reduced functional ability (Fig. 24-3). The resultant loss of chewing efficiency leads to a higher carbohydrate diet of softer, more cariogenic foods. Increased sugar intake to compensate for loss of taste[23,48] and xerostomia[6] are also factors in the renewed susceptibility to decay. Saliva plays a significant role in the maintenance of oral and general health. Aging per se has no significant clinical impact on salivary secretion. The most common cause of salivary hypofunction in the elderly is medication use and is most commonly associated with dental caries and oral fungal infections.[50,65]

FIG. 24-3 Missing teeth and the subsequent tilt, rotation, and supraeruption of adjacent and opposing teeth contribute to reduced functional ability and increased susceptibility to caries and periodontal disease.

Gingival recession, which creates sensitivity and is hard to control, exposes cementum and dentin that are less resistant to decay than enamel. A clinical study of 600 patients older than age 60 years showed that 70% had root caries and 100% had some degree of gingival recession.[81] The removal of root caries is irritating to the pulp and often results in pulp exposures or reparative dentin formation that affects the negotiation of the canal if root canal treatment is later needed (Fig. 24-4).[20] Asymptomatic pulp exposures on one root surface of a multirooted tooth can result in the uncommon clinical situation of the presence of both vital and nonvital pulp tissue in the same tooth (Fig. 24-5).

Interproximal root caries is difficult to restore, and restoration failure as a result of continued decay is common (Fig. 24-6). Although the microbiology of diseases is not substantially different in different age groups, the altered host response during aging may modify the progression of these diseases.[74]

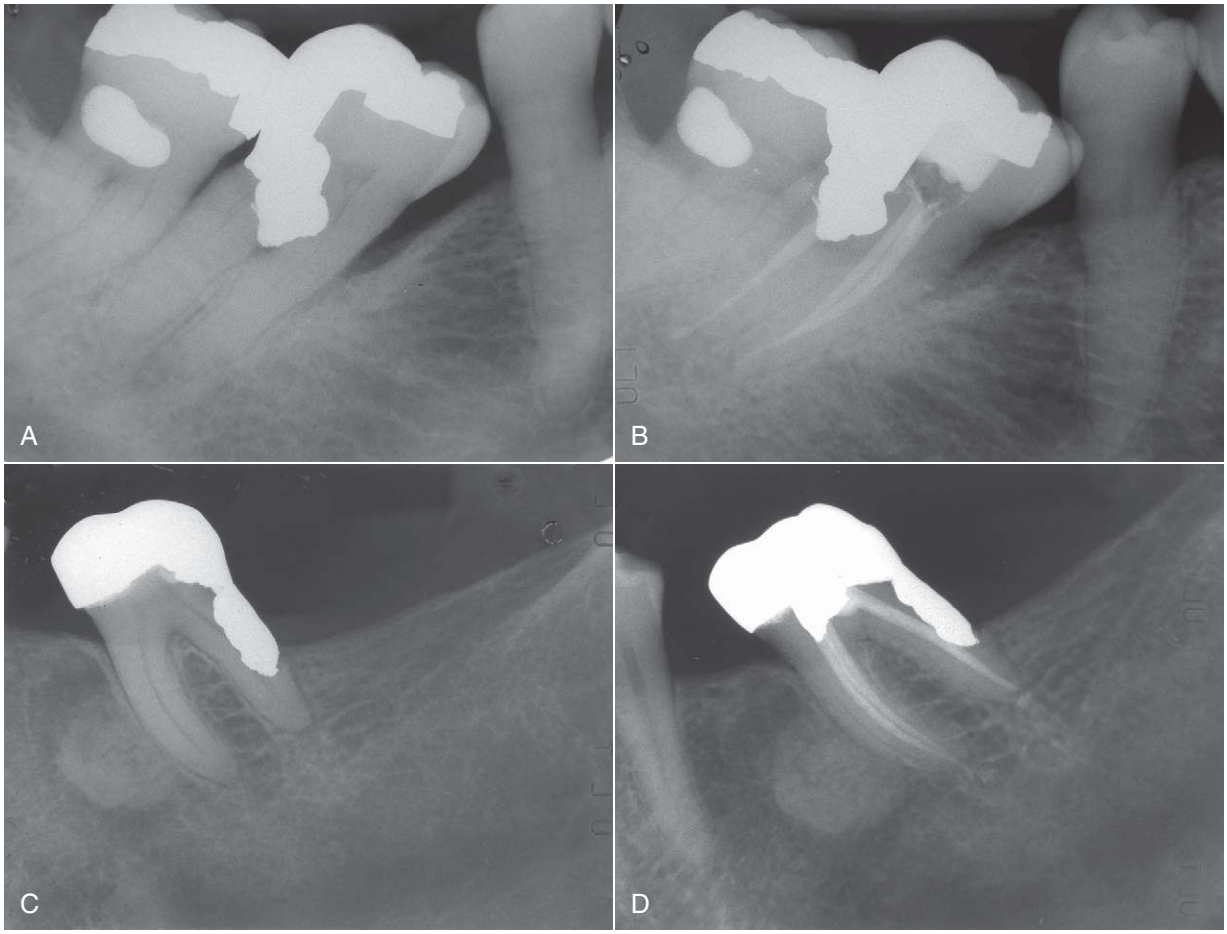

FIG. 24-4 Gingival recession exposes cementum and dentin, which are less resistant to caries. **A-B,** Root caries often results in pulp exposures **(C-D)** that require endodontic treatment.

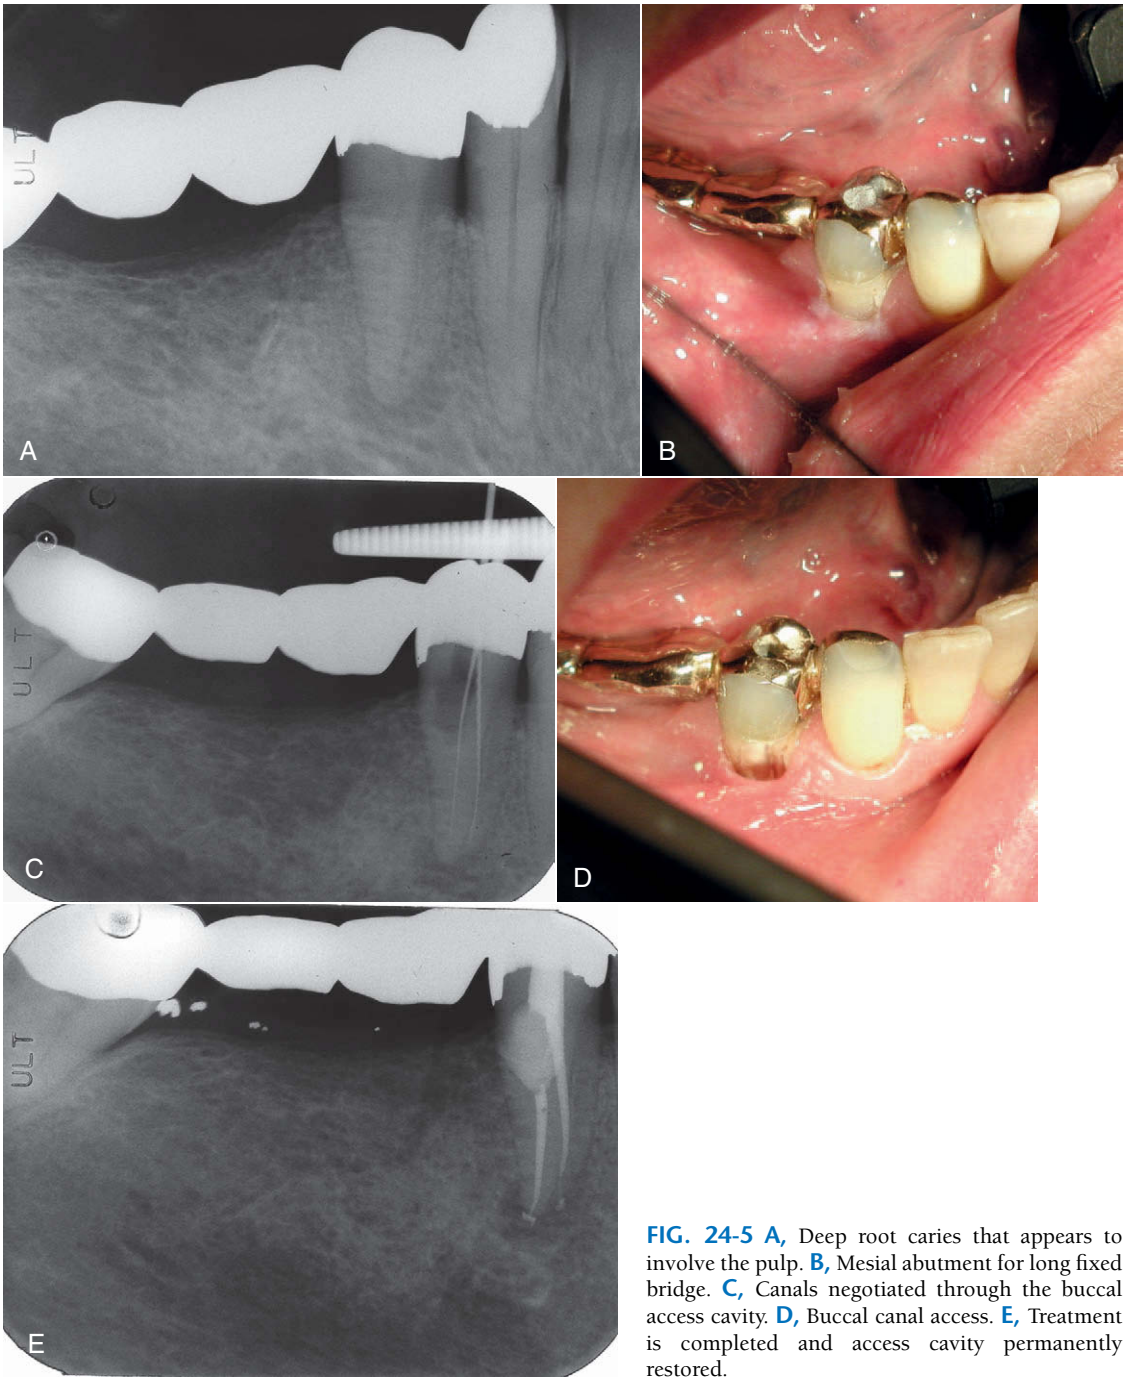

FIG. 24-5 A, Deep root caries that appears to involve the pulp. **B,** Mesial abutment for long fixed bridge. **C,** Canals negotiated through the buccal access cavity. **D,** Buccal canal access. **E,** Treatment is completed and access cavity permanently restored.

Attrition (see Fig. 24-6), abrasion, and erosion (Fig. 24-7) also expose dentin through a slower process that allows the pulp to respond with dentinal sclerosis and reparative dentin.[67] Secondary dentin formation occurs throughout life and may eventually result in almost complete pulp obliteration. In maxillary anterior teeth, the secondary dentin is formed on the lingual wall of the pulp chamber[55]; in molar teeth the greatest deposition occurs on the floor of the chamber.[10] Although this pulp may appear to recede, small pulpal remnants can remain or leave a less calcific tract that may lead to pulp exposure.

In general, canal and chamber volume is inversely proportional to age: as age increases, canal size decreases (Fig. 24-8). Reparative dentin resulting from restorative procedures, trauma, attrition, and recurrent caries also contributes to diminution of canal and chamber size. In addition, the cementodentinal junction (CDJ) moves farther from the radiographic apex with continued cementum deposition (Fig. 24-9).[37] The thickness of young apical cementum[60] is 100 to 200 μm and increases with age to two or three times that thickness.[86]

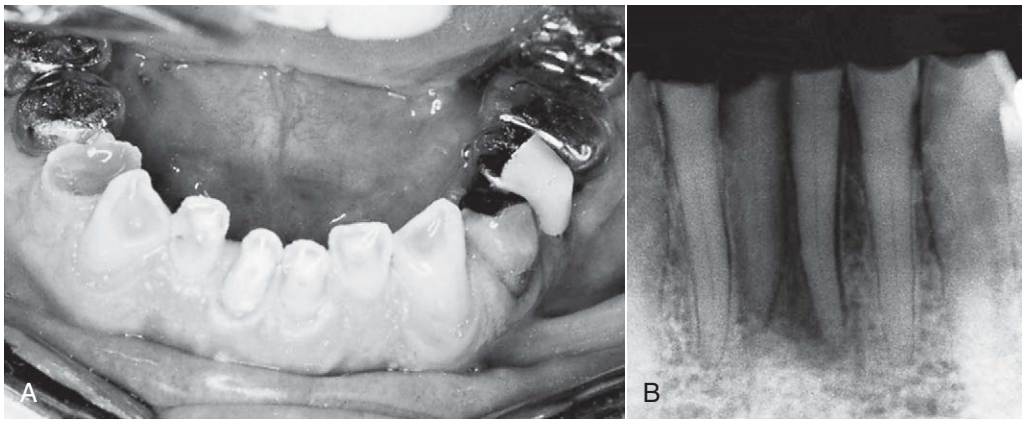

FIG. 24-6 A, Attrition exposes dentin through a slow process that allows the pulp to respond with reparative dentin, but pulp exposure eventually becomes clinically evident **(B)**.

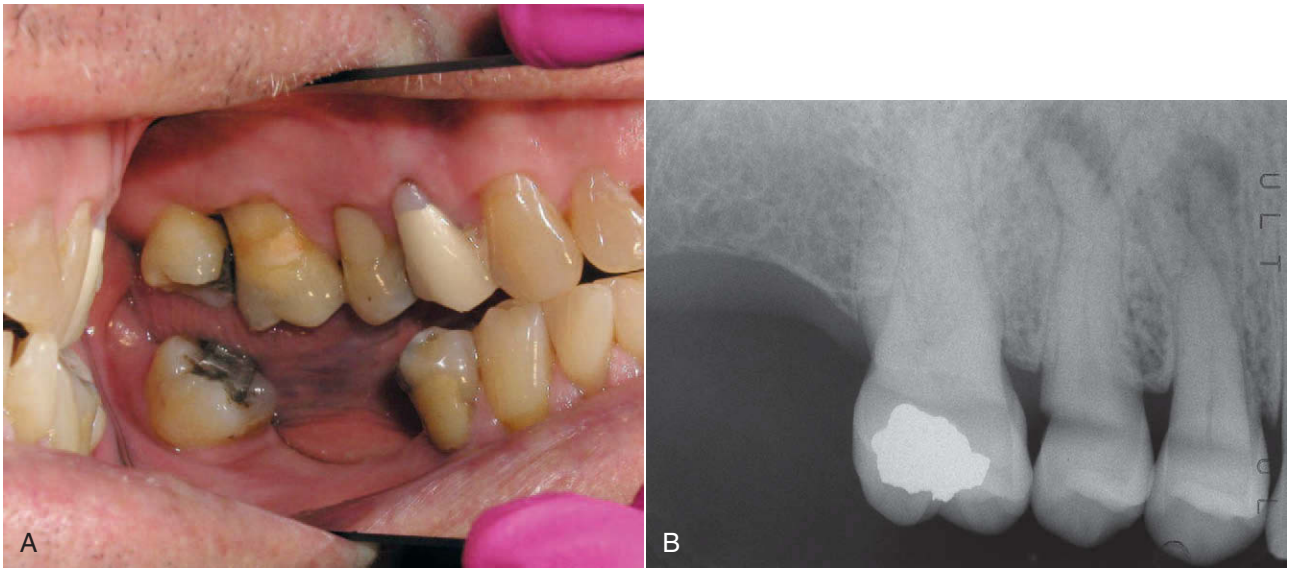

FIG. 24-7 Gingival recession also exposes cementum and dentin that are less resistant to abrasion and erosion, which can expose pulp or require restorative procedures that could result in pulp irritation.

The calcification process associated with aging appears clinically to be of a more linear type than that which occurs in a younger tooth in response to caries, pulpotomy, or trauma (Fig. 24-10). Dentinal tubules become more occluded with advancing age, decreasing tubular permeability.[47] Lateral and accessory canals can calcify, thus decreasing their clinical significance.

The compensating bite produced by missing and tilted teeth (or attrition) can cause temporomandibular joint (TMJ) dysfunction (less common in older adults) or loss of vertical dimension. Diminished eruptive forces occur with age, reducing the amount of mesial drift and supraeruption.[62] Any limitation in opening reduces available working time and the space needed for instrumentation.

The presence of multiple restorations indicates a history of repeated insults and an accumulation of irritants. Marginal leakage and microbial contamination of cavity walls are a major cause of pulpal injury.[11] Violating principles of cavity design combined with the loss of resiliency that results from a reduced organic component to the dentin can increase susceptibility to cracks and cuspal fractures. In any further restorative procedures on such teeth, the clinician should consider the effect on the pulp and the effect on gaining access to and negotiating canals through such restorations if root canal therapy is indicated later.

Many cracks or craze lines (see Fig. 24-7) may be evident as a result of staining, but they do not indicate dentin penetration or pulp exposure.[13,32] Pulp exposures caused by cracks are less likely to present acute problems in older patients and often penetrate the sulcus to create a periodontal defect as well as a periapical one. If incomplete cracks are not detected early, the prognosis for cracked teeth in older patients is questionable (Fig. 24-11).

Periodontal disease may be the principal problem for dentate seniors.[18] The relationship between pulpal and periodontal disease can be expected to be more significant with

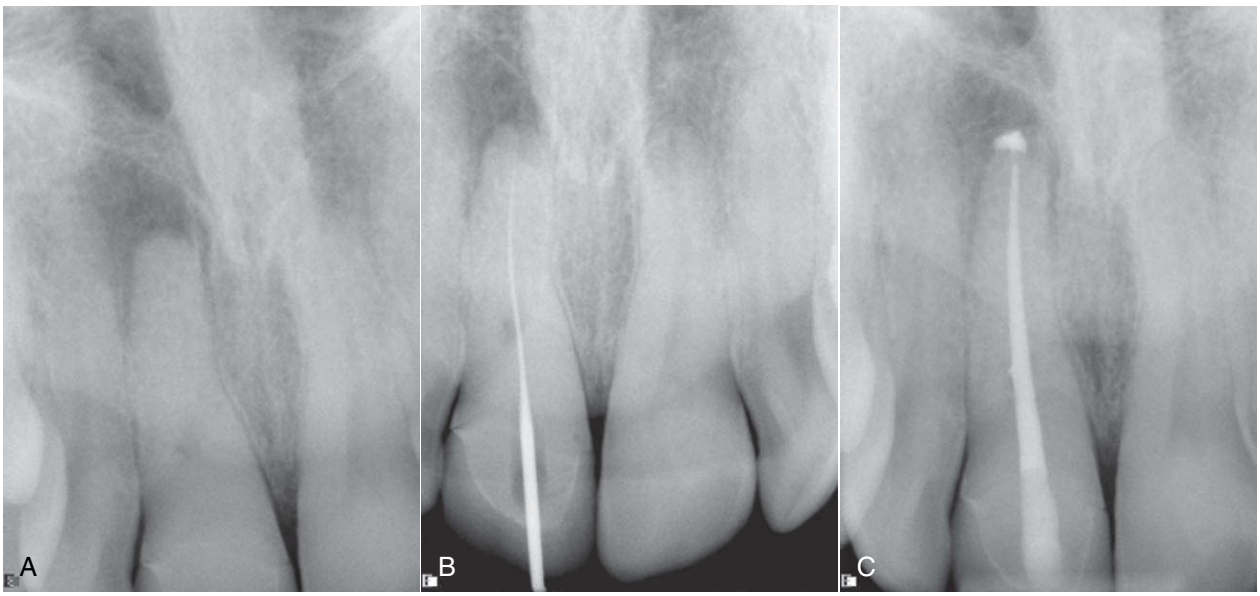

FIG. 24-8 A, In general, canal chamber volume is inversely proportional to age. As age increases, canal size decreases. The upper right central incisor exhibits a reduced canal and chamber volume. **B,** Negotiation using small hand files. **C,** Treatment completed for this calcified canal.

FIG. 24-9 Histologic image of the cementodentinal junction (CDJ) in an older tooth illustrates increased cementum deposition with age and increased distance from the apex. *(Courtesy Dr. Thomas Stein.)*

FIG. 24-10 This radiograph illustrates pulp volume changes in mandibular premolars. *Left to right:* a normal pulp, reparative dentin adjacent to a shallow restoration, more extensive reparative dentin adjacent to a more extensive restoration, and the overall reduced volume that occurs during aging.

age. Retention of teeth alone demonstrates some resistance to periodontal disease. The increase in disease prevalence is largely attributable to an increase in the proportional size of the population who have retained their teeth.[41] The periodontal tissues must be considered a pathway for sinus tracts (Fig. 24-12). Narrow, bony-walled pockets associated with nonvital pulps are usually sinus tracts, but they can be resistant to root canal therapy alone when, with time, they become chronic periodontal pockets. Patients with diabetes have increased periodontal disease in endodontically treated teeth and have a reduced likelihood of success of endodontic treatment in cases with preoperative periradicular lesions.[22]

Periodontal treatment can produce root sensitivity, disease, and pulp death.[40] In developing a successful treatment plan, it is important to determine the effects of periodontal disease and its treatment on the pulp (Fig. 24-13). Age was not a factor in response to periodontal therapy for advanced periodontal tissue breakdown.[39] The mere increase in incidence and

FIG. 24-11 A split tooth should always be considered when a nonvital pulp and chronic apical periodontitis are evident on a nonrestored tooth. The crack usually extends into the periodontium, and the prognosis is generally poor.

severity of periodontal disease with age increases the need for combined therapy. The chronic nature of pulp disease demonstrated with sinus tracts can often be manifested in a periodontal pocket. Root canal treatment is commonly indicated before root amputations are performed. With age, the size and number of apical and accessory foramina are actually reduced as pathways of communication,[59] as is the permeability of dentinal tubules.

Examination of sinus tracts should include tracing with gutta-percha cones to establish the tracts' origins (Fig. 24-14). Sinus tracts may have long clinical histories and usually indicate the presence of chronic periapical inflammation. Their disappearance after treatment is an excellent indicator of healing. The presence of a sinus tract reduces the risk of interappointment or postoperative pain, although drainage may follow canal débridement or filling.

Pulp Testing

Information collected from the patient's complaint, history, and examination may be adequate to establish pulp vitality and direct the clinician toward the techniques that are most useful in determining which tooth or teeth are the object of the complaint. Slow and gentle testing should be done to determine

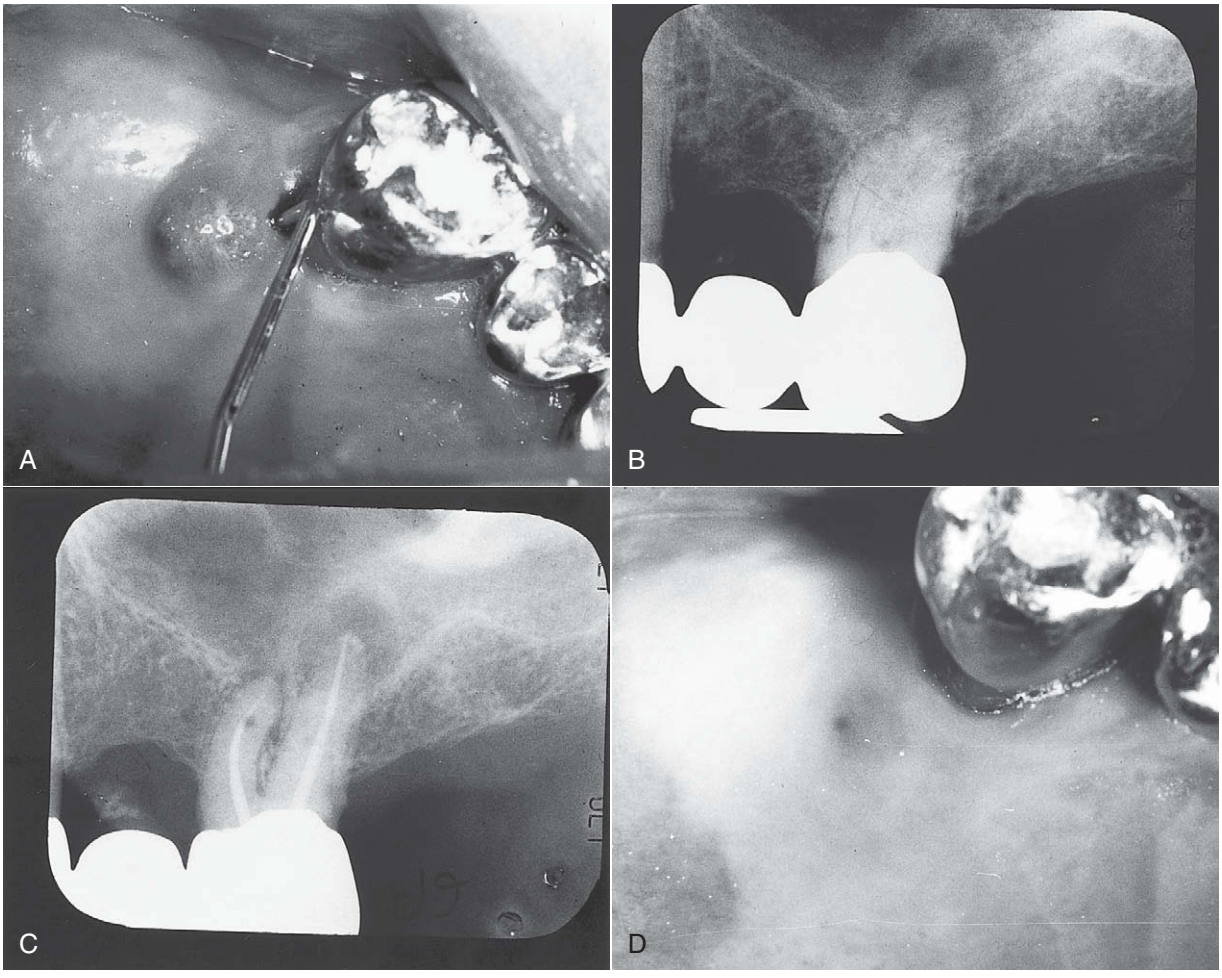

FIG. 24-12 A, A periodontal pocket is probed, and a sinus tract is evident on this maxillary molar abutment. **B,** This could indicate pulpal or periodontal disease or both. **C,** Root canal treatment results in healing **(D)** that confirms the pulpal cause of this periradicular lesion.

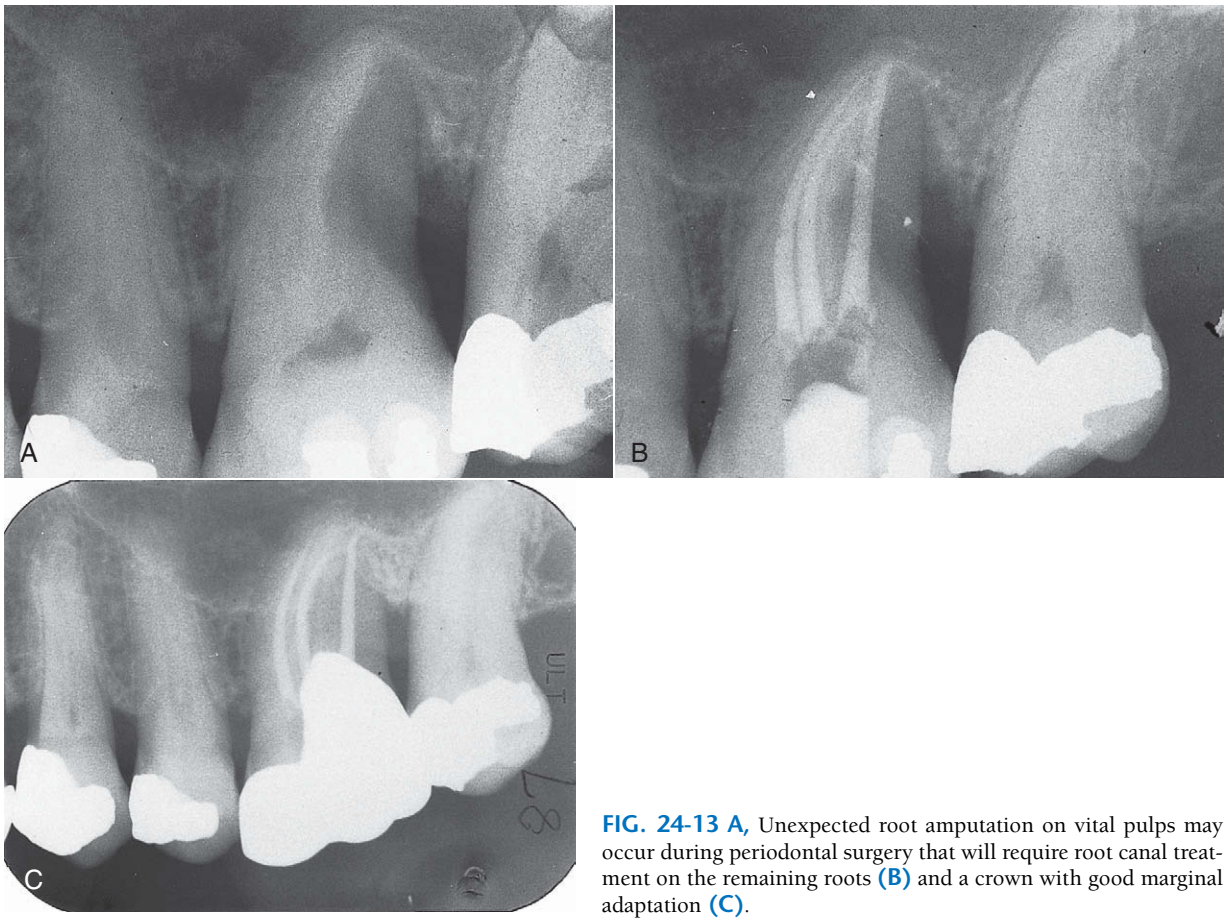

FIG. 24-13 A, Unexpected root amputation on vital pulps may occur during periodontal surgery that will require root canal treatment on the remaining roots **(B)** and a crown with good marginal adaptation **(C)**.

pulp and periapical status and whether palliative or definitive therapy is indicated. Vitality responses must correlate with clinical and radiographic findings and be interpreted as a supplement in developing clinical judgment. (Techniques for clinical pulp-testing procedures are discussed in Chapter 1.)

Transilluminating[56] and staining have been advocated as means to detect cracks, but the presence of cracks is of little significance in the absence of complaints, because most older teeth, especially molars, demonstrate some cracks. Vertically cracked teeth should always be considered when pulpal or periapical disease is observed and little or no cause for pulpal irritation can be observed clinically or on radiographs. The high magnification available with microscopes during access opening and canal exploration permits visualization of the extent of cracks in determining prognosis. Cracks that are detected while the pulp is still vital can offer a reasonable prognosis if immediately restored with full cuspal coverage. The chronic nature of any periapical pathologic condition caused by vertically cracked teeth indicates that it is longstanding, and the prognosis is questionable (even when pocket depths appear normal). Periodontal pockets associated with cracks indicate a poor prognosis.

The reduced neural and vascular components of aged pulps,[9] the overall reduced pulp volume, and the change in character of the ground substance[66] create an environment that responds differently to both stimuli and irritants than that of younger pulps (Fig. 24-15). Arteriosclerosis, a common condition in older people, has not been shown to occur in the pulp.[36]

Fewer nerve branches are present in older pulps. This may be due to retrogressive changes resulting from mineralization of the nerve and nerve sheath (Fig. 24-16).[8] Consequently, the response to stimuli may be weaker than in the more highly innervated younger pulp.

No correlation exists between the degree of response to electric pulp testing and the degree of inflammation. The presence or absence of response is of limited value and must be correlated with other tests, examination findings, and radiographs. Extensive restorations, pulp recession, and excessive calcifications are limitations in both performing and interpreting results of electric and thermal pulp testing. An alternative to the electric pulp test is assessment of pulp vitality by applying a thermal stimulus to the tooth surface. The electric pulp tester, CO_2 snow, and difluorodichloromethane were found to be more reliable than ethyl chloride or ice in producing a positive response.[26] Attachments that reduce the amount of surface contact necessary to conduct the electric stimulus are available (SybronEndo, Orange, CA), and bridging the tip to a small area of tooth structure with an explorer has been suggested.[53] Use of even this small electric stimulus in patients with pacemakers[83] is not recommended; any such risk would outweigh the benefit. The same caution holds true for electrosurgical units.

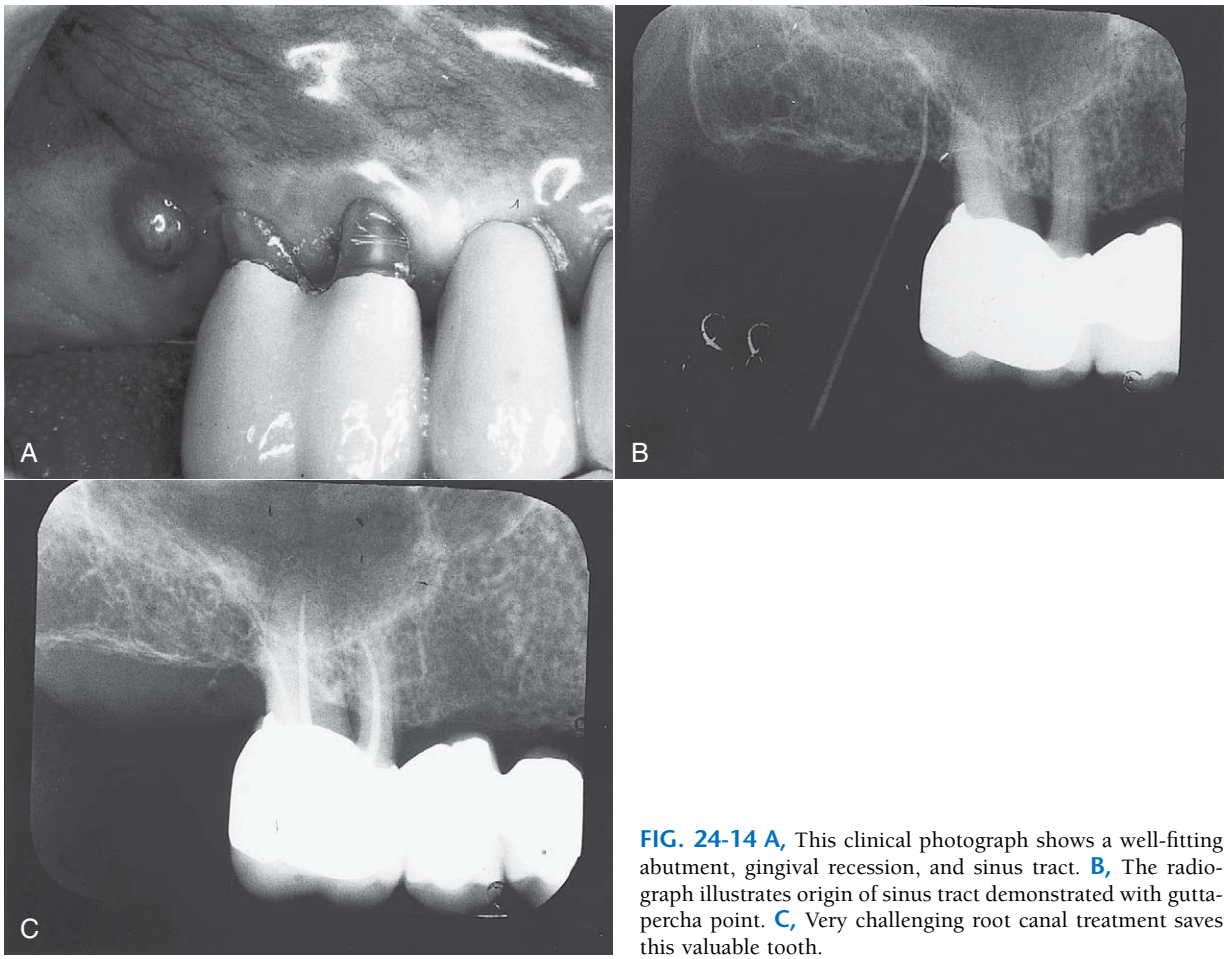

FIG. 24-14 A, This clinical photograph shows a well-fitting abutment, gingival recession, and sinus tract. **B,** The radiograph illustrates origin of sinus tract demonstrated with gutta-percha point. **C,** Very challenging root canal treatment saves this valuable tooth.

FIG. 24-15 The cellularity of older pulp tissue gradually decreases, and the odontoblasts decrease in size and number and may disappear altogether in certain areas, particularly on the pulpal floor in multirooted teeth.

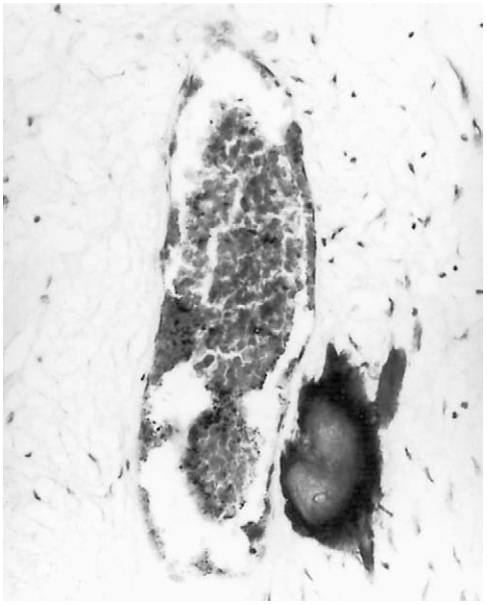

FIG. 24-16 Fibrosis appears to occur along the pathways of degenerated vessels and may serve as foci for pulpal calcification.

A test cavity is generally less useful as the test of last resort because of reduced dentin innervation. Vital pulps can sometimes be exposed and even negotiated with a file with minimal pain (Fig. 24-17); then the root canal treatment becomes part of the diagnostic procedure. Test cavities should be used only when other findings are suggestive but not conclusive.

Diffuse pain of vague origin is also uncommon in older pulps and limits the need for selective anesthesia. Pulpal disease is progressive and produces diagnostic signs or symptoms in a relatively short time. Nonodontogenic sources should be considered when factors associated with pulpal disease are not readily identified or when acute pain does not localize within a short time.

Discoloration of single teeth may indicate pulp death, but this is a less likely cause of discoloration with advanced age. Dentin thickness is greater, and the tubules are less permeable to blood or breakdown products from the pulp. Dentin deposition produces a yellow, opaque color that would indicate progressive calcification in a younger pulp, but this is common in older teeth.

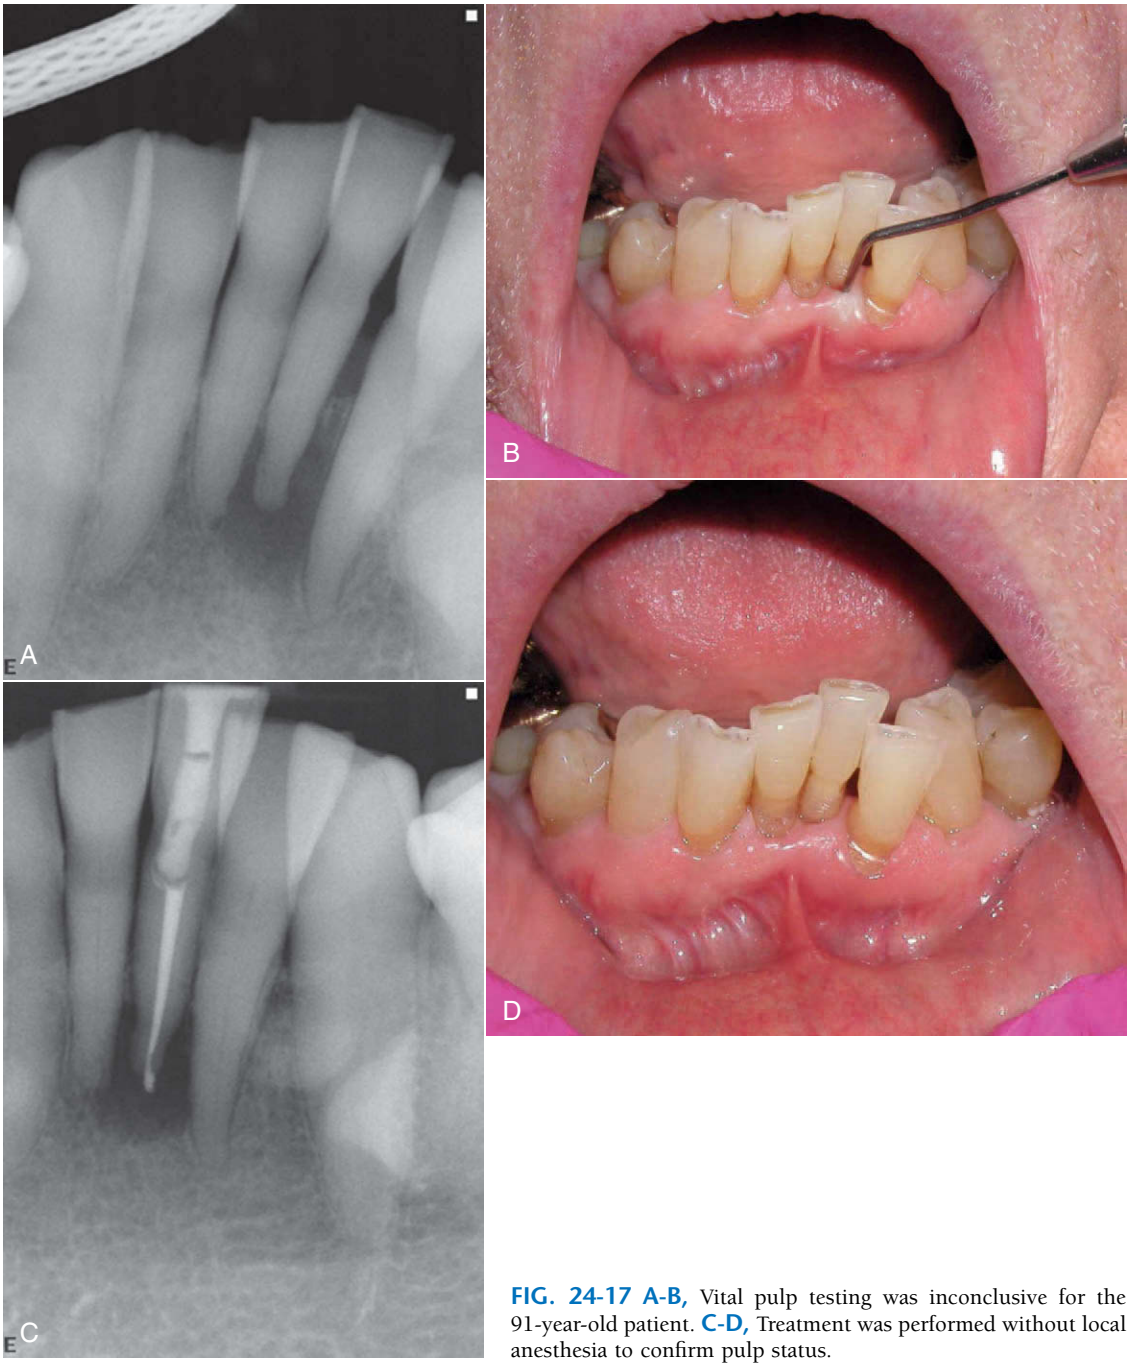

FIG. 24-17 A-B, Vital pulp testing was inconclusive for the 91-year-old patient. **C-D,** Treatment was performed without local anesthesia to confirm pulp status.

Radiographs

Indications for and techniques of taking radiographs do not differ much among adult age groups. However, several physiologic, anatomic changes can significantly affect their interpretation. Film placement may be adversely affected by tori but can be assisted by the apical position of muscle attachments that increase the depth of the vestibule. Older patients may be less capable of assisting in film placement, and holders that secure the position should be considered. The presence of tori, exostoses, and denser bone (Fig. 24-18) may require increased exposure times for proper diagnostic contrast. The subjective nature of interpretation can be reduced with correct processing, proper illumination, and magnification.

The periapical area must be included in the diagnostic radiograph, which should be studied from the crown toward the apex. Angled radiographs should be ordered only after the original diagnostic radiograph suggests that more information is needed for diagnosis or to determine the degree of difficulty of treatment. Digital radiography may be more useful than conventional radiography in detecting early bone changes.[85]

In older patients, pulp recession is accelerated by reparative dentin and complicated by pulp stones and dystrophic calcification. Deep proximal or root decay and restorations may cause calcification between the observable chamber and root canal.

The depth of the chamber should be measured from the occlusal surface and its mesiodistal position noted. Receding pulp horns that are apparent on a radiograph may remain microscopically much higher. Deep restorations or extensive occlusal crown reduction may produce pulp exposures that were not expected. The axial inclinations of crowns may not correlate with the clinical observation when tilted teeth have been crowned or become abutments for fixed or removable appliances. Access to the root canals is the most limiting condition in root canal treatment of older patients.

Canals should be examined for their number, size, shape, and curvature. Pulp has been demonstrated histologically even when not visible on radiographs, but in general, the two measurements did not differ even when pulp calcifications were present.[38] Comparisons with adjacent teeth should be made. Small canals are the rule in older patients. A midroot disappearance of a detectable canal may indicate bifurcation rather than calcification. Canals calcify evenly throughout their length unless an irritant (e.g., caries, restoration, cervical abrasion) has separated the chamber from the root canal. Root-end fillings during root-end resection (more common during retreatment of older patients) indicate missed canals and roots as a common cause of failure.[2]

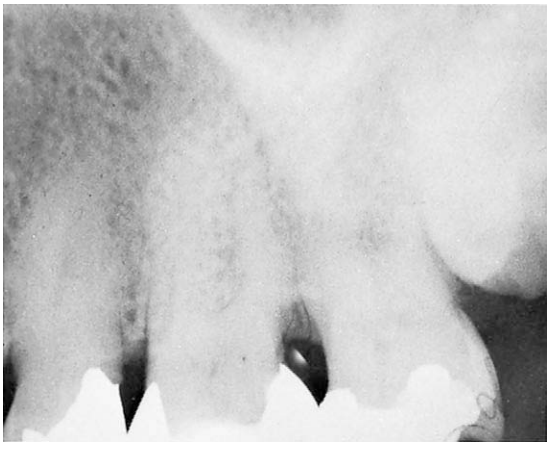

FIG. 24-18 Dense bone may indicate the need for increased exposure times to improve contrast needed to see the canal and root anatomy.

The lamina dura should be examined in its entirety and anatomic landmarks distinguished from periapical radiolucencies and radiopacities. The incidence of some odontogenic and nonodontogenic cysts and tumors characteristically increases with age, and this should be considered when vitality tests do not correlate with radiographic findings. However, the incidence of osteosclerosis and condensing osteitis decreases with age.

Resorption associated with chronic apical periodontitis may significantly alter the shape of the apex and the anatomy of the foramen through inflammatory osteoclastic activity (Fig. 24-19).[15] The narrowest point in the canal may be difficult to determine; it is positioned farther from the radiographic apex because of continued cementum deposition.

A continued normal rate of cementum formation may be demonstrated by a canal or foramen that appears to end or exit short of the radiographic apex, and hypercementosis (Fig. 24-20) may completely obscure the apical anatomy.

DIAGNOSIS AND TREATMENT PLAN

A clinical classification that accurately reflects the histologic status of the pulp and periapical tissues is not possible and not necessary beyond determining whether root canal treatment is indicated. A clinical judgment can be made based on the patient's complaint, history, signs, symptoms, testing, and radiographs as to the vitality of the pulp and the presence or absence of periapical pathologic conditions. This classification has not been shown to be a factor in predicting success, interappointment or postoperative pain, or the number of visits necessary to complete treatment when the objectives of cleansing, shaping, and filling are clearly understood and consistently met.[24] Of great clinical significance in treatment procedures is the assessment of pulp status to determine the depth of anesthesia necessary to perform the treatment comfortably.

One-appointment procedures offer obvious advantages to older patients. The length of a dental appointment does not usually cause inconvenience, as may more numerous appointments, especially if a patient must rely on another person for transportation or needs physical assistance to get into the office or operatory.

Root canal treatment as a restorative expediency on teeth with normal pulps must be considered when cusps have fractured or when supraerupted or malaligned teeth, intracoronal attachments, guide planes for partial abutments, rest seats, or overdentures require significant tooth reduction (Fig. 24-21). Predicting the need for future root canal treatment and a clinician's ability to perform treatment later is even more important because the risk of losing the restoration during later access preparation increases with the thickness of the restoration and the reduction in canal size (Fig. 24-22). Because of a reduced blood supply, pulp capping is not as successful in older teeth as in younger ones, so it is not recommended. Any risk to the

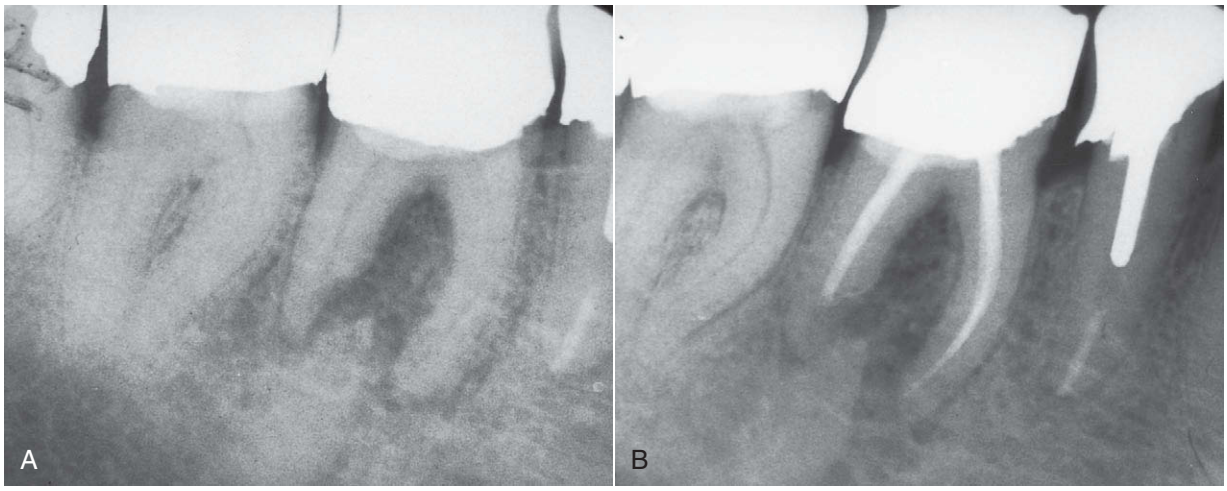

FIG. 24-19 A, Resorption associated with chronic apical periodontitis may alter the shape and position of the foramen through osteoclastic activity. **B,** The narrowest point in the canal is now positioned farther from the radiographic apex.

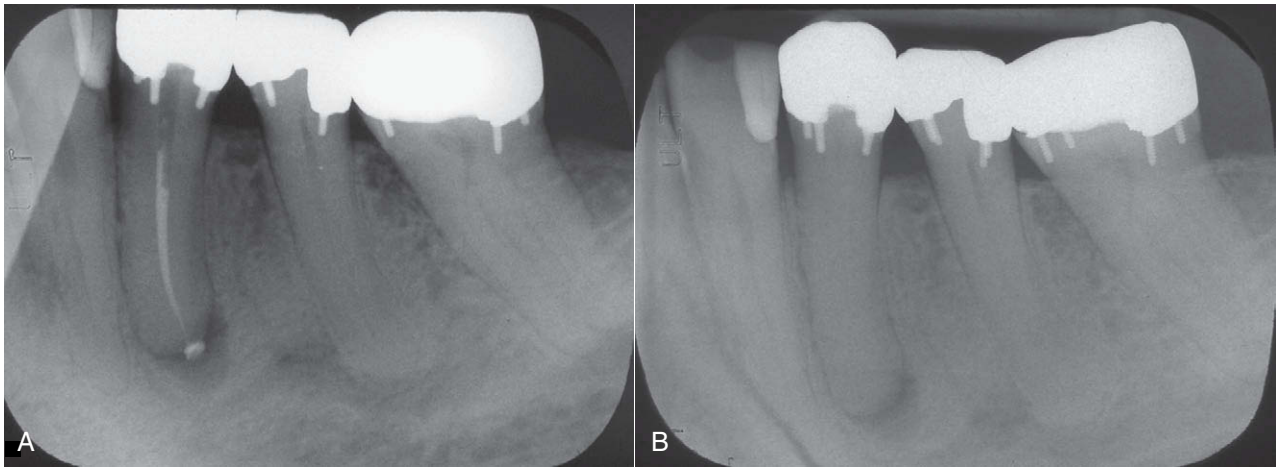

FIG. 24-20 A, Hypercementosis may completely obscure the apical anatomy and result in a constriction farther from the radiographic apex **(B)**.

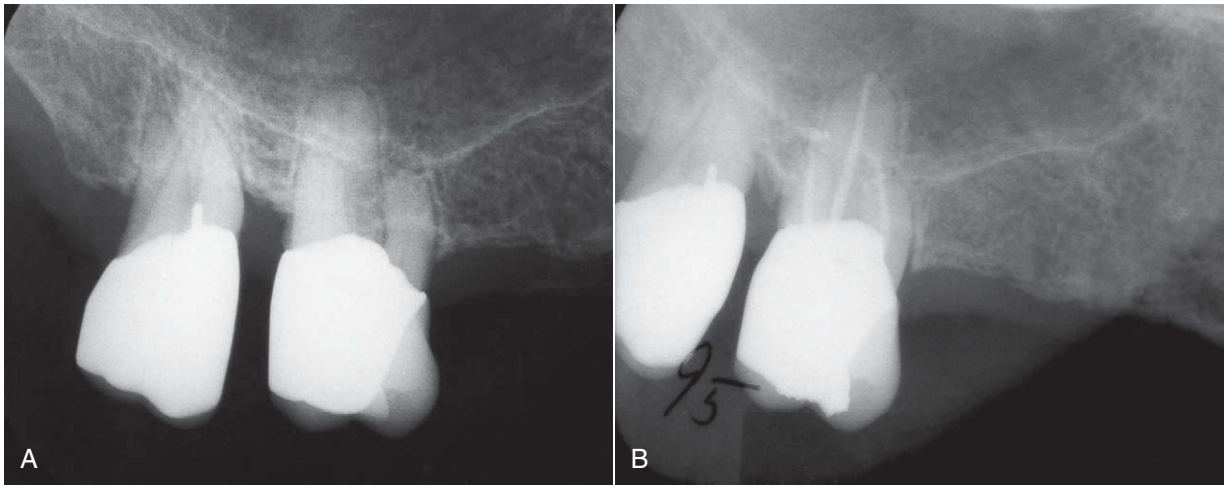

FIG. 24-21 A, Valuable maxillary first- and second-molar abutments in an 85-year-old patient. **B,** Later need for endodontic therapy was made very challenging because of access difficulties.

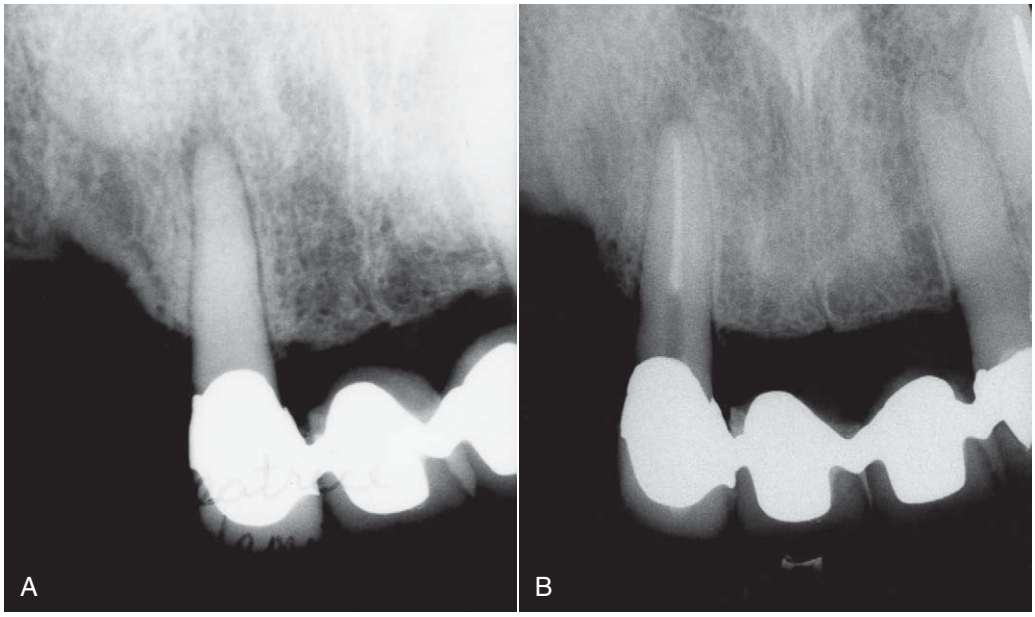

FIG. 24-22 A, Intracoronal attachments, guide planes, and rest seats for partial abutments require significant tooth reduction and a bulk of metal that makes endodontic treatment more likely and difficult. **B,** Successful treatment and preservation of the restoration when the canal is small are challenges to the most skilled clinician.

patient's future health and the effect health may have on his or her ability to withstand future procedures should also be considered. Endodontic surgery at a later time is not as viable an alternative as for a younger patient.

Consultation and Consent

Good communication should be established and maintained with all patients, regardless of whether they are physically impaired or unable to make treatment decisions for themselves. Relatives or trusted friends should be included in consultations if their judgment is valued by the patient or needed for consent, but the clinician should direct the discussion toward the patient (Fig. 24-23).

Clinicians should explain procedures in a way that is completely comprehensible and provides an opportunity for questions from the patient. Patient-friendly pamphlets are available from the American Association of Endodontists (AAE) that thoroughly explain and illustrate most endodontic procedures. Obtaining signed consent to outlined treatment is encouraged and may be especially useful if the patient is forgetful.

Determining the patient's desires is as important as determining his or her needs, and it is required in obtaining informed consent (Fig. 24-24). Priorities in treating pain and infection to properly and esthetically restore teeth to health and function should be unaffected by age (Fig. 24-25). A patient's limited life expectancy should not appreciably alter treatment plans and is no excuse for extractions or poor root canal treatment. It is important that all older patients be well informed of risks and alternatives (Fig. 24-26). Patients deserve a better explanation for their disease than that it is caused by age. When a physician told one patient that the problem with his knee was due to age, he said, "The other knee is the same age and nothing is wrong with it."

Acceptance of the eventual loss of teeth has been replaced by an understanding of the psychologic and functional importance of maintaining dentition. Older patients whose lives have been changed for the worse by a previous surgical procedure may readily recognize the implications of the loss of teeth.

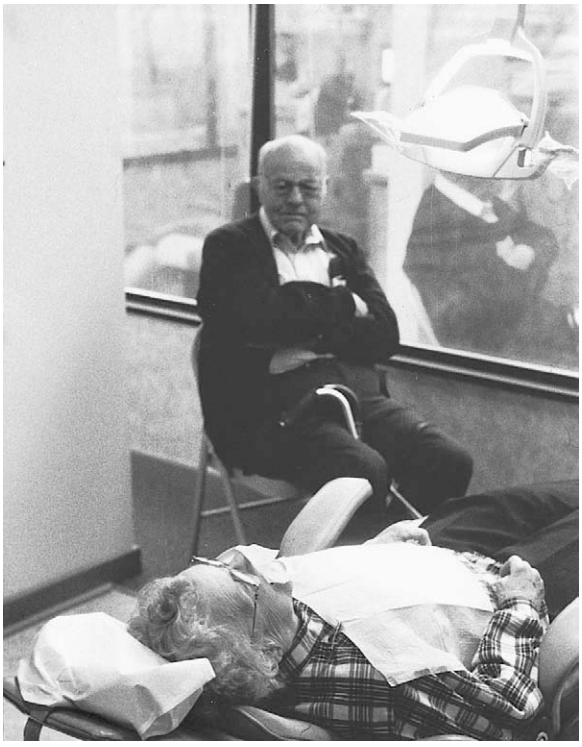

FIG. 24-23 Some patients may request or require that a family member be present during consultation or treatment.

The capability of the clinician and the availability of endodontic specialists should also be considered. The obligation to offer root canal treatment as an alternative to extraction may

exceed a clinician's ability to perform the procedure efficiently or successfully, and referral may be indicated. Older patients are more likely to be aware that there are specialists for performing root canals but will trust and do what their clinician recommends. In advance of the scheduled visit, referring clinicians should provide the endodontist with as much information about the patient as possible (and thoroughly explain the reason for referral to the patient). To support treatment adherence and understanding, clinicians should consider making the referral appointment for the patient while he or she is in the dental office.

Obtaining informed consent before dental procedures usually is not a problem. However, medically compromised or cognitively impaired patients may make it difficult to acquire valid informed consent. Neuropsychiatric impairment may result in gross manifestations and indicate a reduced level of competency. Physicians or mental health experts should be consulted as needed, and no elective procedures should be performed until valid consent is established. Fortunately, acute pulpal and periapical episodes in which immediate treatment is indicated for pain or infection are less common than the low-grade signs and symptoms of chronic disease.

TREATMENT

The vast majority of geriatric patients who need and demand endodontic therapy are ambulatory and not institutionalized. Institutionalized and nonambulatory patients require clinicians trained in those environments and facilities designed for access to dental health care (Fig. 24-27). Such access is a benefit required in most institutions, but alternatives to root canal therapy may be the only services available. Extended health care facilities are now required to have clinicians on staff before Medicare certification can be obtained. The dental

FIG. 24-24 Many geriatric patients benefit from the use of a pillow for neck support.

FIG. 24-25 This 84-year-old patient was pleased to find that all these teeth could be saved with endodontic therapy and crowns. She was eager to make the investment in time and money, despite her limited life expectancy. Her concern focused on why these procedures had not been recommended by her previous dentist, whom she visited regularly.

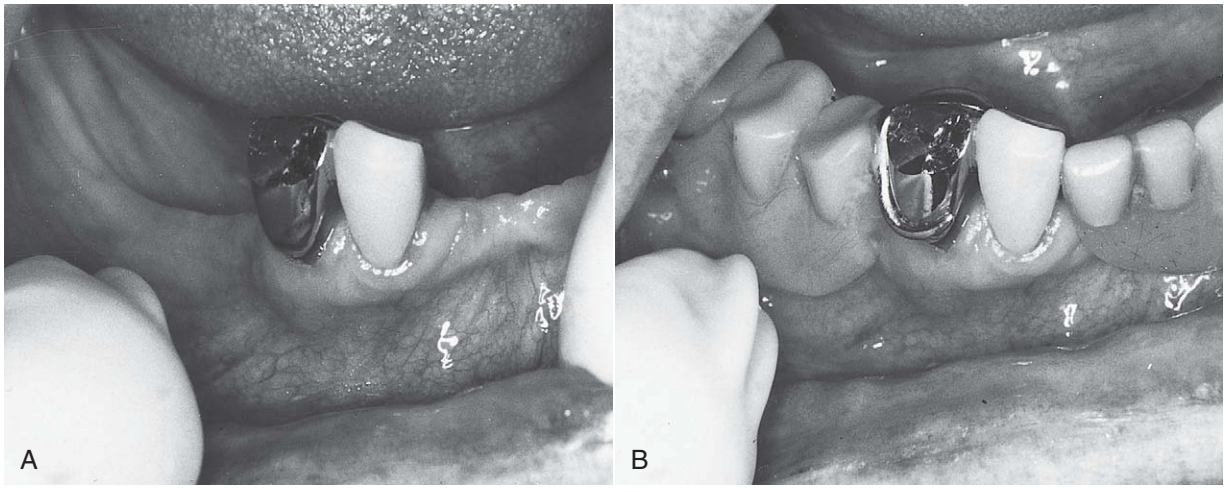

FIG. 24-26 A, These two remaining abutments were the only teeth this 99-year-old patient needed to retain a removable prosthesis **(B)**.

FIG. 24-27 A, Office design should consider access for wheelchairs and walkers. **B,** Staff should be experienced in assisting patients into and out of the dental chair and operatory.

office building, including both the interior design and the exterior approach, must be able to accommodate people with special needs.[52] Access for those who use ambulation aids (e.g., canes, walkers, wheelchairs) should include comfort and safety in the parking lot, reception room, operatory, and rest room. Dental units can be designed to accommodate patients while in their own wheelchairs so that they do not require any transfer.[72]

A physical and mental evaluation of the patient should determine the ideal time of day and length of time necessary to schedule treatment. A patient's daily personal, eating, and resting habits should be considered, as well as any medication schedule. Morning appointments are preferable for some older patients, and their comfort, which varies with the procedure indicated, dictates the length of the appointment. Some patients prefer late morning or early afternoon visits to allow "morning stiffness" to dissipate.[19]

Older patients are more likely to tolerate long appointments, although chair positioning and comfort may be more important for older adults than for younger patients. Patients should be offered assistance into the operatory and into or out of the chair, and chair adjustments should be made slowly (and the ideal position established and used if possible). Pillows should be offered, as well as assistance in positioning them comfortably. Every effort should be made to accommodate the ideal position, even at some expense to the clinician's comfort or access.

The patient's eyes should be shielded from the intensity of the clinician's light. If the temperature selected for the comfort of the office staff is too cool for the patient, a blanket should be available. As much work as possible should be performed at each visit, and a restroom break should be offered at intervals as the patient's needs indicate. Jaw fatigue is readily recognizable and may be the most limiting factor in a long procedure, requiring periods of rest; however, once such fatigue is evident, the procedure should be terminated as soon as possible. Bite blocks are useful in comfortably maintaining freeway space and reducing jaw fatigue.

Retired persons may rely on rides from friends or relatives or public transportation to get to the dental office. Although they often arrive early for appointments, most older patients are in no hurry once they arrive. Enough time should be scheduled to allow some social exchange, and a sincere personal interest should be demonstrated before proceeding. Endodontic specialists need to consider separate consultations for making this initial social contact and evaluating the degree of difficulty that will determine the chair time needed to perform treatment. Staff should allow patients to initiate handshakes, which may be very uncomfortable to people with arthritic joints. From a behavioral and management standpoint, geriatric patients are among the most cooperative, available, and appreciative.

Older, medically compromised patients are at no more risk of complications than those in any other age group, and the chronicity of their diseases can alert the clinician to necessary precautions. Once again, clinicians should recognize that root canal therapy is far less traumatic than extraction for older patients.

The pulp vitality status and the cervical positioning of the rubber dam clamp determine the need for anesthesia. Older patients more readily accept treatment without anesthesia, and sometimes they must be persuaded that anesthesia is necessary for root canal treatment if their routine operative procedures have been performed without it. Generally, older patients demonstrate less anxiety about dental treatment and may have previous experience with root canal treatment.

The cutting of dentin does not produce the same level of response in an older patient for the same reason that a test

cavity is not as revealing during examination. The number of low-threshold, high-conduction-velocity nerve endings in dentin is reduced or absent, and they do not extend as far into the dentin. In addition, the dentinal tubules are more calcified.[9,66] A painful response may not be encountered until actual pulp exposure has occurred.

Anatomic landmarks that are used as guides to needle placement during block and infiltration injections are usually more distinguishable in older patients. The effects of epinephrine should be considered when selecting anesthetics for routine endodontic procedures. Anesthetics should be deposited very slowly (and skeletal muscle avoided) if epinephrine is the vasoconstrictor.

The reduced width of the periodontal ligament[35] makes needle placement for supplementary intraligamentary injections more difficult. Placing an anesthetic under pressure produces an intraosseous anesthesia that extends to the apex and to adjacent teeth, but it also distributes small amounts of solution systemically.[64] Intraosseous injections can significantly increase the success of pulpal anesthesia but can be associated with a transient increase in heart rate when anesthetics contain epinephrine. Smaller amounts of anesthetic should be deposited during intraosseous injections, and the depth of anesthesia should be checked before repeating the procedure. Like intrapulpal anesthesia, intraosseous anesthesia is not prolonged; the pulp tissue must be removed within 20 minutes. The majority of patients receiving an intraosseous injection of 2% lidocaine with 1:100,000 epinephrine (correct ratio) solution experience a transient increase in heart rate. This would not be clinically significant in most healthy patients, but in the older patient whose medical condition, drug therapies, or epinephrine sensitivity suggests caution, 3% mepivacaine is a good alternative for intraosseous injections.[57] Chapter 20 gives further information.

The reduced volume of the pulp chamber makes intrapulpal anesthesia difficult in single-rooted teeth and almost impossible in multirooted teeth. Initial pulp exposures are also hard to identify. Wedging a small needle into each canal to produce the necessary pressure for anesthesia is the method of last resort. Every effort should be made to produce profound anesthesia. Patients should be encouraged to report any unpleasant sensation, and a prompt response should be made to any complaint. Patients should never be expected to tolerate pulpal pain.

Isolation

Either single-tooth or multitooth rubber dam isolation can be used. Badly broken-down teeth may not provide an adequate purchase point for the rubber dam clamp, so alternate rubber dam isolation methods should be considered (see Chapter 5). Multiple-tooth isolation may be used if adjacent teeth can be clamped and saliva output is low or a well-placed saliva ejector can be tolerated (Fig. 24-28). A three-holed rubber dam with the tooth in question in the middle allows for better maneuverability, especially when using the dental operating microscope. A petroleum-based lubricant for the lips and gingiva reduces chafing from saliva or perspiration beneath the rubber dam. Reduction in salivary flow and gag reflex reduces the need for a saliva ejector. Artificial saliva is available and should be used just before isolation, because it is difficult to apply after the dam is in place.

FIG. 24-28 Multiple-tooth isolation techniques protect the patient from instruments but do not provide the fluid-tight environment preferred for the safe use of sodium hypochlorite.

Canals should be identified and their access maintained if restorative procedures are indicated for isolation. The clinician should not attempt isolation and access in a tooth with questionable marginal integrity of its restorations. Fluid-tight isolation cannot be compromised when sodium hypochlorite is used as an irrigant. Difficult-to-isolate defects produced by root decay present a good indication, in initial preparation, for the use of sonic handpieces that use flow-through water as an irrigant.

The many merits of single-visit root canal procedures is generally recommended when isolation is compromised (see Chapters 4 and 5). The few minor benefits of multiple-visit treatment are further reduced if an interappointment seal is difficult to obtain.

Access

Adequate access and identification of canal orifices are likely the most challenging aspects of providing root canal treatment for older patients. Although the effects of aging and multiple restorations may reduce the volume and coronal extent of the chamber or canal orifice, its buccolingual and mesiodistal positions remain the same and can be predicted from radiographs and clinical examination. Canal position, root curvature, and axial inclinations of roots and crowns should be considered during the examination (Fig. 24-29). The effects of access on existing restorations and the possible need for actual removal of the restoration should be discussed with the patient before initiating treatment (Fig. 24-30). Coronal tooth structure or restorations should be sacrificed when they compromise access for preparation or filling (Fig. 24-31). Perhaps all restorations should be removed before endodontic treatment in order to remove the common factors (caries, marginal breakdown, cracks) that may have caused the pulp and periradicular disease and to assess the tooth's prognosis and future treatment needs. One study found that almost all teeth (93%) had these factors; only 56% were detectable clinically or on radiographs.[1] (See Chapter 7 for more details on proper access openings.)

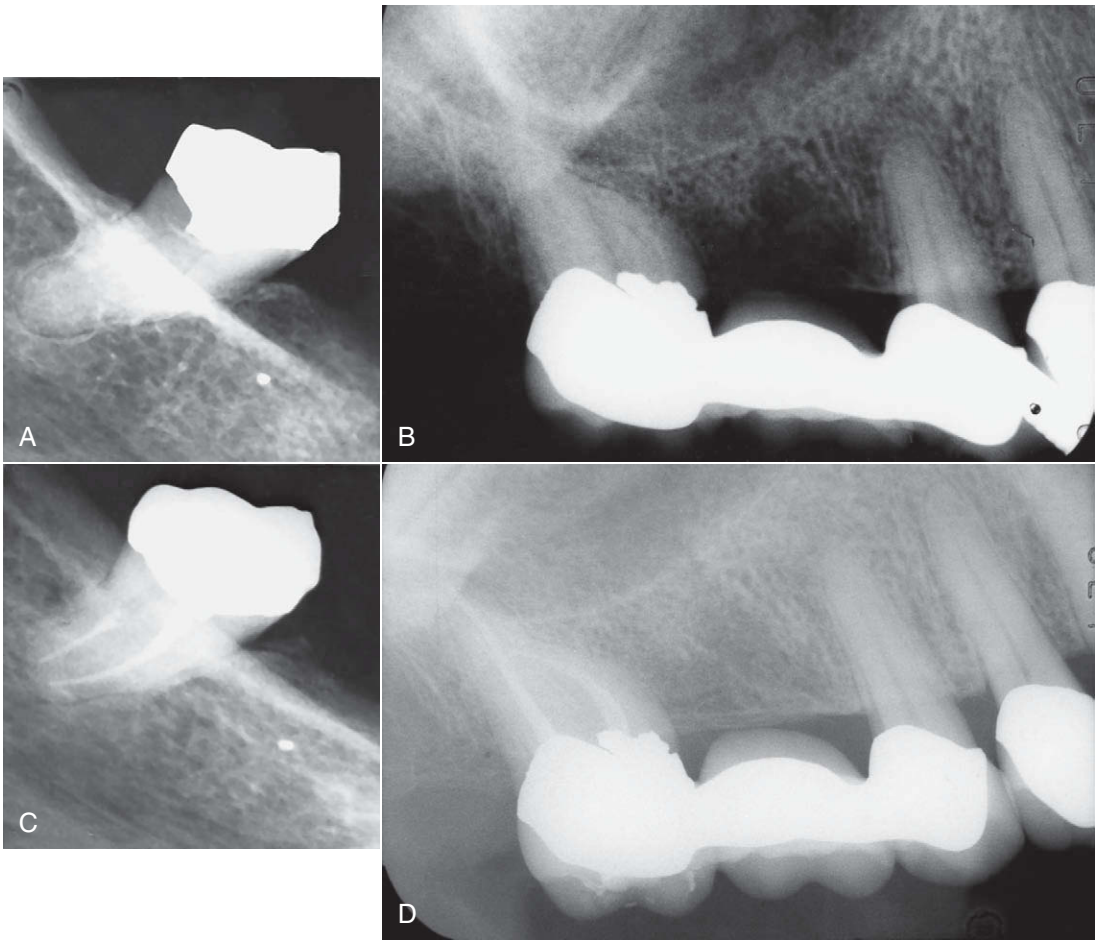

FIG. 24-29 A, This mandibular third molar in a 78-year-old patient has tilted mesially and has been restored with a full crown, upright to allow a path of insertion for a removable partial denture. **B,** Successful root canal treatment is the primary objective. Retaining the crown when possible also represents significant savings to the patient. This crown will be replaced; a post space has been prepared. **C,** This maxillary third molar on the same patient is tilted mesially and rotated, making access **(D)** the most difficult part of this treatment.

Magnification in the range of 2.5× to 4.5× (e.g., Designs for Vision, Ronkonkoma, NY) has become a common tool and can be designed to fit the clinician's most comfortable working distance. The growing acceptance and availability of endodontic microscopes[34] offer clear magnification ranging up to 25× or greater and have obvious advantages in treating smaller and narrower geriatric canals (see Chapter 6, Fig. 6-4).

Location and penetration of the canal orifice are often difficult and time consuming in calcified canals. The most important instrument for initial penetration is the DG-16 explorer. The explorer will not stick in solid dentin, but it will resist dislodgment in the canal. Once the canal has been distinguished, negotiation is attempted with a stainless steel (SS) #8, #10, or #15 K-file. The #6 file lacks stiffness in its shaft and easily bends and curls under gentle apical pressure. Nickel-titanium (NiTi) files lack strength in the long axis and are contraindicated for initial negotiation. The canal can be negotiated using a watch-winding action with slight apical pressure. Chelating agents are seldom of value in locating the orifice but can be useful during canal negotiation. Dyes may distinguish an orifice from the surrounding dentin.

Pain, bleeding, disorientation of the probing instruments, or an unfamiliar feel to the canal may indicate a perforation (Fig. 24-32). The size of the perforation and the extent of contamination determine the success of repair (which should be done immediately) and do not necessarily indicate failure (Fig. 24-33). Supraerupted teeth can be easily perforated (Fig. 24-34) if the reduced distance to the furcation is not noted.

A lengthy, unproductive search for canals is fatiguing and frustrating to both the clinician and the patient. Scheduling a second attempt at this procedure is often productive. Personal clinical experiences and judgment determine when the search for the canals must be terminated and referral or alternatives to nonsurgical root canal treatment considered (Fig. 24-35).

Modifications to enhance access vary from widening the axial walls to increasing visibility or light to complete removal of the crown. Alterations may be indicated after canal penetration to the apex if tooth structure interferes with instrumentation or filling procedures.

Teeth with chronic apical periodontitis will usually have patent canals (Fig. 24-36). Surgical access (Fig. 24-37) may be preferred if the risk of deviation from the long axis exists

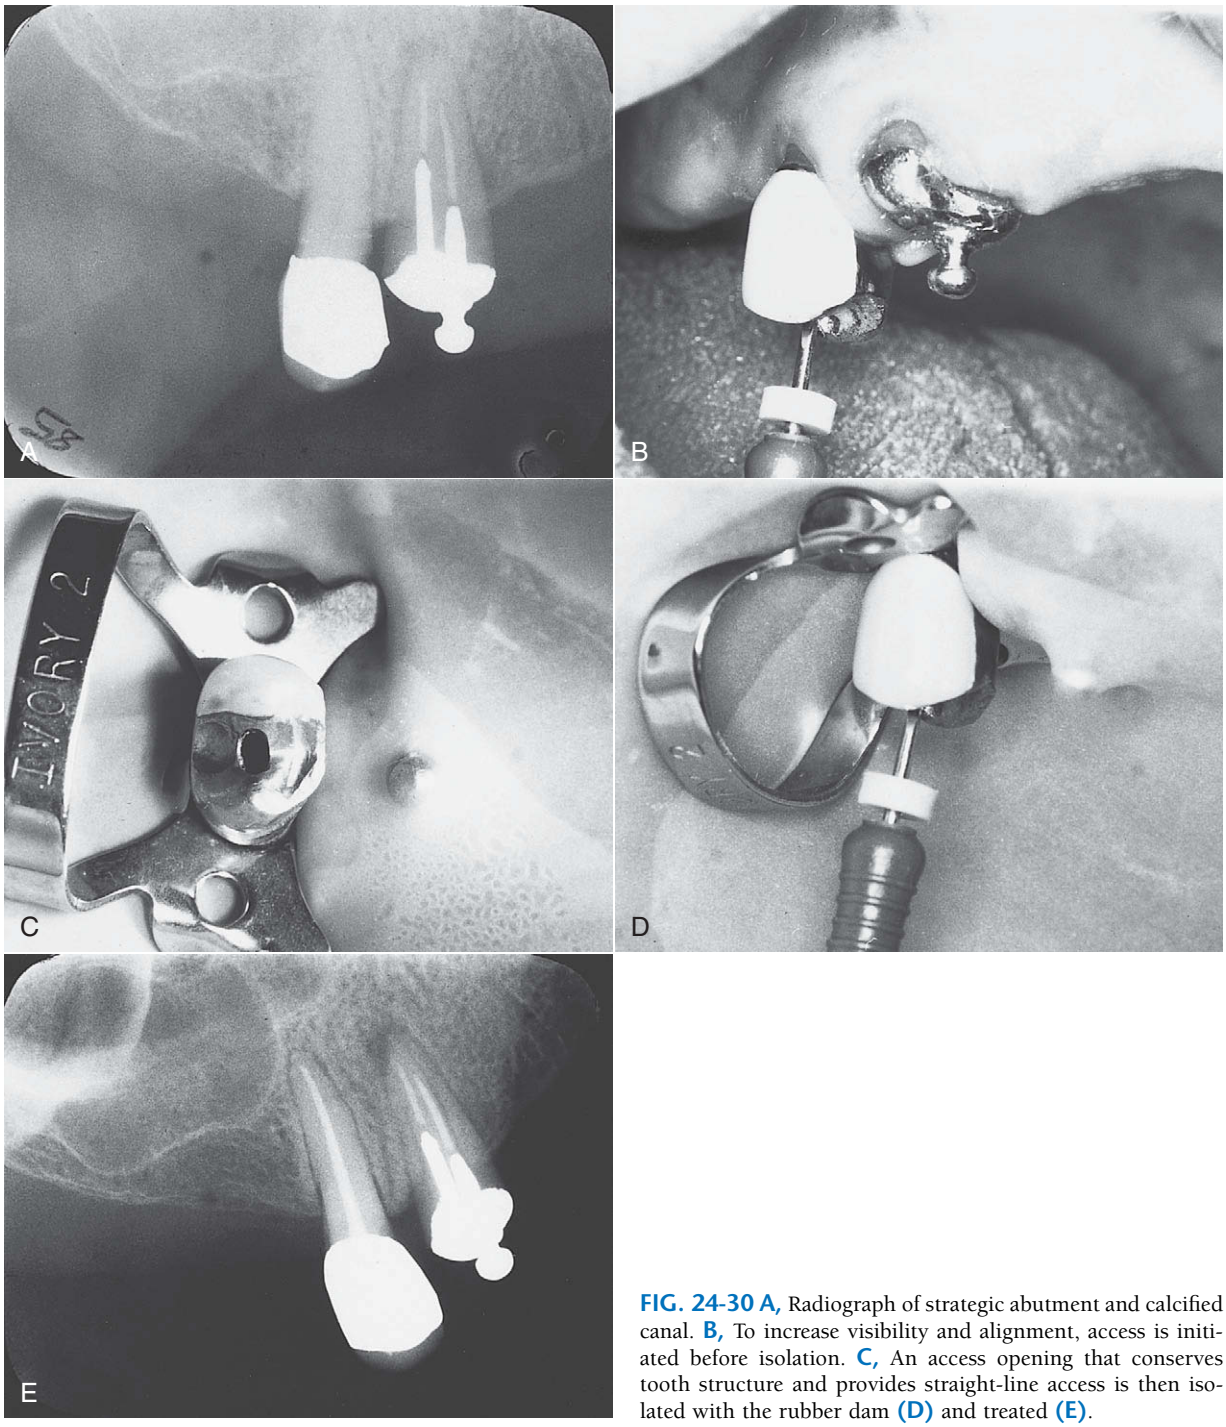

FIG. 24-30 A, Radiograph of strategic abutment and calcified canal. **B,** To increase visibility and alignment, access is initiated before isolation. **C,** An access opening that conserves tooth structure and provides straight-line access is then isolated with the rubber dam **(D)** and treated **(E)**.

when canals are calcified and the tooth is heavily restored (Fig. 24-38).

Very few canals of older teeth, even maxillary anterior teeth, have adequate diameter to allow the safe and effective use of broaches. Older pulps may give a clinical appearance that reflects their calcified, atrophic state with the stiffened, fibrous consistency of a wet toothpick. Any broached canals should be thoroughly cleaned and shaped at the same appointment.

Preparation

The calcified appearance of the canals resulting from the aging process presents a much different clinical situation than that of a younger pulp in which trauma, pulpotomy, decay/caries, or restorative procedures have induced premature canal obliteration. Unless further complicated by reparative dentin formation, this calcification appears to be much more concentric and linear. This allows easier penetration of canals once they

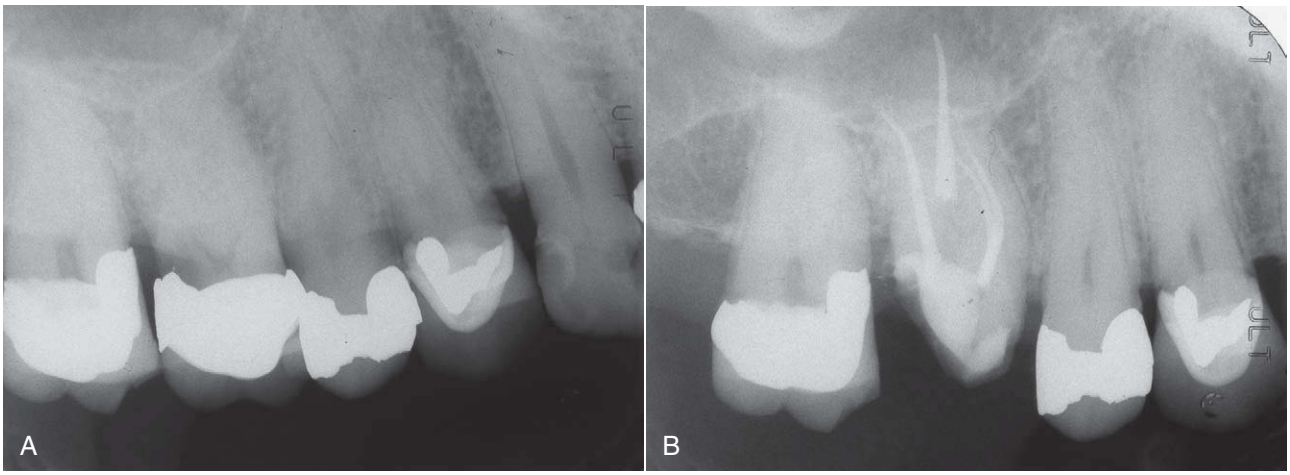

FIG. 24-31 A, Caries control and isolation of this tooth necessitated crown removal. **B,** Endodontic treatment was completed in one visit.

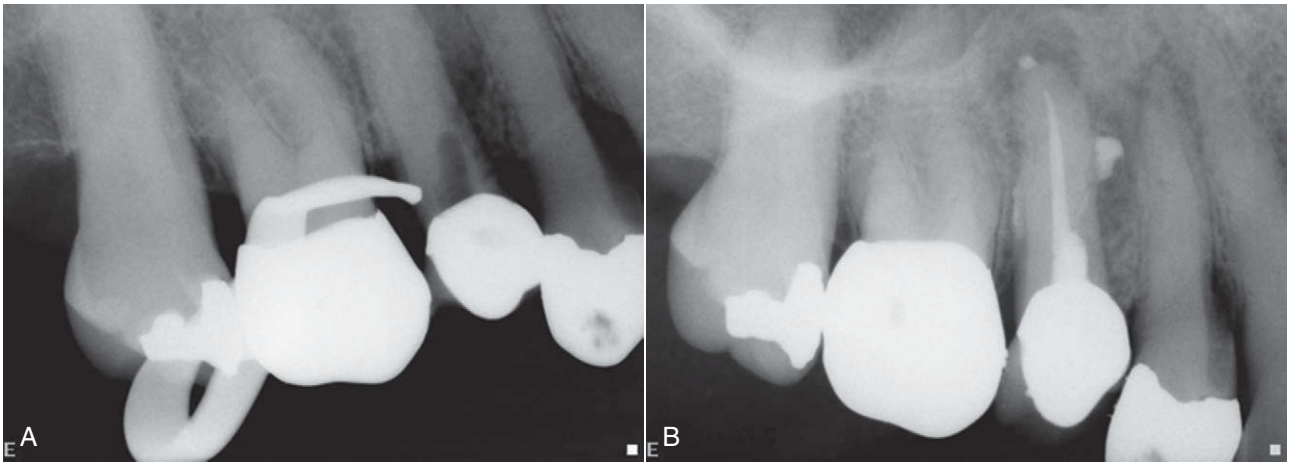

FIG. 24-32 A, Pain, bleeding, or disorientation of the probing instrument may indicate a perforation, which should be immediately investigated with a radiograph. **B,** Repair has the best success when the perforation opening is pinpoint and periodontal tissues are normal.

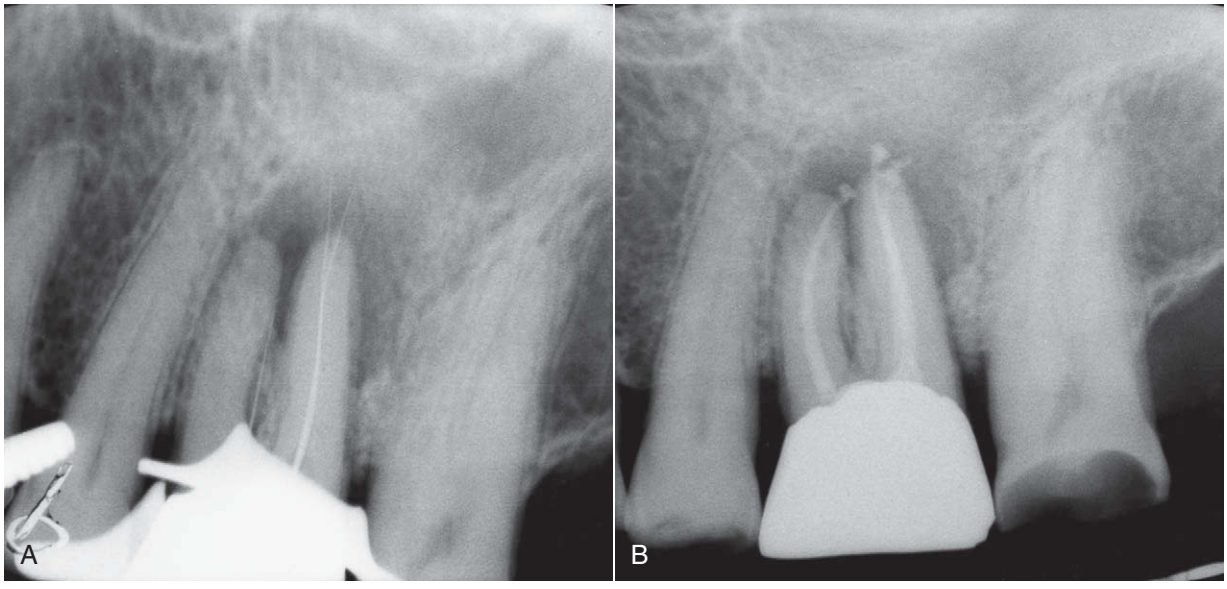

FIG. 24-33 A, Perforation occurred during access of these calcified canals. **B,** Endodontic treatment was immediately completed after the perforation repair.

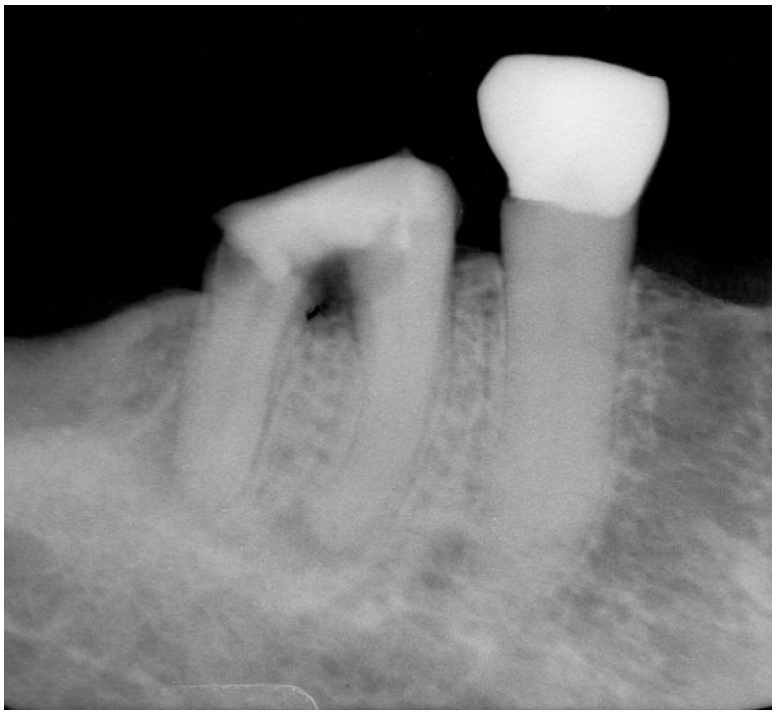

FIG. 24-34 Supraerupted mandibular first molar that was perforated during access.

are found. An older tooth is more likely to have a history of earlier treatments, with a combination of calcifications present. (Chapter 9 includes a description of cleaning and shaping root canals.)

The length of the canal from the actual anatomic foramen to the CDJ increases with the deposition of cementum throughout life.[37] The advantage of this situation in the treatment of teeth with vital pulps is countered by the presence of necrotic, infected debris in this longer canal when periapical pathosis is already present. The actual CDJ width or most apical extent of the dentin remains constant with age.[68]

Flaring of the canal should be performed as early in the procedure as possible to provide for a reservoir of irrigation solution and reduce the stress on metal instruments that occurs when they bind with the canal walls. Thorough and frequent irrigation should be performed to remove the debris that could block access. Files with a triangular or square cross-section may penetrate into the walls with greater force than the fracture resistance of small files (when used with a reaming action) and result in instrument fatigue and fracture. The benefits of instruments with no rake angle and a crown-down technique are recommended.

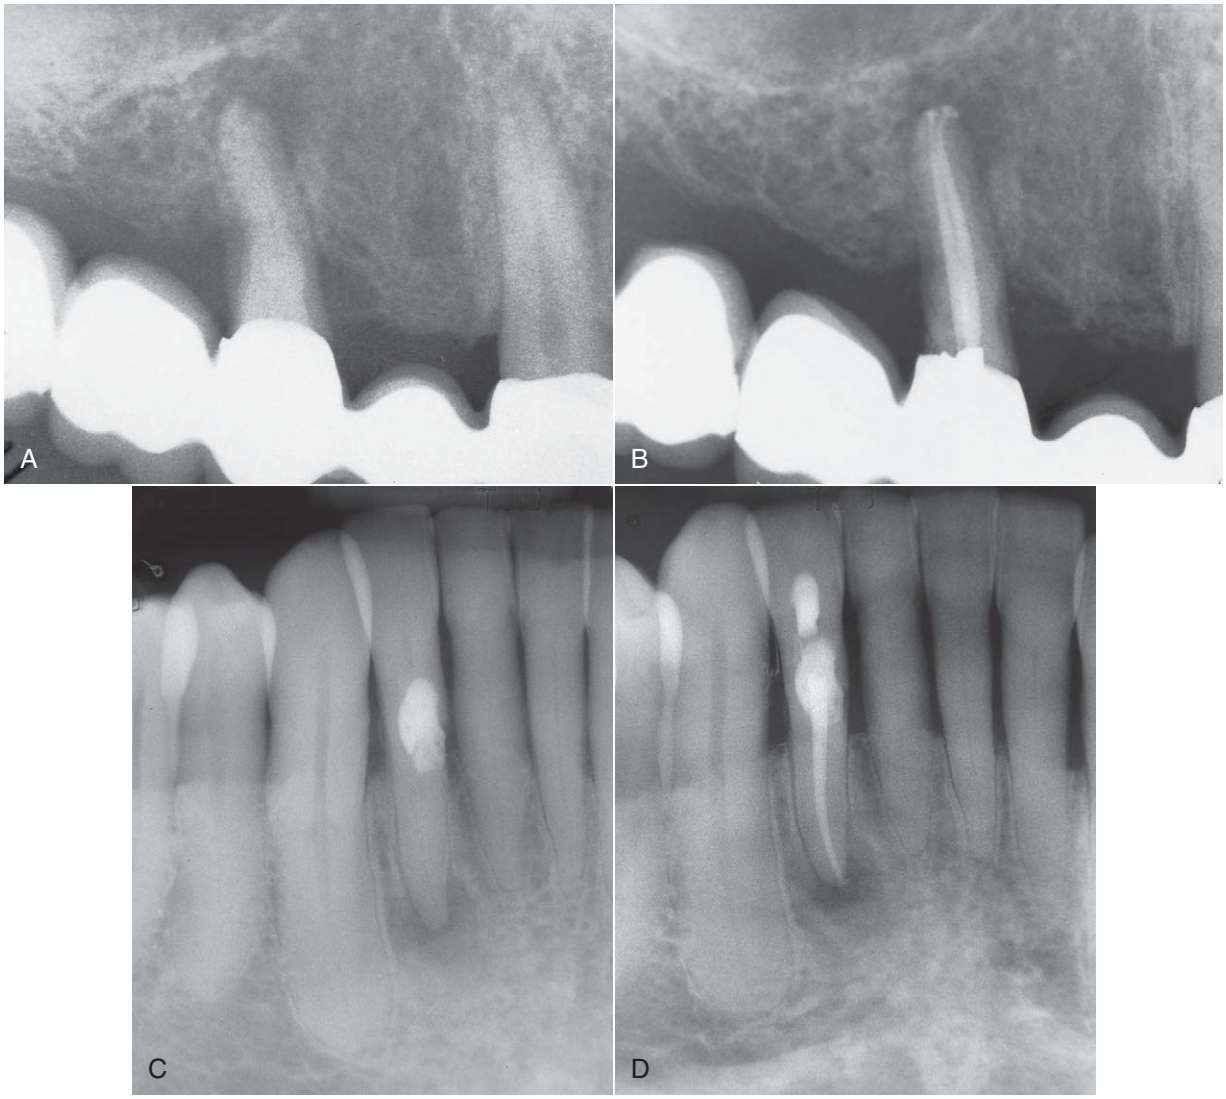

FIG. 24-36 A, Strategic middle abutment for a long fixed bridge presents a challenge to the most skilled clinician to perform predictable root canal treatment. **B,** Poor crown/root ratio makes root-end surgery a poor option. Root canal treatment should have been considered before using this lone-standing premolar as an abutment. **C,** Calcified canals can usually be detected and treated when a nonvital pulp and chronic apical periodontitis are present, even when the canals are not apparent on the radiograph. Asymptomatic, calcified canals on teeth with vital pulps are much more difficult to find and negotiate. **D,** External resorption repair before endodontic treatment made negotiation and instrumentation of this incisor tooth more difficult.

Because this CDJ is the narrowest constriction of the canal, it is the ideal place to terminate the canal preparation. This point may vary from 0.5 to 2.5 mm from the radiographic apex and be difficult to determine clinically. Calcified canals reduce the clinician's tactile sense in identifying the constriction clinically, and reduced periapical sensitivity in older patients reduces the patient's response that would indicate penetration of the foramen. Increased incidence of hypercementosis, in which the constriction is even farther from the apex, makes penetration into the cemental canal almost impossible. Achieving and maintaining apical patency are more difficult. Apical root resorption associated with periapical pathosis further changes the shape, size, and position of the constriction. The use of electronic apex-finding devices is sometimes limited in heavily restored teeth when contact with metal can bleed off the current.

The frequency and intensity of discomfort after cleaning and shaping have not been shown to be related to the amount of preparation, the type of interappointment medication or temporary filling, the pulp or periapical status, the tooth number or age, or whether the root canal filling is completed at the same appointment.[71] The more constricted CDJ permits a much smaller pulp wound and resists penetration, even with the initial small files. Patency is difficult to establish and maintain. Dentin debris creates a matrix early in the preparations[84] and further reduces the risk of overinstrumentation or the forcing of debris into the periapical tissues,[54] which could cause an acute apical periodontitis or

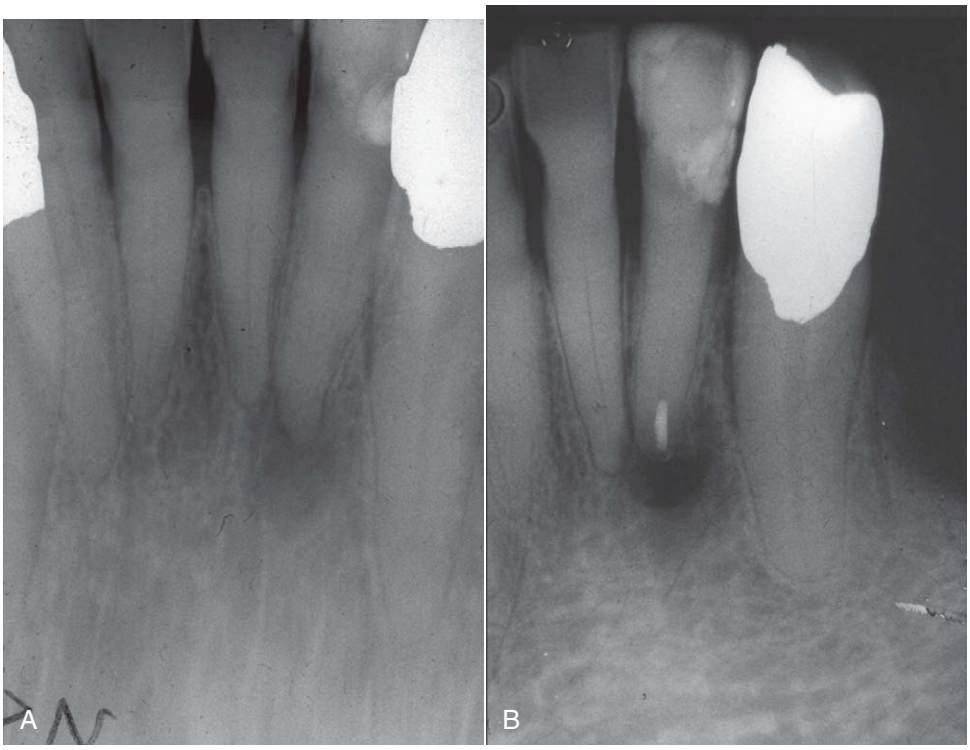

FIG. 24-37 A, Extremely calcified canals and thin roots make the risk of perforation high. **B,** Surgical access and root-end filling was performed rather than weakening the tooth trying to locate the root canal system via an orthograde approach.

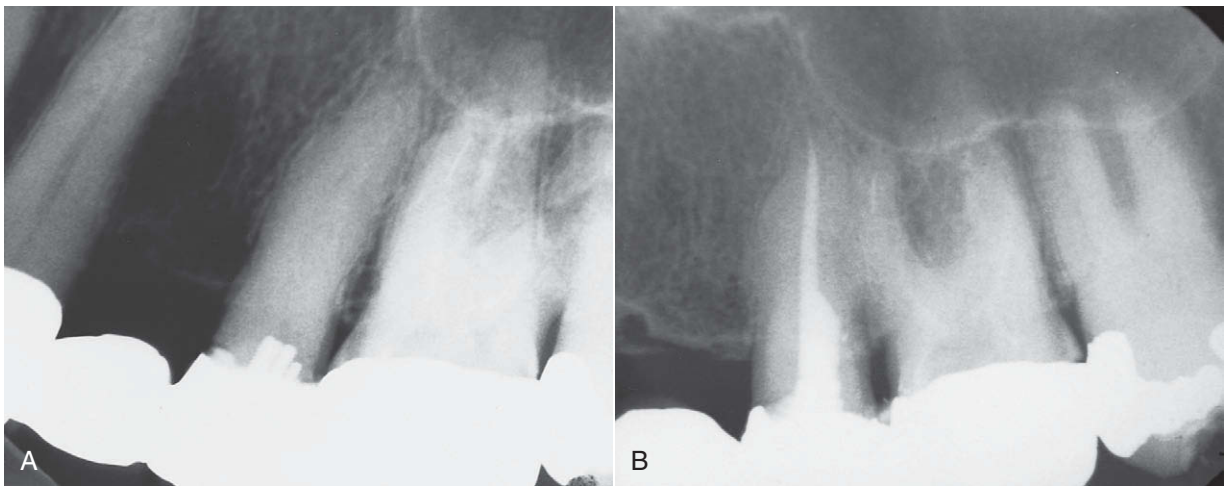

FIG. 24-38 A, Multiple pins were used to restore this middle abutment on a fixed bridge. **B,** Extreme care and exceptional skill are required to maintain proper alignment to find and treat the canal with a deep access opening.

abscess. Further access to periapical tissues through the canal is likewise limited.

Obturation

For the older patient, the prudent clinician selects gutta-percha filling techniques that do not require unusually large midroot tapers and do not generate pressure in this area, which could result in root fracture (Fig. 24-39). (See Chapter 10 for the most appropriate technique to use to seal the canal.)

The coronal seal plays an important role in maintaining an apically healthy environment, and it has a significant impact on long-term success.[70] Even a root-filled tooth should not have its canals exposed to the oral environment. A thermoplastic synthetic polymer-based root-filling material (Resilon) may significantly reduce the coronal leakage that can result from root caries after root canal treatment, as well as increase resistance to root fracture.[61,73] Permanent restorative procedures should be scheduled as soon as possible, and intermediate

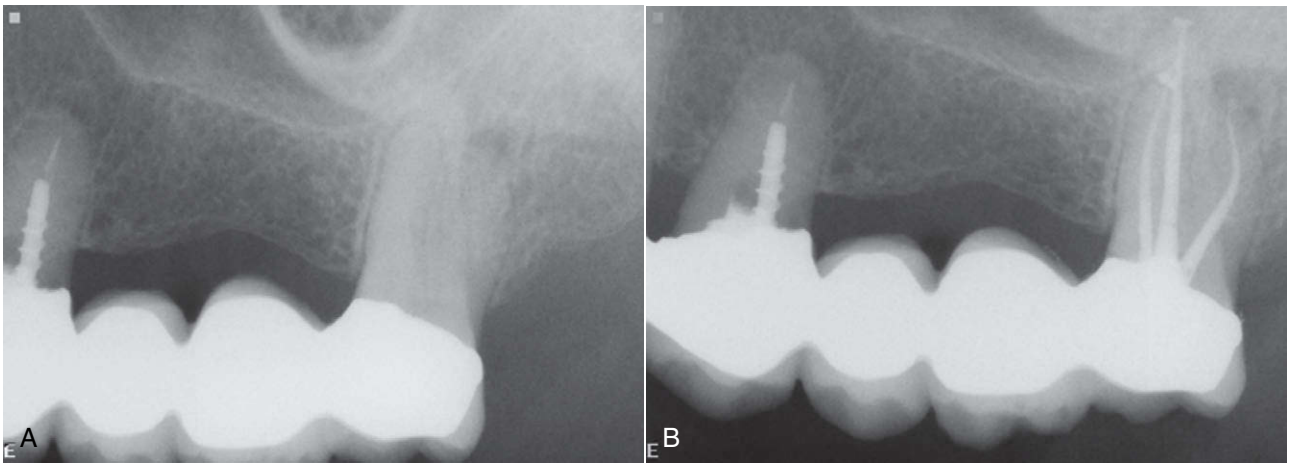

FIG. 24-39 A, Third molar abutment for 7-unit bridge in an 84-year-old patient with limited opening. **B,** Instrumentation of this molar without excessive removal of coronal or midroot dentin.

restorative materials should be selected and properly placed to maintain a seal until that time. When mechanical retention is not ensured with the preparation, glass ionomer cements are recommended.

Success and Failure

Repair of periapical tissues after endodontic treatment in older patients is determined by most of the same local and systemic factors that govern the process in all patients. With vital pulps, periapical tissues are normal and can be maintained with an aseptic technique, confining preparation and filling procedures to the canal space. Infected nonvital pulps with periapical pathosis must have this process altered in favor of the host tissue, and repair is determined by the ability of this tissue to respond. Factors that influence repair have their greatest effect on the prognosis of endodontic therapy when periapical abnormalities are present. With aging, arteriosclerotic changes of blood vessels increase and the viscosity of connective tissue is altered, making repair more difficult. The rate of bone formation and normal resorption decreases with age, and the aging of bone results in greater porosity and decreased mineralization of the formed bone. Although periradicular tissues will heal as readily in elderly as in young patients,[71] a 6-month recall period to evaluate repair by means of radiographs may not be adequate (Fig. 24-40).[25]

Studies that suggest differences in success among age groups must note the smaller numbers (usually in this older treatment group) and the local factors that make treatment difficult. Overlooked canals are a more common cause of failure in older patients (Fig. 24-41), which explains the increased clinical indications for retrograde fillings when surgical treatment is attempted.[2] As an isolated symptom, heat sensitivity may indicate a missed canal. (For further information on assessing failures and possible retreatment, see Chapter 25.)

ENDODONTIC SURGERY

Generally, considerations and indications for endodontic surgery are not affected by age. The need for establishing drainage and relieving pain are not common indications for surgery. Anatomic complications of the root canal system, such as small (Fig. 24-42) or completely calcified canals, nonnegotiable root curvatures, extensive apical root resorption, or pulp stones, occur with greater frequency in older patients. Perforation during access, losing length during instrumentation, ledging, and instrument separation are iatrogenic treatment complications associated with treatment of calcified canals.

Medical considerations may require consultation but do not contraindicate surgical treatment when extraction is the alternative (Fig. 24-43). In most instances, surgical treatment may be performed less traumatically than an extraction, which may also result in the need for surgical access to complete root removal. Many older patients receive low-dose aspirin therapy to prevent blood clot formation and may be subject to embolic formation if the treatment is interrupted. Aspirin therapy should be continued throughout dental procedures, even during extraction or surgery. Local measures are sufficient to control bleeding.[4] Interrupting therapeutic levels of continuous anticoagulation therapy for dental surgery is not based on scientific fact but seems to be based on its own mythology.[79] A thorough medical history and evaluation should reveal the need for any special considerations such as prophylactic antibiotic premedication, sedation, hospitalization, or more detailed evaluation.

Local considerations in treatment of older patients include an increase in the incidence of fenestrated or dehisced roots and exostoses (Fig. 24-44). The thickness of overlying soft and bony tissue is usually reduced, and apically positioned muscle attachments extend the depth of the vestibule. Smaller amounts of anesthetic and vasoconstrictor are needed for profound anesthesia. Tissue is less resilient, and resistance to reflection appears to be diminished. The oral cavity is usually more accessible with the teeth closed together, because the lips can more easily be stretched. The apex can actually be more surgically accessible in older patients. Ability to gain such access varies with the skill of the surgeon; however, some areas are unreachable by even the most experienced clinicians.

The position of anatomic features—the sinus, floor of the nose, and neurovascular bundles—remains the same, but their relationship to surrounding structures may change when teeth have been lost. The need may arise to combine endodontic and periodontal flap procedures, and every effort should be made to complete these procedures in one sitting.

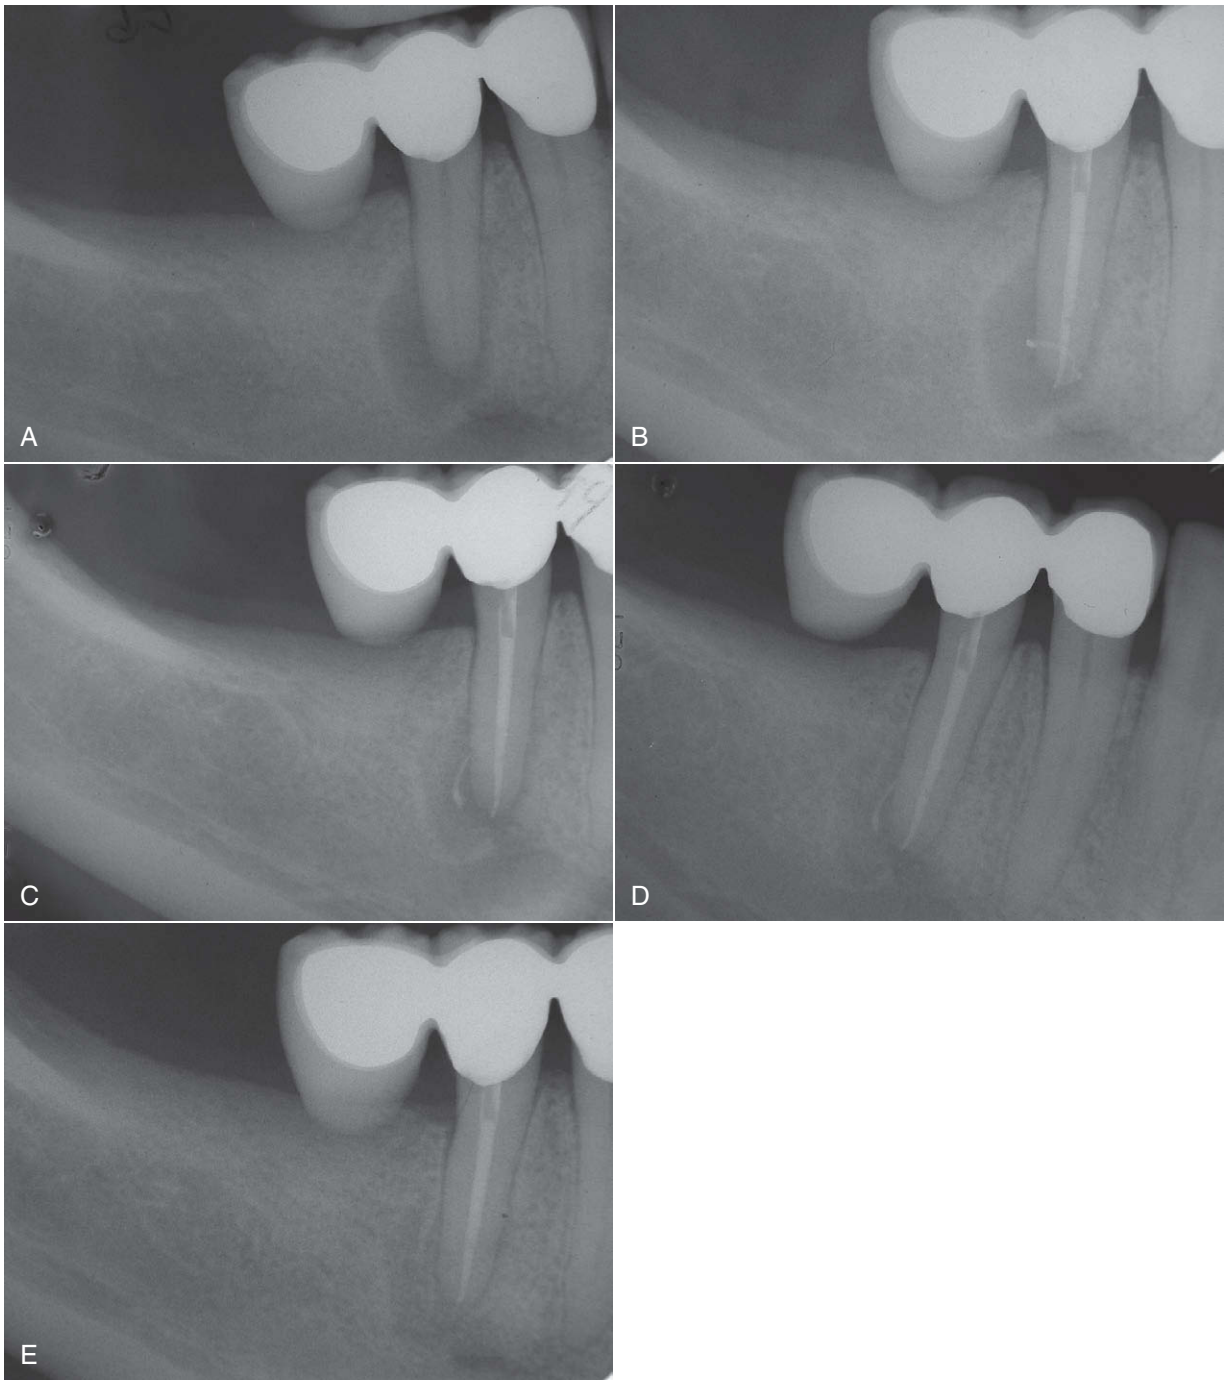

FIG. 24-40 A, Mandibular premolar in an older patient exhibits apical periodontitis. Following endodontic treatment **(B)**, healing was incomplete at 6 months **(C)** and after 1 year **(D)**. Complete healing of the apical periodontitis was seen 5 years postoperatively **(E)**.

When root-end surgery is to be performed, the surgeon must consider whether the root that will be left is long enough and thick enough for the tooth to continue to remain functional and stable (Fig. 24-45). This factor is especially important when the tooth will be used as an abutment (Fig. 24-46). (Detailed surgical procedures are presented in Chapter 21.)

Ecchymosis is a more common postoperative finding in older patients and may appear to be extreme. The patient should be reassured that this condition is normal and that normal color may take as long as 2 weeks to return. The blue discoloration will change to brown and yellow before it disappears. Immediate application of an ice pack after surgery reduces bleeding and initiates coagulation to reduce the extent

FIG. 24-41 The incidence of root-end fillings during periradicular surgery increases with age as calcified canals become more difficult to detect and negotiate as a cause of failure of nonsurgical treatment.

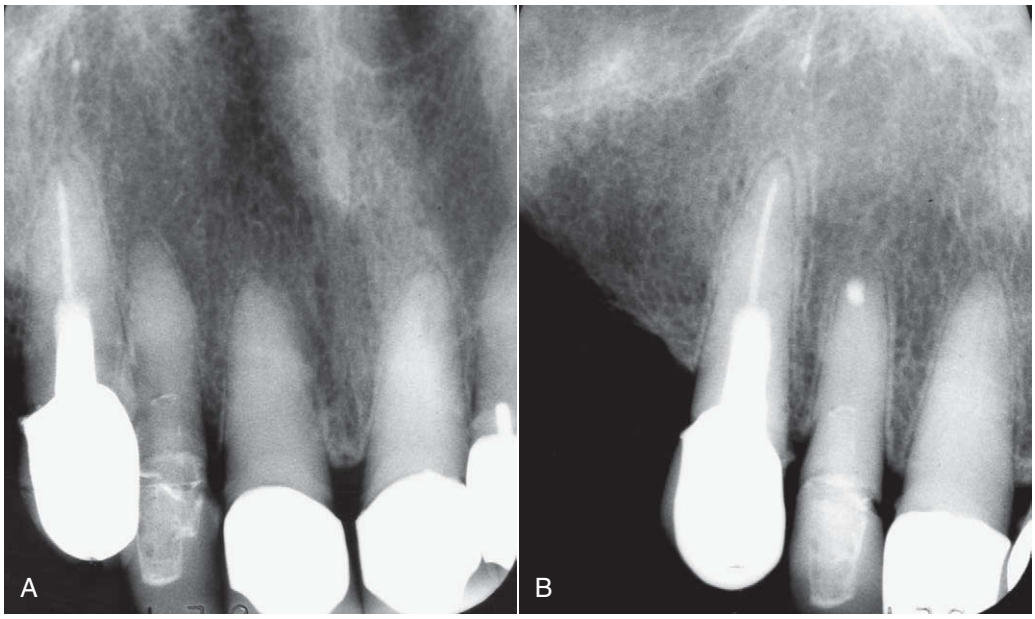

FIG. 24-42 A, Even though a small canal is detectable on the radiograph, it appears that an earlier unsuccessful attempt has been made to find it. **B,** It was decided that the risk of damage to a satisfactory restoration justified surgical treatment for this patient.

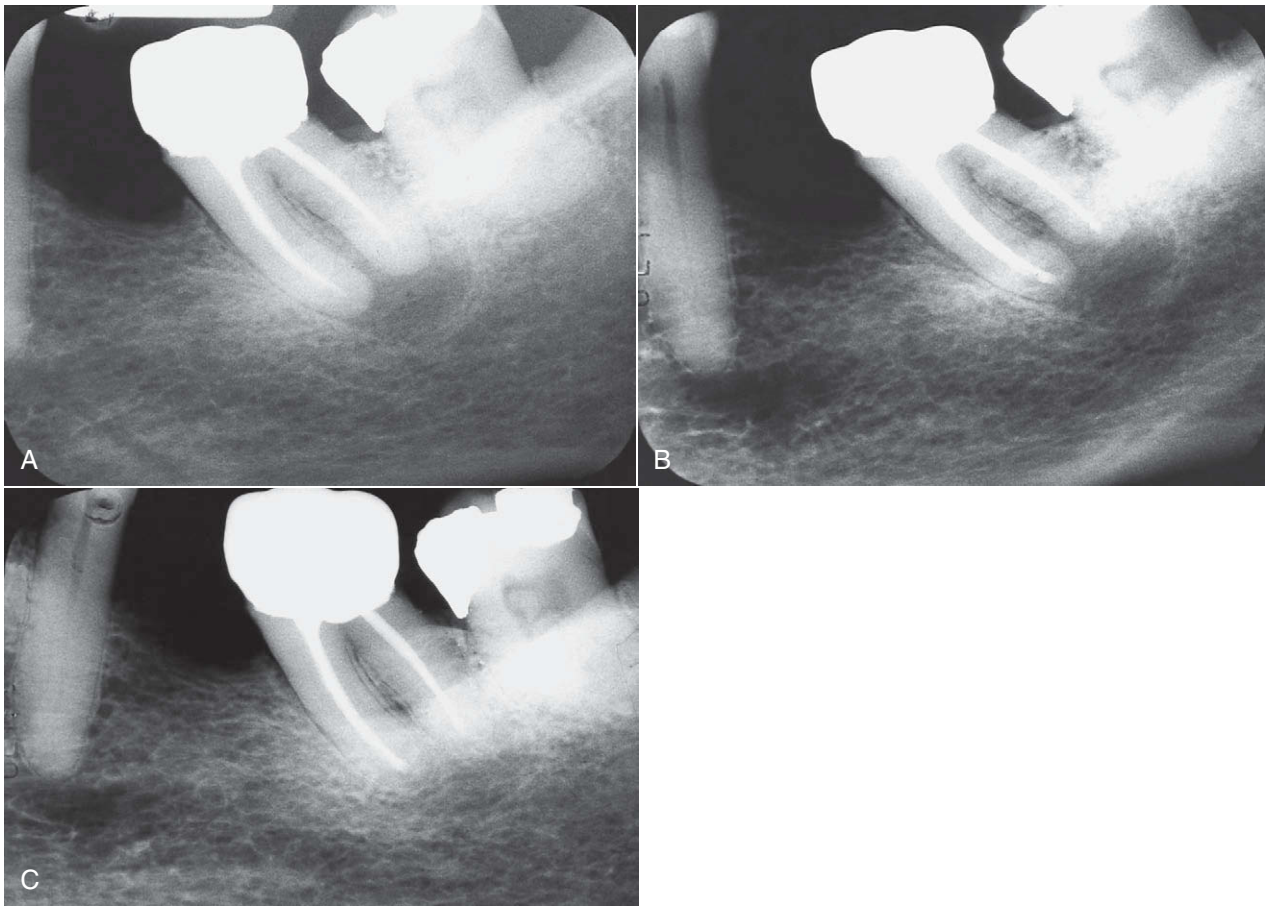

FIG. 24-43 A, Unsuccessful and symptomatic treatment on a mandibular second molar of a 78-year-old patient was surgically treated **(B)**, with less trauma than the extraction alternative. **C,** Complete healing at 1 year, apparently unaffected by age.

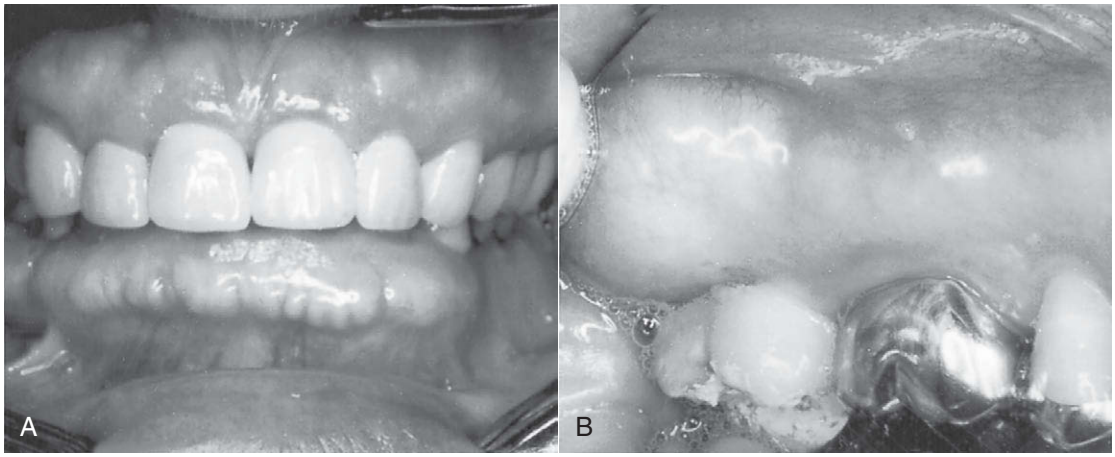

FIG. 24-44 Exostoses, as illustrated in this mandibular anterior tooth **(A)** and maxillary molar **(B)**, covered with thin tissue that can easily be torn during flap reflection, as well as the more obvious heavy bone and its effect on surgical access.

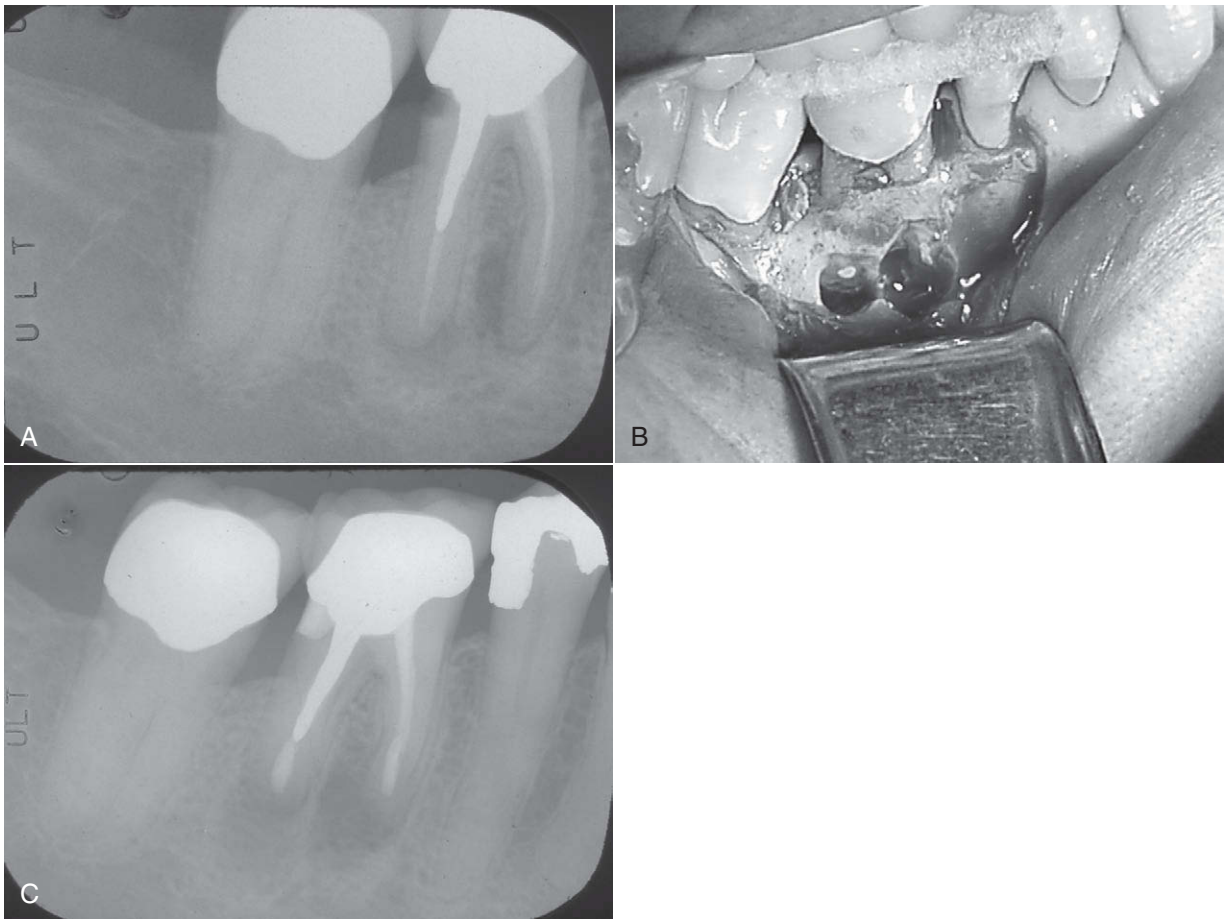

FIG. 24-45 A, Periradicular periodontitis and distal root caries evident in this 78-year-old patient. **B,** Apicoectomy, retrocavity preparation, and retrofilling, and **C,** cervical caries restoration were done for this lower molar tooth.

FIG. 24-46 A, External root resorption accompanied by periradicular periodontitis in an important canine abutment tooth. Endodontic retreatment, surgical repair of the resorptive defect **(B)**, and apicoectomy **(C)** were performed.

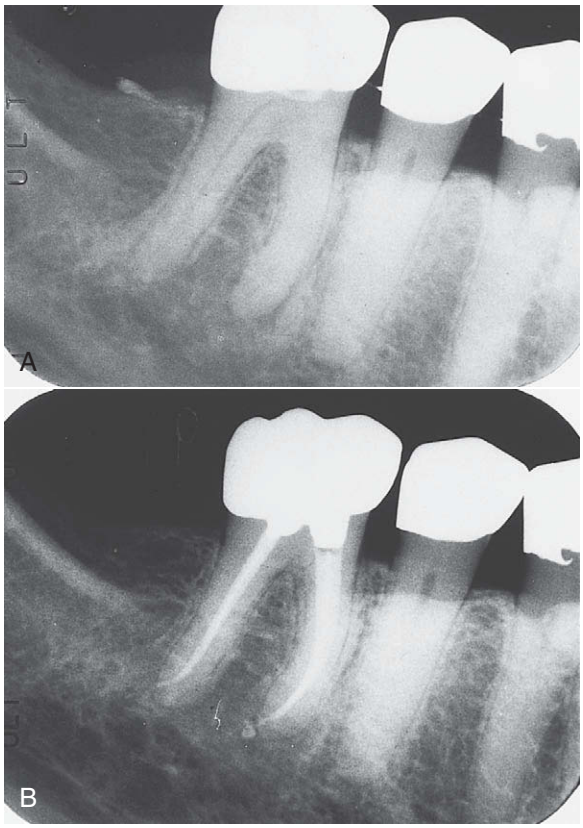

FIG. 24-48 A, Intact margins permitted the continued use of this crown. **B,** The access was restored with an amalgam-bond core.

of ecchymosis. Later, application of heat helps to dissipate the discoloration.

RESTORATION

Root canal treatment saves roots, and restorative procedures save crowns. Combined, these procedures are returning more teeth to form and function than were thought possible just a few decades ago. Special consideration must be given to post design, especially when small posts are used in abutment teeth; root fracture is common in older adults when much taper is used. Post failure or fracture occurs when small-diameter parallel posts are used (Fig. 24-47). Posts are not usually needed when root canal treatment is performed through an existing crown that will continue to be used (Fig. 24-48). (General considerations and procedures for postendodontic restoration are detailed in Chapter 22.)

The value of the tooth, its restorability, its periodontal health, and the patient's wishes should be part of the evaluation preceding endodontic therapy. The restorability of older teeth can be affected when root decay has limited access to sound margins or reduced the integrity of remaining tooth structure (Figs. 24-49 and 24-50). There can also be insufficient vertical and horizontal space when opposing or adjacent teeth are missing. Patient desires to save appliances can sometimes be fulfilled with creative attempts that may outlive them (Fig. 24-51).

In conclusion, geriatric endodontics will gain a more significant role in complete dental care as an aging population recognizes that a complete dentition, and not complete dentures, is a part of its destiny.

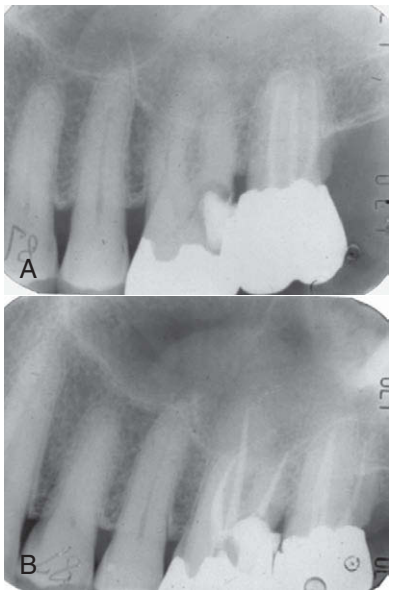

FIG. 24-49 A, This older woman insisted on saving her tooth in spite of extensive root caries on the distobuccal root. **B,** Root canal treatment was performed, and the root caries was removed and restored with Geristore.

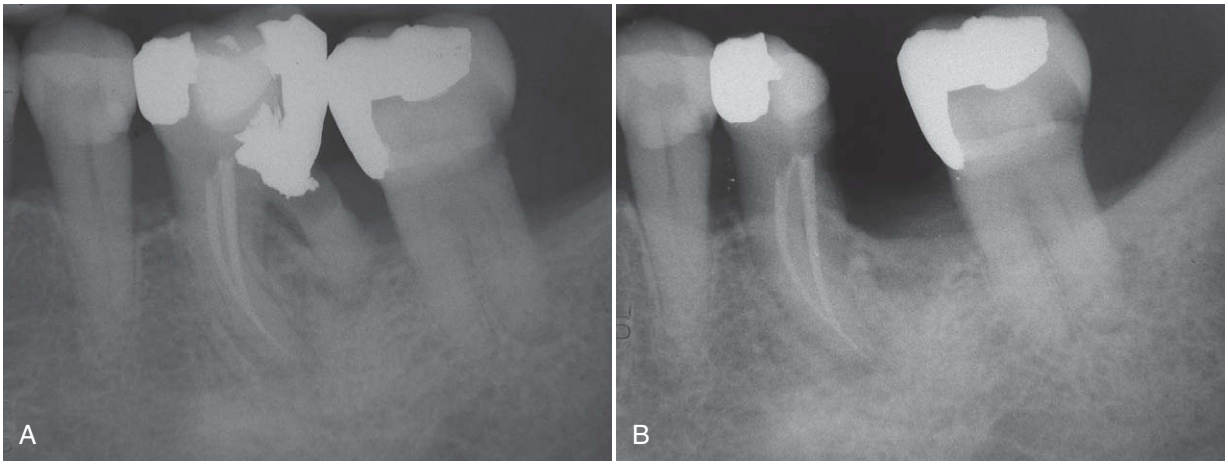

FIG. 24-50 A, Root caries and periodontal involvement of this mandibular molar tooth necessitated hemisection to retain the mesial root for restoration **(B)**.

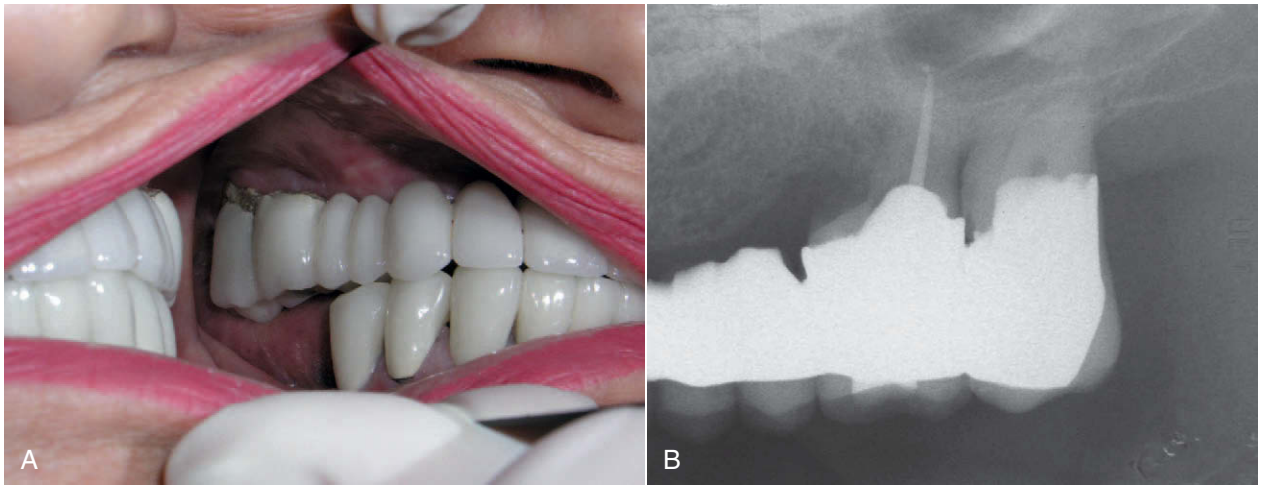

FIG. 24-51 A, Unrestorable caries contraindicated endodontic treatment on this molar abutment. **B,** Root amputation of buccal roots was performed to increase the lifespan of this bridge.

- Regaining Access to the Apical Area
- Removal of Separated Instruments
- Heat Generation During Retreatment Procedures
- Management of Canal Impediments
- Finishing the Retreatment

REPAIR OF PERFORATIONS
PROGNOSIS OF RETREATMENT

Nonsurgical root canal therapy has become a routine procedure in modern dentistry. Recent technical and scientific advances in endodontics have resulted in the retention of millions of teeth that would otherwise be lost. Even as recent advances in surgical and prosthetic restorative care have made tooth replacement less onerous than in the past, it is universally accepted that a natural tooth with a good prognosis is a superior choice to loss and replacement.

Unfortunately, not all treatments result in optimum long-term healing. Given the large numbers of treatments performed, the very small rate of unsuccessful outcomes translates into relatively large numbers of patients requiring further treatment. Clinicians should be able to diagnose persistent endodontic disease and be aware of the options for treatment. If clinicians wish to approach treating these teeth, they should have the appropriate armamentarium and be capable of performing these very specialized techniques at the highest level (Fig. 25-1). Also, clinicians must always have a scientifically sound, evidence-based rationale for every treatment decision that is made so they may best serve the patients who entrust them with their care. The purpose of this chapter is to provide information to allow the reader to maximize the likelihood of success in the treatment of persistent endodontic disease.

ETIOLOGY OF POSTTREATMENT DISEASE

In the past, undesirable outcomes of endodontic therapy were described as failures. Clinicians quote failure rates based on published success/failure studies. Using the words "success" and "failure" may be a holdover from a time when clinicians felt they needed to congratulate themselves on their successes and blame themselves for the failures of their treatment endeavors. This thought process does not reflect reality and can be potentially destructive. There are many instances where treatments performed at the highest level of clinical competence result in an undesirable outcome, and there are other instances where a procedure is performed well below a scientifically acceptable standard and yet provides long-term success.[179,180] We must begin to dissect the science from emotion and ego, and this separation may start with nomenclature. Friedman states that "most patients can relate to the concept of disease-treatment-healing, whereas failure, apart from being a negative and relative term, does not imply the necessity to pursue treatment."[218] He has suggested using the term *posttreatment disease* to describe those cases that would previously have been referred to as treatment failures. This will be the term used in the remainder of this chapter to describe persistent or reintroduced endodontic disease.

Almost 16 million root canal procedures were performed in 1999[26]; with success rates varying between 86% and 98%,[54,55] it has proven to be a very reliable treatment option. Conversely, the incidence of posttreatment disease, although small, translates into a very large number of cases where further treatment is needed. When faced with such a situation, the clinician must determine the etiology of the persistent pathosis and devise a rationale and strategy for treatment.

There are many causes for "failure" of initial endodontic therapy that have been described in the endodontic literature (Fig. 25-2). These include iatrogenic procedural errors such as poor access cavity design, untreated canals (both major and accessory),[235] canals that are poorly cleaned and obturated,[34,96] complications of instrumentation (ledges, perforations, or separated instruments),[148] and overextensions of root filling materials.[141] Coronal leakage[114,127,172,182,207,219] has also been blamed for posttreatment disease, as has persistent intracanal and extracanal infection[143,191,203] and radicular cysts.[139] These etiologies may be obvious at the time of diagnosing the diseased root-filled tooth, or they may remain uncertain until the completion of successful therapy. Occasionally, the cause of posttreatment disease may take years to become discernable or

FIG. 25-1 Some of the armamentarium needed to perform retreatment at the highest level.

may ultimately never be known. The most important causative factors for the clinician, however, are those related to treatment planning and determining prognosis. To effectively plan treatment, the clinician may place the etiologic factors into four groups[148] (Fig. 25-3):

1. Persistent or reintroduced intraradicular microorganisms
2. Extraradicular infection
3. Foreign body reaction
4. True cysts

*1. **Persistent or reintroduced intraradicular microorganisms*** When the root canal space and dentinal tubules are contaminated with microorganisms or their byproducts, and if these pathogens are allowed to contact the periradicular tissues, apical periodontitis ensues. As stated earlier, inadequate cleaning, shaping, obturation, and final restoration of an

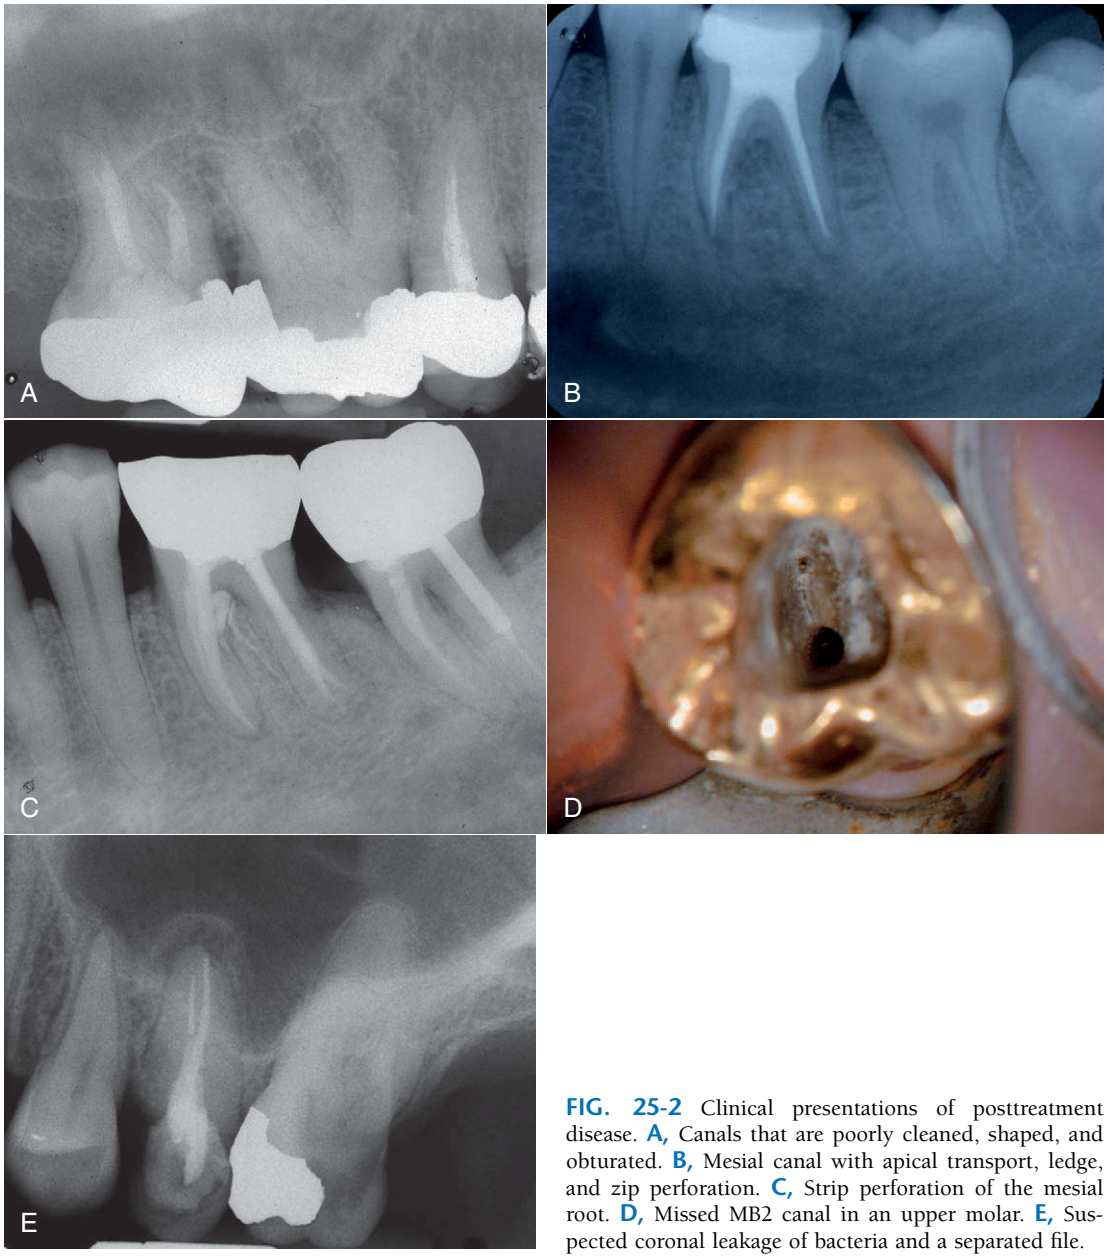

FIG. 25-2 Clinical presentations of posttreatment disease. **A,** Canals that are poorly cleaned, shaped, and obturated. **B,** Mesial canal with apical transport, ledge, and zip perforation. **C,** Strip perforation of the mesial root. **D,** Missed MB2 canal in an upper molar. **E,** Suspected coronal leakage of bacteria and a separated file.

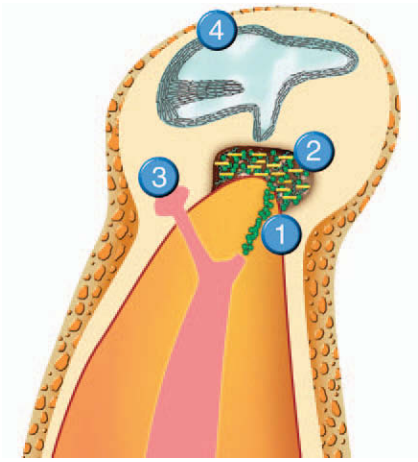

FIG. 25-3 The causes of posttreatment disease. *1,* Intraradicular microorganisms. *2,* Extraradicular infection. *3,* Foreign body reaction. *4,* True cysts. *(Modified from Sundqvist G, Figdor D: In Orstavik and Pitt-Ford* Essential Endodontology, *New York, 1998, Blackwell; diagram courtesy of DENTSPLY Tulsa Dental, Tulsa, OK.)*

endodontically diseased tooth can lead to posttreatment disease. If initial endodontic therapy does not render the canal space free of bacteria, if the obturation does not adequately entomb those that may remain, or if new microorganisms are allowed to reenter the cleaned and sealed canal space, posttreatment disease can and usually does occur. In fact, it has been asserted that persistent or reintroduced microorganisms are the major cause of posttreatment disease.[140] Many iatrogenic treatment complications, such as creation of a ledge or separation of an instrument, result in persistence of bacteria in the canal system. It is not the complication itself that results in persistent disease but the inability to remove or entomb the microorganisms present that creates the pathologic state. Although infected root canals of endodontically untreated teeth generally contain a polymicrobial, predominantly anaerobic flora,[202] cultures of infected, previously root-filled teeth produce very few or even one single species. The infecting flora are predominantly gram positive and not anaerobic. A very commonly isolated species is *Enterococcus faecalis*,[60,158] which has been shown to be very resistant to canal disinfection regimes.[14,30] Interestingly, if the previous root canal treatment is done so poorly that the canal space contains no obturating material in the apical half of the root canal space, its flora is more typical of the untreated necrotic infected pulp than that of classic "failed" root canal therapy.[148] Though posttreatment disease has been primarily blamed on bacteria in the root canal system, fungi, notably *Candida albicans,* are found frequently in persistent endodontic infections and may be responsible for the recalcitrant lesion.[189]

2. Extraradicular infection Occasionally, bacterial cells can invade the periradicular tissues either by direct spread of infection from the root canal space via contaminated periodontal pockets that communicate with the apical area,[187] extrusion of infected dentin chips,[84] or by contamination with overextended, infected endodontic instruments.[226] Usually, the host response will destroy these organisms, but some microorganisms are able to resist the immune defenses and persist in the periradicular tissues, sometimes by producing an extracellular matrix or protective plaque.[220] It has also been shown[143,191,203] that two species of microorganisms, *Actinomyces israelii* and *Propionibacterium propionicum* can exist in the periapical tissues and may prevent healing after root canal therapy.

3. Foreign body reaction Occasionally, persistent endodontic disease occurs in the absence of discernable microorganisms and has been attributed to the presence of foreign material in the periradicular area. Several materials have been associated with inflammatory responses, including lentil beans[186] and cellulose fibers from paper points.[108] In the seemingly endless debate about which endodontic obturation technique is superior, there has been much discussion about the effect of overextended root canal filling materials upon apical healing. Outcomes assessments generally show that filling material extrusion (root filling flush to the radiographic apex or gross overextension) leads to a lower incidence of healing.[148,190] Many of these cases involved not only overextension but also inadequate canal preparation and compaction of the root filling, whereby persistent bacteria remaining in the canal space could leak out. Gutta-percha and sealers are usually well tolerated by the apical tissues, and if the tissues have not been inoculated with microorganisms by vigorous overinstrumentation, healing in the presence of overextended filling materials can still occur.[59,119,148]

4. True cysts Cysts form in the periradicular tissues when retained embryonic epithelium begins to proliferate due to the presence of chronic inflammation. The epithelial cell rests of Malassez are the source of the epithelium, and cyst formation may be an attempt to help separate the inflammatory stimulus from the surrounding bone.[157] The incidence of periapical cysts has been reported to be 15% to 42% of all periapical lesions,[139,196] and determining whether periapical radiolucency is a cyst or the more common periapical granuloma cannot be done radiographically.[20] There are two types of periapical cysts: the periapical true cyst and the periapical pocket cyst. True cysts have a contained cavity or lumen within a continuous epithelial lining. With pocket cysts, the lumen is open to the root canal of the affected tooth. True cysts, owing to their self-sustaining nature, probably do not heal following nonsurgical endodontic therapy[96,142] and usually require surgical enucleation (Fig. 25-4).

When a patient presents with posttreatment disease, clinical decision making depends upon determining the cause of the persistent disease and then making an assessment of how best to treat the pathologic condition. In the following section, the reader will be presented with a rationale and methods for performing endodontic diagnosis that will allow for the greatest likelihood of a successful outcome.

DIAGNOSIS OF POSTTREATMENT DISEASE

It has been stated that "there may be different ways of treating a disease; however, there can be but one correct diagnosis".[7] The proper diagnosis is probably the most important portion of any endodontic procedure. This is not as bold a statement as one may first suspect when consideration is given to what the patient may undergo if treatment is performed based on an incorrect diagnosis (Fig. 25-5). To make a correct diagnosis, clinicians must rule out non-odontogenic etiology, perform all appropriate tests, properly interpret the patient's responses to

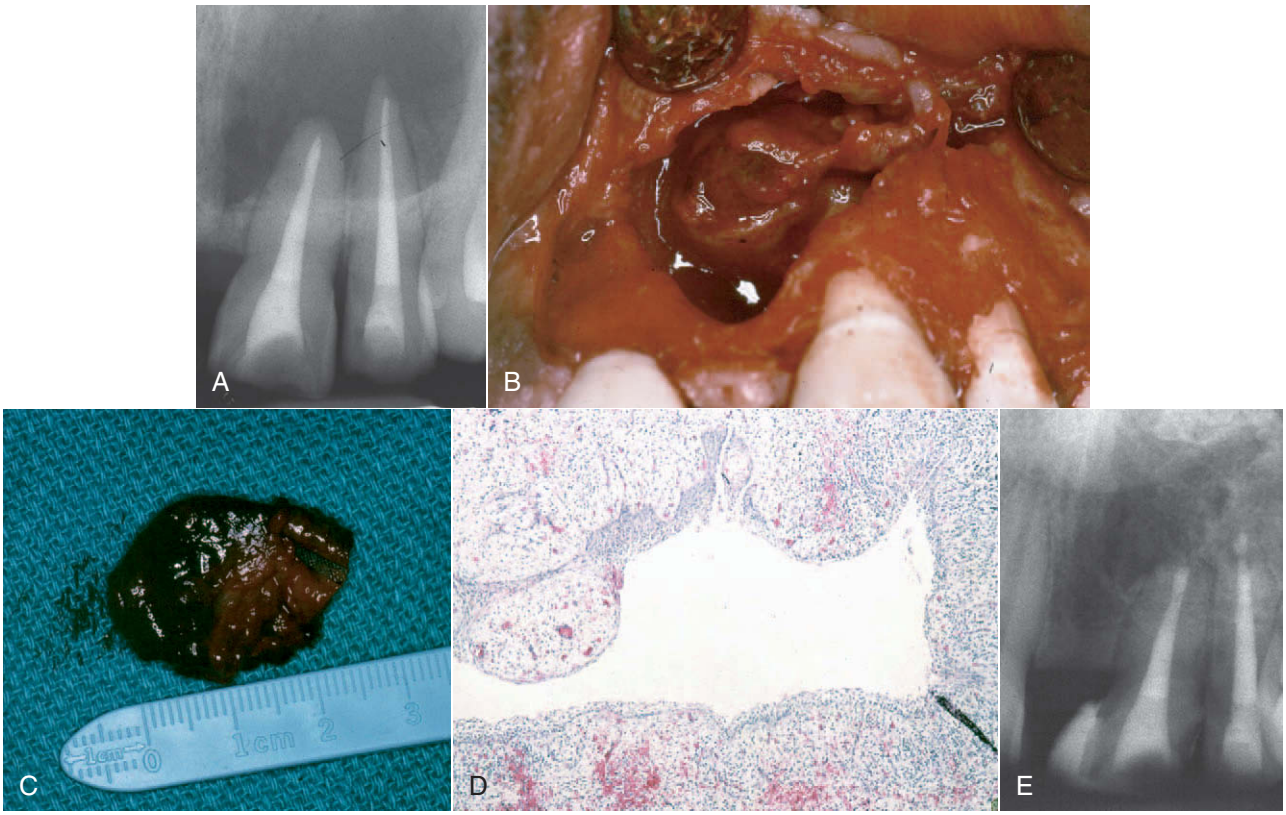

FIG. 25-4 A, Apparently good nonsurgical retreatment with large persistent lesion. **B,** Surgical exposure of apical lesion in situ. **C,** Large lesion removed in toto. **D,** Histopathologic section confirming cystic nature of the lesion. **E,** Four-year postoperative film showing apical scar formation due to the large size of the lesion. The teeth were asymptomatic and in function.

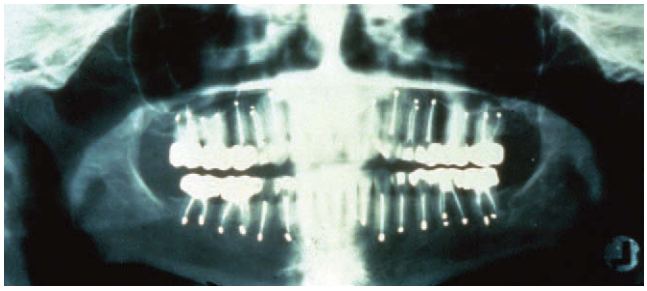

FIG. 25-5 This patient was misdiagnosed for years and underwent unnecessary endodontic therapy. The actual cause of the patient's complaint was nondental pain. *(Courtesy Dr. Ramesh Kuba.)*

these tests, derive a definitive diagnosis, and decide on treatment options. When performing a diagnosis in endodontic cases where there is no history of previous endodontic therapy, both a pulpal and periradicular diagnosis are necessary. In cases of persistent disease, the diagnosis may not be straightforward; the clinician may be dealing with partially treated pulp canals, missed canals, or many other types of problems associated with the previous treatment. These must be included in the diagnostic description for each case.

Endodontic diagnosis has been thoroughly discussed in Chapter 1, and the reader is referred there for further details on these procedures. The diagnostic method requires collecting subjective information, developing objective findings, and using these to arrive at a diagnosis and plan of treatment.

The subjective information is collected by questioning the patient and then actively listening to the responses. Of particular interest in cases of suspected posttreatment disease is whether the patient recalls the use of aseptic techniques during the previous endodontic therapy. If a rubber dam was not used, for example, and this can be confirmed with a call to the previous clinician, nonsurgical retreatment will almost certainly be necessary. The canals can be assumed to be contaminated regardless of how esthetically pleasing the previously filled case may appear on the radiograph. The diagnostician should be careful to avoid or to minimize communicating to the patient any negative feelings he or she has toward the previous treatment, however bad it may seem. This approach allows the patient to become more comfortable with the current clinician and the proposed corrective treatment. An irate patient is an irate patient, and negativity will color their emotional state, level of trust, and ability to accept current or future treatment plans. If the patient asks a direct question about the previous treatment, an honest answer is necessary, but avoid the temptation to imply superiority by disparaging the former clinician. To state the situation honestly and correctly without being inflammatory, use a sentence such as, "Well, it may be that your previous dentist (endodontist) had some difficulty with that tooth. Let's see if we can figure out what could have been the problem."

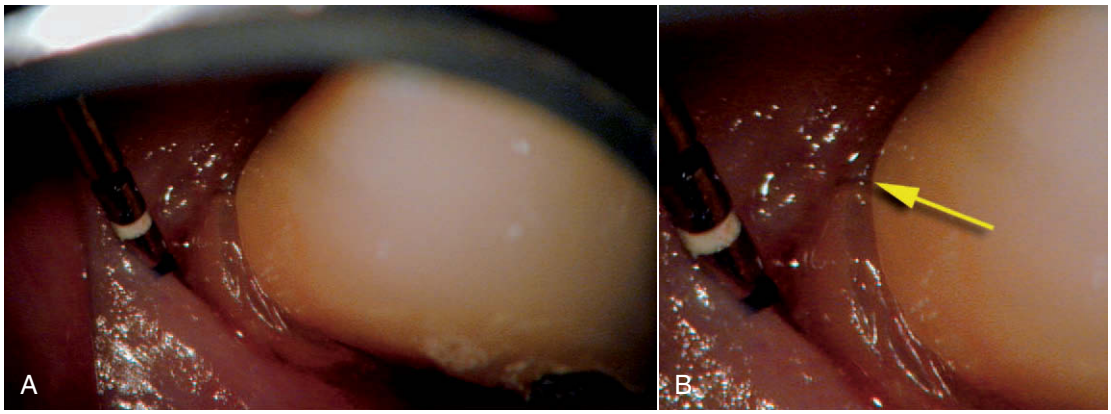

FIG. 25-6 A, Buccal aspect of a premolar with posttreatment disease. **B,** Higher magnification reveals a vertical fracture *(Courtesy Dr. Jay Rosenthal.)*

Following a thorough review of the patient's health history, the next step is to gather all of the objective information needed to obtain an accurate diagnosis, including clinical and radiographic examinations. The clinical examination should include a visual extraoral and intraoral examination and a thorough periodontal evaluation. Visual examination is greatly aided by magnification and illumination, which can allow the clinician to identify significant conditions invisible to the naked eye, such as very fine fractures on root surfaces (Fig. 25-6). Exposed dentin from recession and narrow-based probing defects may be the result of an endodontic infection draining through the sulcus; however, they are sometimes indicative of vertical root fracture (for further information, please refer to Chapter 1). The presence of occlusal wear facets indicates the presence of occlusal trauma that may complicate diagnosis and treatment outcome by predisposing the tooth to fracture[75]; this condition has been associated with posttreatment disease.[97]

Radiographic assessment is obligatory. Even though radiographs may be a critical aid to the clinician, they should never be the sole support for a conclusive diagnosis. They are only one piece of the puzzle in determining endodontic etiology.[49] In cases with previous endodontic therapy, radiographs are very useful in evaluation of caries, defective restorations, periodontal health, the quality of the obturation, existence of missed canals, impediments to instrumentation, periradicular pathosis, perforations, fractures,[209] resorption, and canal anatomy. If films are used, radiographs should be properly exposed and have a sharp, clear image. They should include the tooth and surrounding tissues, and multiple angulated films should be used to determine endodontic etiologies, using the "buccal object moves most rule" (Fig. 25-7). Bitewing radiographs are useful in determining periodontal bone height and to look for caries or fractures. All sinus tracts should be traced with a cone of gutta-percha followed by a radiograph to localize their origin.[96]

Comparative testing is the next procedure performed to collect objective information about the pulpal and periradicular status. Most useful are the periradicular tests that include percussion, bite, and palpation.[218] These will allow the diagnostician to begin developing a sense of the status of the periradicular tissues. Such tests are of great importance any time an endodontic diagnosis is needed. However, they are of even greater importance when evaluating teeth that have been previously treated with endodontic therapy, owing to the lack of significant and consistent evidence that can be gained from pulp vitality tests in these cases. If a tooth exhibits percussion tenderness, it may be due to persistent endodontic disease, but recent trauma or occlusal trauma may also cause this finding,[75] as can periodontal disease.[218]

Pulp vitality tests are often of little value when examining teeth with previous endodontic therapy, but if the patient's chief complaint reveals the need for these tests, they must be performed. When there is vital tissue remaining in the canals of a previously root-filled tooth, either by way of a completely missed canal or from an improperly cleaned canal, patients may complain of sensitivity to heat or cold.[75] Pulp vitality tests should then be performed to assess the situation. They are also useful in testing adjacent and opposing nonendodontically treated teeth to rule out those as etiologies for poorly localized pain. Once the tissue is removed from the pulp chamber after root canal therapy, the results of these tests should almost always be negative, even with radicular pulp remaining. Thus, a negative response with previously treated teeth is not necessarily conclusive, but a positive response usually means there is responsive pulp tissue remaining in the tooth.[75] Care is always warranted in interpreting pulp test results, however, since false-positive and false-negative results may occur.[180] As with cold tests, the same limits apply to heat tests as far as the reasons for false results and accuracy relative to retreatment cases.

The remaining pulp vitality tests, electric pulp test, test cavity, and direct mechanical dentin stimulation are of even less value than thermal testing when evaluating teeth that have already received endodontic therapy. These are usually precluded by the existing restoration or endodontic therapy.

When all diagnostic information is collected, a diagnosis must be developed. It is important to record the diagnosis in the patient's record so that anyone reading the record can discern the clinician's rationale for treatment. The pulpal diagnosis will usually be recorded as previous endodontic treatment, but the periradicular diagnosis will vary depending on the clinical picture presented. In the case of previous endodontic treatment, however, a brief note about the suspected etiology of the persistent disease is warranted.

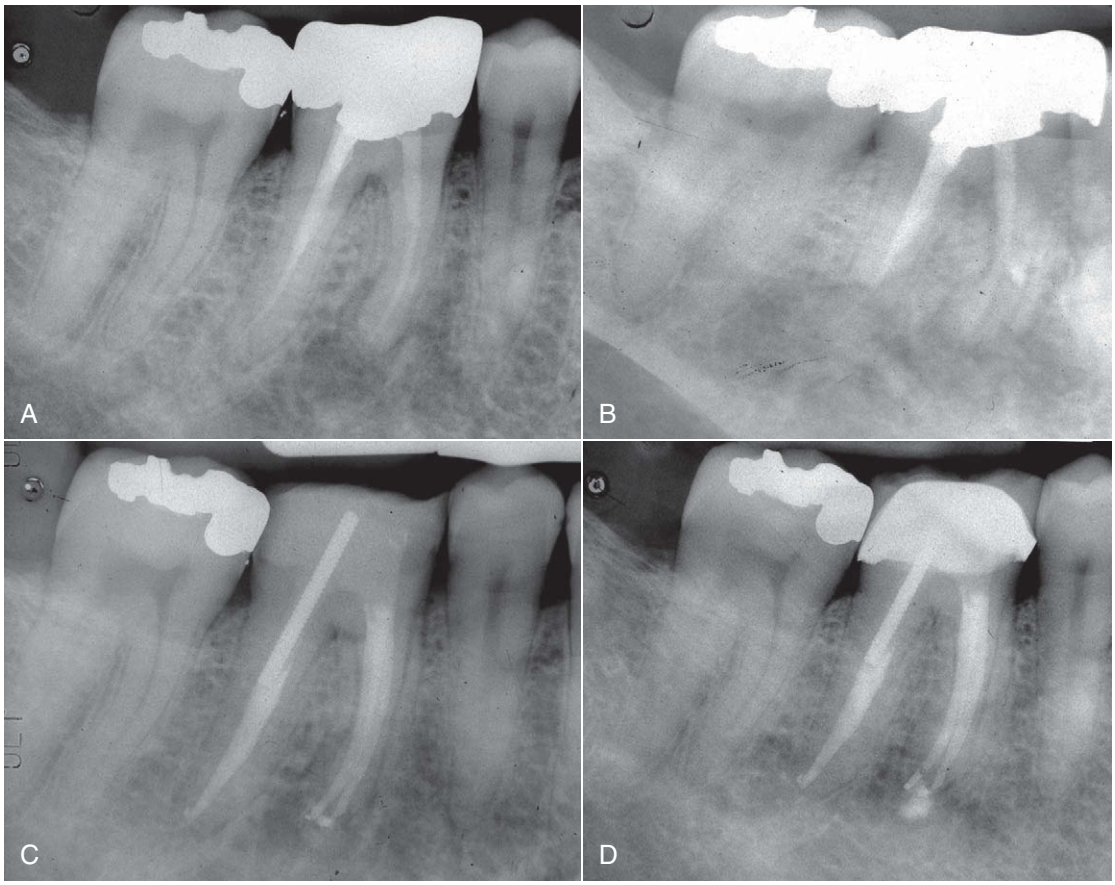

FIG. 25-7 A, Posttreatment disease. Previous endodontic therapy performed 3 years previously. **B,** Distal angle radiograph reveals asymmetry, indicating the presence of an untreated mesiobuccal canal. **C,** Immediate postobturation film showing treated MB canal. **D,** Fourteen-month postoperative view. The patient was asymptomatic.

TREATMENT PLANNING

Once the diagnosis is complete, the cause of the persistent disease will usually become apparent. At this point in the clinical process, information must be given to the patient by the clinician as to what treatment options are available and the likely outcomes of each choice. The patient is then allowed to make a decision based upon his or her own perceptions of the options, not by the clinician's opinion about what is "best" for the patient. The reader is reminded, however, that if the cause of the posttreatment condition remains unknown despite a thorough diagnostic workup, any decision results in an empirical, trial-and-error type of treatment. This approach should be avoided if possible, and prior to definitive treatment, consultation with an endodontist or other colleague is in order. This consultation may be as simple as a brief conversation or even referral of the patient, but a second opinion is extremely useful in these situations. Because of the interdisciplinary nature of modern dentistry, consultation with other clinicians who are treating the patient often becomes a necessity to enhance the potential for successful treatment outcomes.

Occasionally a patient will have persistent symptoms that mimic posttreatment disease, but these symptoms are actually the result of nonendodontic conditions such as occlusal trauma, concurrent periodontal disease, or nondental pain conditions. Appropriate diagnostic procedures should allow the clinician to sift through these options and treat accordingly.

The patient harboring true endodontic posttreatment disease has four basic options for treatment:

1. Do nothing
2. Extract the tooth
3. Nonsurgical retreatment
4. Surgical retreatment

The first option is to do nothing with the condition and allow it to take its course (Fig. 25-8). This approach is sometimes a useful, short-term option if the etiology of the condition remains unknown and the clinician feels that another diagnostic sampling would help with diagnosis. Even though most clinicians would find this approach to be less than desirable as a long-term course of action, the decision belongs to the patient. The clinician is bound, however, to ensure that the patient has complete information about what will happen if nothing is done. The events in the progression of the disease and a reasonable timeline are necessary, and the conversation needs to be thoroughly documented in the patient record to avoid possible subsequent accusations of abandonment. The question of whether the clinician is required to follow up with the patient or dismiss them from the practice is one that each clinician must make based upon the clinician's experience, judgment, and knowledge of the patient.

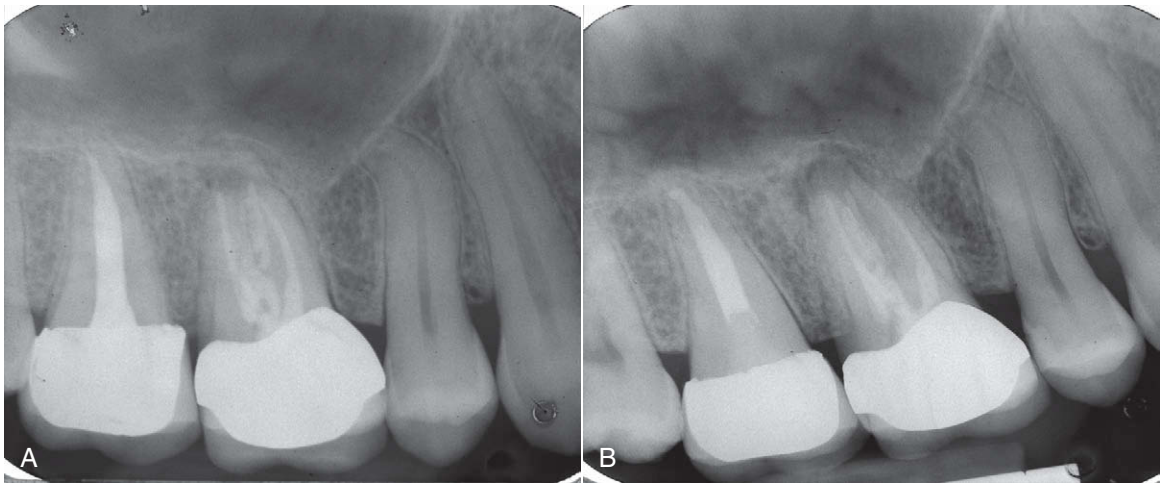

FIG. 25-8 A, Radiograph indicating presence of asymptomatic persistent apical periodontitis 7 years after initial treatment. The patient elected no treatment at that time. **B,** Six-year follow-up. Lesion has enlarged, and the tooth has become symptomatic.

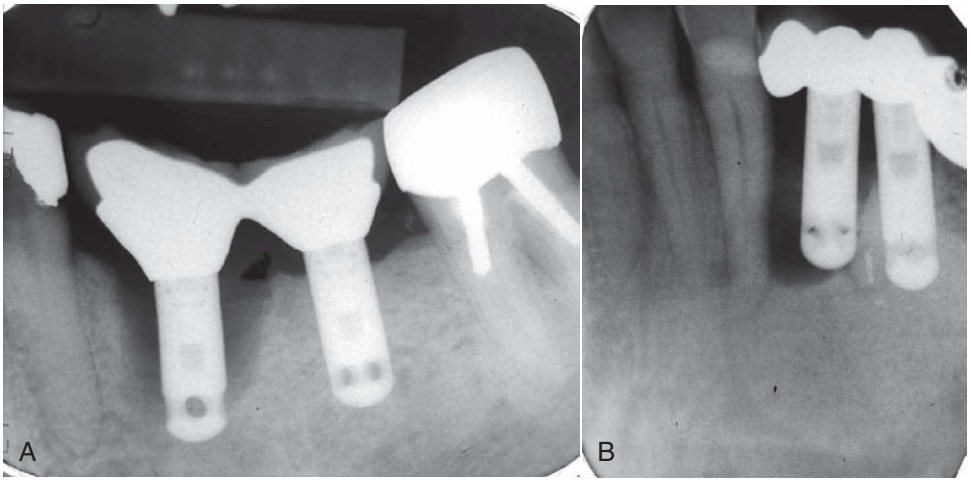

FIG. 25-9 A, Classic periimplantitis. The implant needed removal. **B,** Another periimplantitis. Note the endodontically treated root tip apical to the implant that may have contributed to the persistent disease. Perhaps apicoectomy should have been performed.

Extraction of the tooth is usually considered a viable option. Recent advances in both prosthetic reconstruction techniques and dental implantology have made extraction and replacement a more desirable option in certain cases where previously "heroic" (read: expensive with an unknown prognosis) methods were needed to "save" the tooth. This alternative, however, provides results that are inferior, more expensive, and much more time consuming than preserving the natural tooth. The average titanium root-form implant restoration can take up to 6 months to finish, not counting site preparation prior to the implant, which can add months more. Despite published long-term success rates for dental implants,[2] post-implant disease does occur[2,71,72] (Fig. 25-9) and can leave the patient with very few options. The cost of implant treatment is high and usually not covered under dental benefit plans, so the net financial impact on the patient is large. Implant esthetics can be inferior to that of natural teeth in the esthetic zone of the mouth, and there are patients that are just not candidates for implant procedures.[2] Fixed partial dentures are another replacement alternative with a very long history of successful use, but there are negative outcomes possible also. Most concerning to the endodontist is the likelihood that retainer fabrication procedures will result in endodontic disease of the abutment teeth[79] that may potentially occur at a rate of up to 10%[130,224] (Fig. 25-10). Removable partial dentures are a less desirable option to the patient because they are generally less comfortable, usually require a long period of patient adaptation, and frequently result in damage to adjacent oral tissues (teeth, gingiva, and mucosa) if not meticulously cleaned. Owing to these factors, patient compliance with removable dentures is relatively low, and their use is declining. Occasionally a patient will choose to have a tooth extracted and not pursue replacement. This decision is usually disastrous for the patient, but there are a few situations where this choice is a reasonable alternative. Diseased maxillary second molars with no opposing tooth, or with an opposing tooth in class I or class III occlusion that articulates with another tooth, may be extracted without concern for future inappropriate movement

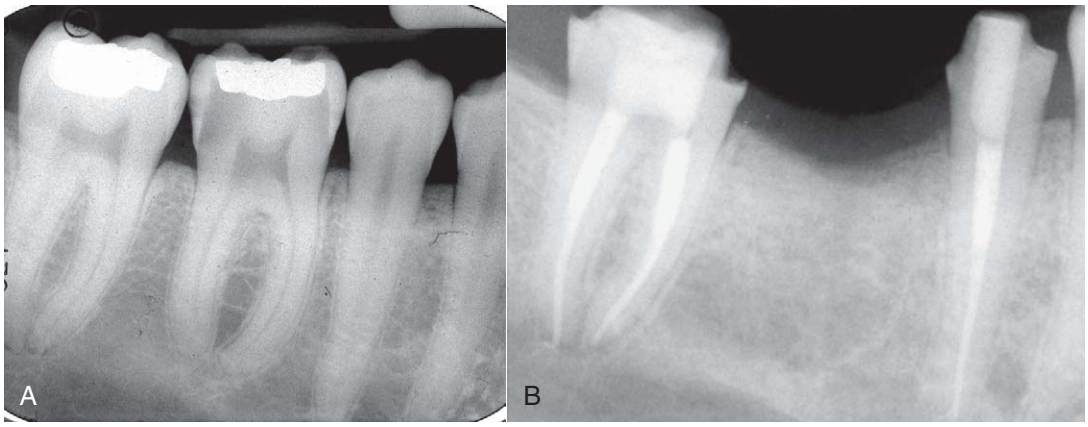

FIG. 25-10 A, Preoperative film showing deep caries approaching the pulp. The patient's holistic dentist advised extraction and replacement rather than endodontic therapy to retain the tooth. **B,** Fixed partial denture fabrication procedures resulted in irreversible pulpitis on both abutments, requiring endodontic therapy.

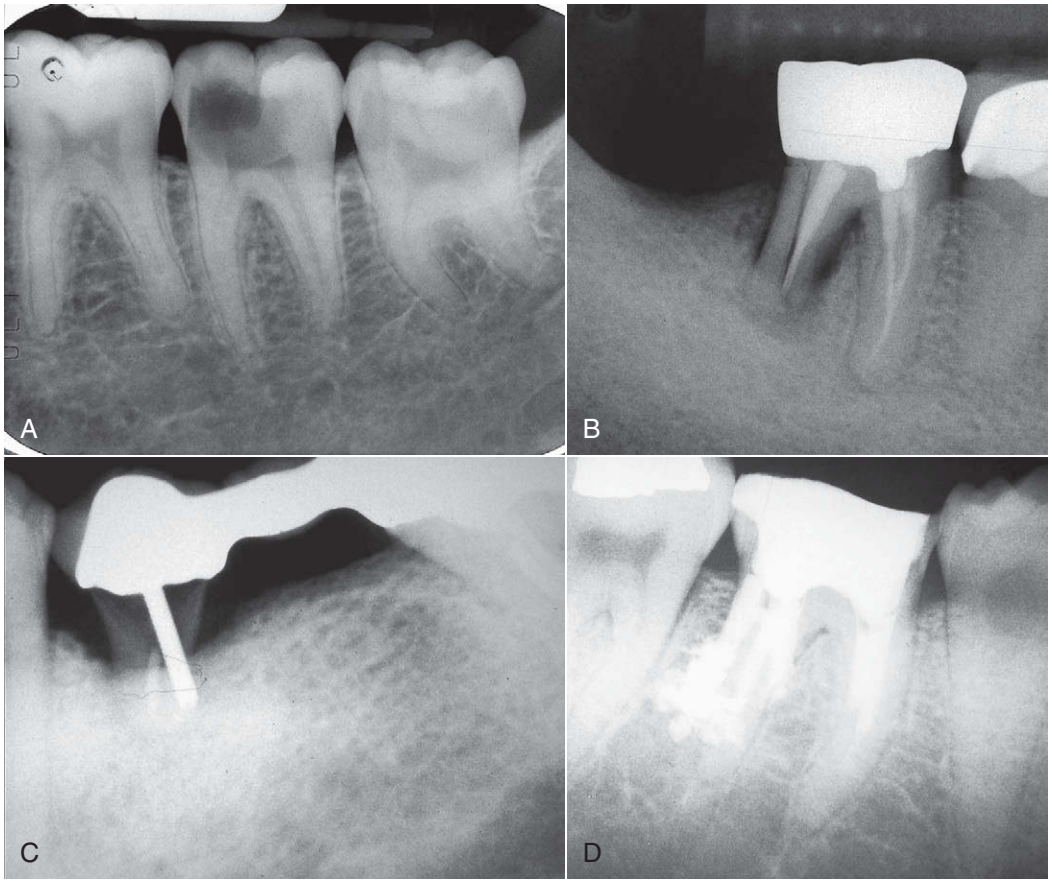

FIG. 25-11 A, Deep caries approaching the furcation and the biologic width. Necessary crown-lengthening surgery would open the furcation to bacterial invasion and persistent periodontal disease. **B,** Distal root vertical fracture resulting in a split root. **C,** Severe caries and post perforation. Inadequate root structure remaining to restore. **D,** Multiple distal root perforations so weaken the root as to make it unrestorable. NOTE: Cases A, B, and D could have resective endodontic surgery such as hemisection, but long-term prognosis is poorer than for extraction and replacement.[28,111]

of the remaining teeth, which can be so occlusally and periodontally damaging. In most instances, however, removal of a tooth will result in the need for replacement, and unless the tooth is hopelessly unrestorable, retaining the tooth with endodontic procedures is better for the patient.

Various situations may render a tooth unrestorable (Fig. 25-11), but the line of demarcation between restorable and unrestorable is a movable one, depending on who is evaluating the tooth. There are several widely agreed upon situations that render a tooth unrestorable. These include extensive

caries or coronal fracture approaching or entering the furcation or the biologic width. This situation may render preprosthetic periodontal procedures ineffective (leaving a furcation involvement or poor crown-to-root ratio, for example) or worse, removes bone that would otherwise be useful for implant procedures. Terminal periodontal disease (extensive pocketing or mobility) or root fracture generally result in loss of the tooth despite all efforts at treatment. If the patient has a life-threatening endodontic infection with extensive trismus, most oral surgeons are going to extract the tooth rather than allow less aggressive management. Some previously root-filled teeth may have endured procedural complications, such as an irretrievable separated instrument or irreparable ledge formation. In combination with the proximity to vital anatomic structures, such as the inferior alveolar canal, endodontic retreatment, either surgical or nonsurgical, may not be feasible. Extraction may be the only option. These situations are fortunately quite rare, and in most instances, teeth presenting with posttreatment disease can be retained with endodontic procedures.

Once the decision has been made to retain the tooth, there are several choices for treatment. These can be grouped together into either nonsurgical or surgical endodontic treatments. The surgical options can be further broken down into periradicular curettage, apical root resection (with or without root filling), root amputation or hemisection, and intentional replantation (extraction/replantation).[76,147] A situation sometimes arises that will require both nonsurgical and surgical types of treatment to effect healing. The American Association of Endodontists has published guidelines that may help the clinician with clinical decision making.[5] However, the choice of which option to undertake will be determined by the clinician's experience, knowledge, patient considerations, and the preoperative diagnosis. If the etiology of the posttreatment disease can be made known, the choices become more obvious. In a previous section, four basic etiologies were presented. If the suspected etiology is in the first group, which is persistent or reintroduced microorganisms, several choices are available. If the cause of the posttreatment disease is persistent extraradicular infection, foreign body reaction, or the presence of a true cyst, nonsurgical root canal therapy has little likelihood of allowing healing to occur, and surgical methods should be employed.[148] The problem for the clinician is that in most instances, it cannot be determined which of these etiologies exist, so the treatment becomes more empirical.

The choice of nonsurgical retreatment versus apical surgery becomes the focus of the decision in most instances. Outcomes assessment studies provide some help in making this decision. The reported healing rates of nonsurgical retreatment range between 74% and 98%,[55] but with apical surgery alone, only 59% heal completely.[148] When apical surgery is preceded by orthograde retreatment, however, the incidence of complete healing rises to 80%.[148] In general, nonsurgical retreatment will be the preferred choice, since it seems to provide the most benefit with the lowest risk. It has the greatest likelihood of eliminating the most common cause of posttreatment disease: intraradicular infection. Nonsurgical retreatment is usually less invasive than surgery and has a less traumatic postoperative course. There is less likelihood of incurring damage to adjacent vital structures such as nerves, adjacent teeth, and sinus cavities. However, nonsurgical retreatment may be more costly than surgical treatment, especially if large restorations must be sacrificed during disassembly procedures prior to the retreatment. In addition, the amount of time needed for retreatment is usually longer than surgical intervention. There are times when the clinician may not be able to achieve the complete elimination of microorganisms from the canal space, and complete obturation may not be possible. Apical surgery is chosen, therefore, when nonsurgical retreatment is not possible or when the risk-to-benefit ratio of nonsurgical retreatment is outweighed by that of surgery.[124,218]

There are many factors to consider when deciding whether to retreat surgically or nonsurgically. The patient must be fully aware of the proposed treatment and the alternatives, and he or she must be motivated to follow through with all treatment, including the final restoration. The patient must have adequate time to undergo the required procedures. If they do not, then apical surgery alone may be indicated, although the patient must be made aware of the potentially compromised nature of the treatment. The clinician must be armed with the best equipment and knowledge available, and critical self-evaluation should allow the experienced clinician to know what they can treat and what they cannot. The tooth must be restorable and retreatable. Attempting nonsurgical retreatment on teeth where there is little likelihood of improving the previous treatment provides little benefit to the patient. Thus, in disease situations where there is an apparently adequate root filling and no evidence of coronal leakage, surgery may be indicated. If the previous treatment falls below any acceptable standard and there is no evidence of apical periodontitis, then there is no indication for any treatment unless a new coronal restoration is planned. In that case, conservative retreatment is indicated, and the reported success rates are very high.[55,148] If there has been a previous procedural complication, such as a ledge that cannot be bypassed or a separated instrument that cannot be removed, surgery may become a better option. Most times, it is still prudent to attempt the retreatment, since ledges or separated instruments that appear impenetrable on diagnostic films can frequently be bypassed. Even if they cannot, nonsurgical retreatment can enhance the success of subsequent apical surgery, as noted earlier. The clinician must be careful not to worsen the situation by overly vigorous attempts to treat the previous complication; root perforation, worsening of a ledge, or another separated instrument may be the result. Previous failed apical surgery should be retreated nonsurgically and then followed up, since many surgical failures are due to poorly cleaned and filled canal systems[163] (Fig. 25-12). In many instances, performing the surgery a second time can be avoided altogether. If there is evidence of root fracture (narrow-based probing defect and/or a J-shaped radiolucency encompassing the root apex and progressing in a coronal direction,[208] (Fig. 25-13) nonsurgical retreatment would be unlikely to improve that situation. Apical exploratory surgery may be necessary that could result in root resection or even extraction of the tooth.

Each case should be approached as a unique set of considerations that must be reviewed and interpreted prior to selecting a treatment method. Once the selected option is undertaken, the prudent clinician is always watchful because additional pieces of information can be discovered during treatment that may modify previous decisions.

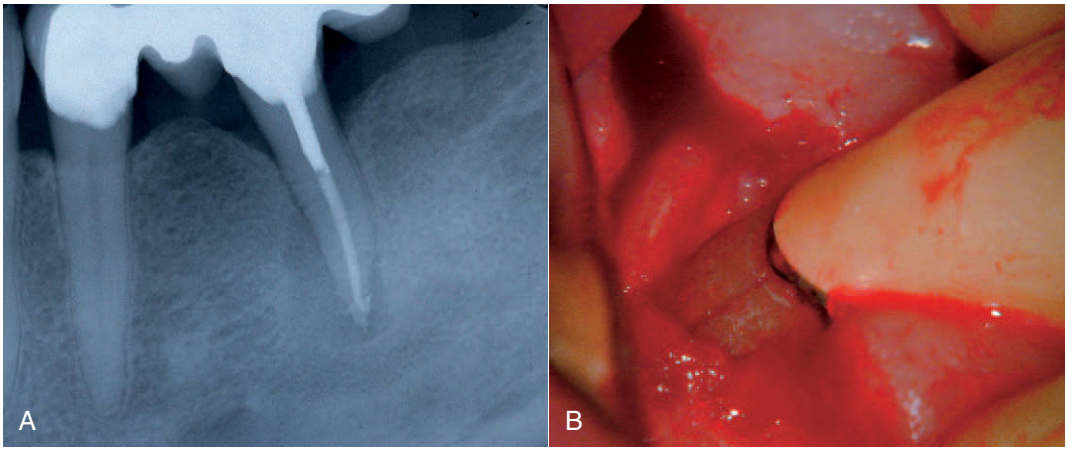

FIG. 25-13 A, The J-shaped radiolucency possibly indicates root fracture. **B,** Exploratory surgery confirms presence of vertical root fracture.

NONSURGICAL ENDODONTIC RETREATMENT

The primary difference between nonsurgical management of primary endodontic disease versus posttreatment disease is the need to regain access to the apical area of the root canal space in the previously treated tooth. After that, all of the principles of endodontic therapy apply to the completion of the retreatment case. Coronal access needs to be completed, all previous root filling materials need to be removed, canal obstructions must be managed, and impediments to achieving full working length must be overcome. Only then can cleaning and shaping procedures be instituted that will allow for effective obturation and case completion. The remainder of this chapter will be devoted to these topics in the order they generally present themselves to the clinician treating the previously root-filled tooth.

Coronal Access Cavity Preparation

Retreatment access has been called *coronal disassembly*[163,164] because of the frequent need to take apart or remove the previous coronal and radicular restoration. Following initial endodontic therapy, most teeth require and receive a full coverage restoration, and many times that restoration is supported by a post and core. Coronal-radicular access for retreatment is much more complicated in these cases when compared to endodontically treated teeth that have been minimally restored. The goal of the access preparation is to establish straight-line access to the root canal system while conserving as much tooth structure as possible. The ideal access preparation allows for instruments to enter the canals without being deflected by the access cavity walls. This is reasonably easy to achieve when the tooth is completely intact and a pulp chamber is present, since surface and internal anatomic landmarks can guide the search for the canals. Unfortunately, when endodontic retreatment is necessary, the tooth structure has almost always been altered and is commonly quite misrepresentative of the original anatomy of the tooth.

When presented with a tooth in need of retreatment that has a full-coverage restoration, the decision for the clinician becomes whether to attempt to preserve the restoration or plan its replacement. This decision is made simpler if there is a defect or caries associated with the restoration or if the treatment plan calls for a new crown. The old one is simply removed and replaced later in the treatment sequence (Fig. 25-14). When the crown is considered to be satisfactory, the decision becomes more complex. If the restoration is maintained, the cost for replacement can be avoided, isolation is easier, the occlusion is preserved, and the esthetics will be minimally changed. Even if the crown requires replacement, the clinician may elect to retain it during the endodontic retreatment to

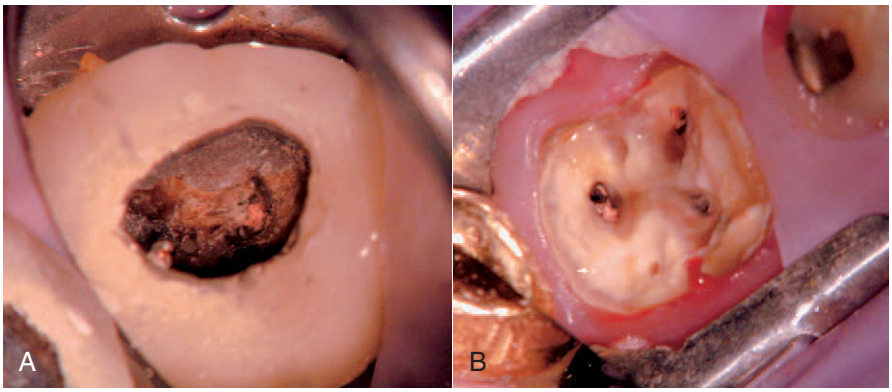

FIG. 25-14 A, Limited visibility and access with crown present. **B,** Enhanced visibility and access with crown off. Note the isolation achieved using a Silker-Glickman clamp and sealing putty.

allow for better isolation with the rubber dam. Unfortunately, retreatment may be more difficult with the crown in place, because this could lead to an increased chance for an iatrogenic mishap due to restricted visibility. In addition, removal of canal obstructions such as posts will be more difficult, and there is an increased chance the clinician may miss something important such as hidden recurrent caries, a fracture, or an additional canal. To preserve the restoration, two approaches can be taken: access through the crown or crown removal and replacement when retreatment is completed. The simplest choice is to prepare an access cavity through the existing crown, although there is a significant risk of damaging the restoration, resulting in the need to replace it.[137] This risk must be communicated to the patient prior to instituting therapy. If the clinician decides to access through the existing restoration, there are several choices of access burs to use, depending on what material the preparation will be cut through. If the access will be primarily cut through metal (amalgam alloy or cast metal) or composite resin, carbide fissure burs such as the #1556 are usually chosen. With many restorations, it is advisable to consider using a combination of burs to achieve access. For example, when a porcelain fused to metal (PFM) crown is encountered, a round diamond is used to cut through the porcelain layer. Once the metal substructure is encountered, an end-cutting bur, such as the Transmetal bur (DENTSPLY Maillefer, Tulsa, OK) or the Great White bur (SS White, Burs Inc, Lakewood, NJ), can be used to cut through to and remove the core material efficiently. An important consideration for the clinician is the potential for porcelain fracture, which may occur during the preparation or possibly at a later date after completion of the treatment. This damage is especially common with porcelain jacket crowns. Restorations fabricated completely of porcelain are becoming more and more popular, thus creating added concern owing to the increased likelihood of crack formation during access. Porcelain is a glass, and drilling through this material will create many microfractures, which in turn may weaken the structure of the restoration, making it more prone to future failure.[80] Copious coolant water spray and the use of diamond burs are recommended during access through porcelain to minimize occurrence of this event.[206] In a novel approach, researchers[165] recently showed that compared to the use of drills, air abrasion produced almost no defects in the porcelain structure of all ceramic crowns when used for endodontic access. It was, however, significantly more time consuming to access through the crown this way.

If the decision is made to remove the crown for reuse, the visibility is increased, allowing for much easier removal of canal obstructions and a decrease in the potential for operator error; however, rubber dam clamp placement and tooth isolation may become a bigger problem. Also, despite all of the varying techniques and armamentaria available for removal of an existing restoration, the procedure remains unpredictable and many times can also result in damage to the restoration or the inability to remove it at all.

The clinician must decide how to remove the crown. If the crown is of no value, even as a temporary, the clinician can take the easiest road and simply cut it off. If the crown is to be preserved, a more conservative approach must be used. Two considerations that may influence the decision about removal of a crown or bridge are what material the restoration is made of and what is it cemented with. Conservative removal efforts are difficult with traditional, all-metal restorations cemented with nonbonded cements. This situation is even more of a concern lately because of the increasing popularity of tooth-colored restorations, mainly different types of porcelain or PFM restorations, which are being bonded to the tooth. These restorations are less likely to withstand the stresses of removal than those composed completely of metal, and restorations that are bonded are much more difficult to remove because of the adhesive strengths of bonding agents. Each new generation of bonding agent is stronger than the previous, making removal increasingly more difficult as cosmetic dentistry advances.

There have been many devices developed specifically for the conservative removal of crowns. Some of the more commonly used devices are forceps that have been designed specifically for crown removal, such as the K.Y. Pliers (GC America, Alsip, IL) (Fig. 25-15), which uses small replaceable rubber tips and emery powder to enable a firm grasp of the crown without damaging it. Other instruments of this type include the Wynman Crown Gripper (Miltex, York, PA), the Trial Crown Remover (Hu-Friedy, Chicago, IL), and the Trident Crown Placer/Remover (CK Dental Industries, Orange, CA). Unfortunately, a crown that has been cemented with long-term cement or has been bonded to the tooth will usually not be removed with one of these instruments. There are also forceps designed specifically to engage the margins of the crown while using an adjacent tooth as a fulcrum. Squeezing the handles together will cause the crown to be elevated off of the tooth. The Roydent Bridge Remover (Roydent Dental Products, Johnson City, TN) works in this fashion and can be effective

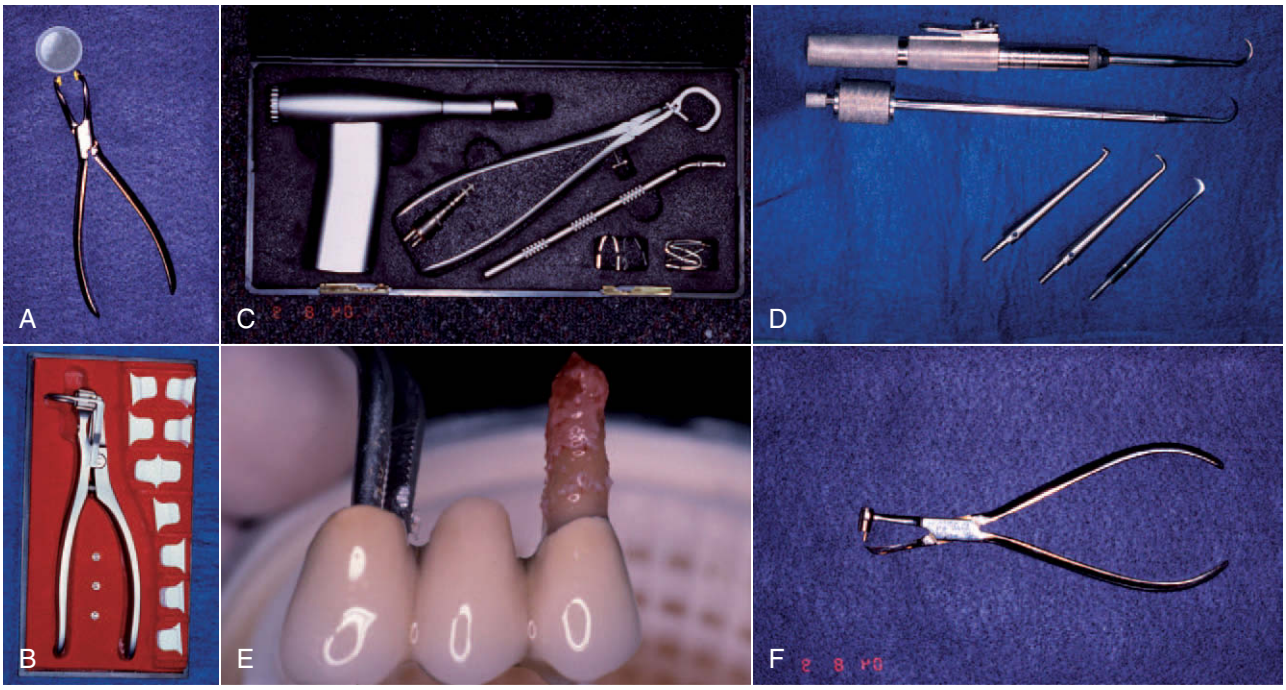

FIG. 25-15 A, KY Pliers (GC America, Alsip, IL) and supplied emery powder. **B,** Roydent Bridge Remover (Roydent Dental Products, Johnson City, TN). **C,** CoronaFlex Kit (KaVo Dental Corp, Lake Zurich, IL). **D,** *Top,* Crown-A-Matic (Peerless International, N. in crown removal, but care must be taken to avoid damage to fine, fragile margins, especially on porcelain crowns. Another type of instrument can be engaged under the margin, and a subsequent impact delivered at this site will dislodge the restoration. The Easy Pneumatic Crown and Bridge Remover (Dent Corp, White Plains, NY) and the Coronaflex (KaVo, Lake Zurich, IL) create this impact from compressed air, whereas the Morrell Remover (Henry Schein, Melville, NY) applies the force manually using a sliding weighted handle. The ATD Automatic Crown & Bridge Remover (J. Morita, Irvine, CA) uses vibrations to break the crown-to-preparation bond, and the Crown-A-Matic (Peerless International, S. Easton, MA) delivers a shock impulse to loosen the crown. As mentioned before, crown margin damage may result as can inadvertent extraction of the tooth if the periodontium is compromised[159] (see Fig. 25-15, *E*). A different approach to conservative crown removal involves drilling a small hole through the crown in order to allow a device to thread a screw through the hole. This approach creates a lifting force that separates the crown and the tooth. The instruments that work in this manner are the Metalift (Classic Practice Resources, Baton Rouge, LA), the Kline Crown Remover (Brassler, Savannah, GA), and the Higa Bridge Remover (Higa Manufacturing, West Vancouver, BC, Canada). Although very effective on metal crowns, these instruments may cause damage to porcelain occlusal surfaces on PFM restorations, so their use on anterior teeth and all porcelain restorations is generally precluded.

Another interesting technique designed to remove a crown without causing damage is performed using the Richwil Crown & Bridge Remover (Almore, Portland, OR). This material is a water-soluble resin, which is softened using warm water (Fig. 25-16). The small block of material is placed on the crown to be removed, and the patient bites into this material until the resin cools and hardens, at which point the patient opens the mouth, generating enough force to pull the crown off. Care must be taken by the clinician to avoid using this technique when the opposing tooth is extensively restored, since the opposing restoration may inadvertently be removed during the procedure. None of these techniques works in every case, and they may produce damage to the restoration being removed or possibly others. These are, however, methods that are available and may work while permitting reuse of the restoration.

Post Removal

Once the access is prepared, it is very common to encounter a post, inasmuch as posts are frequently used in the restoration of endodontically treated teeth. There are many different types of posts the clinician may encounter during retreatment (Fig. 25-17). These can be classified into two categories: prefabricated posts and custom-cast posts. Historically, cast posts were more commonly used than prefabricated posts, but over the past 2 decades, cast posts have become much less popular.[177] The main reason for this decrease is the convenience of placing the prefabricated post immediately after post preparation as opposed to waiting for a laboratory to fabricate the casting. There is also less likelihood of the interappointment contamination that frequently occurs with temporary post/core/crowns that are needed for cast/custom post-and-core fabrication. Prefabricated posts come in a variety of shapes, designs, and materials. The shapes can be subclassified into two groups: parallel sided or tapered. The design of posts also can be subclassified into active (threaded), passive, vented, fluted, and

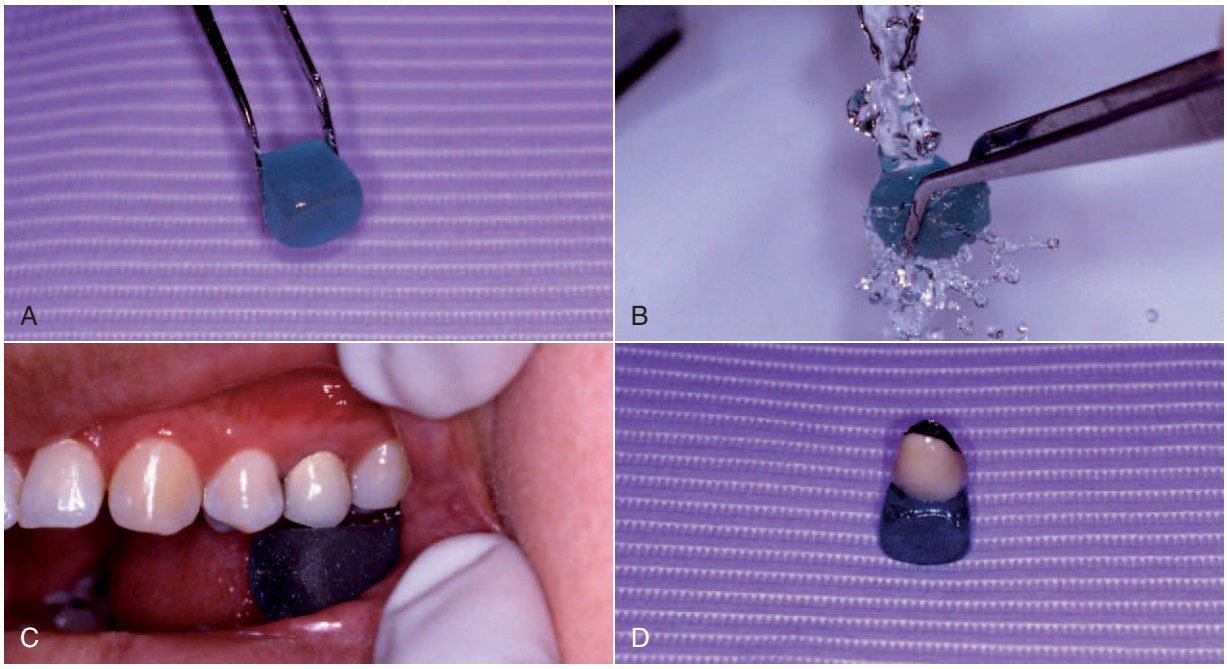

FIG. 25-16 A, Richwil Crown and Bridge Remover (Almore International Inc, Portland, OR). **B,** Using hot water to soften the material. **C,** Remover is placed on the restoration to be removed, and patient bites into the material. **D,** The removed crown adhering to the material.

acid-etched groups. There are also many materials that have been used to fabricate posts: stainless steel, gold, titanium, ceramic, zirconium, and fiber-reinforced composite posts. Cast posts, which are fabricated in a laboratory, will always be made up of precious or non-precious metal alloys. These posts will also come in a variety of shapes and configurations, since they are custom manufactured for each root in which they are placed. Most of these will have some degree of taper, and many will be cast in one piece with the core included.

In addition to the shape, design, and material of posts, there are two more very important factors that will have some influence on the clinician's ability to remove them. These factors are the adhesive material used to cement the post and the location in the arch of the tooth that requires post removal.

The same concerns regarding cements that were discussed in the section on crown removal apply to post removal. The main consideration is whether the post was cemented with traditional cement or bonded with a composite resin and dentin-bonding agent. Several post systems on the market today, such as the ProPost (DENTSPLY Tulsa Dental, Tulsa, OK), use acid-etched metal posts that are bonded into the canal with cements such as Panavia (Kuraray America, Houston, TX) or C&B Metabond (Parkell Inc, Edgewood, Farmingdale, NY). Removal of these posts is extremely difficult and occasionally impossible regardless of which technique is used.[70] A study[62] has shown that heat generation with ultrasonic vibration may help to decrease retention of resin-cemented posts, but concern for heat-generated periodontal ligament damage may preclude this technique.[177]

With regard to location, the more posterior in the arch, the more difficult the post is to remove. This predicament is a result of accessibility. The more accessible the tooth is, the easier the post is to remove, since the clinician will have more techniques and instruments available to use.[1] Also, the more anterior the tooth is, the less the opposing occlusion will interfere with post removal.

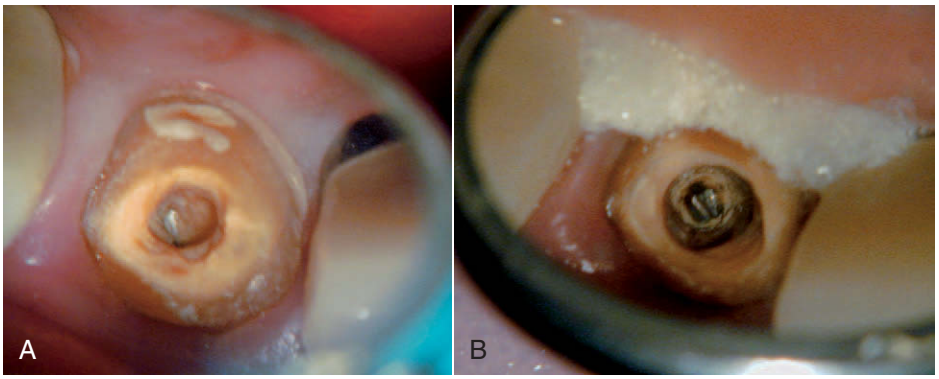

FIG. 25-18 A, Broken post (incisal view before excavation). **B,** Root has been so thinned and weakened by excavation procedures, restorability is questionable.

Post Removal Techniques

After the initial access and the post to be removed has been located, the clinician is faced with the decision of how to remove it. There have been many techniques developed for the sole purpose of post removal. Regardless of which technique is chosen, there is one simple yet extremely important rule to follow: it is not only what is removed, but what is left behind that is important. This rule applies to the removal of all intracanal obstructions. The reason for this rule is to make sure that the remaining tooth, after removal of the obstruction, can be restored predictably with a good long-term prognosis. For example, there is little use in successfully removing a post and leaving behind a root that is eggshell thin and prone to fracture (Fig. 25-18).

The first step in post removal is to expose it properly by removal of all adjacent restorative materials. With preformed posts, the bulk of the core material around the post and within the chamber can be removed with a high-speed handpiece using cylindrical or tapered carbide or diamond burs. When the majority of the restorative material is removed, a less aggressive instrument, such as a tapered bur in a slow-speed handpiece or a tapered midsized ultrasonic tip, should be used to remove the last of the embedding core material. This process is greatly facilitated by use of magnification and illumination. Once there is minimal restorative material remaining, a smaller-sized ultrasonic instrument should be used to minimize the risk of removing unnecessary tooth structure or thinning the post. The more post that is left, the more options for removal, and the more tooth structure that is left, the more options for restoration. At this point, a high-speed bur is too risky to use. When the core is cast in one piece with the post, a high-speed instrument can perform this process to generate a shape that can facilitate removal.

Once the post is well isolated and freed from all restorative materials, the clinician can begin the retrieval process. There are many instruments and kits on the market that can be used to remove posts; however, prior to using one, the retention of the post should be reduced. The clinician can usually continue to use the same medium-sized ultrasonic tip that helped get to this point. Using this instrument at the interface between the post and the tooth (the cement line) and constantly moving it around the circumference of the post will disrupt the cement structure along the post/canal wall interface and decrease post retention, facilitating removal[16,29,103]—although the effects of ultrasonic vibration may be minimal in reducing retention of well-fitted, long, large-diameter titanium posts.[17] Titanium has a lower modulus of elasticity than stainless steel, so it may dampen the ultrasonic vibrations, which may decrease the effectiveness of the ultrasonic; however, a study[83] failed to duplicate this effect. Nonetheless, care should be taken not to push the ultrasonic tip against the post with too much force, because this will dampen the ultrasonic wave and actually reduce the effectiveness of this technique. Taking away a small amount of the dentin around the coronal aspect of the post is not critical at this time and will aid in the reduction of post retention without unduly weakening the root. If the root is thin and the amount of space between the cement line and the root surface is restricted, the size of the tip that can be used may be limited. Unfortunately, the smaller tips are not only less effective for post removal, they are also more prone to breakage. At this point, the ultrasonic handpiece should be used with copious air/water spray as a coolant. Owing to the heat that can be generated from this procedure, the tip should be removed from the access every 10 to 15 seconds to allow the use of an air/water syringe to clean not only the area of debris but also reduce the temperature produced that could potentially cause damage to the periradicular tissues.[177] If a rubber dam is in place, the area around the post may be flooded with a solvent such as chloroform prior to activating the ultrasonic instrument; this will help dissolve the cement around the post. Using a solvent in conjunction with removal of cemented obstructions may prove beneficial, since the ultrasonic energy produced will set up shock waves in the solvent and make it penetrate deeper into the canal space, exerting a faster solvent action on the cement.[67]

Using an ultrasonic instrument in this fashion is not simply helpful in reducing post retention, it may also prove to be all that is needed to remove the post. Many times, after judicious use of the ultrasonic instrument, the post will loosen and actually spin out of the preparation, completing post removal (Fig. 25-19). In addition, if post removal cannot be accomplished in this manner, the resulting post exposure will be very beneficial in contributing to the predictable use of other techniques. Many of the instruments to be discussed involve using a trephine bur to shape the coronal end of the post, and ultrasonic exposure will facilitate this process. Another instrument to consider for exposing and loosening a post is the Roto-Pro bur

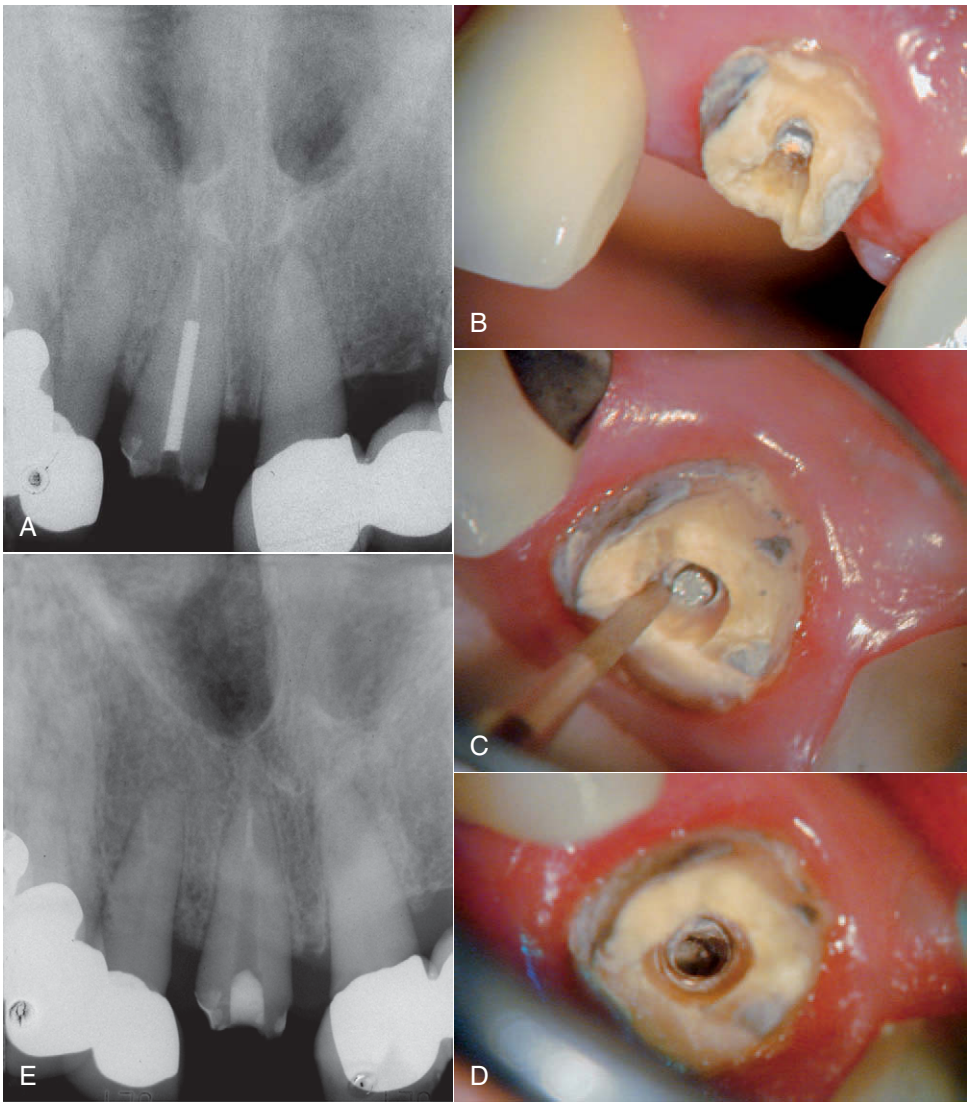

FIG. 25-19 A, Radiograph of fractured post. **B,** Fractured post, labial view. **C,** Ultrasonic troughing. **D,** Post removed by ultrasonic alone. **E,** Check film confirming complete post removal.

(Ellman International, Oceanside, NY) (Fig. 25-20). There are three shapes available, all of which are six-sided, non-cutting tapered burs that are used in a high-speed handpiece around the circumference of the post. The vibrations created when the non-cutting flutes come in contact with the post decrease the retention of the post, facilitating its removal.

If retention reduction does not remove the post, some form of vice is needed to pull the post from its preparation. Many post removal kits are available on the market today with varying degrees of effectiveness. One such device is the Gonon Post Removing System (Thomas extracteur de pivots, FFDM-Pneumat, Bourge, France) that is a very effective instrument for removing parallel or tapered, nonactive preformed posts.[125,167] This kit utilizes a hollow trephine bur that is aligned with the long axis of the post and placed over its newly exposed end. The trephine then cuts in an apical direction, shaving off the post's outer layer, not only to remove tooth structure adjacent to the post but also to reduce the circumference of the post to a specific size and shape. This procedure is necessary to allow a specific, matched-size extraction mandrel to create or tap a thread onto the exposed milled portion of the post. Once the extraction mandrel with its associated washer/bumpers (Fig. 25-21) is attached to the post, the extraction forceps or vice is applied to the tooth and post. Turning the screw on the handle of the vice applies a coronal force in a similar fashion as a corkscrew removes a cork from a bottle of wine. This method is effective because all the force is applied to the bond between the tooth and the post, ideally in the long axis of the root. The main problem with this technique is the size of the vice that can make access in the molar region and between crowded lower incisors difficult. Also, if the extraction force applied is not directed in the long axis of the root, root fracture may occur.[32]

The Thomas Screw Post Removal Kit (Thomas extracteur de pivots, FFDM-Pneumat) (Fig. 25-22) is an instrument designed specifically for the removal of active or screw posts. The trephine burs are identical to those used with the Gonon Post Removal System, but the extraction mandrels

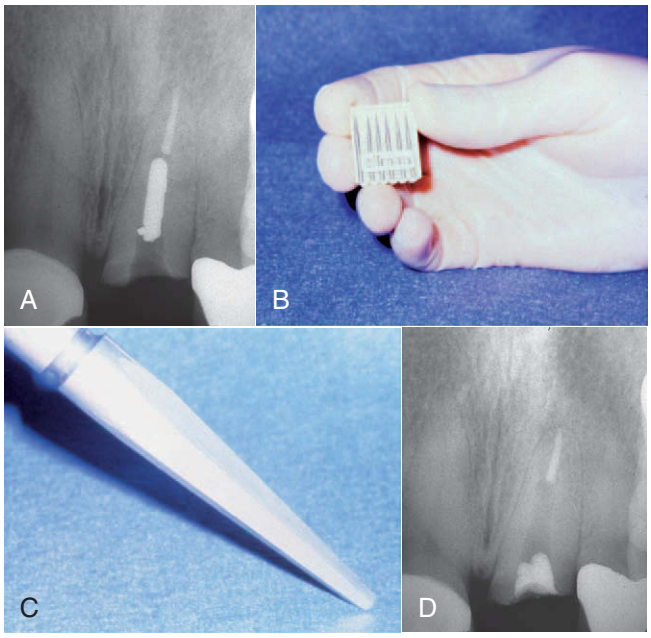

FIG. 25-20 A, Radiograph of fractured post. **B,** Roto-Pro Kit (Ellman International, Oceanside, NY). **C,** Roto-Pro Bur. **D,** Post removed by vibration of the instrument alone.

are threaded in the opposite direction. The mandrels are reverse threaded to enable them to tap onto the screw post in a counterclockwise direction so that continued torquing force while creating the thread will unscrew the post.

The Ruddle Post Removal System (Sybron SybronEndo, Orange, CA)[163] (Fig. 25-23) and the Universal Post Remover (Thomas extracteur de pivots, FFDM-Pneumat) were designed to combine the properties of both the Gonon and Thomas Kits. Both of these very similar kits are not only useful in the removal of parallel or tapered passive types of posts but also in removing screw posts. They can even be adapted to remove large separated instruments in the coronal straight portion of a large canal. These kits also use a trephine bur to machine the post to a specific size that will dictate which mandrel to use. These mandrels tap in the counterclockwise direction so that the same taps can be used for both passive and active posts. Once the mandrel is tapped onto the post, the extraction jaws, or vice, can be applied and activated, enabling removal of passive posts; or the tap is continuously rotated counterclockwise to unthread screw-type posts.

Another device that works in a similar fashion as the Gonon and the Ruddle Post Removal System is the JS Post Extractor (Roydent Dental Products). The biggest advantage of this kit is the size. This is the smallest of the kits that work using a pulling action, which may help with cases where access is difficult. However, this kit does have one disadvantage: a smaller variety of trephine burs and extraction mandrels than some of the others. Therefore, the size of the post may be a limiting factor.

Another post removal device is the Post Puller, also known as the Eggler Post Remover (Automaton-Vertriebs-Gesellschaft, Germany)[200] (Fig. 25-24). This device works in a similar manner as some of the others, except there are no trephine burs or extraction mandrels. The design of this instrument enables it to be used more efficiently with the crown removed. In addition, the design also allows this instrument to be used for cases in which the post and core are cast as one unit. This device consists of two sets of jaws that work independently of one another. With this device, both the post and the tooth are reduced to allow attachment of the post puller. Since there are no trephine burs, this reduction is done with a high-speed handpiece and bur. Next, the first set of jaws are attached to the post while the second set of jaws push away from the tooth in line with the long axis of the tooth, removing the post from the canal.[200] Care must be taken to align the pulling forces of this instrument with the long axis of the root to prevent fracture[32]; this technique is not recommended for the removal of screw posts. In a survey of the Australian and New Zealand Academy of Endodontists, this was the most commonly used technique for post removal.[31] However, in a survey of the American Association of Endodontists, it was one of the least used techniques.[201] Clearly, techniques that are common in one country are not always that common in another.

The recent increased popularity of cosmetic dentistry has created an impetus towards the use of tooth-colored posts that are fabricated from ceramic, zirconium, or various types of fiber-reinforced composite. Unfortunately, as with all posts, cosmetic posts also will need to be removed periodically. Neither the use of the Gonon Kit nor ultrasonic instruments allows for removal of fiber posts. The use of a high-speed bur to channel down through the post may result in a high rate of root perforation.[154,177] The use of the Largo Bur (DENTSPLY Limited, Surrey, UK)[64] and the Peeso drill[154] to remove these posts has been advocated, and most of the post manufacturers have removal burs in the kit.[40] These manufacturers' removal kits have been shown to be more efficient at removing their own fiber posts than the use of diamond burrs and ultrasonics.[120] In addition, a new bur, the GyroTip (MTI Precision Products, Lakewood, NJ), has been designed for the specific purpose of removing fiber-reinforced composite posts (Fig. 25-25). These drills consist of a heat-generating tip designed to soften the matrix that binds the fibers within the fiber-reinforced post. The fibers within the post are parallel, which assists the axial travel of the drill through the center of the post. The fluted zone of the drill allows the fibers to be safely removed, creating access to the root canal filling. Above the fluted zone, a layer of plasma-bonded silica carbide reduces the heat generation that would otherwise occur if a smooth carbide surface were rotating in contact with enamel and/or dentin. This abrasive zone also provides for a straight-line access preparation and facilitates the placement of a new post. Ceramic and zirconium posts are usually impossible to retrieve. They are more fragile than metal posts, and though ceramic posts may be removed by grinding them away with a bur (a procedure with a high risk of root perforation), zirconium has a hardness approaching that of diamond and cannot be removed by this method.[177]

Regardless of the post type or retrieval method used, once the post has been removed, the final step in exposing the underlying root filling material is to ensure that none of the post cement remains in the apical extent of the post space. This step can be easily accomplished by visualizing the cement using magnification and illumination and then using a straight ultrasonic tip to expose the underlying canal filling.

Potential Complications of Post Removal

As with many dental procedures, post removal has risks. These risks include fracture of the tooth, leaving the tooth unrestorable, root perforation, post breakage, and inability to remove the post.[201] An additional concern is ultrasonically generated heat damage to the periodontium.[177]

Even though there may still be some who feel posts strengthen teeth, it is widely accepted that they do not.[177] Actually, it has been shown that post preparation alone weakens teeth.[221] It seems obvious that any additional work that may require removal of further tooth structure will weaken the tooth, increasing the likelihood of fracture. An in vitro study showed that cracks can form in radicular dentin during post removal using both the Gonon Kit and using ultrasonics, but there was no significant difference between these two groups and teeth with posts that were not removed.[4] The authors speculated that the potential for vertical root fracture might be increased, but the clinical significance of this remains unknown. A more recent study, however, concluded that the incidence of root fracture during post removal was extremely low and that with good case selection, post removal is in fact a very predictable procedure.[1] But if post removal would also leave the remaining tooth structure in a state that may not be predictably restored with a good prognosis, and if this situation can be predicted ahead of time, surgery may be the preferred treatment option.

Perforation is an additional possible complication that can happen during post removal, especially if the post is removed by simply attempting to drill it out with high-speed burs.[154] If perforation occurs, the clinician should repair it immediately; the prognosis will worsen as the time between perforation and repair lengthens.[21,102,182] Once a perforation occurs, the clinician must reconsider the prognosis and determine whether or not the tooth should be salvaged. Terminating the procedure and pursuing a different treatment option could be considered at this point. Extraction and replacement with an implant and/or a fixed prosthesis was a treatment option prior to initiating the retreatment, and some may consider this treatment the best option once a perforation has occurred. However, with the recent development of mineral trioxide aggregate (Pro-Root MTA, DENTSPLY Tulsa Dental), perforations can

be repaired with a favorable prognosis.[160] The techniques and materials for perforation repair will be discussed in detail in a later section of this chapter.

Another complication is separation of the post, causing removal of the coronal segment and leaving a small portion of the post with even less accessibility. This separation will decrease the likelihood of removal and occurs more frequently when attempting to retrieve titanium posts.[177]

The use of ultrasonic energy for prolonged periods of time can generate excessive amounts of heat. The heat generated can cause damage to the surrounding periodontium.[67,177] This damage may be as serious as both tooth and permanent bone loss (Fig. 25-26). For this reason, stopping periodically to cool off the area with a water spray is necessary. This will be discussed in detail in a later section.

If the clinician is unable to remove the post, he or she will be faced with a decision of what to do. This decision is based on whether the post is being removed for restorative purposes or due to the persistence of disease. If the reason is for restorative purposes and the clinician can adequately restore the tooth with the existing post or post segment, then he or she should do so. If the tooth cannot be properly restored without removal of the post and placement of a new post, extraction and replacement with an implant and/or fixed prosthesis will be needed. If the reason for post removal is the persistence of disease, the tooth should be treated surgically and restored as well as possible.

Regaining Access to the Apical Area

Once the coronal-radicular access is made and all posts and obstructing restorations have been removed, the clinician must regain access to the apical area by removing the previous root-filling materials (Fig. 25-27). This part of nonsurgical retreatment is complicated by the large variety of types of root fillings used. Today, the majority of root fillings are performed using gutta-percha in various forms, but many other materials have been and are still being used. Silver points were very popular until the 1970s, and various types of pastes are unfortunately still in use. The authors have seen cases of definitive root filling with phenol-soaked paper points and sometimes no root filling at all. New materials such as Resilon (Resilon Research LLC, Madison, CT), a soft polyester material that is bonded into the canal space, are coming on the market all the time. Though all root-filling materials have their advocates and their critics, the only certainty is that all will have some incidence of persistent disease and will need retreatment.

During the diagnostic phase, it is very important to ascertain the nature of the root filling to minimize surprises when attempting retreatment. Sometimes this is readily apparent, but in other instances, this determination may require contacting the previous clinician to discover what type of root filling was used. Occasionally this information cannot be determined until canal entry, so extreme caution should be used when performing access so as not to possibly remove parts of the

root filling that may be useful in its removal, such as the core material in solid core obturators.

Gutta-percha Removal

One of the great advantages of using gutta-percha for root filling is its relative ease of removal. When the canal contains gutta-percha and sealer or a chloropercha filling, it is relatively easy to remove this material using a combination of heat, solvents, and mechanical instrumentation.[58,163] Upon access, it is usually relatively easy to find the treated canal orifices with the visible pink gutta-percha material inside. Initial probing with an endodontic explorer into the material can help rule out the possibility that there is a solid core carrier. If there is a plastic carrier, then heat should not be used to remove the coronal gutta-percha (more on this later). If there is no carrier, heat is applied using an endodontic heat carrier that has been heated to a cherry red glow in a torch. Unfortunately, the carrier begins to cool upon removal from the flame, so many endodontists are now using other heat sources—such as the Touch 'n Heat (SybronEndo) or DownPak (Hu-Friedy, Chicago, IL) (Fig. 25-28, *A*)—to provide constant, consistent heat application to soften the gutta-percha in the

coronal portion of the canal.[75] Care must be exercised to not overheat the root, which can cause damage to the periodontal ligament.[115,169,170] Heat should be applied in a short burst to allow the instrument to penetrate the gutta-percha mass, followed by cooling, which will cause the material to adhere to the heat carrier, facilitating its removal (Figure 25-28, *B*). After removing as much gutta-percha as possible with the heated instrument, then remove any remaining coronal material with

small Gates-Glidden drills, taking care not to overenlarge the cervical portion of the canal. However, since the previously treated tooth may have had an underprepared cervical third of the canals, these drills can also be used to flare the coronal aspect in an anticurvature direction to facilitate enhanced straight-line access to the apical third of the canal and create a reservoir for potential solvent use.[129] Again probe the canal, this time using a #10 or #15 K-file. It is sometimes possible to remove or bypass the existing cones of gutta-percha if the canal has been poorly obturated, thus eliminating the need for solvents.[199] If that is not possible, a gutta-percha solvent must be used to remove the remaining material in the apical portion of the canal.

Several solvents have been recommended to dissolve and remove gutta-percha for retreatment (Fig. 25-29), including chloroform,[132] methylchloroform,[228] eucalyptol,[242] halothane,[90,110] rectified turpentine,[104] and xylene.[78] All of the solvents have some level of toxicity,[12,35] so their use should be avoided if possible; however, a solvent is usually needed to remove well-condensed gutta-percha. The most popular solvent is chloroform, since it dissolves the gutta-percha rapidly and has a long history of clinical use. In 1976, the U.S. Food and Drug Administration (FDA) banned the use of chloroform in drugs and cosmetics after a report of suspected carcinogenicity.[222] There was no associated ban on its use in dentistry,[132] but the report did result in the search for alternatives, some of which are listed. When used carefully, chloroform is regarded as a safe and effective endodontic solvent.[35,132] All of the others generally have been reported to be less effective or have some other drawback that limits their use. Xylene and eucalyptol dissolve gutta-percha slowly and only approach the effectiveness of chloroform when heated.[238] Rectified turpentine has a higher level of toxicity than chloroform[12] and produces a very pungent odor in the operatory. Halothane has been shown to be as effective a solvent as chloroform in several studies,[90,110] but a more recent study indicated that the time for removal of the root filling was longer than using chloroform.[231] The increased cost and volatility of halothane and the potential for idiosyncratic hepatic necrosis make it less desirable to use as a gutta-percha solvent.[35] Although methylchloroform is less toxic than chloroform, it is also less effective as a solvent for gutta-percha.[228] Both halothane and chloroform have been

shown to affect the chemical composition of dentin[43,105] and may affect bonding strengths of adhesive cements to the altered dentin.[44] The clinical significance of these effects remains unknown. The evidence for the carcinogenicity of chloroform in humans is suspect,[132] but with careful use, its toxicity may be eliminated as a risk factor to both the patient[35] and the personnel in the operatory.[3] As such, its continued use as a gutta-percha solvent is recommended.

Using an irrigating syringe, the selected solvent is introduced into the coronal portions of the canals, which will then act as a reservoir for the solvent. Then, small hand files (sizes #15 and #20) are used to penetrate the remaining root filling and increase the surface area of the gutta-percha to enhance its dissolution. This procedure can be facilitated by using precurved rigid files such as the C+ File (DENTSPLY Maillefer, Johnson City, TN) (Fig. 25-30), which can penetrate the gutta-percha mass more efficiently than the more flexible types of K-files. The newly introduced C+ file is a stainless steel, end-cutting hand file that is twisted from a square blank. The secret to its stiffness is that the taper varies along the shaft, giving it the rigidity and strength to cut through well-condensed gutta-

FIG. 25-30 C+ files. These rigid instruments remove gutta-percha more efficiently than more flexible types of K-files.

percha efficiently. The gutta-percha must be removed carefully, however, to avoid overextending the resultant mixture of gutta-percha and solvent beyond the confines of the canal to minimize the risk of severe postoperative pain.[75] Unfortunately, electronic apex locators, which in non-retreatment situations are very accurate,[106] seem to frequently misread the working length when gutta-percha is initially being removed. This clinical observation may be a result of the file being covered with chloropercha that may affect its conductivity. It has been shown that apex locators may be less accurate in retreatment situations,[227] but in this study, the error was that readings indicated a working length that was too short. In a more recent study, an apex locator built into a rotary handpiece indicated working lengths that were too long in simulated retreatment situations.[223] To avoid overextending root filling materials into the periodontium, it is recommended that a radiograph be made to gain a preliminary measurement when the estimated length is approached. Well into the retreatment, after the root fillings have been thoroughly removed, the apex locator will regain its accuracy if a clean file is used. Once the working length is reached, progressively larger-diameter hand files are rotated in a passive, nonbinding, clockwise reaming fashion to remove the bulk of the remaining gutta-percha until the files come out of the canal clean (i.e., with no pink material on them). Frequent replenishment of the solvent should be used, and when the last loose fitting instrument is removed clean, the canal is flooded with the solvent, which then acts as an irrigant. The solvent is then removed with paper points. The wicking action of the absorbent points[163] will remove much of the remaining film of gutta-percha and sealer that remains adherent to the canal walls and in the irregularities of the canal system.[234] Cleanliness of canals after gutta-percha removal is not improved by using a microscope[10]; however, using kinked small files, the clinician should probe the canal wall looking for irregularities that may harbor the last remnants of gutta-percha. These irregularities can usually be felt rather than seen and should be cleaned using this method.[75]

It should be noted that there exists a glass ionomer–based endodontic sealer (Ketac-Endo, 3M, Pymble, Australia) that is used in conjunction with gutta-percha.[156] This sealer is virtually insoluble in both chloroform and halothane[230] and must be retreated by removing the gutta-percha and then using ultrasonics to débride the canal walls. Canal cleanliness can approach that of other gutta-percha retreatment cases, but it is difficult and time consuming to achieve this result.[56,136]

Overextended gutta-percha removal can be attempted by inserting a new Hedstrom file into the extruded apical fragment of root filling, using a gentle clockwise rotation to a depth of 0.5 to 1 mm beyond the apical constriction. The file is then slowly and firmly withdrawn with no rotation, removing the overextended material[133] (Fig. 25-31). This technique works frequently, but care must be taken not to force the instrument, or further extrusion of the gutta-percha or separation of the file may result. The overextended apical fragment should not be softened with solvent, because this application can decrease the likelihood of the Hedstrom file getting a solid purchase, hindering retrieval.[199]

Using rotary systems to remove gutta-percha in the canals has been advocated for their enhanced efficiency and effectiveness in removing gutta-percha from treated root canals.[163] This has generally been borne out in the literature. There are several

types of mechanical rotary systems available for gutta-percha removal, including rotary file systems such as the ProFile (DENTSPLY Limited) (Fig. 25-32), a mechanical push-pull, quarter-turn file system, the Canal Finder (Endo Technique Co, Tustin, CA), and dedicated gutta-percha removal instruments, such as the GPX (Brasseler, Savannah, GA), the ProTaper Universal retreatment files (DENTSPLY Limited) (Fig. 25-33), and the Mtwo R (Sweden and Martina, Padova, Italy). These engine-driven instruments mechanically chop up the gutta-percha and sealer while thermoplasticizing the root filling mass via frictional heat to aid in removal. A survey of Australian dentists showed that 54% of the respondents who perform endodontic retreatment used rotary instrumentation to remove gutta-percha either always (15%) or sometimes (39%), with an increased likelihood of rotary gutta-percha removal if the clinician had more experience with the use of these instruments.[151] In vitro studies have generally shown these systems to be efficient in that they generally need less time to remove the bulk of the gutta-percha filling material

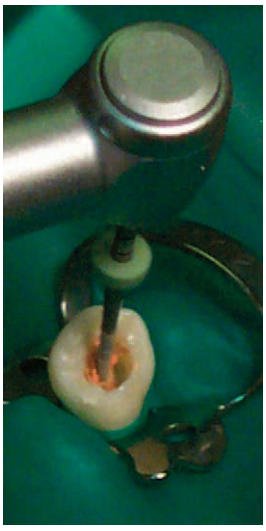

FIG. 25-32 Nickel-titanium rotary Profile thermoplasticizing and removing gutta-percha. Optimum rotary speed is 1500 rpm.

than hand removal,* although in two studies, they were slower to remove the root filling than hand filing.[13,93] Assessments of canal cleanliness and extruded apical debris generally indicated that there were no overall differences between hand and mechanical gutta-percha removal.† In one study using Quantec SC instruments (Tycom, Irvine, CA), however, it was found that hand files with solvent cleaned canals more effectively.[19] This finding has been repeated recently using the ProTaper retreatment files,[77] but in another study in the same journal issue, ProTaper retreatment files were found to leave canals cleaner than hand files.[66] Clearly, this is an area where further research is warranted. It is recommended that after rotary gutta-percha removal, subsequent hand instrumentation is needed to remove the residual obturating materials completely from the canal. In several studies of mechanical gutta-percha removal, fracture of the mechanical instruments or the tooth root occurred.‡ This result was reported to occur less frequently when the instrument rotary speed was increased from 350 to 1500 rpm.[24] One study showed no separation or other canal defects when using dedicated retreatment files, the ProTaper Universal and Mtwo R instruments.[194] The dedicated retreatment files have end-cutting tips to enhance penetration and removal of the root filling mass, increasing their efficiency[210] (see Fig. 25-33, *B*). This in combination with flute design and techniques advocated may be the reason for the potential reduced risk of separation. While the mechanical gutta-percha removal systems may provide enhanced efficiency, the increased risk of instrument separation, further complicating retreatment, may outweigh this benefit. Dedicated retreatment files may reduce this risk.

Use of the Nd:YAG laser to remove gutta-percha from root-filled teeth has been investigated in vitro.[225] The time taken to remove the gutta-percha was within the range of other studies of mechanical gutta-percha removal, and the addition of solvents did not improve the performance of the laser. As in most other studies, gutta-percha in varying amounts was left in the canals after laser removal. Root surface temperatures did increase, so without further investigation proving safety and efficacy, laser gutta-percha removal cannot be recommended at this time.

Resilon (Resilon Research LLC) (Fig. 25-34) is a thermoplastic polyester polymer that is bonded into the canal space using an unfilled resin bonding system (Epiphany; Pentron). It is also marketed as RealSeal (Sybron Endodontics, Orange, CA). It has been advocated as a root canal obturating material to replace traditional gutta-percha and sealer because of its apparent enhanced sealing ability[185] and potential to strengthen root resistance to fracture as a result of internal bonding.[212] Resin-bonded obturation systems have been advocated in the past,[118] but the inability to retreat canals filled with this obturating material has prevented its widespread use. The Resilon polymer itself is reported by the manufacturer to be soluble in chloroform and may be removed by heat application, a behavior that is similar to gutta-percha. Recent studies have shown that the polycaprolactone polymer of the Resilon is removed easily and leaves canal walls cleaner than removal of gutta-percha and AH+ sealer,[38,39,47,175] although this finding has been disputed. Hassanloo et al. found that there was less residue on the walls when removing gutta percha/AH+ if the materials were allowed to set for a longer period.[82] This finding has been corroborated[175,211] and indicates that there may be a temporal effect that introduces a methodological bias in these studies. There may also be a problem with removal of the unfilled Epiphany resin sealer, especially since the sealer tags have been shown to penetrate deep into dentinal tubules[185] and presumably also into anatomic ramifications of the canal that need cleaning during retreatment. More research into this interesting material and technique is warranted, especially to determine the best technique for retreatment. After the Resilon core has been removed using heat and chloroform, the authors would recommend the use of a resin solvent such as Endosolv-R (Septodont, Kent, UK) (Fig. 25-35) to attempt elimination of the unfilled resin sealer prior to instrumentation.

Managing Solid Core Obturators

Solid core canal obturation systems, such as Thermafil, Dens-Fil, and the GT Obturator (DENTSPLY Tulsa Dental), have become very popular since their introduction several years ago. After cleaning and shaping procedures are completed, the clinician heats a solid core obturator (alpha-phase gutta-percha surrounding a core that is attached to a handle) in an oven and places the carrier in the canal. The solid core carries the gutta-percha down into the canal and condenses it while the material is cooling. This system provides a rapid and simple technique for warm gutta-percha endodontic obturation. As with any obturating material, retreatment will be necessary occasionally.

Retreatment of solid core materials is considered to be more complex and difficult than removal of gutta-percha alone, owing to the presence of the solid carrier within the mass of gutta-percha. The nature of the carrier will determine the method used and complexity of the retrieval. There are two types of carriers found in these systems: metal (stainless steel or titanium) and plastic. The plastic carriers are smooth sided,

as are some brands of metal carriers; however, most metal carriers are fluted and resemble endodontic hand files with a layer of gutta-percha on the outside. The fluted metal carriers present an exceptional challenge to the retreating clinician, since many times they are improperly inserted and either wedged or screwed into the canal to make up for inadequate canal shaping or the lack of skilled use of the size-verifying techniques available. This makes them especially difficult to remove. Once the carrier has been placed, it is cut off in the pulp chamber using a bur, and the tooth is restored. The level at which the metal carrier is severed is important in its retrieval. If it is cut down to the level of the canal orifice, retrieval is difficult,[75] so the prudent clinician plans for retrievability by severing the handle from the carrier, leaving 2 to 3 mm of carrier exposed in the access above the pulp chamber floor to allow easier removal if retreatment is ever needed. Unfortunately, this is not always the case. The technique of placing a nick in the midcanal level of the carrier to allow the clinician to rotate the carrier handle and sever the obturator deep in the canal is sometimes used to allow creation of a post space, but the rotational force used to create the "twist-off" apical plug can engage the flutes of a metal carrier, increasing the complexity of removal if retreatment is needed.[243]

It is advantageous to determine prior to initiating treatment whether there is a solid core obturation in the root-filled tooth. The preoperative radiograph may show this, since stainless steel carriers will exhibit a fluting effect on the radiograph (Fig. 25-36); however, titanium carriers rarely are distinguishable from gutta-percha, and plastic ones never are. In most instances, the clinician finds that they are dealing with a carrier-based obturator after initial access to the pulp chamber. This is why, as was stated in an earlier section, careful access and probing of the root-filling material is necessary when entering a canal. If there is a carrier, it will be detected as either a metallic

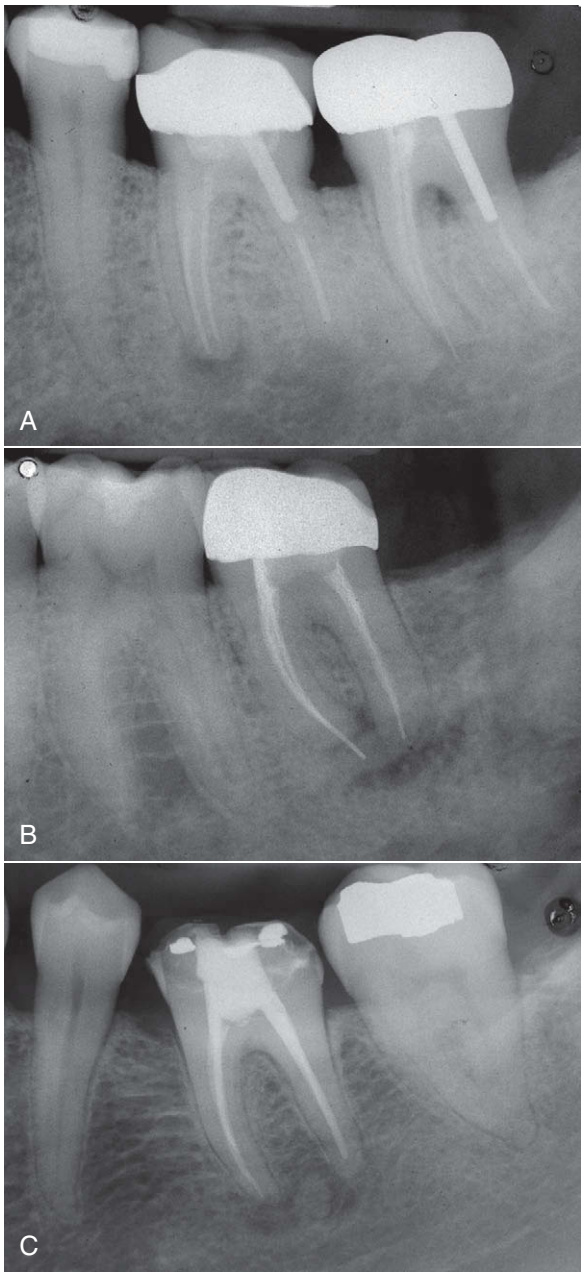

FIG. 25-36 Comparison of radiographic appearances of three different obturating materials. **A,** Gutta-percha. **B,** Stainless steel Thermafil carrier (note subtle fluting effect in the fill). **C,** Plastic Thermafil carrier.

structure embedded in the gutta-percha mass or a black spot, indicating a plastic carrier. Occasionally the carrier may be found embedded in the coronal core material, so careful excavation with small burs and straight, tapered ultrasonic tips may be necessary to preserve the carrier intact to help with removal.[75]

Removal of a metal carrier is accomplished with initial use of heat application to the carrier that can soften the gutta-percha surrounding it, facilitating its removal with Peet silver point forceps (Silvermans, New York, NY) or modified Steiglitz forceps (Pulpdent Corporation, Watertown, MA)[75,173,232,233] (Fig. 25-37). Often there is not enough of the carrier remaining in the access to grasp with forceps, and removal will require solvent application and removal of the surrounding coronal gutta-percha using small hand instruments, usually followed by ultrasonic excavation around the carrier and removing it like a separated instrument[75,163] (Fig. 25-38), as described in a later section of this chapter. Care should be exercised to avoid excessive heat generation during this procedure. This is also the case if the metal carrier has been sectioned for post space preparation. The metal carrier has been shown to be much more difficult to remove than plastic ones,[53,243] frequently resulting in nonretrieval. Fortunately, their use in endodontic therapy has been declining.

Removal of plastic carriers is similar to removal of gutta-percha root fillings, except that generally, heat should be avoided to minimize the likelihood of damaging the carrier.[75] The older Thermafil plastic carriers were made of two different materials depending on their size. In the smaller sizes (up to size #40) the material used was Vectra, which is insoluble in available solvents; the larger sizes used polysulfone, which is soluble in chloroform.[152] Solvents, on the other hand, seem not to affect the newer GT plastic carriers, so their use can be recommended[18] (Fig. 25-39). The access is flooded with a solvent such as chloroform, and the gutta-percha surrounding the carrier is removed with hand files in a larger to smaller sequence (e.g., #25, #20, #15, etc.), each file progressively penetrating deeper around the carrier. The solvent should be replenished frequently, and when a #08 file can penetrate to the apical extent of the carrier and there is little remaining gutta-percha, a larger Hedstrom file is inserted into the canal alongside the plastic carrier and gently turned clockwise to engage the flutes. When the file is withdrawn, it invariably brings the carrier with it, and the rest of the gutta-percha and sealer removal proceeds as described earlier. Care must be taken to avoid overstressing the Hedstrom file. It should not be "screwed" into the canal, or separation of the file or the carrier may result.[18] Occasionally, grasping pliers will be needed to remove the carrier if it is accessible[95,163] after the gutta-percha has been removed. Another potential problem with retrieval is present if the carrier has been overextended beyond the apical foramen during the previous root canal treatment. This overextension may make it prone to separation and unable to be retrieved, potentially resulting in the need for apical surgery.[92]

A technique for plastic carrier removal has been described using a System B HeatSource (SybronEndo) to soften the gutta-percha surrounding the carrier without melting the carrier itself.[236] The temperature is set at 225° C, and the heat plugger is placed buccal and lingual to the carrier, after which #50 to #55 Flex-R hand files are placed around the carrier and braided to engage the carrier and remove it. This technique has been shown to require significantly less time to remove the carrier compared to using solvent.[236] Concerns regarding heat generation in the periradicular tissues have been raised,[121] with the authors concluding that caution should be exercised when using this technique. When other techniques have been unsuccessful, and the plastic carrier has been sectioned apical to the orifice, resulting in limited access, the clinician may attempt to retrieve the carrier by placing a heated System B tip directly into it. As apical pressure is maintained, the heat is turned off. This allows

the plastic carrier to adhere to the tip while cooling and may result in its removal upon withdrawal of the heat tip (Fig. 25-40).

Rotary instruments have been advocated for use in removal of plastic carriers and gutta-percha, and a recent study showed that removal of plastic carriers was successful in all but one of the teeth obturated with them.[11] Unfortunately, root fracture occurred in the lone specimen that did not have a successful retrieval, and two instances of rotary instrument fracture also occurred in the study. As with gutta-percha removal, the clinician must carefully weigh the risks of rotary carrier removal against the perceived benefits.[162]

Once the carrier has been removed, the remaining gutta-percha and sealer must be removed from the canal, and like removal of root-filling materials described previously, there is no technique that completely removes all materials from the canal system. Canal cleaning may be even more difficult when removing carrier-based obturations, since the more highly processed gutta-percha used with these carriers may be more difficult to remove than other forms of the material. One study described a sticky film of gutta-percha and sealer adhering to the canal walls upon removal of metal carrier obturators and found more of it than if the canals had been obturated with lateral condensation.[243] Their findings have not been corroborated, however, and other studies have shown no difference in residual debris remaining after carrier-based removal.[53,95,243] It is important to remove as much of the residual gutta-percha and sealer from the pulpal anatomic spaces as possible, so flooding the canal with solvent and "wicking" it out with paper points is also recommended for carrier-based retreatment.[163]

Paste Retreatment

Various pastes have been used as root canal obturating materials, especially outside North America. There are such a wide variety of paste compounds used in endodontics that it is impossible to categorize them all. The individual clinician who is using it formulates most pastes, so the ultimate composition of a paste found in a tooth with persistent disease is generally indiscernible. Many of the pastes used, such as N2 or RC2B, contain formaldehyde and heavy metal oxides, making them toxic and a potential danger to the patient's health, both local and systemic if overextended beyond the confines of the root canal system.[22,150] None has the potential to seal the canal effectively, and many render a tooth impossible to retreat,[176] so their use is strongly discouraged. On radiographic examination, they can usually be discerned by their lack of radiopacity, the presence of voids, and evidence of inadequate canal shaping and poor length control (Fig. 25-41). When a paste fill is suspected or found in a tooth, a telephone call to the previous treating dentist should be made if possible to find out the exact formulation of the paste, since this information may help in its removal.

For purposes of retreatment, paste fills can be categorized as soft or hard, and all should be considered potentially toxic.

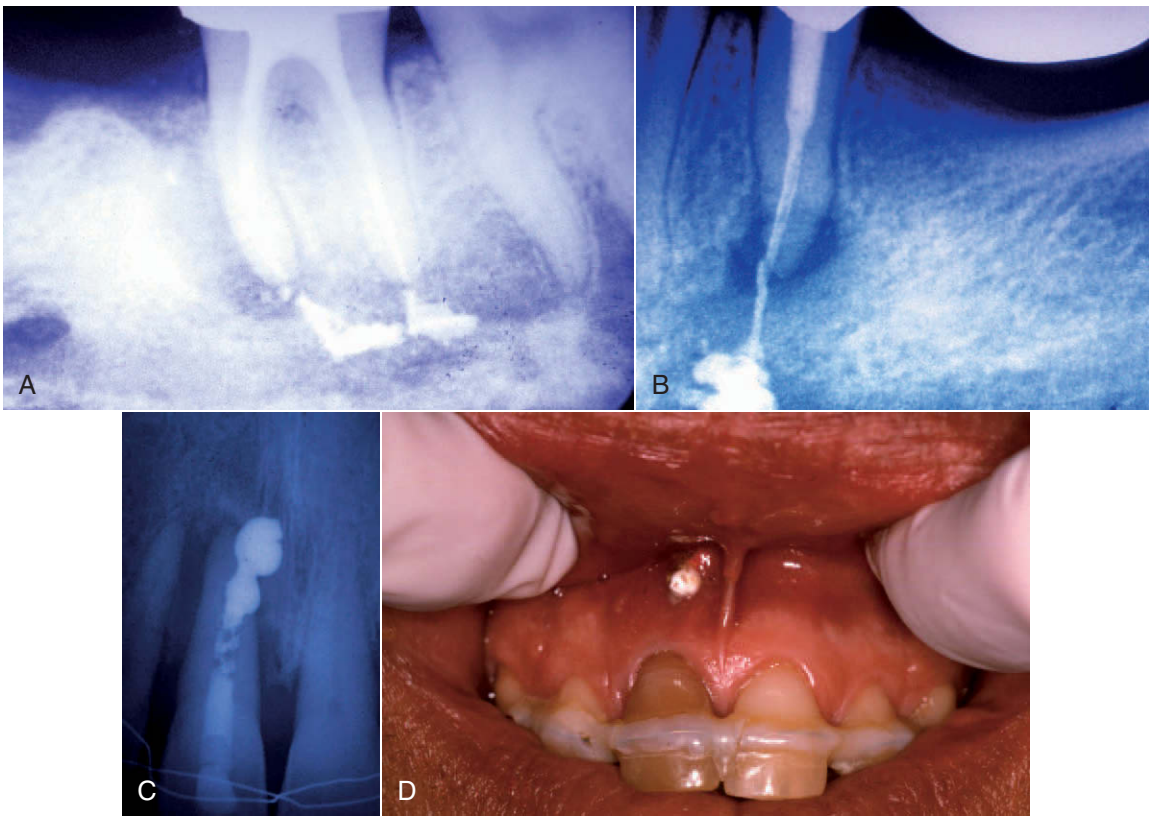

FIG. 25-41 Example of poor length control with paste root fillings. **A,** Overextended paste filling into the inferior alveolar canal. **B,** Overextended paste filling into the mental foramen. **C,** Overextended paste filling extending through a perforation in an upper central incisor. **D,** Clinical appearance of the case in part **C.** Note the material extending out through a sinus tract.

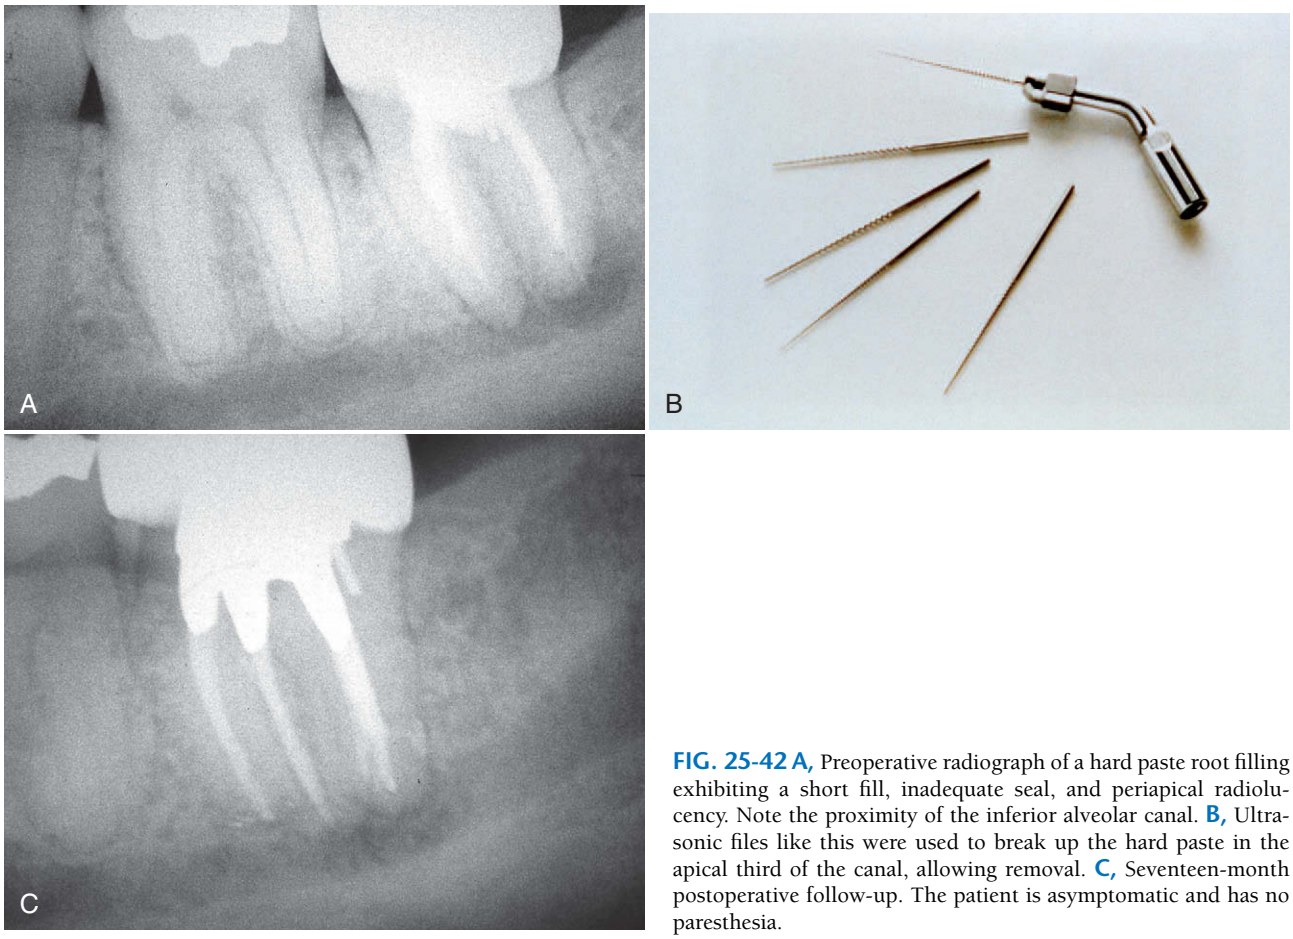

FIG. 25-42 A, Preoperative radiograph of a hard paste root filling exhibiting a short fill, inadequate seal, and periapical radiolucency. Note the proximity of the inferior alveolar canal. **B,** Ultrasonic files like this were used to break up the hard paste in the apical third of the canal, allowing removal. **C,** Seventeen-month postoperative follow-up. The patient is asymptomatic and has no paresthesia.

Great care should be exercised when removing the paste to avoid overextension, potentially severe postoperative pain,[73] and possible paresthesia/dysesthesia from the paste's potential neurotoxicity.[25,183] Soft pastes are generally easy to remove using crown-down instrumentation with copious sodium hypochlorite irrigation to minimize extrusion.[75] Greater difficulty arises when the paste is set hard.[176] Since the nature of the paste remains unknown, removing it becomes an empirical process. Following access preparation and coronal orifice exposure, the paste is probed with an endodontic explorer and files. If hard and impenetrable, then the coronal paste can be removed with burs[58] or a straight, tapered ultrasonic tip in the easily accessible straight portions of the canal, using magnification and illumination.[163] Once the canal curvature is reached, further use of this method will result in damage to the canal walls and possible perforation. Precurved small hand files are inserted to probe the apical area. Many times the density of the paste filling material decreases in the apical extent of the fill, so penetration to the apex may be possible.[163] If not, a solvent must be used to attempt to soften the remaining paste. The choice of solvent is usually made by trial and error, starting with chloroform. If that does not soften the material in a reasonable amount of time and does not allow penetration with small files, then the chloroform is wicked out of the canal and another solvent is chosen. There are two frequently used solvents for paste fills: Endosolv-E and Endosolv-R (Septodont, Kent, UK) (see Fig. 25-35). The Endosolv-E is selected if the paste contains zinc oxide and eugenol, and the Endosolv-R is chosen for resin-based pastes. The obvious problem is that the nature of the paste is usually unknown at the time of removal, so contacting the previous clinician (if possible) can help with this choice. Otherwise, the choice is just a guess. The chosen solvent should be placed in the access, and attempts should be made to penetrate the paste with hand or ultrasonic files. Care must be taken to avoid creating a ledge or other defect in the canal that may preclude successful retreatment. The progress is frequently slow,[61] and the clinician may elect to leave some solvent in the canals between appointments to soften the paste.[164] Care should be taken in the choice of temporary restoration, since the solvent left in the canal may also soften the temporary, potentially leading to breakdown of the interappointment seal.[135]

Ultrasonically activated files have been advocated for use in penetrating hard-set pastes in the curved apical segments of canals[101,109] (Fig. 25-42). The ultrasonic energy breaks up the paste, and the irrigation floats the fragments in a coronal direction until the apical terminus is reached.[58] This technique is reported to be very time consuming, and care must be exercised to avoid instrument separation, perforations, or alteration of canal morphology. On occasion, despite all best efforts, the paste cannot be removed from the tooth, so apical surgery or extraction should be considered in these cases.[73]

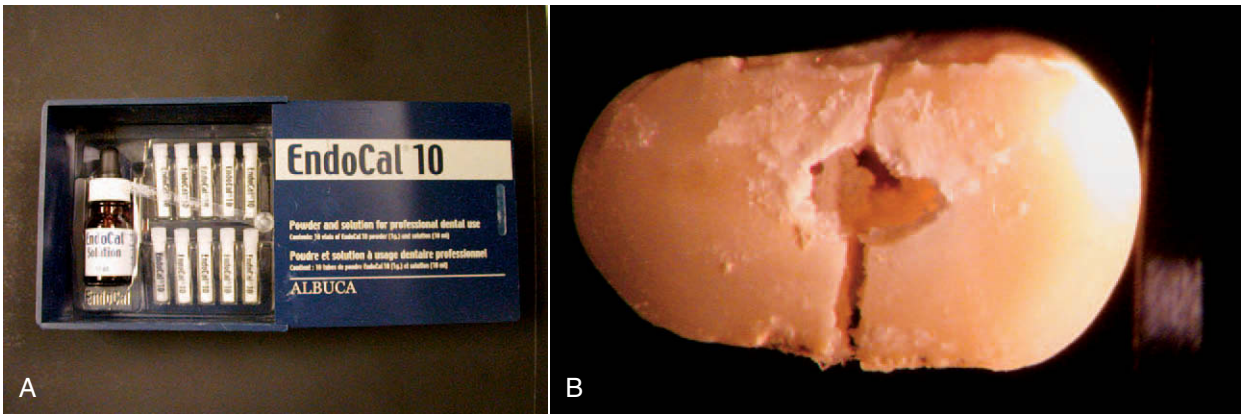

FIG. 25-43 A, Endocal 10 (formerly Biocalyx [Albuca Inc, Montreal, Canada]). **B,** Split root in a case filled with Endocal 10. *(Courtesy Dr. Rob Goldberg.)*

Biocalex 6.9 (currently known as Endocal 10) (Fig. 25-43) is a hard-setting calcium oxide paste that has been popular in Europe for over 30 years but is now being used in North America since its recent FDA approval.[69] The paste seems to seal well, but there is an unacceptably high incidence of root fracture due to the large amount of expansion on setting.[69] Retreatment will be complicated by the hard-setting nature of this material, but since it is a calcium oxide paste, ethylenediamine tetra-acetic acid (EDTA) may soften it, facilitating its removal. Because EDTA also softens dentin, care must be taken not to gouge or ledge the canal walls during retreatment, and root fractures must be suspected as a potential complicating factor in the outcome.

Silver Point Removal

Historically, the use of silver points for endodontic therapy has been extremely popular and quite successful because of their ease of handling and placement, ductility, radiopacity, and because silver appears to have some antibacterial activity.[178] However, over the past few decades, the usage of silver points has dramatically diminished. Presently they are considered a deviation from the standard of care. The main reason for this change is because they corrode over time (Fig. 25-44), and the apical seal may be lost.[23] Also, silver points do not produce an acceptable three-dimensional seal of the canal system; rather, they simply produce a plug in the apical constriction while not sealing the accessory canals that are frequently present[123,174] (Fig. 25-45). The corrosion of silver points occurs when they come into contact with tissue fluids and certain chemicals used in endodontics, including sodium hypochlorite and some sealers.[74] This corrosion produces chemicals such as silver sulfide, silver sulfate, silver carbonate, and silver amine hydrate,[181] which have been shown to be cytotoxic in tissue culture.[178] Corrosion occurs mainly at the apical and coronal portions of the points, indicating that leakage is responsible.[181] Gutta-percha root-filling techniques do not suffer from these disadvantages and have replaced the use of silver points in endodontics. Owing to this decrease in usage over the past quarter century, the quantity of cases the clinician will come across that will require silver point removal has also decreased. Nevertheless, there are still occasions when their removal will be necessary.

Many of the same techniques described for removing separated instruments in the following section apply to the removal of silver points. Silver points have a minimal taper, are smooth-sided, and corrosion may loosen the cone within the preparation. Therefore, the clinician should encounter a much easier time removing them than would be the case with separated instruments, which may be mechanically engaged into canals. Silver point canal preparation techniques produced a milled, round preparation in the apical 2 to 3 mm of the canal. Coronal to that, the clinician will frequently find space between the round silver point and the flared canal walls that can usually be negotiated with hand files, facilitating point removal.[163]

The first step in removal of silver points is to establish proper access. Frequently, the coronal portion of the cone is embedded in the core material. This material must be carefully removed with burs and ultrasonics, taking care to not remove any of the silver point within the access cavity preparation. The more of the silver point the clinician has to work with, the more predictable will be its removal. Once proper access is established, the clinician should flood the access preparation with a solvent such as chloroform to soften or dissolve the cement, enabling easier removal. An endodontic explorer or small file may be used to carry the solvent down along the silver point to dissolve as much of the cement as possible. The chamber can be rinsed and dried, and this step may be repeated, since fresh solvent enhances the efficiency of cement removal. At this point, the easiest technique, which is also very predictable, is to grasp the exposed end of the silver point with a Stieglitz pliers (Henry Schein, Melville, NY) (see Fig. 25-37) or other appropriate forceps and gently pull it out of the access cavity preparation. If too much extraction force is needed, the point may separate, so slow force application is advised. The clinician will need a variety of sizes and angles of forceps available to deal with the variety of cases that will need to be treated. Occasionally, the forceps may not get a good purchase on the silver cone and will slip off. In these instances, gripping the cone with the forceps and then gripping the forceps in a hemostat or needle driver to increase the squeezing force of the forceps will allow removal of the cone[75] (Fig. 25-46). If the silver point is held tight by the frictional fit in the preparation, indirect ultrasonics may be employed to loosen it. The silver point is retained in a pair of forceps, and

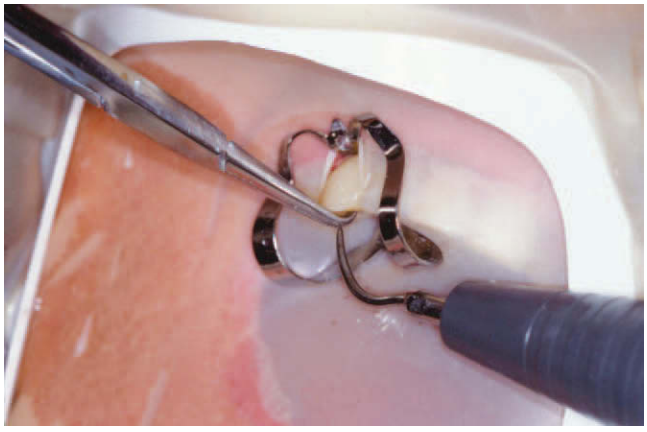

FIG. 25-47 Application of indirect ultrasonic energy to a silver point by placing the ultrasonic tip against forceps that are holding the silver point.

ultrasonic energy is applied to the forceps, not the point (Fig. 25-47). This transmits energy down the cone and may loosen it. If there is not much of the silver point exposed in the chamber, the clinician can attempt to remove it using the Caufield silver point retrievers (Miltex Inc. York, PA). This instrument is a spoon with a groove in the tip (Fig. 25-48) that can engage the exposed end of the silver point so it may be elevated from the canal or possibly elevated to the point where it may be grasped by forceps.[75] The Caufield silver point retrievers are available in three sizes: 25, 35, and 50.

If the silver point cannot be dislodged by the forgoing techniques, the clinician should consider using Hedstrom files to remove the silver point. The Hedstrom file technique requires at least some coronal length of canal space around the silver point to be negotiated first.[122] The sealer is dissolved as previously mentioned, then files are negotiated as far apically as possible in two to three areas around the silver point. If only one space can be negotiated, this technique may still be effective. The spaces surrounding the silver point are carefully instrumented to size 15, and small Hedstrom files are gently screwed in as far as possible apically. To prevent breakage, they should not be screwed in too tightly. The flute design of the Hedstrom file allows for much better engagement into the silver point, compared to other file designs. The files are then twisted together and pulled out through the access (Fig. 25-49). If the first attempt fails, this technique may be repeated, possibly using larger Hedstrom files. If this technique does not completely remove the silver point from the canal, it may still be dislodged to the point where it can be grasped by forceps and removed.

If the clinician needs to expose more of the silver point to enable removal, the use of trephine burs and microtubes or ultrasonics may be necessary.[58] Trephine burs are used in the same manner as described for separated instrument removal; however, the clinician must be more careful when using ultrasonic instruments for retrieval of silver points. When using ultrasonics for post removal or separated instrument removal, the tip of the ultrasonic instrument can be placed at the interface between the obstruction and the canal wall. Although applying ultrasonic energy directly to a post or file may prove beneficial in vibrating them loose, silver points are much softer. If ultrasonic instruments are applied directly to them, the portion in contact may be shredded, leaving a smaller segment to work with because elemental silver rapidly erodes during mechanical manipulation.[163] The ultrasonic instrument is used on tooth structure circumferentially around the silver point. This is a very delicate process requiring a microscope or other powerful source of magnification. The energy supplied by the careful use of the ultrasonic instrument can safely expose silver points as well as break up the cement around them.

In many cases, a silver point may have been sectioned deep in the canal to allow post space preparation. In these cases, where the most coronal portion of the silver point is well below the orifice, the use of Gates-Glidden burs to obtain straight-line access to the most coronal extent of the point may be necessary. The burs should be used in a brushlike manner, cutting on the outstroke while applying gentle pressure in an anticurvature direction to decrease the risk of root perforation. Following this, techniques that involve the use of an end-cutting trephine bur to remove tooth structure around the

point and then use of an extraction device to remove it may be employed (Fig. 25-50). There are many kits that use these principals with slight variations from one another, including the Endo Extractor (Brasseler),[198] the Masserann Kit (Medidenta International, Woodside, NY), and the Extractor System (Roydent, Troy, MI) (Fig. 25-51). Additional techniques that are effective for removing silver points include the S.I.R. (Separated Instrument Retrieval) System (Vista Dental Products, Racine, WI), the use of a dental injection needle with a 0.14-mm wire, the use of stainless steel tubing with a Hedstrom file,[163] and the Instrument Removal System (DENTSPLY Tulsa Dental, Tulsa, OK).

These kits are not only effective in the removal of silver points but also in the removal of separated instruments. Because of this common approach to removing both during endodontic retreatment, these techniques will be discussed in detail in the following section on separated instrument removal.

After the silver point is removed, it is very important that subsequent instrumentation procedures be performed in a crown-down manner to minimize extrusion of the silver corrosion products into the periradicular tissues to decrease the occurrence of painful acute flare-ups. This goal is complicated by the fact that ledges are frequently encountered at the level of the apical extent of the silver point as a result of the type of milled preparation that was frequently used in this technique. Managing ledges will be discussed in a following section of this chapter.

Occasionally the apical portion of a silver point will separate upon the removal attempt. If it cannot be bypassed or removed, the case should be completed and followed carefully (Fig. 25-52). Apical surgery or extraction could be necessary in the future (Fig. 25-53).

Removal of Separated Instruments

Causes of Instrument Separation

Occasionally during nonsurgical root canal therapy, an instrument will separate in a canal system, blocking access to the apical canal terminus. This instrument is usually some type of file or reamer but can include Gates-Glidden or Peeso Drills, lentulo spiral paste fillers, thermomechanical gutta-percha compactors, or the tips of hand instruments such as explorers or gutta-percha spreaders. During retreatment, it may be obvious after completing the diagnostic phase that there is a separated instrument in the canal system, or it may only become apparent after removal of the root filling materials (Fig. 25-54). It is useful to expose a check radiograph after removal of the root filling to see if there is any metallic

obstruction in the canal. Regardless of which type of instruments the clinician uses, whether stainless steel or nickel-titanium, and how they are used, by hand or engine driven, the potential for separation exists. The incidence of hand instrument separation has been reported to be 0.25%[98]; for rotary instruments, it ranges from 1.68% to 2.4%.[98,237]

The most common causes for file separation are improper use, limitations in physical properties, inadequate access, root canal anatomy, and possibly manufacturing defects.

A very common cause for instrument separation is improper use. Included in this are overuse or not discarding an instrument and replacing it with a new one when needed. The following is a list of guidelines for when to discard and replace instruments.[75]

1. Flaws, such as shiny areas or unwinding, are detected on the flutes.
2. Excessive use has caused instrument bending or crimping (common with smaller-sized instruments). A major concern with nickel-titanium instruments is that they tend to fracture without warning; as a result, constant monitoring of usage is critical.
3. Excessive bending or precurving has been necessary.
4. Accidental bending occurs during file usage.
5. The file kinks instead of curving.
6. Corrosion is noted on the instrument.
7. Compacting instruments have defective tips or have been excessively heated.[75]

Another type of improper use is to apply too much apical pressure during instrumentation,[218] especially when using rotary nickel-titanium files. This pressure can lead to deflection of the instrument within the canal system or increased frictional binding against the canal walls that can overstress the metal, resulting in separation. Regardless of which type of files the clinician uses, they should never use them in a dry canal, because attempting to instrument a dry canal will cause excessive frictional stresses on an instrument.[218] Continual lubrication of the canal with either irrigating solutions or lubricants is required.[75] This will reduce the frictional resistance as well as increase the efficiency of the instrument. All files have flutes that have the ability to build up with dentin shavings, which will decrease the efficiency of the instrument, leading to greater frictional forces and ultimately separation.

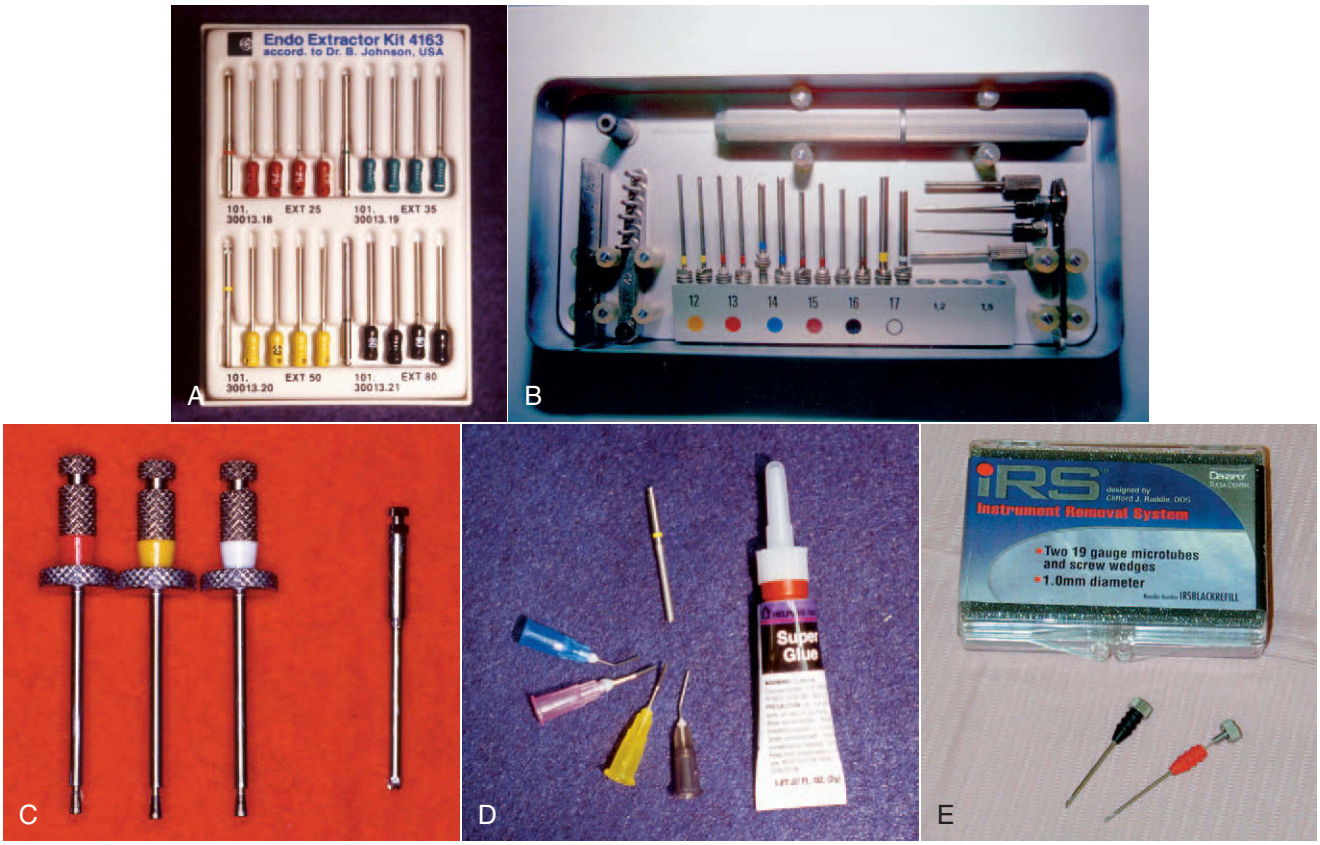

FIG. 25-51 A, Brasseler Endo Extractor kit (Brasseler USA, Savannah, GA). **B,** Masserann kit (MICRO-MEGA Dentalvertrieb GmbH & Co. KG, Germany). **C,** Roydent Extractor System (Roydent Dental Products, Johnson City, TN). **D,** Separated Instrument Retrieval System (SIR) (Vista Dental Products, Racine, WI). **E,** Instrument Removal System (IRS) (DENTSPLY Tulsa Dental, Tulsa, OK). (***B** Courtesy Dr. Daniel Erickson.*)

Therefore, files should be periodically removed and cleaned during the instrumentation process.

Inadequate access cavity preparations can lead to many problems, one of which is excessive or unnecessary force applied to the instrument if it is not allowed to enter the canal freely without interference from the access cavity walls. If the file is in contact with the access cavity wall during instrumentation, the chance for separation is greatly increased. Inadequately enlarged access preparations also increase the number and severity of curvatures the file must negotiate. This under prepared access can lead to the creation of an iatrogenic S curve that can overstress the instrument. This situation is especially hazardous when using rotary instrumentation, since traversing an S curve greatly stresses the rotating file, leading to separation (Fig. 25-55).

Anatomy, such as abrupt curvatures or anatomic ledges, increases the likelihood of instrument fracture. When the file's progress is hindered, it is quite natural to try to force it further. This approach will rarely result in the file advancing along the naturally occurring path and indeed may result in file separation, perforation, or ledge creation.

Some clinicians would like to blame instrument separation on manufacturing defects; however, this has never been shown to be of clinical relevance and is quite rare.[218]

The best treatment for the separated instrument is prevention. If proper techniques for cleaning and shaping of the root canal system are followed, file separation should be an infrequent occurrence. Nevertheless, an occasional event may take place. When instrument separation occurs, a radiograph should be taken immediately.[218] This radiograph will not only confirm the separation, it will give the clinician information that may aid in removal, such as location, size of the file segment, root canal anatomy, and ultimately the possibility of removal. The patient should be advised of the accident and its effect on the prognosis.[36] In addition, when a file separates, as with other procedural accidents, detailed documentation is necessary for medicolegal considerations,[218] and the remaining segment of the file should not be discarded but placed in a coin envelope and kept in the patients record.[36]

Prognosis

A separated instrument does not necessarily mean surgery or loss of the tooth. Actually, the prognosis may not be reduced at all, depending on what stage of instrumentation the separation occurs, the preoperative status of the pulp and periradicular tissues, and whether or not the file can be removed or bypassed.[197] The presence of a separated instrument in the canal in itself does not predispose the case to posttreatment disease. Rather, it is the presence of any necrotic, infected pulp tissue that remains in the apical canal space that determines the prognosis. The outcome is better if the canal was instrumented to the later stages of preparation when the separation

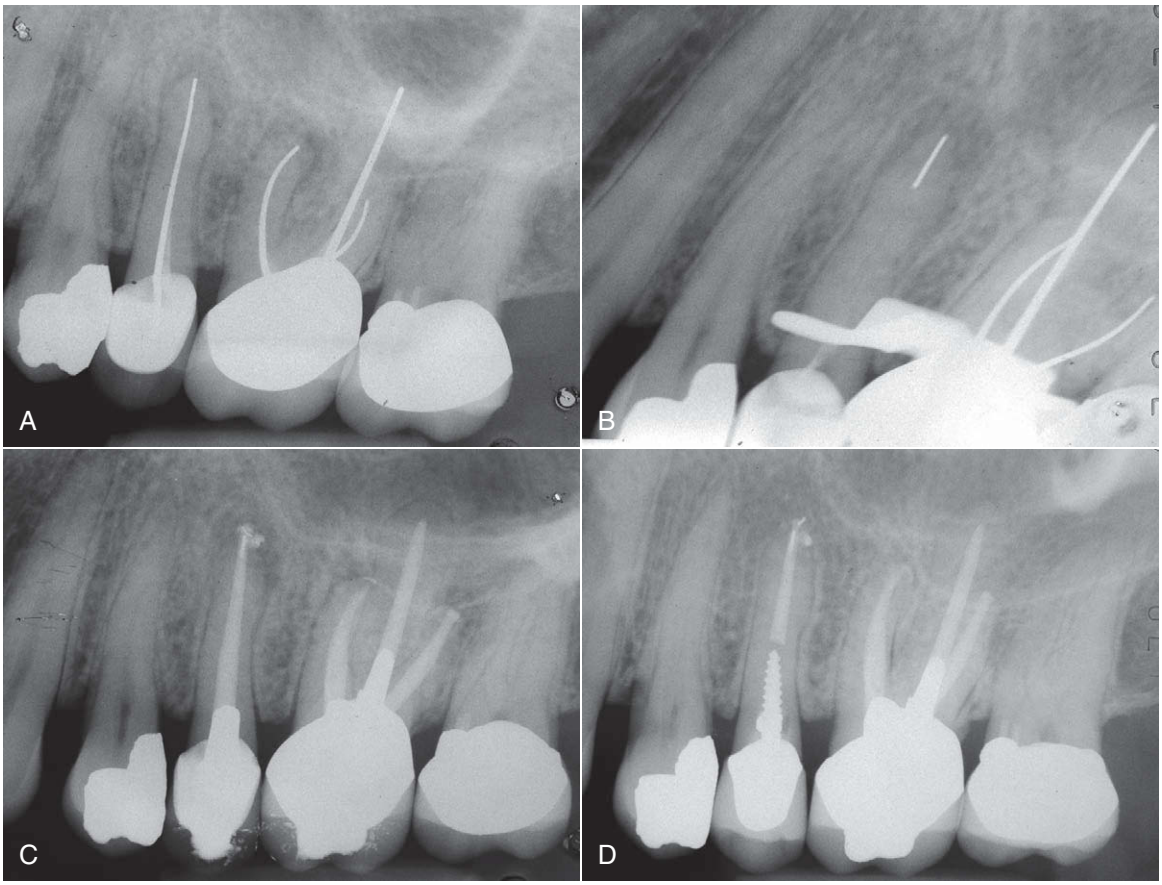

FIG. 25-52 Case illustrating healing despite inability to remove a separated silver point. **A,** Preoperative radiograph showing persistent disease in an upper premolar and molar. **B,** Working film showing the separated cone that could not be retrieved despite extensive clinical efforts. **C,** Final obturation after two-appointment procedure using a calcium hydroxide interappointment medicament. **D,** Four-year follow-up showing apical healing.

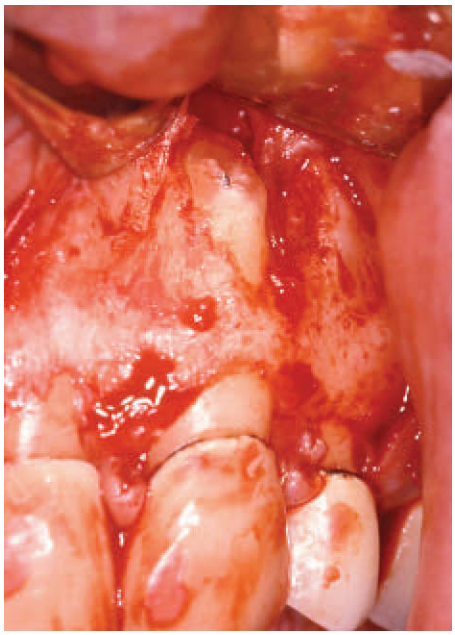

FIG. 25-53 If silver point retreatment is unsuccessful, apical surgery may be needed. Note the silver point visible on the resected root end. If the point cannot be pulled out in a retrograde direction, ultrasonic root-end preparation may be complicated by its presence; root-end preparation using rotary burs may be necessary.

occurs.[218] If the preoperative pulp was vital and uninfected (irreversible pulpitis, for example), and there was no apical periodontitis, the presence of the separated instrument should not affect the prognosis.[37] If the file can be removed without excessive overenlargement of the canal or causing an additional iatrogenic mishap such as a perforation, the prognosis will not be affected. Bypassing the instrument and incorporating it into the obturation should also have no affect on the prognosis. However, if the instrument cannot be removed or bypassed in a tooth with a necrotic infected pulp and apical periodontitis, the prognosis will be uncertain. These cases should be followed closely. If symptoms persist, apical surgery or extraction should be considered.[218,240]

The potential to remove a separated instrument depends on many factors that should be considered during the diagnostic workup. The location of the separated instrument is of critical importance. If the separated instrument extends into the straight coronal portion of the canal, retrieval is likely, but if the instrument has separated deep in the canal and the entire broken segment is apical to the canal curvature, orthograde removal will not be possible, and attempts to do so could lead to a much higher rate of iatrogenic complication.[184,195] If there is persistent disease and the file cannot be bypassed safely, either apical surgery or extraction will be necessary. Because of the need to enlarge the coronal radicular access, root cur-

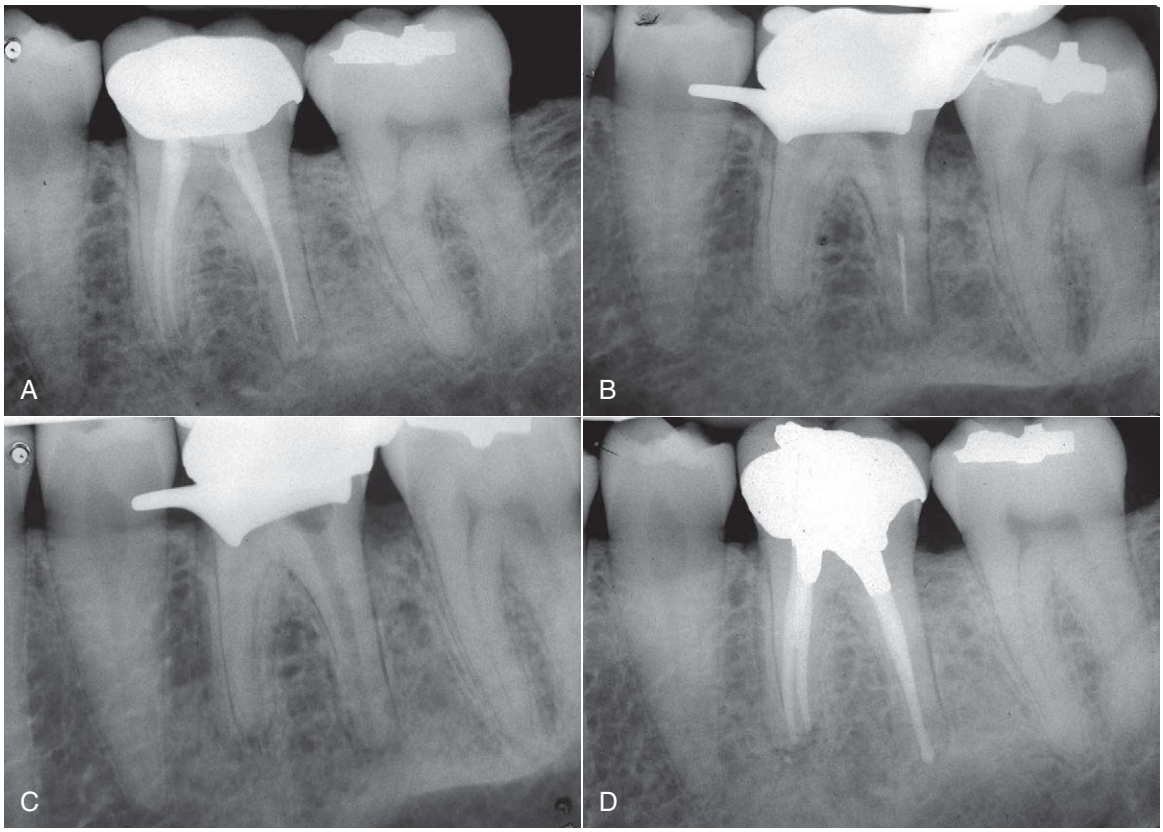

FIG. 25-54 A, Preoperative radiograph of a tooth with symptomatic posttreatment disease. **B,** Although not readily apparent on the preoperative film, there is a separated nickel-titanium instrument in the distal canal. **C,** Check film showing that ultrasonics has removed the separated file. **D,** Thirteen-month recall film. The patient was asymptomatic.

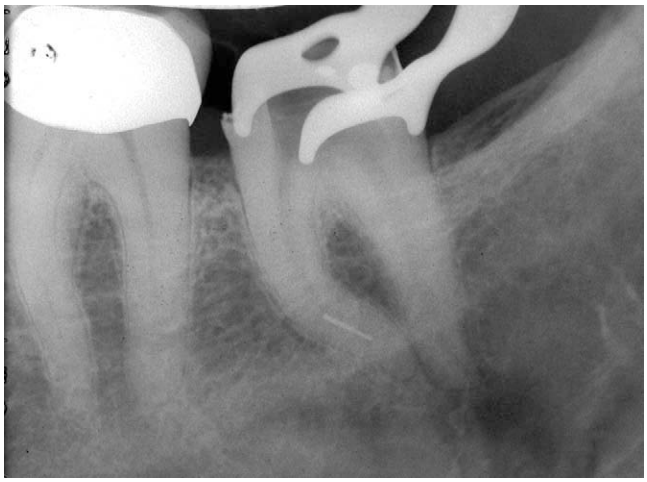

FIG. 25-55 Complicated canal anatomy can increase stress on rotary instruments, leading to separation such as in this S-shaped canal.

vatures, external root concavities, and root thickness all will be important factors to consider when deciding which treatment option will provide the best chance of long-term success. Teeth with thin roots and deep external root concavities have a greater likelihood of being perforated during the coronal radicular access, so surgery should be considered as an alternative to orthograde instrument retrieval. The type of material the separated instrument is made of will affect the chances of removal. Nickel-titanium files tend to shatter when ultrasonic energy is applied to them, hindering removal, whereas stainless steel instruments are more robust and more easily removed with ultrasonics.[163]

Removal Techniques

Many different instruments and techniques will be discussed in this section, all of which are important to include in the armamentarium for separated instrument removal. None, however, is more important than the operating microscope (Fig. 25-56). This instrument will not only increase visibility by the use of magnification and light, it will also increase the efficiency and safety of almost all of the techniques to be discussed. The use of a headlamp and magnifying loupes will help with the removal of many canal impediments, but the enhanced lighting and magnification the operating microscope offers has caused a quantum leap in visualization.[107] Many of the techniques to be described should not even be attempted without the use of this valuable tool.[205]

Once the patient has been advised of the treatment options and the decision has been made to attempt removal, the clinician's first choice in treatment will be based on the location of the instrument. If the file is clinically visible in the coronal access and can be grasped with an instrument such as a hemostat or Stieglitz Pliers (Henry Schein, Melville, NY) (see

Fig. 25-37), these should be used to obtain a firm hold of the file and extract it out through the access cavity preparation. Many different sizes and angles of forceps are available, and almost all are necessary in order to have the ability to remove obstructions from the many different angles and levels of accessibility presented to the clinician. These will work well if the object is loose fitting within the canal and if the clinician has good access. However, establishing a firm purchase can sometimes be difficult without removing excessive tooth structure. Once a purchase onto the file has been achieved, it is best to pull it from the canal with a slight counterclockwise action. This action will unscrew the flutes that are engaged in the dentin as the file is being removed. This is the easiest technique for removal of a separated file. Unfortunately, many files separate at a point where these forceps cannot be used.

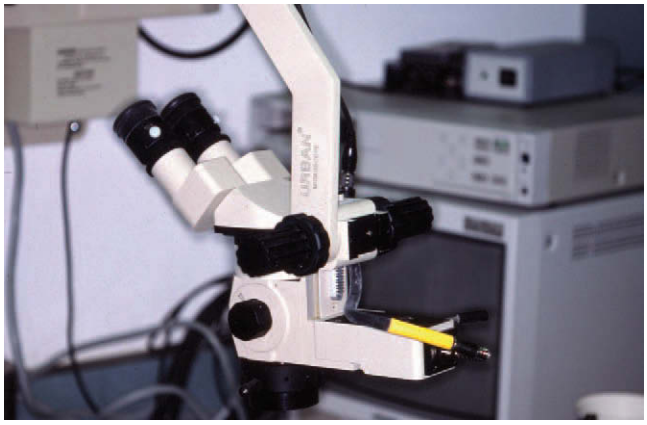

FIG. 25-56 The surgical operating microscope is not only invaluable in helping to remove separated instruments, it is in fact a necessary tool for these procedures.

Frequently a file will separate at a point deeper in the canal where visibility is difficult. To remove separated root canal instruments predictably, the clinician must create straight-line coronal radicular access. Either removing the crown or creating a large access cavity preparation establishes adequate coronal access to allow the use of the appropriate instruments. Straight-line radicular access can be created with the use of modified Gates-Glidden drills. These drills may be ground down or sectioned with a bur at their maximum cross-sectional diameter. This process will create a circumferential staging platform to facilitate ultrasonic use (Fig. 25-57).[163] A recent study showed that use of a similarly modified Lightspeed nickel-titanium rotary instrument (Lightspeed Technology Inc, San Antonio, TX) created a staging platform that was more centered in curved canals than the Gates-Glidden drills.[99]

Ultrasonic instruments have been shown to be very effective for the removal of canal obstructions.[33,138,163] The ultrasonic tip is placed on the staging platform between the exposed end of the file and the canal wall and is vibrated around the obstruction in a counterclockwise direction that applies an unscrewing force to the file as it is being vibrated. This technique will help with removing instruments that have a clockwise cutting action. If the file had a counterclockwise cutting

The tip has been ground off to the maximum diameter of the cutting head. **D,** Staging platform created in the straight coronal section of the canal. Note the enhanced visibility and the triangular cross-section of this rotary instrument.

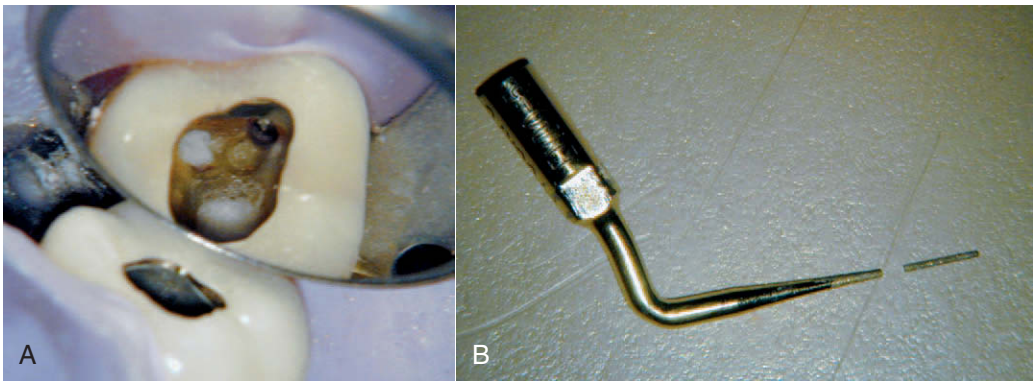

FIG. 25-58 A, Cotton pellets protecting the orifices of the other canals when ultrasonic obstruction removal is needed. **B,** Ultrasonic tip separated during excavation around separated instrument. If the adjacent canals were not protected, further unnecessary complication could result.

action (such as the hand GT files), then a clockwise rotation will be needed. The energy applied will aid in loosening the file, and occasionally the file will appear to jump out of the canal. It is prudent to cover the orifices of the adjacent open canals with cotton or paper points to prevent the removed file fragment from falling into them, causing further case complication[163] (Fig. 25-58). There are many different sizes and angles of ultrasonic tips available for this purpose, but in general the deeper in the canal the obstruction is, the longer and thinner an ultrasonic tip must be. It should be remembered that long, thin tips must be used on very low power settings to prevent tip breakage (Fig. 25-59). Occasionally, if the separated instrument can be bypassed, the use of ultrasonic files can loosen it. Care must be taken, however, to avoid ultrasonic file separation or root perforation.[87] As mentioned previously, nickel-titanium instruments often break up into fragments when subjected to the energy supplied by an ultrasonic instrument. The clinician may be tempted to use this information to their advantage by applying the tip of the ultrasonic directly onto nickel-titanium files. Although this method may work, the chance of pushing the separated file further into the canal or beyond the apical foramen may increase the risk of this technique.

If the direct application of ultrasonic energy does not loosen the separated instrument sufficiently to remove it, the fragment must be grabbed and retrieved. This is accomplished with a variety of techniques, most using some variant of a microtube. The staging platform is further reduced by ultrasonics until enough of the separated instrument is exposed to retrieve (about 2 to 3 mm).[163] This reduction must be done carefully to avoid root perforation. One relatively simple microtube technique is to use a short piece of stainless steel tubing that is pushed over the exposed end of the object. A small Hedstrom file is then pushed between the tube and the end of the object, using a clockwise turning motion that produces a good mechanical lock between the separated instrument, the tube, and the Hedstrom file. The three connected objects can then be removed by pulling them in a coronal direction[204] (Fig. 25-60).

Another technique is to use a 25-gauge dental injection needle along with a 0.14-mm diameter steel ligature wire. The needle is cut to remove both the beveled end and the opposite end so it no longer extends beyond the hub. Both ends of the wire are then passed through the needle from the injection end until they slide out of the hub end, creating a wire loop that extends from the injection end of the needle. Once the loop has passed around the object to be retrieved, a small hemostat is used to pull the wire loop up and tighten it around the obstruction, then the complete assembly is withdrawn from the canal.[161] Occasionally, a larger diameter tube and thinner 0.11-mm ligature wire will facilitate assembly of this extractor (Fig. 25-61).

Another effective technique, especially in cases where access or obtaining an adequate purchase on the file is difficult, is to use an end-cutting trephine bur to remove tooth structure around the file and then use an extraction device to remove it. There are many kits that use these principles with slight variations from one another, including the Endo Extractor (Brasseler USA Inc), the Masserann Kit (Medidenta International Inc), and the Extractor System (Roydent Dental Products) (see Fig. 25-51).

The Endo Extractor kit includes a cyanoacrylate adhesive which is used to bond a hollow tube to the exposed end of the file for removal. This kit also includes four sizes of trephine burs and extractors. The most important factor in using this kit is the snugness of fit between the extractor tube and the obstruction. It has been shown that even with only 1 mm of overlap between the extractor tube and the obstruction, if there is a snug fit, the bond created with the cyanoacrylate may be strong enough to remove many obstructions. However, the recommended amount of overlap between the tube and the obstruction is 2 millimeters. The time needed for the adhesive to set to ensure adequate bond strength for removal is 5 minutes for a snug fit and 10 minutes for a loose fit.[65,198] One disadvantage of this instrument is that the trephine burs are much larger than their ISO equivalents, so the manufacturer has also added a separate smaller trephine bur that is sold separately from the kit. This bur corresponds better with the smaller extractors and removes less dentin, which can decrease the likelihood of weakening the root and the risk of fracture.[52] Another disadvantage is that the burs cut very aggressively when new but dull rather quickly. When new, their aggressive cutting may lead to perforation or even separation of the obstruction, so great care is needed when using this instrument (Fig. 25-62). Once the separated instrument has been removed, the extractors may be reused, either by using the debonding agent included in the kit to remove the embedded instrument from

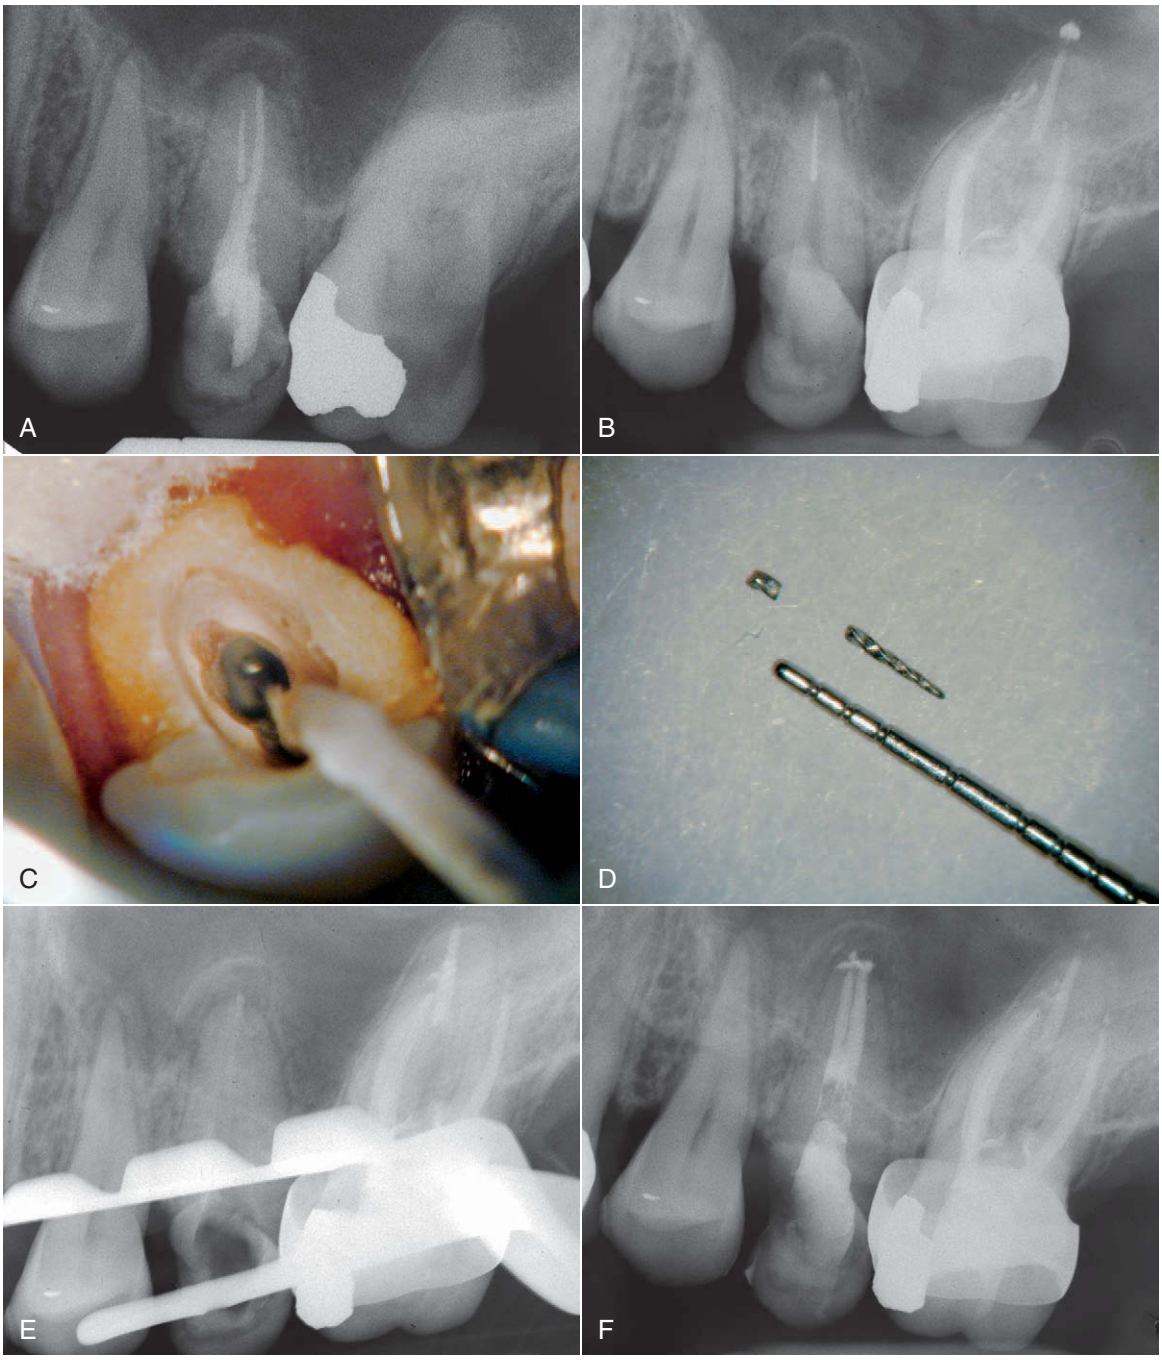

FIG. 25-59 A, Preoperative radiograph showing a separated file in the palatal canal, potential coronal leakage, and apical periodontitis. **B,** Check film showing the separated instrument after gutta-percha removal. **C,** Photograph showing the separated instrument in the palatal canal and a paper point in the buccal canal to protect it. **D,** Separated nickel-titanium file removed. the extractor tube or by simply cutting the extraction device with a bur beyond the extent that the separated instrument has penetrated.

The Masserann technique has also been recommended for the removal of separated instruments.[131] This technique is similar to the Endo Extractor in that it uses trephine burs and a specific extraction device. This kit comes with a very convenient gauge that aids in predicting the size of the bur and the extractor to be used, and it contains many different sizes of trephine burs. In addition, the trephine burs with this kit cut in a counterclockwise direction that provides an unscrewing force on separated files. The extraction mandrels have an internal stylus that wedges the file against the internal wall of the mandrel, allowing the obstruction to be removed. Although effective, this technique may require removal of an excessive amount of radicular dentin,[58] leading to root weakening and

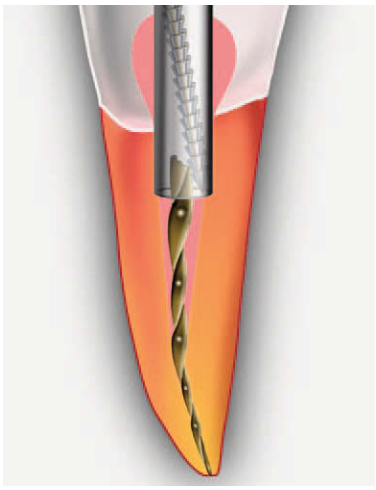

FIG. 25-60 Tube and Hedstrom file removal technique. The tube is slipped over the obstruction, and a Hedstrom file is gently screwed into the space between the tube and the obstruction. Pulling the tube and Hedstrom file together can withdraw the obstruction. *(Diagram courtesy DENTSPLY Tulsa Dental, Tulsa, OK.)*

the risk of perforation[241]; therefore, this instrument must be used with caution.

The Extractor System from Roydent comes with only one bur and three extraction devices. The bur is very conservative and removes a minimal amount of tooth structure, enabling access to the obstruction. The extractor tubes are also quite small and will only work for the removal of small obstructions. The extractor surrounds the obstruction with six prongs that can be tightened onto the object, enabling removal. This works in the same way a drill chuck tightens onto a drill bit (Fig. 25-63). The disadvantages of this kit are the lack of variety of instruments, the possibility of separating the obstruction with the bur, and the potential problem of breakage of the prongs in the extractor if they are submitted to bending rather than applying strict tensile force during removal.

Two techniques have been designed specifically for removing instruments in conjunction with the operating microscope: the Cancellier instrument and the Mounce extractor (SybronEndo) (Fig. 25-64). The Cancellier instrument works in a very similar manner to the Brasseler Endo Extractor

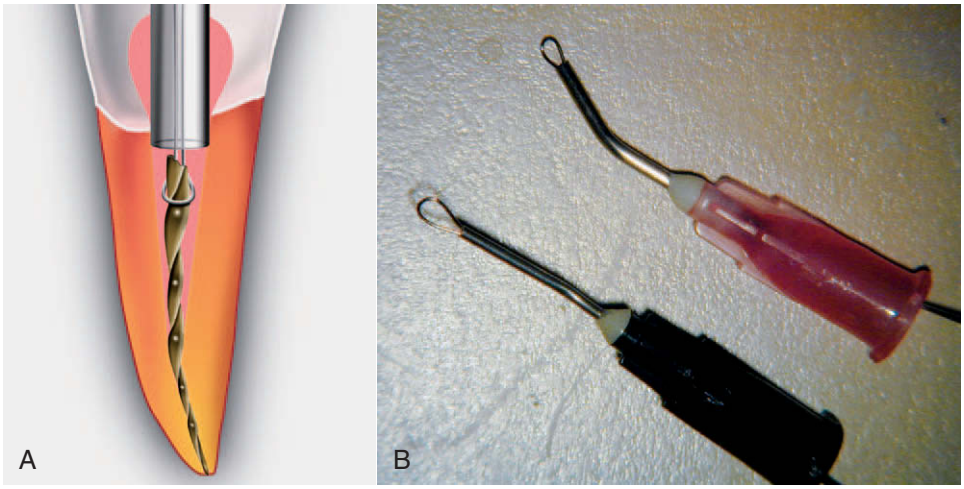

FIG. 25-61 A, Diagram illustrating the wire-loop-and-tube method of obstruction removal. The wire loop is carefully placed around the obstruction, tightened, then removed. **B,** Larger-diameter tubes and smaller-diameter 0.11 mm ligature wire enhances the efficiency of this technique. *(**A** Courtesy DENTSPLY Tulsa Dental, Tulsa, OK.)*

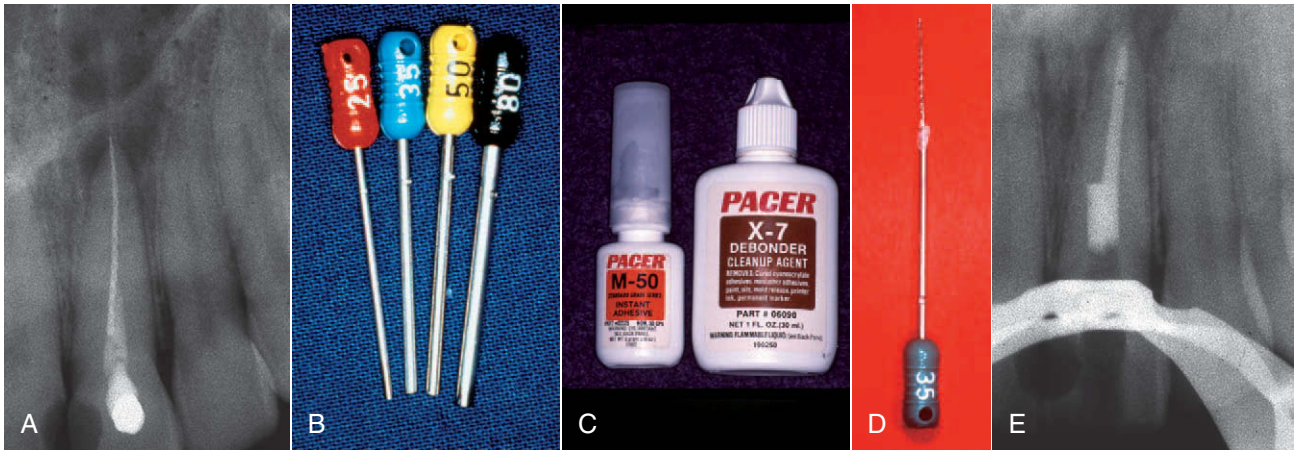

FIG. 25-62 A, Separated file wedged into an upper incisor. **B,** Brasseler Endo Extractor tubes. **C,** Cyanoacrylate cement and debonding agent. **D,** Separated file pulled out by the bonded tube. **E,** Final obturation. Note the excessive amount of tooth structure removal by the trephine bur that was needed to bond the tube.

in that they are used in conjunction with cyanoacrylate adhesive to bond onto the separated end of the instrument. Unlike the Brasseler extractors, the Cancellier extractors are attached to a handle that enables them to be used without blocking visibility when using the operating microscope. The Brasseler extractors are finger instruments that interfere with the line of sight the microscope requires. There are no trephine burs in the Cancellier kit; rather, it is used in conjunction with ultrasonic exposure of the separated instrument. There are four sizes of extractor tubes available, each of which corresponds to specific file sizes. The Mounce extractors are also hand instruments that enable usage with the operating microscope. These instruments are similar to a ball burnisher with slots cut into the ball end. These slots are cut at various angles and are designed to slide onto the broken end of the file. Cyanoacrylate is used to bond the extractor to the file, allowing removal. This instrument can be used when the separated file is lying against the canal wall, but the ball tip is relatively large and is only useful in retrieving instruments that are in the most accessible coronal portion of the canal.

FIG. 25-63 Close-up view of the Roydent Extractor tip. The tip is placed over the separated instrument and tightened to grasp the obstruction.

Another device designed specifically for the purpose of separated file removal is the Instrument Removal System (DENTSPLY Tulsa Dental, Tulsa, OK) (see Fig. 25-51). This kit consists of two different sizes of extraction devices that are tubes with a 45-degree bevel on the end and a side cutout window. Each tube has a corresponding internal stylus or screw wedge. Prior to usage of this instrument, 2 to 3 mm of the obstruction is exposed by troughing around it with an ultrasonic instrument. Once the file is exposed, the appropriate size microtube is selected and slid into place over the obstruction. Once in place, the screw wedge is turned counterclockwise to engage and displace the head of the obstruction through

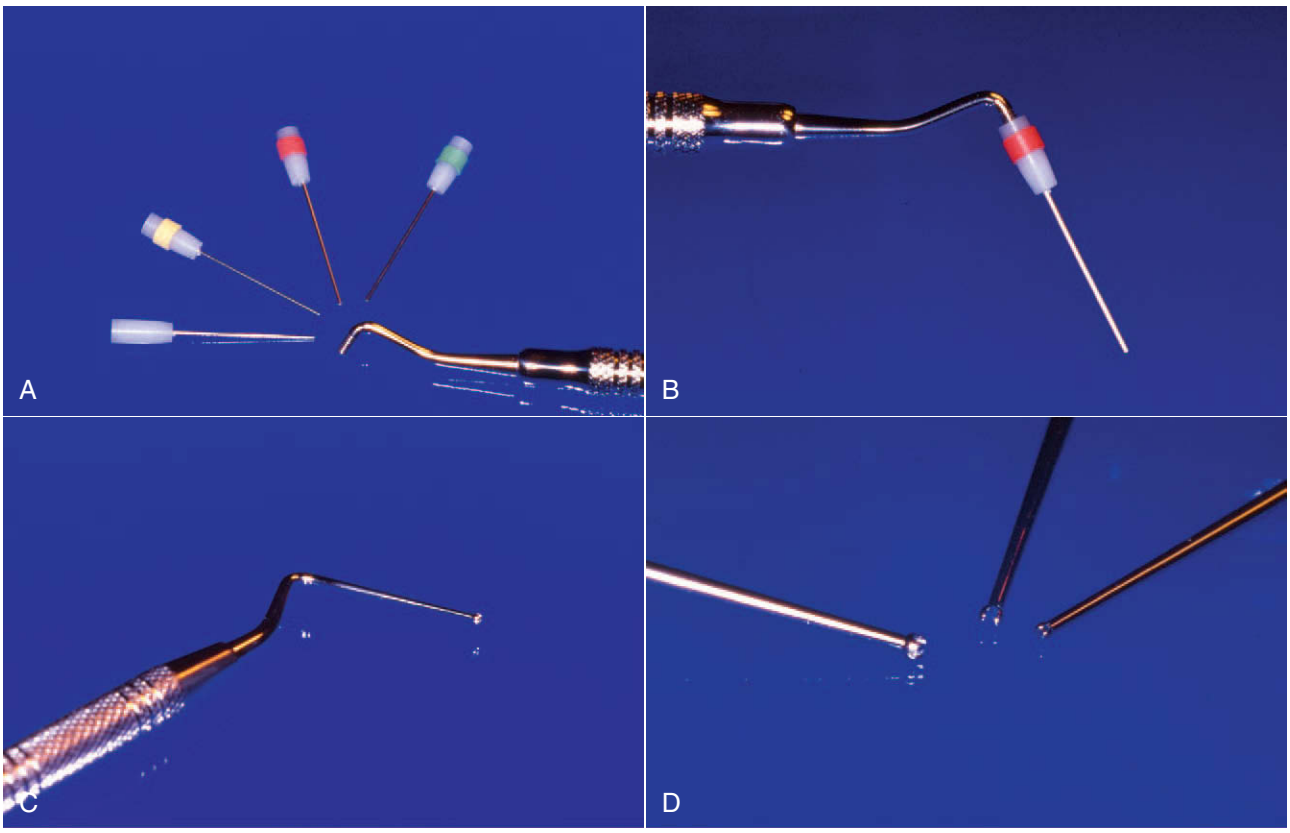

FIG. 25-64 A, The Cancellier Kit (SybronEndo, Orange, CA) with four tube sizes available. **B,** The Cancellier instrument is used with superglue to bond the obstruction, but its design allows for greater visibility during use. **C,** The Mounce instrument. **D,** Varying tip sizes for the Mounce instrument.

the side window. The assembly is then removed.[163] This instrument is very useful in the straight portion of the canal, but it is difficult to force large-diameter separated files through the cutout window, hampering their removal (Fig. 25-65).

The S.I.R. (Separated Instrument Retrieval) System (Vista Dental Products) (see Fig. 25-51) is another microtube method of separated instrument retrieval. Like the Cancellier instrument, it utilizes extractor tubes bonded onto an obstruction, enabling removal. Once the obstruction is exposed using ultrasonics or the trephine burs from one of the other kits described, the bendable dead-soft tubes are bonded onto it. Once the adhesive is set, the obstruction is removed through the access cavity preparation. Included in this kit are the necessary bonding agent, a bottle of accelerator, five different sizes of tubes, assorted fulcrum props, and a hemostat. The accelerator causes the bonding agent to set almost instantaneously. The ability to bend these tubes allows for access in most areas of the mouth. A hemostat allows the clinician to establish a firm purchase onto the tube, creating the ability to lever the bonded obstruction out of the canal. A vinyl autoclavable instrument prop provides protection for the next most anterior tooth, which is to be used as a fulcrum. If the clinician has access to grasp the extractor with their fingers to remove the extractor/obstruction unit, the hemostat may not be necessary.

Heat Generation During Retreatment Procedures

There are many procedures in endodontic therapy that can generate heat, but perhaps the area with the greatest risk of heat-related tissue damage occurs during nonsurgical retreatment. Use of heat to soften canal filling materials to aid in their removal[115,121] and use of ultrasonics to dislodge posts[168] and separated instruments[81,126] can potentially generate enough heat to raise the temperature of the external root surface by 10° C or more. Temperature elevations of the periodontal ligament in excess of 10° C can cause damage to the attachment apparatus.[9,45,170,171]

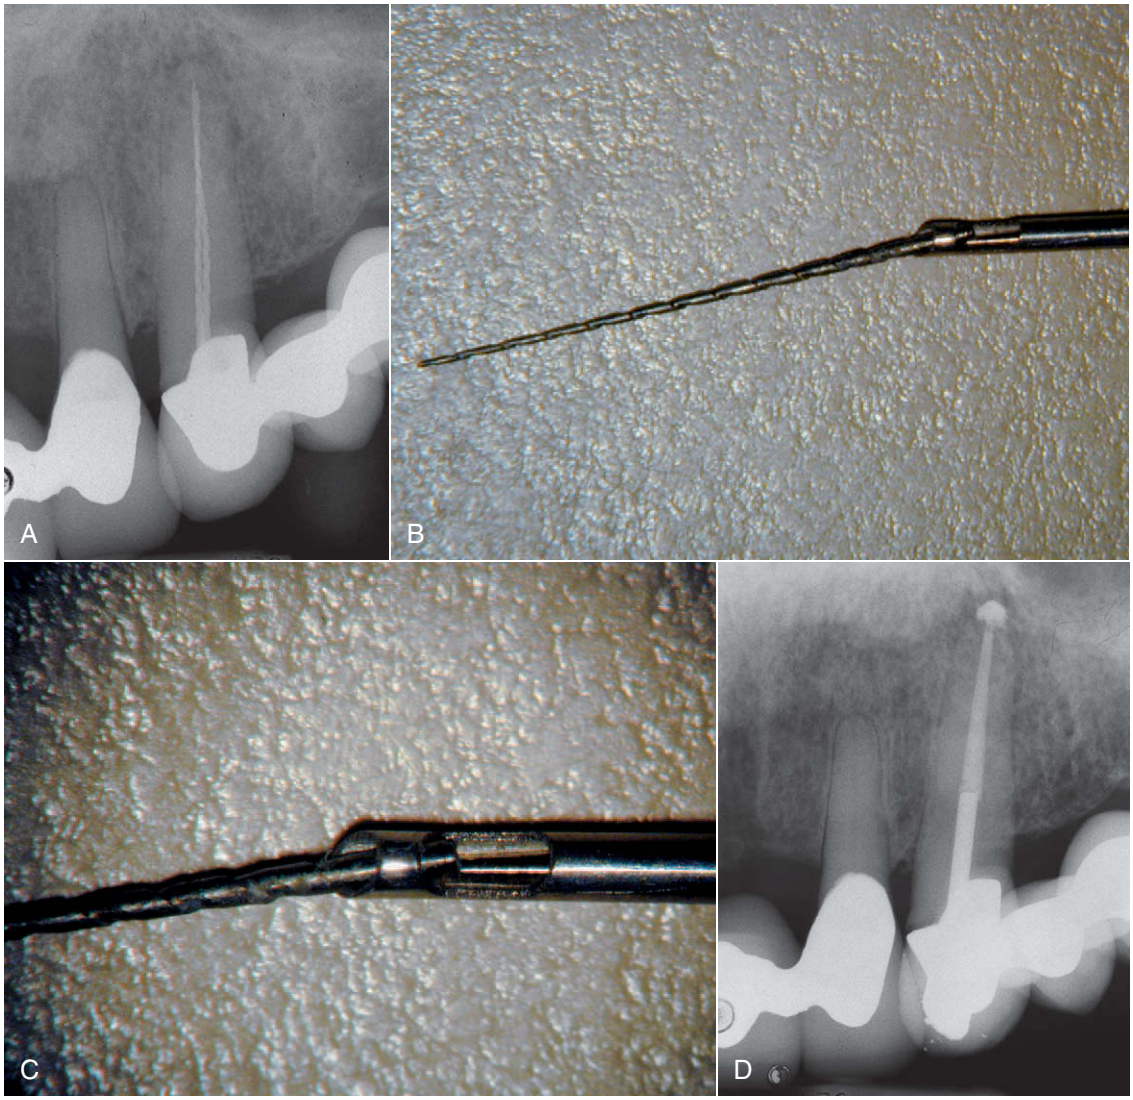

FIG. 25-65 A, Preoperative radiograph showing two separated instruments in one tooth. **B,** IRS instrument with a removed file. **C,** Note that large-size files are difficult to push through the cutout window. **D,** Postoperative radiograph.

The greatest danger of heat-related damage occurs with the use of ultrasonic energy to dislodge foreign objects in the canal space to gain access to the apical portion. As noted earlier, this has recently become an extremely important and useful part of the clinician's armamentarium because of the ability of ultrasonic energy application to conserve tooth structure while removing the obstruction. These instruments have allowed clinicians to perform predictable retreatment when surgery would have been previously indicated. As with most instruments used in dentistry, however, these devices must be used with caution. In vitro research and clinical case reports imply that they have the potential to damage the tooth attachment apparatus as a result of the heat generated during usage.[27,67,177] One in vitro study has showed that ultrasonic vibration for post removal without coolant can cause root surface temperature increases approaching 10° C in as little as 15 seconds.[41] Thermal damage to the periradicular tissues may be so serious as to result in both tooth loss and permanent bone loss (see Fig. 25-26). This is not to say that ultrasound energy should be avoided for the removal of canal obstructions, since it is many times the only way to reach the apical area of the canal.

The factors that may contribute to a heat-induced injury are the length of the post, post diameter, post material, and type of luting cement. Studies to establish heat-reduction protocols based on these variables are needed. Some have proposed that the dentin thickness between the outer surface of the post and the root surface may affect root surface temperature rise,[68,96] and one study showed this.[168] However, a more recent study has shown that the dentin thickness is statistically insignificant as a factor in root surface temperature rise.[86] One possible mitigating factor would be the effect of the periradicular blood supply, which could act as a heat sink, dissipating the generated thermal energy and helping to prevent injury. This may be why the effect of seemingly similar conditions of ultrasonic application can have such differing results on different patients. Clearly, more in vivo research is needed in this area.

It has become accepted that the heat-induced damage to periradicular tissues during the use of ultrasound energy for post removal is time dependent.[27,91] Studies have suggested that cooling the ultrasonic tips can greatly reduce heat buildup,[27,91] but this reduces the efficiency of debonding resin-bonded posts.[41,62] The amount of time the clinician can use these instruments safely is very difficult to determine; specific evidence-based protocols using in vivo research have yet to be established. The authors feel that any specific recommendations regarding rest intervals between usage of ultrasound energy, ways of monitoring heat buildup, or duration of consistent activation cannot be made based on the available research at the time of publication. However, the authors do feel strongly with regards to several recommendations for the use of ultrasound energy during the removal of canal obstructions, and they are as follows:

- Use ultrasonic tips with water ports whenever possible.
- If your ultrasound device does not have tips with water ports, have your assistant use a continuous coolant air/water spray during usage.[46]
- Take frequent breaks to let the tooth cool down.
- Avoid using the ultrasound on the high power setting.[46]

Prudent clinicians must take extreme care when applying ultrasound energy to a canal obstruction. It has been shown that even with the use of water coolant, root surfaces can increase in temperature rapidly.[41,168] Until evidence-based heat-reduction protocols are developed, caution when using instruments that can generate heat in the periodontal ligament is required.

Management of Canal Impediments

Following removal of all root-filling materials, further progress to the apical constriction may be prevented by the presence of a block or a ledge in the apical portion of the canal. Most of these impediments are iatrogenic mishaps resulting from vigorous instrumentation short of the appropriate working length and failure to confirm apical patency regularly during instrumentation. A blocked canal contains residual pulp tissue (sometimes necrotic, often fibrosed or calcified) and packed dentinal "mud" in the apical several millimeters of the canal system.[163] This debris is frequently infected, resulting in persistent disease, and must be removed if possible. A ledge is the result of placing non-precurved, end-cutting instruments into curved canals and filing with too much apical pressure.[75,100] It is a type of canal transportation that results in a canal irregularity on the outside of the canal curvature that is difficult or impossible to bypass. The canal space apical to the ledge is not thoroughly cleaned and sealed, so ledges frequently result in posttreatment disease. The best treatment for blocked and ledged canals, as with all iatrogenic problems, is prevention. If the clinician is careful and attentive during the instrumentation process, the chance for an impediment to develop is minimized. When the clinician becomes careless or hurried, problems occur. The reader is referred to Chapter 9 for strategies to prevent blocks and ledges. During the treatment planning phase, blocks and ledges may be detectible on radiographs as a root filling short of the ideal working length, and the patient should be warned that they might prove impenetrable and require future apical surgery or extraction.[57] This should not deter the clinician from choosing nonsurgical retreatment, however. In a recent study, 74% of teeth showing short root fillings were successfully negotiated to adequate length, with the authors stating that presence of a short fill should not be considered a technical contraindication to retreatment.[48] The clinical encounter usually occurs after removal of the previous root-filling material when apical advancement of small files is impeded. At this point, the clinician may be unaware of which type of impediment exists, but a common approach to management is helpful in the early stages of the process. The coronal portion of the canal should be enlarged to enhance tactile sensation and remove cervical and middle third obstructions in the canal space. The canal should be flooded with irrigant, and instrumentation to the level of the impediment should be accomplished using non–end-cutting rotary files, such as the Lightspeed (Lightspeed Technology), the Profile or GT instruments (DENTSPLY Limited), or the K-3 instrument (SybronEndo) in a crown-down manner. This procedure will enlarge and flare the canal space coronal to the impediment while minimizing the likelihood of worsening any ledge present.

At this point, the impediment should be gently probed with a precurved #8 or #10 file to determine if there are any "sticky" spots that could be the entrance to a blocked canal. A directional silicone stop should be used so the clinician knows in which direction the tip of the instrument is pointing, which helps in visualizing the three-dimensional layout of the canal

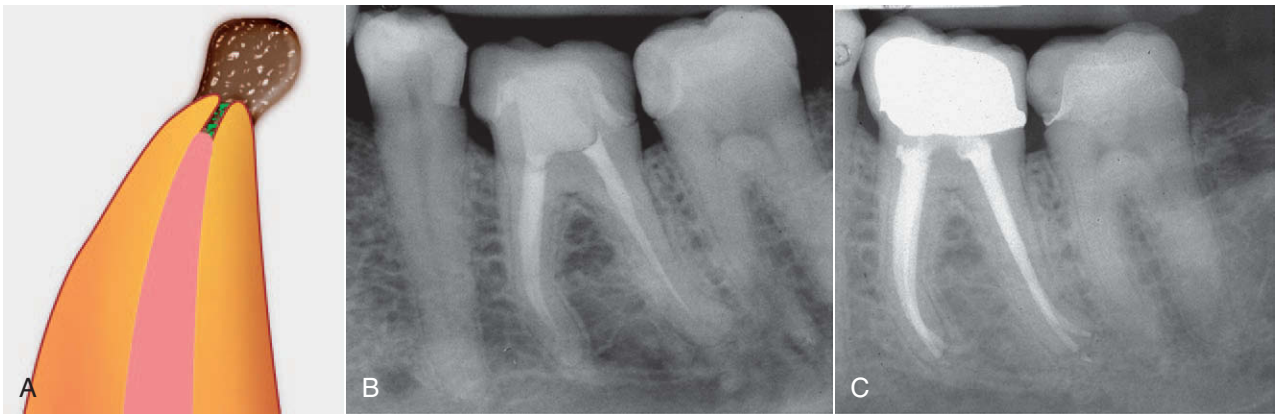

FIG. 25-66 A, Diagrammatic representation of a canal block. Fibrotic and/or calcified pulp and debris that is potentially infected remains in the apical segment of the canal when the canal is instrumented short of the apical constriction. **B,** Preoperative radiograph showing obturation short of ideal length. The patient was symptomatic, and the canals were blocked. **C,** Three months post treatment. Treatment took a total of 3.5 hours over three appointments because of the time-consuming nature of bypassing blocked canals. *(**A** Courtesy DENTSPLY Tulsa Dental, Tulsa, OK.)*

system. Frequently, evacuating the irrigant and using a lubricant such as RC Prep (Premier, Plymouth Meeting, PA) or Pro-Lube (DENTSPLY Tulsa Dental) will enhance the ability to place the small file into the apical canal segment. If repeated, gentle apical pressure or "pecking" of the hand file against the blockage results in some resistance when withdrawing the instrument on the outstroke ("stickiness"), the clinician should continue to peck at the sticky spot until further apical advancement is accomplished.[163] This is frequently a slow and tedious process. The endeavor can be made more efficient by using precurved stiff files such as the C+ file (DENTSPLY Maillefer), but there is a risk of deviating from the original canal path, creating a ledge, and ultimately a false canal leading to zip perforation.[75] It is prudent to make a working radiograph when some apical progress has been made to confirm the placement of the instrument into the suspected apical extent of the canal. The clinician should resist the urge to rotate the file excessively. If the tip of a small instrument is tightly bound in the blocked segment of the canal and the tip has been worked by pecking, it is prone to fracture in the apical area, further complicating the case.[163] The separated file tip is frequently irretrievable, and surgery or extraction may be the result. Dropping down to the next smaller size file and using a very gentle reciprocal rotational motion ("twiddling") will aid in advancement through the blocked canal. Frequently, as apical progress is being made, the clinician will be using an electronic apex locator to gauge the proximity of the apical constriction. Unfortunately, the apex locator is sometimes not able to give an accurate reading in a blocked canal, and because of the continued sticky feel that occurs even as the instrument bypasses the foramen and penetrates apical tissues, an overextension may result. To prevent this complication—with its attendant risk of a painful postoperative flare-up—when the estimated working length is reached, a working length radiograph is necessary.[129] Once apical working length is achieved, apical patency should be confirmed, and gentle, short-amplitude 1- to 2-mm push/pull strokes should be made until the file can pass freely to the apical constriction (Fig. 25-66).

If after a reasonable amount of time, no sticky spot can be found, the clinician must consider the possible presence of a

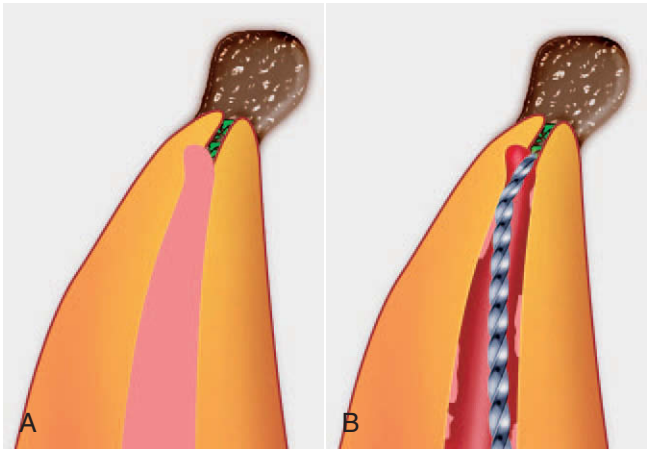

FIG. 25-67 A, Diagrammatic representation of a ledged canal. Potentially infected debris remaining in the apical segment can result in posttreatment disease. **B,** Attempting to bypass the ledge with a small file having a 45-degree bend in the tip. Note that the opening to the apical canal segment is on the inside of the canal curvature and coronal to the level of the ledge. *(**A** Courtesy DENTSPLY Tulsa Dental, Tulsa, OK.)*

ledge, despite possibly not detecting it on the preoperative radiograph. The main problem with ledges is that instruments will invariably find their way to the ledge, whereas finding the original canal is many times impossible. Ledges feel like a hard brick wall, short of length when encountered, and care must be used to prevent worsening them by indiscriminately burrowing into them.[218] To manage a ledge, the tip of a small #08 or #10 file has a small bend placed in it 1 to 2 mm from the end,[100,218] so the tip of the file forms an approximately 45-degree angle with the shaft of the instrument. The directional stop is oriented to the bend, and the file is carefully negotiated to the level of the ledge. Since ledges form mainly on the outside of curvatures, the directional stop (and thus the bent tip of the file) is turned in the direction of the suspected apical curvature away from the ledge (Fig. 25-67). The file tip is slowly scraped along the internal wall of the canal curve slightly coronal to

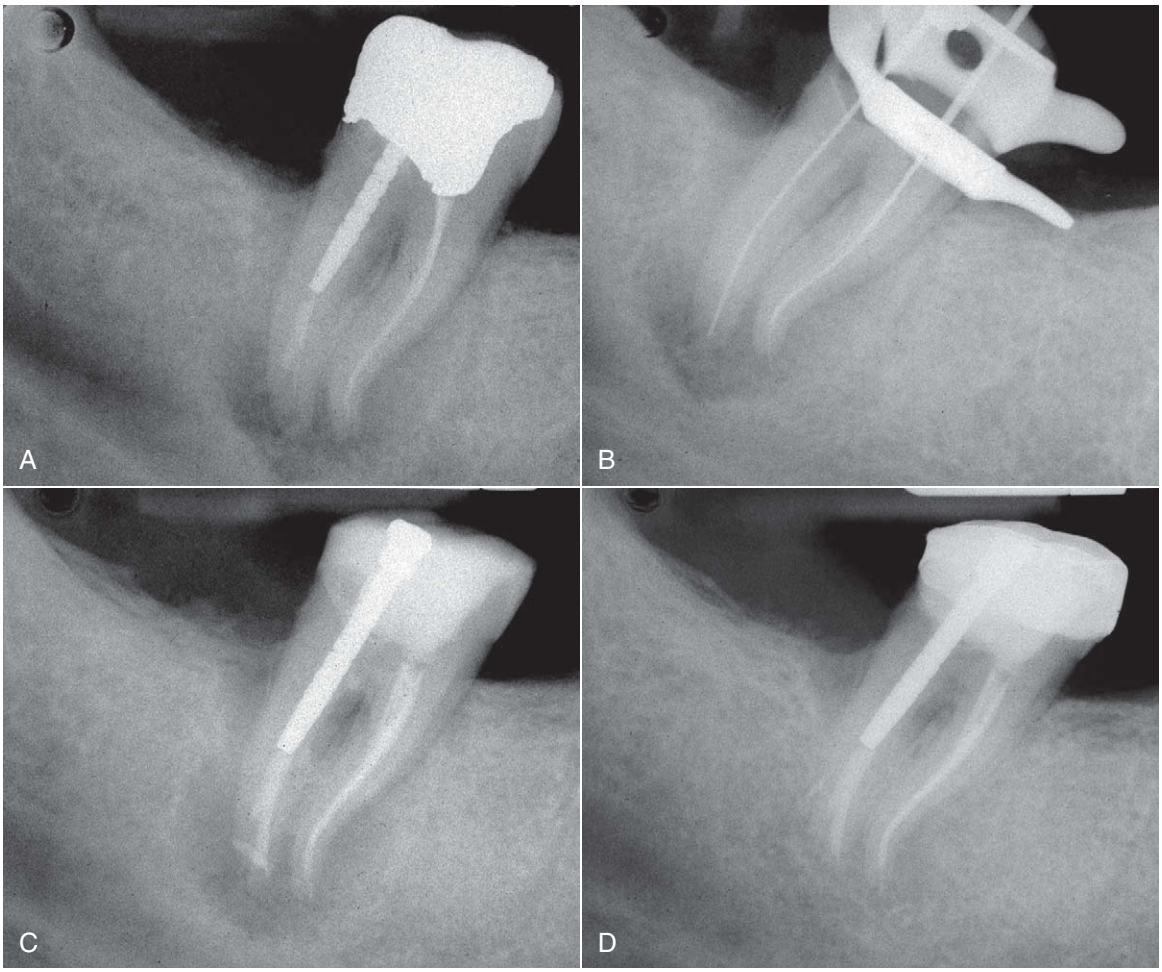

FIG. 25-68 A, Preoperative radiograph showing a distal canal ledge with a small amount of sealer that has entered the apical segment. The ledge prevented proper cleaning and sealing of the canal system, resulting in posttreatment disease. **B,** The ledge has been bypassed. The attempt is made to blend the ledge into the contour of the prepared canal wall. **C,** Final obturation showing the filled ledge and apical segment. **D,** Thirteen-month recall showing healing. The patient was then directed to have a definitive coronal restoration placed.

the level of the ledge,[218] looking for another sticky spot. This spot will be the entrance to the apical canal segment, and gentle reciprocal rotation will usually allow the file to be negotiated to the canal terminus. Confirm with a radiograph. Once the ledge has been bypassed, short-amplitude push/pull and rotational forces, keeping the file tip apical to the ledge, will be needed to clean and enlarge the apical canal space. When the file can be easily negotiated around the ledge, anticurvature filing will enable the clinician to blend the ledge into the canal preparation (Fig. 25-68). Many times this cannot be completely accomplished,[218] but so long as the apical segment can be cleaned and obturated, the prognosis should not be adversely affected.

The use of Greater Taper (GT) NiTi hand files (DENTSPLY Tulsa Dental) for the blending of ledges has been advocated.[163] The advantage these instruments have is that they are non–end cutting, and their rate of taper is two to six times that of conventional 0.02 tapered files, so they can do the work of multiple 0.02 tapered hand files. Once the ledge has been bypassed and the canal can be negotiated with a conventional size #15 or #20 K-file, a GT hand file is selected. The K-file creates a pilot hole so the tip of the GT file can passively follow this glide path beyond the ledge. The GT file must have a tip diameter of 0.2 mm (#20) and a taper that will vary depending on the requirements of the preparation. The largest taper that will enter the apical segment is used; however, these instruments must be precurved, which presents a challenge since they are made from nickel-titanium alloy. To precurve this superelastic shape-memory alloy, a file-bending tool such as the Endo Bender Pliers (SybronEndo) is needed. The pliers grasp the tip of the instrument, and the file is overcurved between 180 and 270 degrees to plastically deform the alloy. At this time, the appropriate tapered GT file is then carried into the canal, and the rubber stop is oriented so that the instrument's precurved working end can bypass and move apical to the ledge. The GT file is then worked to length, and the ledge is either reduced or eliminated (Fig. 25-69).

If the canal blockage or ledge cannot be negotiated, then the canal space coronal to the impediment should be cleaned, shaped, obturated, and coronally sealed. The patient must be informed of this complication, the guarded prognosis, and the need for regular reevaluation (Fig. 25-70). If symptoms of posttreatment disease arise subsequently, apical surgery or extraction will be needed.[163,218]

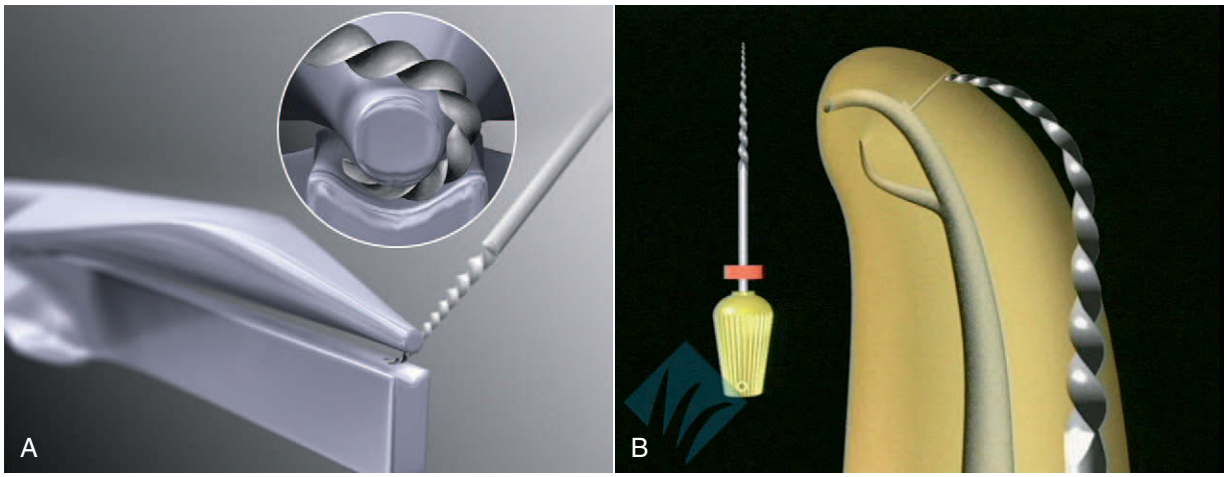

FIG. 25-69 A, Endobender Pliers (SybronEndo) used to over bend a nickel-titanium Hand GT file (DENTSPLY Tulsa Dental). **B,** GT hand file can hold a bend to allow it to bypass ledges. *(Courtesy Dr. Steve Buchanan.)*

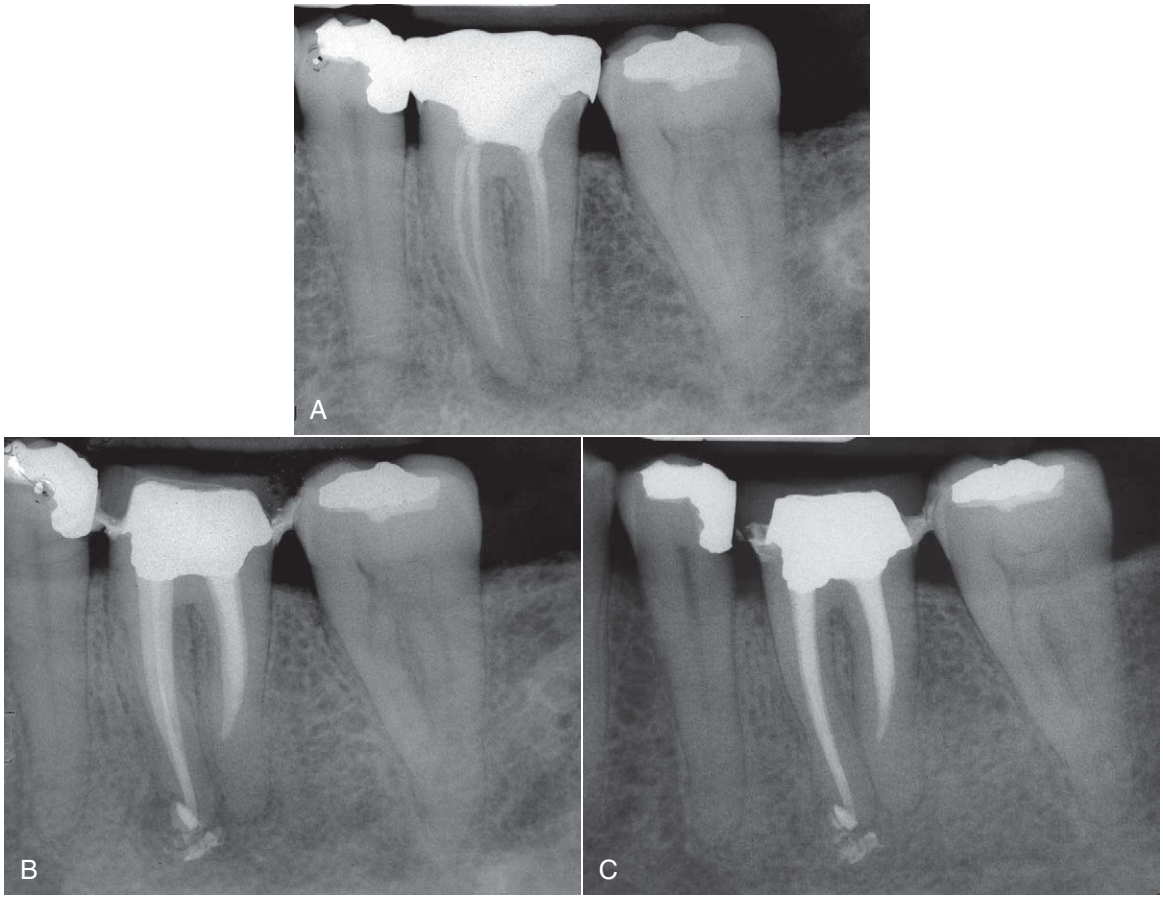

FIG. 25-70 A, Preoperative radiograph showing mesial canal blockages and potential distal root ledging with accompanying posttreatment disease. **B,** Final film showing mesial blockages bypassed but inability to negotiate beyond the distal ledge. The patient elected to pursue no further treatment at this time. **C,** One-year recall. Despite not achieving all the aims of conventional endodontic therapy, periradicular healing is apparent. The patient is asymptomatic and will now begin the final restoration with the knowledge that apical surgery may be needed in the future.

Finishing the Retreatment

After regaining the apical extent of the canal system, routine endodontic procedures are instituted to complete the retreatment. Any missed canals must be found using magnification, microexcavation techniques, and most importantly, the knowledge of canal anatomy that is discussed in another section of this text (Fig. 25-71). One cannot find a canal unless one suspects it is there. Cleaning and shaping procedures must focus on a crown-down approach to minimize extrusion of irritants into the periradicular tissues, and also must emphasize enlargement of the apical portion of the preparation to ensure complete removal of apical debris. These aims are best accomplished using technique hybridization during instrumentation, keeping the goals of the retreatment procedure in mind. These matters are covered in detail in Chapter 9.

Canal disinfection procedures are, however, paramount after the completion of cleaning and shaping. Since the primary cause of posttreatment disease is usually microbial,[140,218] and these microbes (i.e., *Enterococcus faecalis*) are frequently resistant to traditional canal disinfection regimes,[14] every effort must be made to eliminate these organisms from the canal system. This effort is complicated by the fact that no instrumentation regime can predictably remove the entire previous root filling from the canal space after retreatment.[10] This leaves areas where microbes can reside underneath fragments of root filling materials and remain protected from standard antimicrobial canal irrigants such as sodium hypochlorite. Whether the canal space can be adequately disinfected when completing treatment in one visit or whether an interappointment medicament such as calcium hydroxide is needed is still a matter of debate, and the reader is directed to the appropriate chapter of this text for details of the problem. It is important to keep in mind, however, that teeth that require retreatment also require the highest level of disinfection possible to ensure the most favorable outcome.

REPAIR OF PERFORATIONS

Occasionally, posttreatment endodontic disease will be the result of root perforation.[96] Root perforations are created pathologically by resorption and caries and iatrogenically

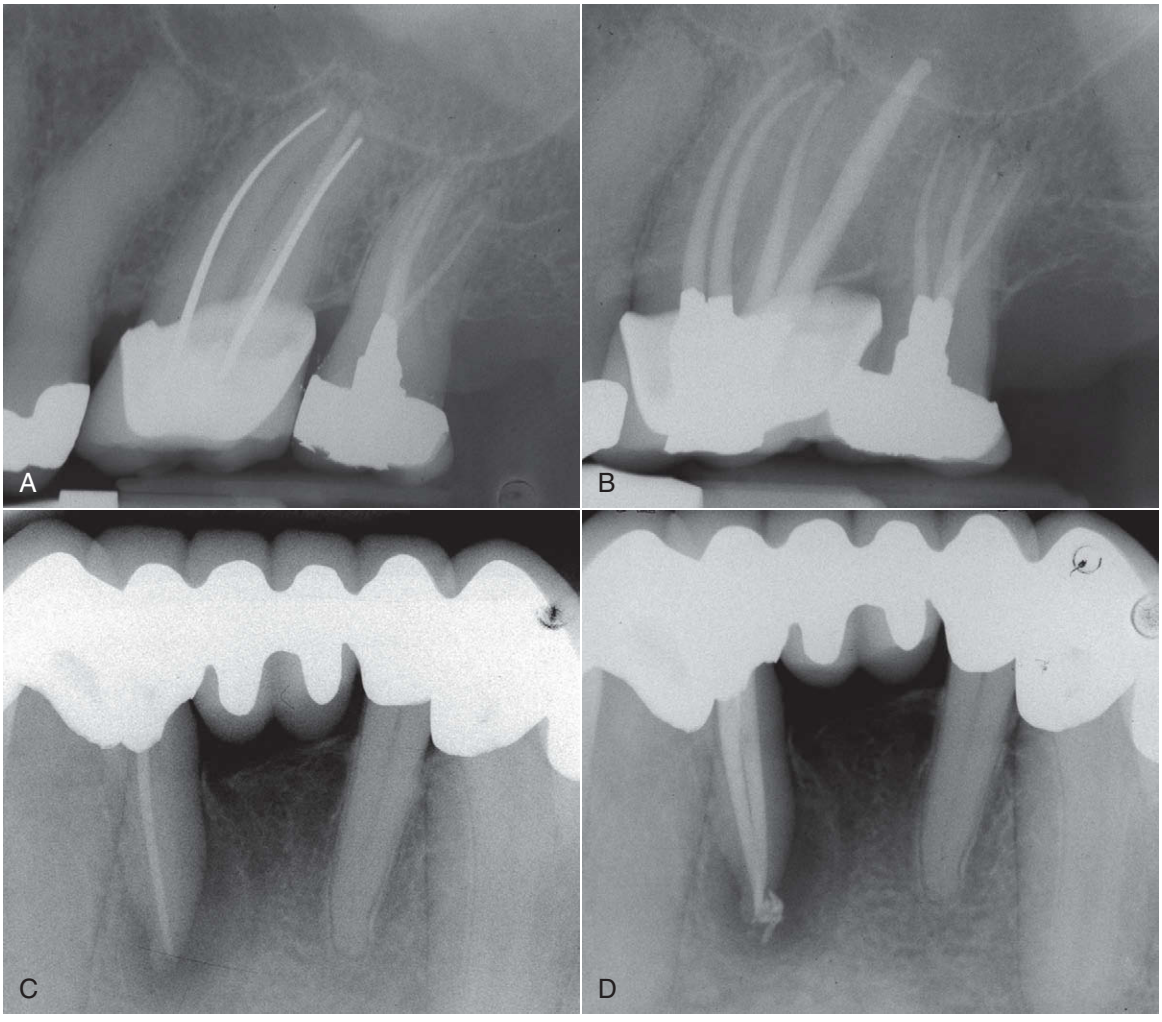

FIG. 25-71 Frequently missed canals that may result in posttreatment disease. **A,** Missed second mesiobuccal canal (MB2) in an upper molar. **B,** Final obturation showing cleaned, shaped, and filled MB2 canal. **C,** Missed lingual canal on a lower incisor results in posttreatment disease. **D,** Immediate postoperative film showing management of the missed canal.

during root canal therapy (zip, strip, and furcation perforations) or its aftermath (e.g., post preparation perforation)[160] (Fig. 25-72). When they are present, perforations may usually be found during the diagnostic phase as areas where the root filling materials, or possibly restorative materials such as posts, are found radiographically to have left the confines of the presumed canal space and approach or cross the radiographic interface between the dentin and the periodontal ligament. Angled radiographs are of paramount importance in determining whether a perforation exists and locating which surface or surfaces of the root have been perforated. This information is necessary when deciding upon treatment options. Frequently, cervical and occasionally midroot perforations are associated with epithelial downgrowth and subsequent periodontal defects, so thorough periodontal assessment is required[128,182] (Fig. 25-73). If there were no evidence of posttreatment disease associated with the defect or tooth, then no treatment would be indicated. If, however, there is evidence of periradicular periodontitis, repair may be instituted in one of two ways, either nonsurgically by approaching the defect internally through the tooth, or surgically by using an external approach

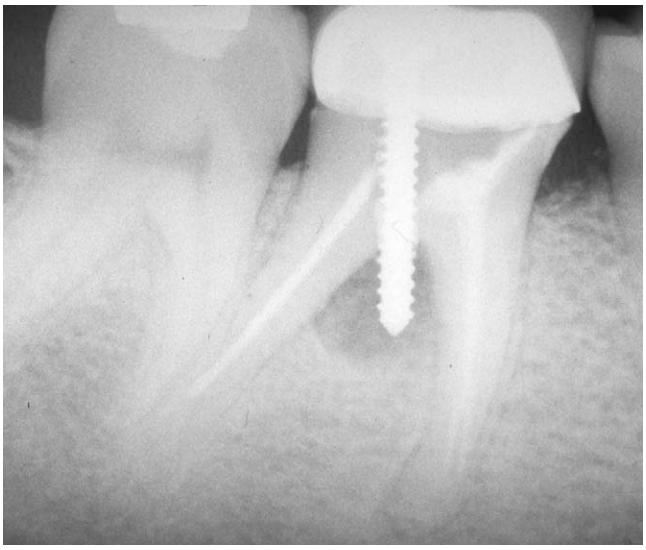

FIG. 25-72 Furcal post perforation resulting in persistent infection and furcal bone loss.

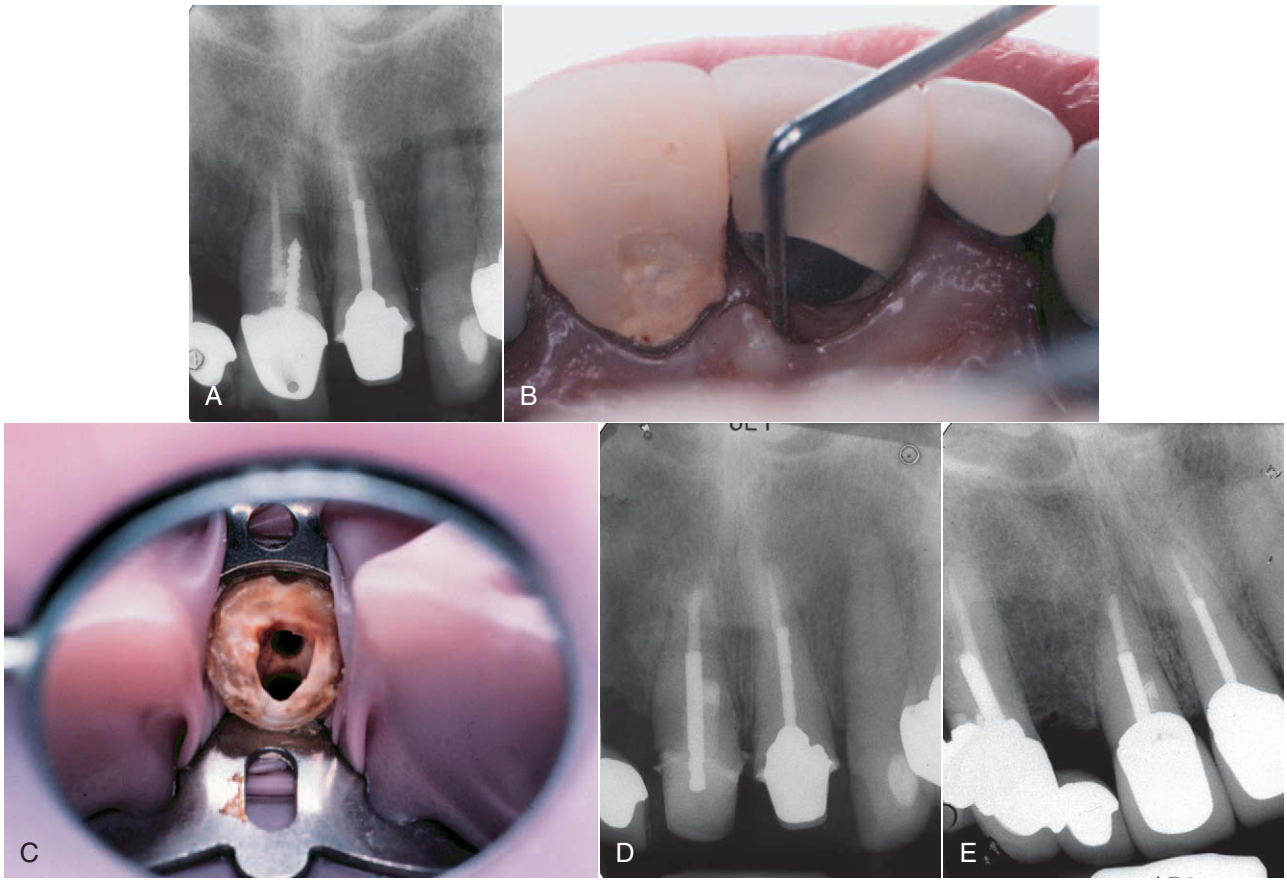

FIG. 25-73 A, Mesially angulated preoperative radiograph showing a palatally oriented post perforation in an upper incisor. **B,** An 8-mm narrow-based probing defect on the mesiopalatal corner of the tooth. **C,** Following coronal disassembly, the true canal can be seen lying in a facial direction relative to the palatal post preparation. **D,** The perforation was repaired with an external matrix of Colla-Cote and MTA. Subsequently, in conjunction with a periodontist, periodontal flap surgery was used to remove periodontal disease etiology from the longstanding pocket, and guided tissue regeneration procedures were instituted. **E,** Three-year reevaluation. The tooth is asymptomatic, and mesiopalatal probing depth is 4 mm.

through the periradicular tissues.[160] In general, if all other factors are considered equal, internal nonsurgical perforation repair will be the preferred method, since it is usually less invasive, produces less destruction of periradicular tissues via the surgical access wound needed, and isolation from microbes and disinfection is usually enhanced. If, however, the defect is readily accessible surgically, and disassembly of the existing restorations would impose an unacceptably high cost and long treatment time to the patient, surgical repair should be selected. If a longstanding defect has a periodontal lesion that has formed around it, surgery (perhaps with guided-tissue regeneration) will usually be needed. In most of these cases, nonsurgical retreatment and internal perforation repair prior to surgery will be beneficial to the treatment outcome. A multidisciplinary approach will be required, usually in consultation with the restorative dentist, a periodontist, and perhaps an orthodontist.[163,229]

Factors that affect the prognosis of perforation repair include location of perforation, time delay before perforation repair, ability to seal the defect, and previous contamination with microorganisms.[112,182,188] Generally, the more apical the perforation site, the more favorable is the prognosis, but the converse is true for the repair procedure itself. The difficulty of the repair will be determined by the level at which the perforation occurred. If the defect is in the furcal floor of a multirooted tooth or in the coronal third of a straight canal (access perforation), it is considered easily accessible. If it is in the middle third of the canal (strip or post perforations), difficulty increases, and in the apical third of the canal (instrumentation errors), predictable repair is most challenging; frequently apical surgery will be needed.

Immediate repair is better than delayed repair, since delay can cause breakdown of the periodontium, resulting in endoperio lesions that are difficult to manage,[110,186] and elimination of microbial contamination of the defect and sealing it properly are critical to success. Many materials have been advocated for the repair of perforations in the past, but none provided predictable healing after treatment. Commonly used materials include amalgam, Super EBA cement (Bosworth, Skokie, IL), various bonded composite materials, and more recently, mineral trioxide aggregate (ProRoot MTA, DENTSPLY Tulsa Dental)[163] (Fig. 25-74).

Since the recent introduction of MTA for perforation repair, the choice of which repair material to use is more clear.[128,160] MTA has many advantages over other restoratives when being used for perforation repair. This material seals well[144,239] even when the cavity preparation is contaminated with blood.[214] It is very biocompatible,[149,155,215,217] rarely eliciting any response from the periradicular tissues, and a cementum-like material has been consistently shown to grow directly on the material after placement.[85,155] MTA has also been shown to have a high degree of clinically favorable long-term outcomes when used as a perforation repair material.[128,160] The main disadvantage of MTA is the long time required for setting[216] that makes this material inappropriate for transgingival defects such as those associated with cervical resorption. If the material is in contact with oral fluids, it will wash out of the defect prior to setting, so a more rapid-setting resin ionomer such as Geristore (Den-Mat, Santa Maria, CA) is recommended for lesions that cross the gingival margin[15,42,173] (Fig. 25-75). MTA is available in the original gray-colored formulation and a newer, more esthetic off-white color for treatments in the esthetic zone of the mouth, although there is little research on the differences between the two formulations. Their sealing ability seems comparable,[51] but questions remain as to whether white MTA exhibits the same biocompatibility[153] and will have the same long-term success as the older variety.

FIG. 25-74 ProRoot MTA is a medical grade of Portland cement that has had the arsenic removed so it can be used in the human body. It is the material of choice for endodontic perforation repair. *(Courtesy DENTSPLY Tulsa Dental, Tulsa, OK.)*

FIG. 25-75 Geristore Kit (Den-Mat, Santa Maria, CA). This and other resin ionomers have been advocated for cervical perforation repair, owing to good biocompatibility and the shorter, more controlled setting times that make them useful for transgingival root fillings.

If the perforation is to be repaired nonsurgically through the tooth, coronal-radicular access to the defect is prepared as stated previously (Fig. 25-76). First, the root canals are located and preliminarily instrumented to create enough coronal shape to allow them to be protected from blockage by the repair material. The defect is cleaned and sometimes enlarged with the use of ultrasonics or appropriate rotary drills such as the Gates-Glidden to remove any potentially contaminated dentin surrounding the perforation. Use of a disinfectant irrigating solution such as sodium hypochlorite should be considered if

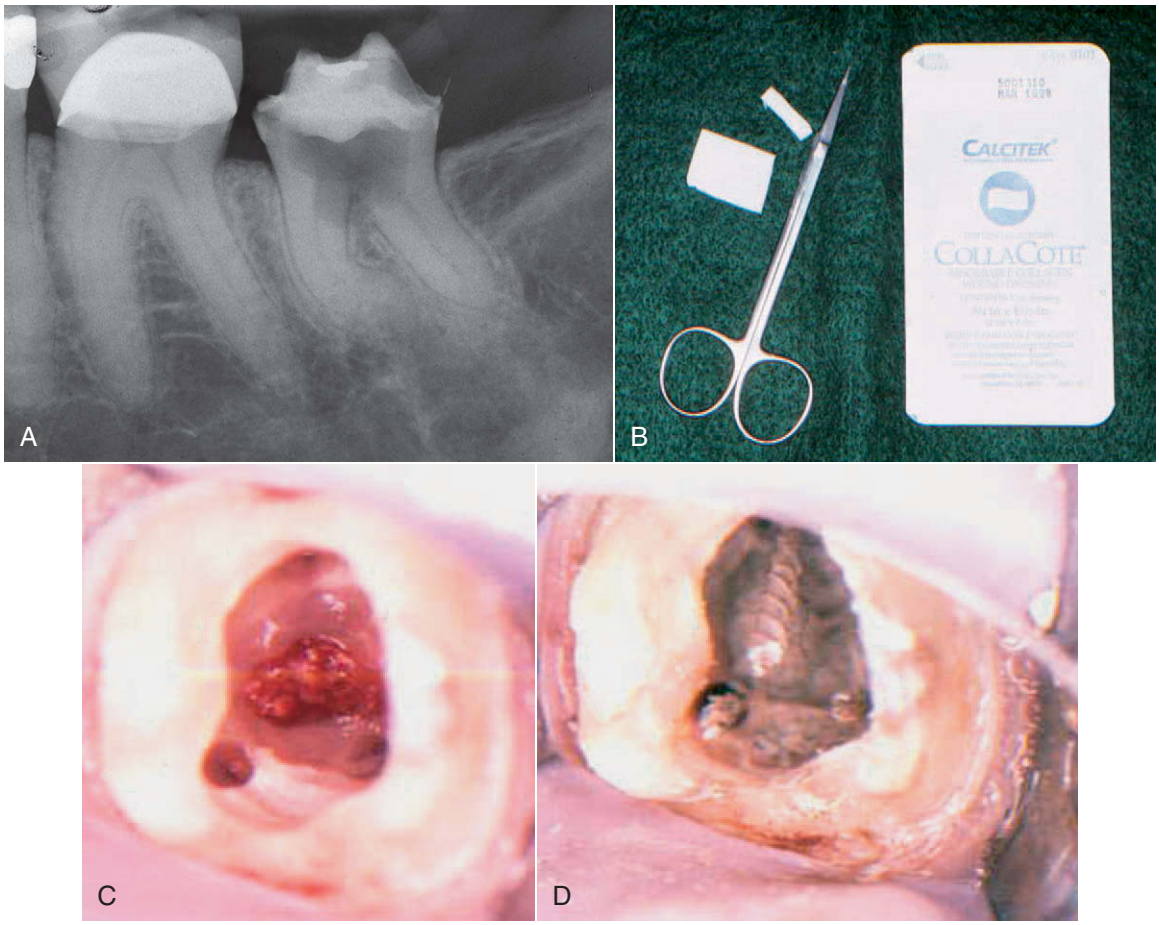

FIG. 25-76 A, Large furcal perforation created during an attempt at endodontic access. **B,** Colla-Cote (Integra Life Sciences, Plainsboro, NJ) to be used as an external matrix material to recreate the external root contour. **C,** Canals have been found, preliminarily instrumented, and the external matrix has been placed. **D,** Canals are protected from being blocked using large endodontic files cut off above the orifice. MTA has been placed into the defect.

the perforation is not so large as to allow the irrigant to significantly damage the periradicular tissues. If the perforation is large, sterile saline should be used as an irrigant, and disinfection of the margins of the defect is performed using mechanical dentin removal. Investigators[8] have advocated the use of copious flushing of the defect with 2.5% hypochlorite, but in light of the potential severe complications of hypochlorite overextension through a perforation,[63] extreme care should be used. After the defect has been cleaned, vigorous bleeding may result. Hemostasis should be undertaken using collagen (Colla-Cote, Integra Life Sciences, Plainsboro, NJ) (see Fig. 25-76, *B*), calcium sulfate (Capset, Lifecore Biomedical, Chaska, MN), or calcium hydroxide[163]; however, astringents such as ferric sulfate should be avoided, since the coagulum they leave behind may promote bacterial growth and may compromise the seal of the repair.[117]

When the bleeding has been controlled, some easily removable material should be placed over the entrances to the deeper portion of the canals to prevent the repair material from blocking reaccess to the apical terminus. The canals may be protected with cotton, gutta-percha cones, paper points, or shredded collagen. The use of severed files is not recommended, because removal of the files after placement of the repair material is very difficult, since the material tends to lock into the instrument's flutes (see Fig. 25-76, *F*). After protecting the canals, the perforation site is inspected to determine whether an external matrix is needed to ensure a proper contour of the restoration.[116] If the surrounding bone is closely adapted to the defect margins, minimal to no matrix material will be necessary. If the perforation is associated with a large osseous defect, this must be filled with an external matrix to minimize overcontouring of the repair restoration. The matrix material should be a biocompatible, usually absorbable material such as collagen, freeze-dried demineralized bone allograft (FDDB), hydroxylapatite, gelfoam, or calcium sulfate.[160,163] Care must be exercised so that the external matrix material is not condensed so forcefully that it damages adjacent vital structures, such as the mental nerve or the floor of the sinus.

Following preparation of the defect, the repair material is placed. It may be carried in a small syringe or amalgam carrier, and it is condensed with pluggers or microspatulas. In the case of MTA in an accessible defect, the butt end of paper points make an excellent compactor, since they can wick some of the water out of the material, giving it a firmer consistency and

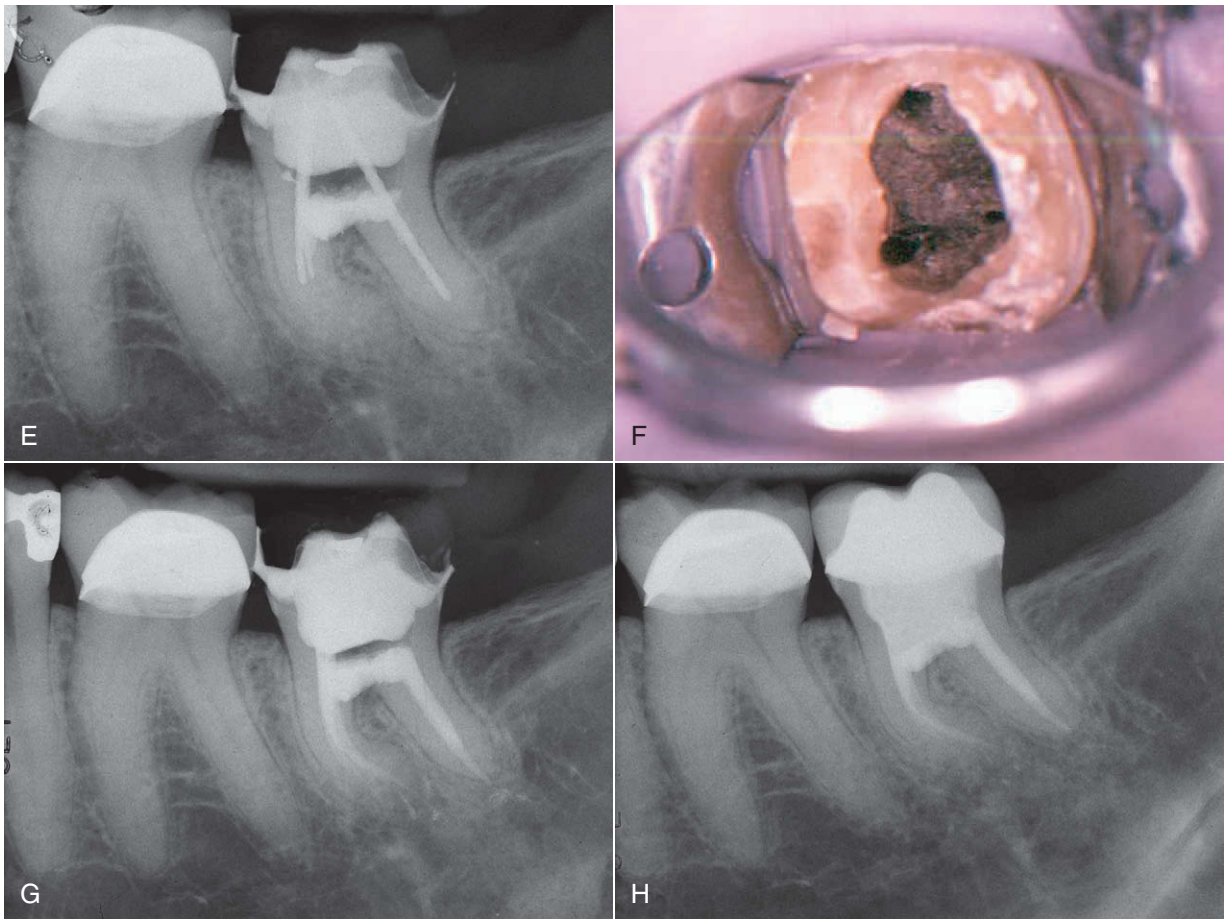

FIG. 25-76, cont'd E, Radiograph showing the initial repair with MTA recreating the vault of the furcation. **F,** On the second appointment, the blocking files are removed with difficulty, since the MTA has flowed into the flutes and set. At this time, endodontic therapy is completed as normal. **G,** Postobturation radiograph. Note the radiolucency in the furcal vault, which represents the Colla-Cote external matrix material. **H,** Nineteen-month reevaluation. The patient is asymptomatic, and there is evidence of healing in the furcal vault area.

aiding compaction. When the MTA has been placed, a moist cotton pellet is placed over it to hydrate the material, and the tooth is sealed to allow the MTA to set. Upon reentry, the material should be set hard and well retained in the perforation site[192] (see Fig. 25-76, *F*). If there is an overextension of the material beyond the normal external root contour, it seems not to affect the prognosis of the repair.[8,160]

If the perforation is deeper in the canal, the objectives and principles of repair as just outlined all apply, except that access to the defect is more complicated (Fig. 25-77). Protecting the canal from blockage is somewhat more difficult, and placement of the repair material requires the enhanced vision provided by the surgical operating microscope. Ideally, the canal should be fully shaped prior to the repair attempt,[163] and a canal patency protector should be placed apical to the defect. In some of these instances, protecting the canal can be accomplished by using a severed file, notwithstanding the previous warning, since not only can it protect the canal from blockage, it can also be used as an indirect carrier for transmitting ultrasonic energy to the MTA, causing it to "slump" into the defect when direct compaction is impossible. The file is placed into the canal to a level well below the defect, and the MTA is carried to place. Once compaction has been performed as well as possible, the coronal extent of the file is touched with an ultrasonic tip to vibrate the MTA into the defect. After this is accomplished, the file must be vigorously instrumented in a short, 1- to 2-mm amplitude push/pull motion to free it from the placed MTA so that it can be easily removed after the material is set[163] (Fig. 25-78). There is some evidence that ultrasonic placement of MTA may enhance the seal against bacteria in an apexification model,[113] although other researchers have not agreed with this conclusion and found poorer canal wall adaptation when filling the apical extent of canals using ultrasonic compaction compared with hand filling.[6] Further study of ultrasonic MTA placement is warranted, but clinical observation suggests that this method has merit.

If the perforation is in the apical portion of the canal, it is usually due to a procedural accident during instrumentation of a curved canal and is invariably accompanied by a block or ledge. This type of perforation is the most difficult to repair, since repair not only involves cleaning and sealing the defect but also finding, cleaning, and filling the apical canal segment. All of the aforementioned techniques for managing blocks and ledges are required to find and clean the apical canal segment.

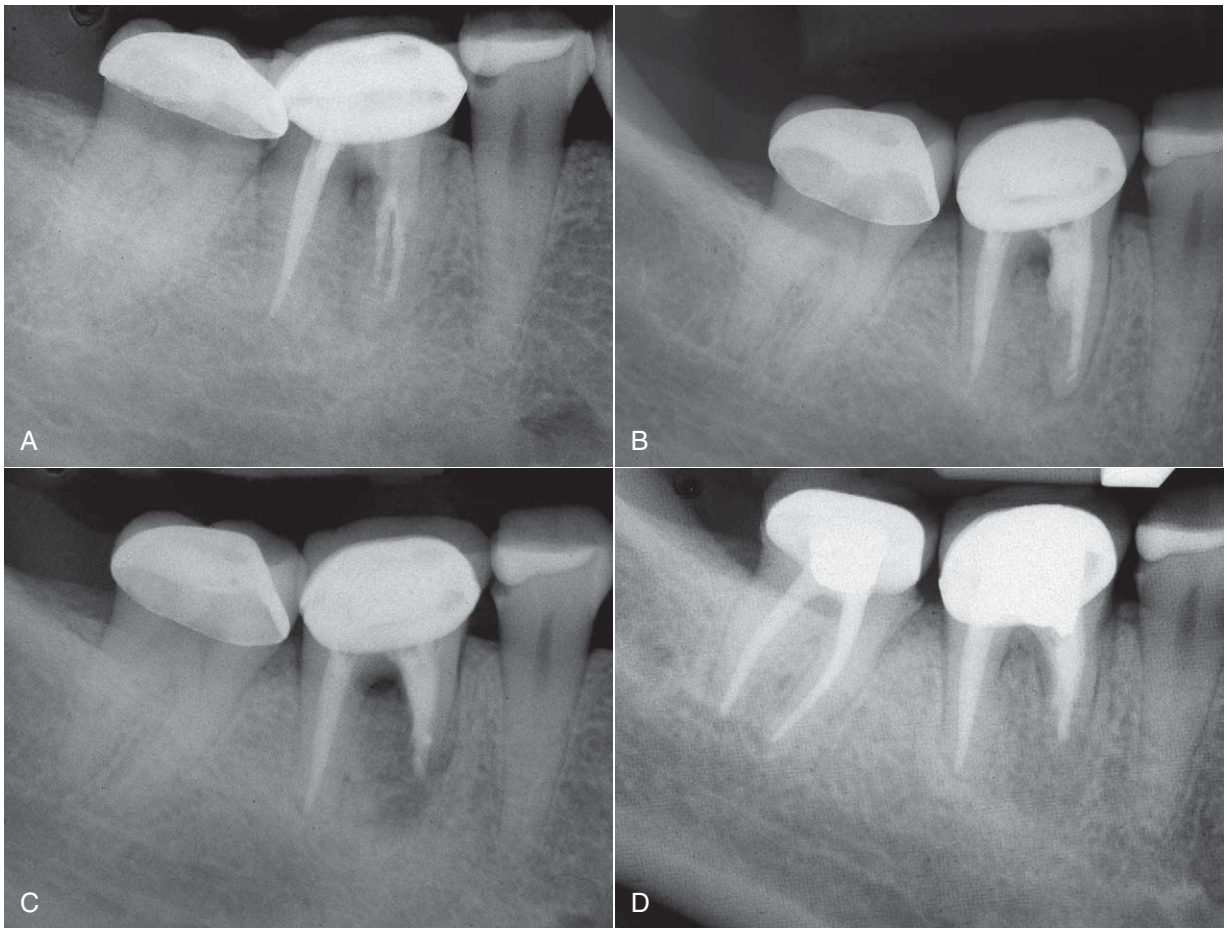

FIG. 25-77 Midroot-level perforation repair. **A,** Preoperative film showing mesial strip perforation with bone loss. **B,** Nonsurgical internal repair with inability to negotiate canals to the apical terminus and MTA overextension into the furca. **C,** Apical and perforation repair surgery performed. **D,** One-year follow-up showing complete healing.

When this has been accomplished, the decision is made as to whether the canal should be filled with MTA or with gutta-percha and sealer. The MTA is undoubtedly more effective in sealing the canal (especially if it cannot be dried) and is much more biocompatible, but carrying it predictably to the apical extent of a curved canal is problematic. If a holding file is placed in the apical canal segment to anticipate eventual gutta-percha placement after the MTA repair material is set, the presence of the file precludes consistent extension of the MTA into the apical end of the defect, even when ultrasonically vibrated. If a holding file is not placed, the MTA will also flow into the prepared apical segment, which may not be completely three-dimensionally obturated. Generally, whichever choice is made, the outcome will be unpredictable, so the patient must be advised that regular reevaluation is necessary, and apical surgery or extraction may ultimately be needed.

PROGNOSIS OF RETREATMENT

When the proper diagnosis has been made and all of the technical aspects of retreatment are carefully performed, orthograde retreatment can be highly successful (Fig. 25-79). The prognosis depends to a large extent on whether apical periodontitis exists prior to retreatment.[146] In a recent systematic review of outcomes studies,[55] investigators report that in the absence of prior apical periodontitis, the incidence of healed cases after both initial treatment and orthograde retreatment ranges from 92% to 98% up to 10 years after treatment. When prior apical periodontitis is present, the incidence of healing drops to 74% to 86%, regardless of whether initial treatment or orthograde retreatment was performed. The authors state that this "similar potential to heal after initial treatment and orthograde retreatment challenges the historic perception of the latter having a poorer prognosis than the former."[55]

Unfortunately, these numbers mean that the desired outcome will not occur in potentially a fourth of retreatment cases. Many techniques and devices for endodontic retreatment have been mentioned here to aid the clinician. However, none of this will guarantee success. Even when strict endodontic principles and fundamentals are followed, the result may be persistent posttreatment disease. When healing does not occur, the clinician is faced with the decision of what to do next. The choice is between four treatment options: observation, endodontic surgery, extraction-replantation, or extraction.

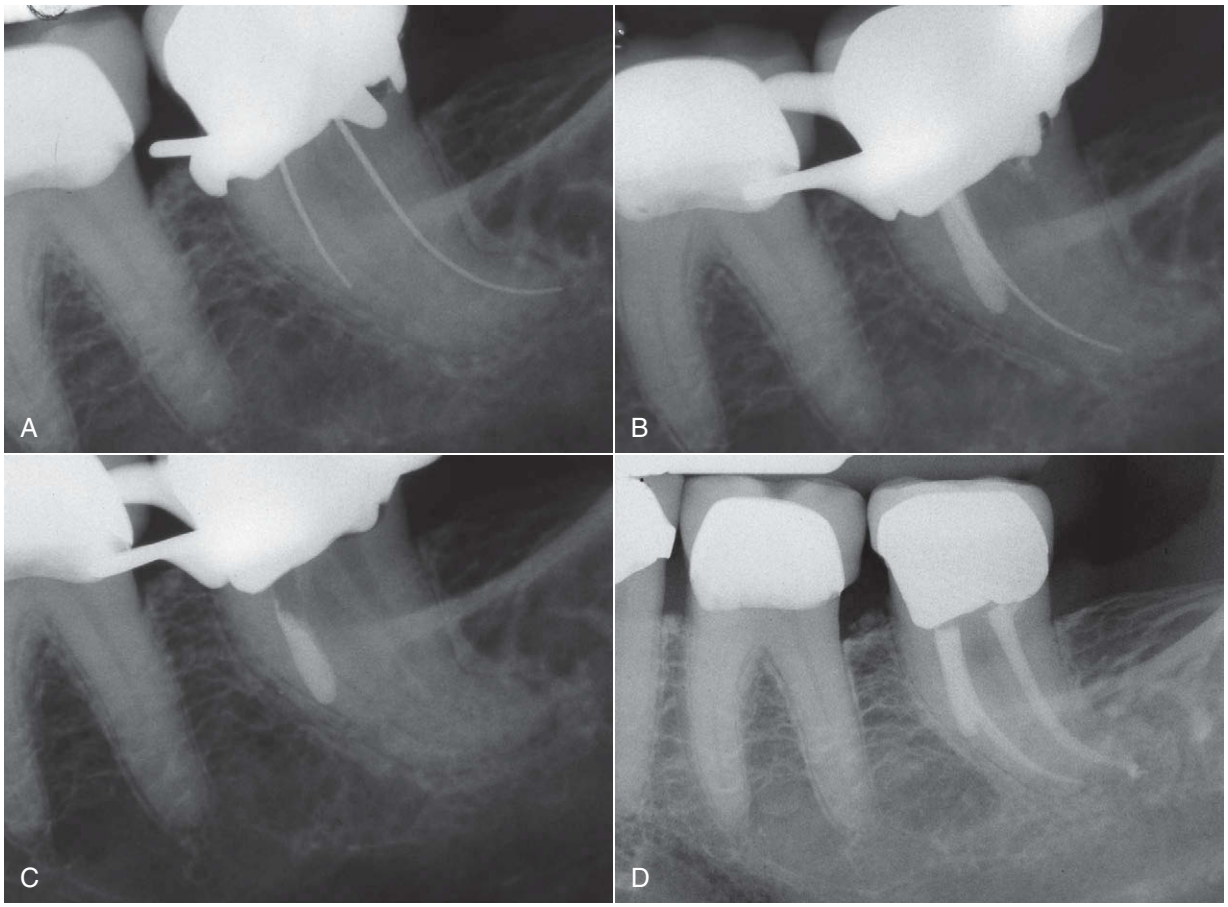

FIG. 25-78 A, This patient was in extreme pain following initial endodontic instrumentation by her dentist. Midroot-level perforation found on access. **B,** The original canal was found and protected with an endodontic file. MTA was vibrated using ultrasonic energy applied to the file, and it flowed into the defect. Then the file is moved in a push/pull manner to dislodge it from the MTA prior to closure. Note that the defect was intentionally enlarged to allow for more predictable application of the MTA. **C,** On the second appointment, the file is withdrawn easily, since it was detached from the MTA repair material. Now the endodontic therapy is concluded as normal. The patient has been asymptomatic since the end of the first appointment. **D,** Follow-up at 27 months, showing complete healing.

Many times a tooth that has persistent apical periodontitis may remain in asymptomatic function for an extended period of time, a state that has been referred to as *functional retention of the tooth*.[55] If the patient's goal of treatment is not necessarily complete healing of the tooth but simply to retain it in function and without pain, then regular evaluation by the clinician is warranted. If signs and symptoms of worsening infection (e.g., progressive enlargement of a periapical radiolucency, pain, periodontal pocket formation, or sinus tract eruption) occur, then further treatment may be needed. However, many teeth classified early on as uncertain healing may indeed be retained for many years.[134]

Endodontic surgery (Fig. 25-80) is a very predictable procedure[55,76] that can be performed on most teeth, but there are some anatomic and medical concerns regarding treatment planning for this procedure which are covered in detail in Chapter 21. Extraction-replantation (Fig. 25-81), also referred to as *intentional replantation*,[147] is another treatment option. This involves extraction of the tooth and performing the apicoectomy and root-end filling while the tooth is out of the patient's mouth, followed by replantation and splinting if indicated. This procedure is also discussed in detail in another chapter. Extraction and replacement should be the treatment of last resort, to be selected only when the tooth has been shown to be irreparable. If the decision is made to extract the tooth, usually replacement will be necessary to prevent shifting of the dentition with its attendant problems. Replacement can be with an implant, a fixed partial denture, or a removable partial denture.

SUMMARY

Posttreatment endodontic disease does not preclude saving the involved tooth. In fact, the vast majority of these teeth can be returned to health and long-term function by current retreatment procedures. In most instances, the retreatment option provides the greatest advantage to the patient, since there is no replacement that functions as well as a natural tooth. Armed with the information in the preceding section, appropriate armamentaria, and the desire to do what is best for the patient, the clinician will provide the foundation for long-term restorative success.

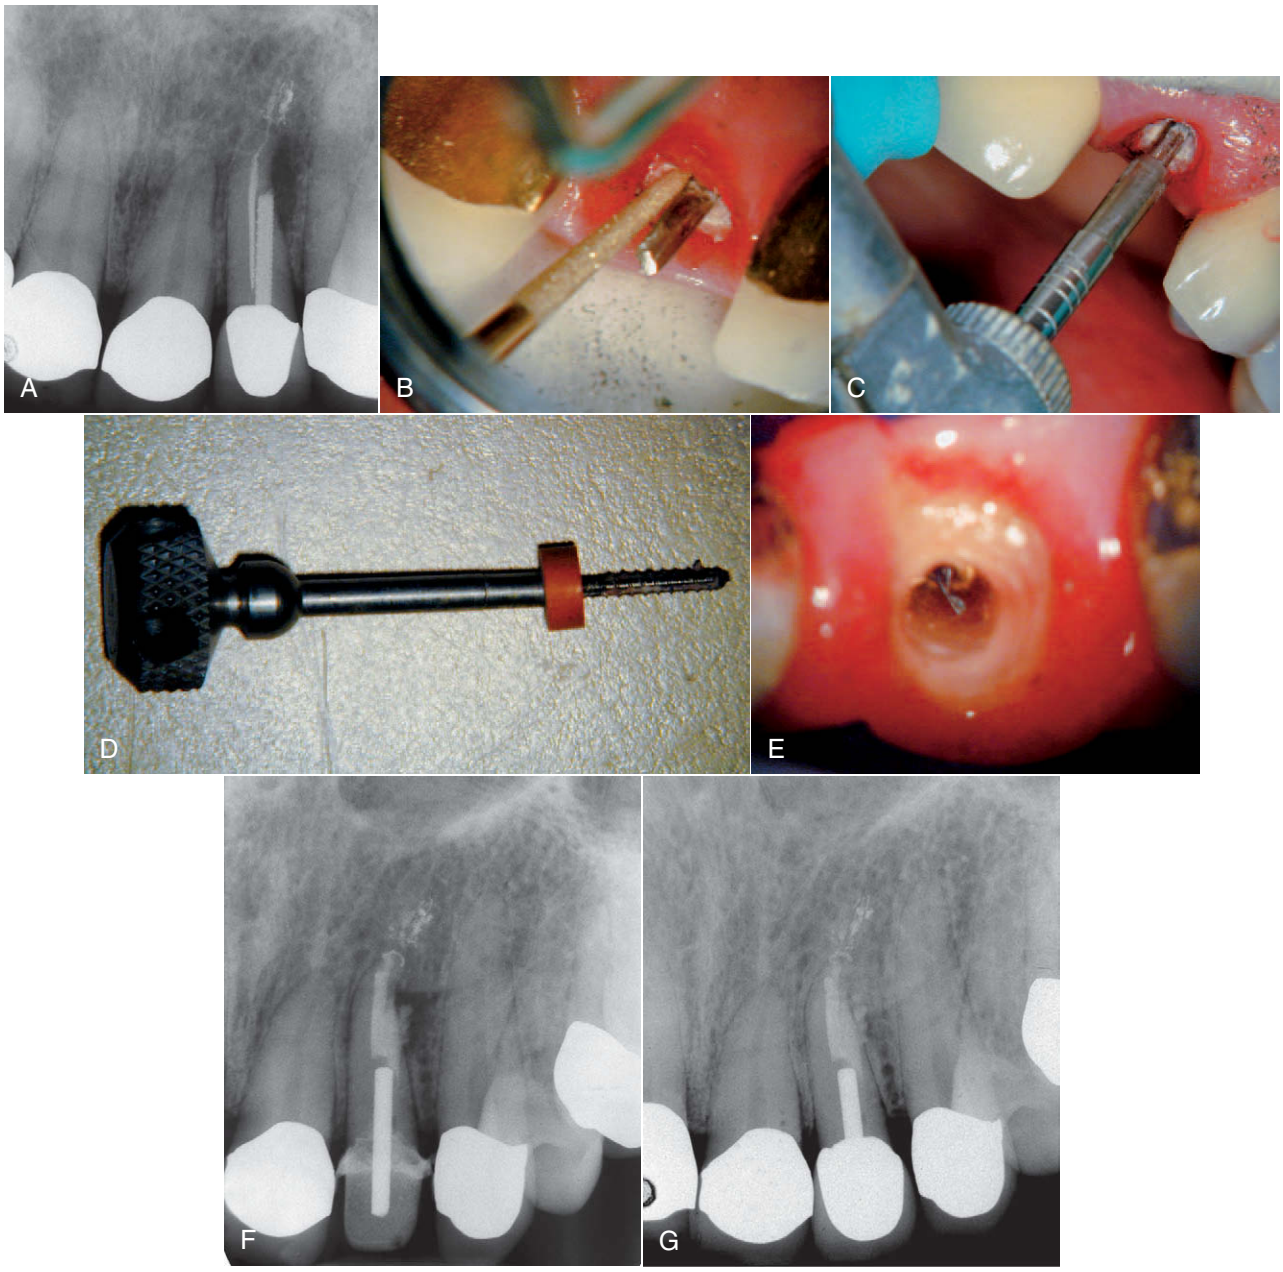

FIG. 25-79 A, Preoperative radiograph showing midroot-level post perforation and associated periradicular periodontitis. **B,** The crown was removed, and ultrasonic energy was applied to the post. **C,** Using the trephine bur from the Ruddle Post Removal kit to mill the endo of the post. **D,** The screw post is removed using the wrench from the Ruddle kit. **E,** After removal of the post and gutta-percha, a plastic solid core carrier is found in the canal and removed using the techniques described in this chapter. **F,** Postoperative radiograph showing MTA perforation repair, canal seal with gutta-percha, and post and core fabrication. **G,** Thirteen-month recall showing healing around the perforation repair site.

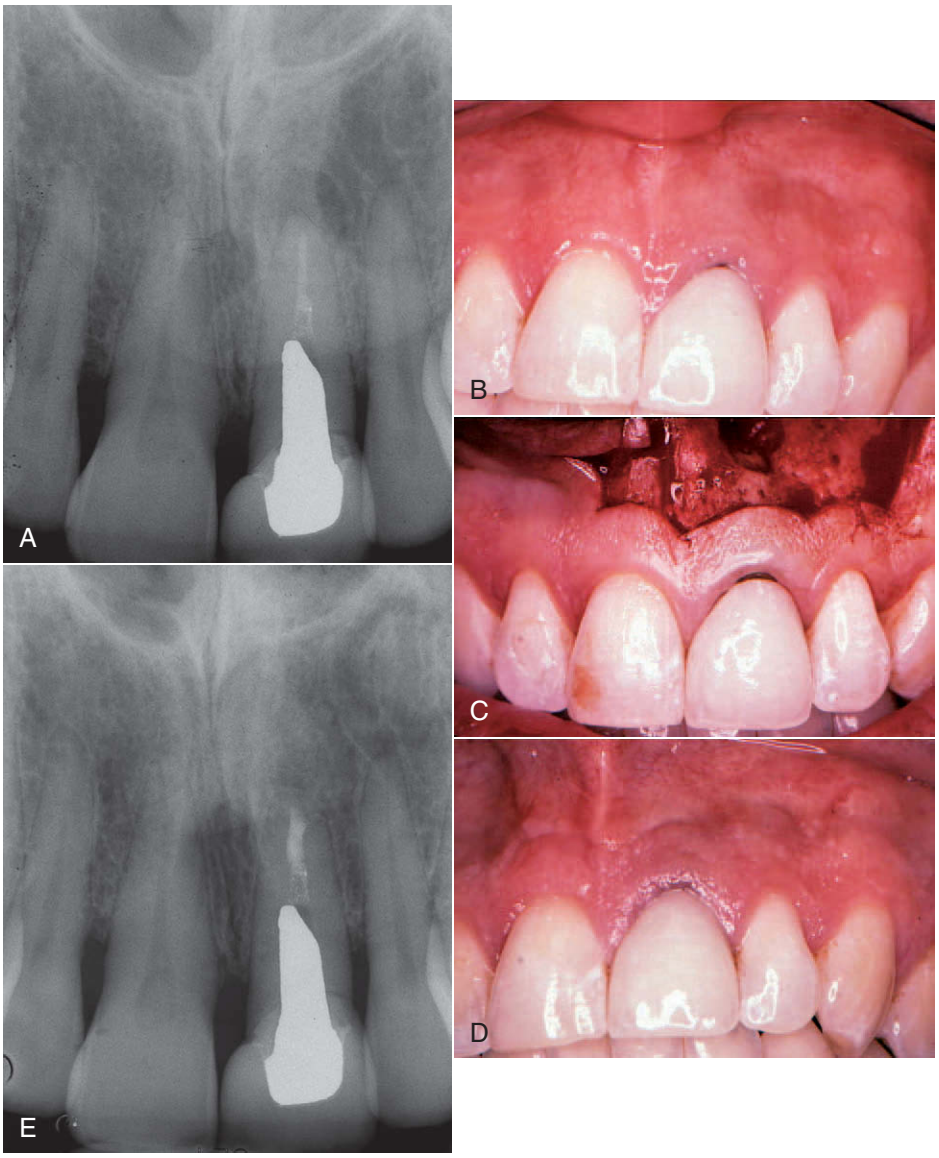

FIG. 25-80 A-B, Preoperative images showing posttreatment disease in the upper left central incisor and a large custom cast post. The patient elected to leave the post and perform surgery rather than risk damage to his new crown. **C,** Submarginal rectangular flap design. **D,** Three-week follow-up showing excellent soft-tissue healing. **E,** Eighteen-month follow-up showing excellent healing of the periradicular tissues.

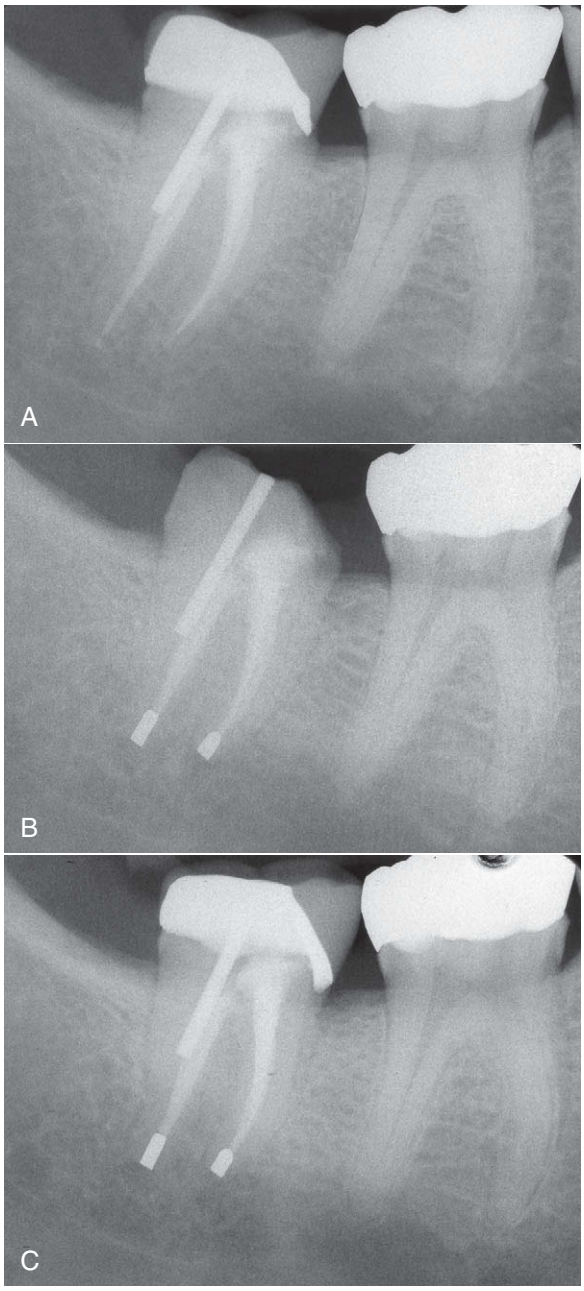

FIG. 25-81 A, This lower second molar remained symptomatic despite nonsurgical retreatment. Surgery was precluded by the poor access and proximity of the inferior alveolar canal. **B,** Intentional replantation was performed using amalgam alloy retrograde fillings. Better materials such as MTA or Super-EBA are available now. **C,** Fifteen-month reevaluation showing apical healing. The patient was asymptomatic.

CHAPTER 26

Understanding and Managing the Fearful Dental Patient

HENRIETTA L. LOGAN

CHAPTER OUTLINE

ANXIETY AND FEAR
MECHANISMS
INTER- AND INTRAVARIABILITY IN RESPONSES
Variability in Stress Response
Variability in Pain Response
MANAGEMENT OF PAIN AND ANXIETY
Patient Communication
Behavioral Interventions

The hand froze as she started to dial, almost as if some other life form had seized control of her body. She stood there for what seemed like minutes before she could bring herself to dial the number. Her heart was beating faster—she just couldn't do it. As she rushed to disconnect, she heard a cheery voice on the other end of the line: "Dr. Rodriq's office, dentistry with a personal touch. May I help you…?" She muttered under her breath, "I can't do it now. I'll try tomorrow."

The scenario is familiar to many people. The mere act of making a dental appointment requires greater courage than is available, and except for the moments when oral pain becomes unbearable, pursuing dental treatment is out of the question.[78]

Many fears are regarded as socially unacceptable. The presence of dental fear, however, is widely accepted and carries little social stigma. Several studies confirm that dental anxiety and fear are common among the general U.S. population, as well as being a worldwide problem.[68,69,74] About 50% of adults in the United States report some dental fear, with 8% to 12% fearful enough that simply making a dental appointment is problematic.[82] Although women account for more than half of fearful patients, clinicians should not assume the men they treat as patients are without dental fear and anxiety. Men may not express their fears as openly as women, but exaggerated emotions such as anger or impatience may be masking their dental fear.[34] As the fictional scenario demonstrates, many clinicians have attempted to make their practices inviting by presenting a warm and friendly image to the patient who calls. Yet data show that in the United States, the rate of dental anxiety/fear has remained stable during the past 50 years.[81]

Worldwide, the prevalence of dental phobia (an extreme form of fear) is also common. In Australian adults, the level of dental fear ranges from 10% to 14%,[32] whereas in Iceland, Taiwan, and Japan, adult respondents who report at least some dental fear are 21%, 50%, and 82%, respectively.[26,72,75] Studies of children have shown considerable global variation in the prevalence, with some estimates as high as 43%.[31] Given the international prevalence and universal acceptance of dental fear and anxiety, it is impossible for any clinician to avoid fearful patients. Consequently, it is worth the clinician's time and energy to understand the nuances of dental fear and anxiety.[5] This chapter presents general information about fear and anxiety, including proposed mechanisms, and highlights individual differences in response and management strategies. It begins with a section describing biologic and psychologic characteristics of anxiety and fear.

ANXIETY AND FEAR

Anxiety and fear play an adaptive role as an alarm in response to danger. Both are crucial and adaptive components of the overall behavioral and autonomic stress response. In response to dangerous situations that threaten to disturb homeostasis, some biologic systems are activated and others are inhibited in a largely predictable manner. Short-term reaction proportional to the challenge elicits an appropriate response (often escape and avoidance) and is of fundamental importance as a survival strategy. This survival strategy, however, taxes the patient's resources, and stress-induced dysregulation may result in a diverse set of health risks ranging from increased susceptibility to viral infection[14,15,86] and activation of latent virus[8,59] to impaired wound healing after surgery[64] and increased mortality.[11]

Anxiety and fear lie at the interface of neurobiology and psychology and are controlled by a highly complex system of both inhibitory and facilitatory mechanisms. These stress mechanisms are dynamic and redundant.[70] The purposes include maintaining an appropriate degree of emotion under

nonthreatening conditions, efficiently responding to potential threats, producing behavioral responses such as "fight or flight," and, finally, allowing the patient to rapidly return to "baseline" after the danger has passed. Authors have attempted to make a distinction between anxiety and fear, and for the purposes of this chapter, those distinctions may be helpful in understanding dental patients' responses to actual and potential treatment.[69,88]

Fear is described as an individual's physiologic and emotional response to a perceived immediate and identifiable threat or danger. It is accompanied by an unpleasant cognitive or affective state of impending doom, with physiologic changes involving the sympathetic branch of the autonomic nervous system (e.g., hyperventilation, enlarged pupils, gastrointestinal upset, changes in salivary flow, elevated catecholamines) and overt behavior that may involve pacing, shaking, combativeness, or attempts to escape the situation.

Anxiety may or may not differ in the degree of physiologic and emotional arousal compared with fear, but the source of the threat is typically ambiguous, ill defined, and not immediate. Using this paradigm, the emotional and physiologic response a patient reports when imagining a dental appointment would be classified as anxiety, whereas the elevated psychologic and physiologic arousal of a patient receiving an injection of local anesthetic while seated in a dental chair would be characterized as fear.

Dental phobia is a special case of dental fear, characterized as a consistent and persistent fear that interferes with one's social or role functioning and often leads to avoidance of dental treatment of almost any type. Although the distinction between anxiety, fear, and phobia is useful to consider, most patients do not make such a distinction; consequently, the caregiver should be aware that the terms are often used interchangeably.

For most people, the level of anxiety and fear expressed is commensurate with the level of danger or threat present, and the individual quickly adapts to the threatening event, either through reassessment of the level of danger or development of more effective coping skills. For most dental patients, the level of threat from treatment is balanced with the potential to benefit from maintaining good oral health, leading the patient to seek and receive treatment. For others, the fear may be disproportionate to the level of threat, and the individual's behavior is perceived by an outsider to be maladaptive (avoiding treatment until the last moment). For still others, the anxiety experienced is paralyzing with respect to the stimulus and persists in the absence of threats, producing high levels of intrusive thoughts and memories.[22] At its most extreme, this reaction qualifies as a phobia, and the avoidance is of such a proportion that it produces extreme distress and may, at the mere mention of the word *dental,* provoke an immediate and intense anxiety response.

MECHANISMS

This paradox—that the systems activated by stress-inducing stimuli cannot only protect and facilitate but also damage the body—was recognized nearly 70 years ago.[27] Since that time, the interactive roles of the autonomic nervous system, the hypothalamic-pituitary-adrenal axis, and the cardiovascular, metabolic, and immune systems during stressful responses have been documented, and the price of the continual accommodation to stress has been characterized.[65]

The stress system coordinates the generalized stress response, which has both central nervous system and peripheral components. The main elements of the stress system's central components are located in the brainstem and the hypothalamus and include the arginine vasopressin neurons of the paraventricular nuclei of the hypothalamus; the parvocellular neurons of corticotrophin-releasing hormone; the corticotrophin-releasing hormone neurons of the paragigantocellular and parabrachial nuclei of the medulla and the locus ceruleus; and other largely noradrenergic cell groups in the medulla and pons (LC/NE). (The reader is referred to an excellent paper[10] for details of the endocrinology of the stress response.)

INTER- AND INTRAVARIABILITY IN RESPONSES

Variability in Stress Response

The stress system receives and integrates a diversity of inputs that arrive through distinct pathways arising from the individual's unique biology, psychology, and environment. Activation of the stress system is remarkably similar across species, but individual differences do exist that arise from variations in genetics and individual experiences. The knowledge resulting from research into the effects of stressful responding is far-reaching and shows associations across a broad range of health conditions, including wound healing,[80] the severity of infectious diseases,[15,60] inflammatory response,[61] chronic diseases such as cancer,[83] and pain levels.[21,71,73,90]

For instance, psychologic stress has been shown to impair human wound healing in a number of well-controlled studies. In one study, investigators[47] placed 3.5-mm punch biopsy experimental wounds on the arms of chronically stressed caregivers and well-matched controls of patients with Alzheimer's disease to study dermal wound healing. Alzheimer caregivers took an average of 24% longer to heal standardized wounds, with group differences in wound size appearing within the first week of healing. The ability to mount an inflammatory response was tested using an ex vivo endotoxin-stimulated interleukin 1 beta (IL-1β) gene expression assay in whole blood. Alzheimer caregivers produced significantly less IL-1β than controls. These results indicate that stress begins to have an impact in the early phases of wound repair, specifically the inflammatory phase, resulting in delayed wound closure. In an oral wound model, with wounds placed 3 days before examinations, dental students healed an average of 40% slower than wounds made in the same students during summer vacation, and the differences were quite reliable. No student healed as rapidly during examinations as during vacation.[64] These data show that an event as transient, predictable, and relatively benign as examination stress may have significant consequences for wound healing, even in young adults.[63] It seems quite likely that similar phenomena would be found in fearful dental patients after surgery, but no study to date has tested the question. It is beyond the scope of this chapter to review this important body of work,* but two important factors largely determine individual responses to potentially stressful situations: the way a person perceives the situation and the person's general state

*References 12, 41, 42, 45, 48, and 85.

of health, which is influenced by both genetic factors and lifestyle.[66] Under this paradigm, it is not surprising that both interindividual and intraindividual differences exist in response to potentially aversive stimuli.[24] Nowhere are variations in an individual's response to a stressor more apparent than in a dental office. The following section describes one highly relevant dental outcome that has been shown to be influenced by fear, anxiety, and stress and exhibits remarkable interindividual variability.

Variability in Pain Response

Two patients with comparable dental disease may report vastly different levels of pain associated with their disease and treatment. One patient may be distressed and report high levels of pain. The other may seem less bothered by the problem and report low to moderate levels of pain. Is one patient an outlier and the other typical? Or are both legitimate expressions of the individual's experience?

The role of these individual differences in the response to stress is complex, and the part these differences play in pain perceptions is only partially understood. Investigators showed that experimentally induced anxiety led to increased pain reactivity, whereas high levels of fear led to decreased pain.[77] Whether the dental setting produces fear or anxiety is not clear, but within the dental care context, patients may have worried for days about a scheduled treatment, resulting in elevated levels of autonomic arousal and high levels of anxiety. This elevated arousal may produce heightened levels of plasma catecholamines, which in laboratory studies have been shown to lower the pain threshold and tolerance.[9] It is not surprising that many highly anxious patients show elevated levels of pain reactivity during dental treatment compared with less anxious patients.[50] Therefore, clinicians should anticipate that anxious patients will have more sensory and affective distress during dental treatment than less anxious patients and treat them accordingly.[62]

A body of literature exists that shows pain is strongly influenced by factors including affective, cognitive, psychosocial history, and social learning (see also Chapter 19). One study[57] demonstrated that patients' perception of pain was associated with the amount of personal control they believed they would have during dental treatment coupled with the amount of control they wished to have. Dental patients with the largest discrepancy between the amount of control they desired and the amount they believed was available were at greatest risk for elevated levels of expected, experienced, and recalled pain during dental treatment.[37] Catastrophizing, a form of coping characterized by expecting the worst, predicts greater severity of postoperative pain; it has been linked with both experimental pain sensitivity and clinical pain symptoms.[46] In addition, negative mood predicts greater severity of acute pain and is related to greater pain sensitivity.[38,58]

Negative mood also influences the level of pain that is recalled. Overall, pain is remembered inaccurately and becomes exaggerated over time, with the amount of exaggeration strongly influenced by the intensity of the negative emotions at the time of the painful encounter. Moreover, the elevated recall of pain influences the level of pain experienced at a second painful encounter—such as in dental treatment.[36] These research findings reinforce the significance of efforts to reduce a patient's level of negative emotion prior to dental treatment.

There is increasing evidence that women with high levels of dental fear are more likely to have a history of sexual/physical abuse than other women. The current estimate of childhood sexual abuse in the general U.S. population is 5.8% to 34% for women and 2% to 11% for men, which is considered by many to be a conservative estimate.[30,91] The sheer number of patients who have experienced sexual abuse strongly suggests that clinicians frequently treat sexually abused patients, and a greater understanding of the impact of abuse on dental attitudes and reactions may help both the patient and clinician to form an effective treatment partnership. A study of sexually abused European women who were categorized by whether they had been exposed to sexual touching, intercourse, or oral penetration showed that women in the oral penetration group scored significantly higher on dental fear than women in the other two groups.[92] In addition, women with a history of childhood sexual abuse and high levels of dental fear considered interpersonal factors related to the clinician as more important than did women with high levels of dental fear but without a history of childhood sexual abuse. These important interpersonal factors included not feeling the clinician can be trusted and not feeling in control.[93] It is not hard to understand the parallel between some elements of abuse and receiving dental care, including discomfort and pain, as well as a reluctance for the abused patients to believe that the clinician can be trusted.[84]

From a more general perspective, one study found that a self-reported history of physical or sexual abuse among a nonclinical sample was associated with increased pain complaints and lower perceived health status.[29] Not surprisingly, health care utilization and psychologic distress, including the tendency to catastrophize about upcoming events, was greater among women with an abuse history compared with other women.[29] The clinical implications of the association between sexual abuse and dental fear is that clinicians should be prepared to talk to their patients about sexual and physical abuse and the influence of that abuse on receiving dental care.

Fear of pain differs greatly among dental patients and is associated with elevated levels of anxiety.[90] Of particular concern to the clinician is the finding that anxious patients tend to be more fearful of dental pain *after* they experience a procedure than before, whereas less anxious patients tend to report less fear of pain after the procedure has been experienced. Specifically for highly anxious dental patients, experiencing treatment tends to make their fear of pain even greater.[90] Evidence of the biologic correlates of the individual differences in pain response reported before is beginning to emerge from a variety of sources, including those using functional magnetic resonance imaging (fMRI). One study found through neural imaging that fear of pain predicted activation of the right lateral orbital prefrontal cortex during a heat pain task.[73] This region of the brain has been linked with attempts by fearful individuals to regulate pain by determining how much threat the stimulus represents. This phenomenon of assessing the primary threat level in conjunction with the coping resources available is well documented in dental patients[5,16,55] and, in conjunction with recent research using fMRI, provides biologic evidence to support behavioral observation that differences in pain perception are true representations of the individual's experience.[73]

Although a variety of cultural, psychologic, and physiologic factors contribute to variability in both clinical and

experimental contexts, the role of genetic factors in human pain sensitivity is increasingly recognized. The most dramatic manifestation of individual variations in pain response is congenital insensitivity to pain, caused by single mutations of the *NTRK1* gene. This well-documented genetic defect, which causes pain insensitivity by influencing the receptor tyrosine kinase for nerve growth factor, underscores the role of individual genes in the reaction to painful stimuli.

One study[49] evaluated genetic influences on variability in human pain sensitivity associated with gender, ethnicity, and temperament. Loci in the vanilloid receptor subtype 1 gene *(TRPV1),* delta opioid receptor subtype 1 gene *(OPRD1),* and catecholamine *O*-methyltransferase gene *(COMT)* were genotyped using 5′ nuclease assays. They demonstrated that gender, ethnicity, and temperament contribute to individual variation in thermal and cold pain sensitivity by interacting with *TRPV1* and *OPRD1* single-nucleotide polymorphisms. Another study[25] found that the *COMT* gene was related to experimental pain sensitivity and risk of developing temporomandibular pain (TMD).

In a fascinating study,[76] 207 cancer patients were genotyped receiving morphine treatment with respect to the Val-158Met polymorphism and compared the morphine doses, serum concentrations of morphine, and morphine metabolites between the genotype groups. Patients with the Val/Val genotype (n = 44) needed more morphine (155 ± 160 mg/24 h) when compared with the Val/Met (117 ± 100 mg/24 h; n = 96) and the Met/Met genotype (95 ± 99 mg/24 h; n = 67) groups ($P = 0.025$). This difference was not explained by other factors such as duration of morphine treatment, performance status, time since diagnosis, perceived pain intensity, adverse symptoms, or time until death. These results show that genetic variation in the *COMT* gene may contribute to variability in the efficacy of morphine in cancer pain treatment.

There is further evidence of a genetic basis for differences in patients' response to pain control agents. One study[71] demonstrated a significant link between melanocortin-1 *MC1R* gene sequence, pain tolerance, and efficacy of morphine-6-glucuronide in both humans and laboratory animals. In addition, the distinctive molecular processes that are associated with different types of pain and changes in gene expression over time support the idea that heterogeneous responses to pain stimulus is typical, and one-size-fits-all attempts at pain management are unrealistic. It follows that failure to achieve anesthesia in some dental patients may reflect real anatomic and genetic differences. Limited research on the effectiveness of local anesthetic agents has been conducted in the past 50 years, and almost none has focused on individual differences in genetic composition and anatomic structure. With one in seven patients reporting inadequate anesthesia when his or her teeth are stimulated with a drill, even after administration of local anesthetic,[69] it may be time to launch research into the impact of individual differences in genetic composition on drug efficacy.[87]

Brain imaging studies provide additional support for the need to adapt to individual differences in pain mechanism. One study[13] used fMRI to evaluate cerebral responses and, through this approach, confirmed that identical experimental pain stimuli produced different activation in pain-related regions of the cortex. These differences systematically varied in subjects who were sensitive to the pain and those who were not.[13] This study provides additional and persuasive evidence that individual differences in pain responses reflect actual variability in the experience of pain. Incorporating pain management strategies into dental treatment with the understanding that individual differences in pain response are rooted in true biologic, psychologic, and social differences will lead to better outcomes for patients and less stress for clinicians.

Considerable evidence has been presented supporting the existence of differences among individuals in their responses to dental treatment. It follows that a single management approach for anxious patients will be less effective than adapting the strategy to the needs of the individual patient. In the next section, a few selected strategies are outlined, with special emphasis on tailoring communication to the fearful patient.

MANAGEMENT OF PAIN AND ANXIETY

Patient Communication

Individualizing the doctor-patient communication to identify, acknowledge, and reassure the distressed patient is one of the most effective anxiety-reducing strategies available to the dental team. It is a three-pronged strategy, involving the establishment of rapport with the patient, the use of a standard interview protocol, plus the use of effective nonverbal communication. Each of the prongs of communication requires a dialogue with the patient, rather than one-sided listening to the patient at one extreme or a monologue, with the clinician not providing opportunities for the patient to comfortably speak up, at the other. For most patients, having the clinician listening attentively sets a context on which to build a trusting doctor-patient relationship.

Establishing Rapport

Fearful patients often cite poor communication with the clinician as a factor in maintaining anxiety. In particular, patients report that they do not believe their clinician adequately listens to their concerns.[35] Accurate diagnostic information is the foundation of any treatment, but to obtain that information, the clinician must first develop a trusting relationship with the patient so a free exchange of information is possible. The first step in building a trusting relationship with a fearful patient is to develop rapport.

Rapport development can begin in the first few minutes of getting acquainted. In fact, because many first impressions are unconsciously made, the clinician may be wise to carefully consider patients' first impressions of the dental provider and his or her staff. There is probably no better way to make a positive first impression than to demonstrate a sincere and genuine interest in the patient. What is the first question the patient is asked by the staff? Often, it concerns the payment policy of the practice and how the patient will be paying. Although it is essential to know about the patient's financial status, making that the first question the patient hears may immediately set an impersonal tone. Research shows that the clinician who initially talks about nondental topics is more likely to be perceived by the patient as friendly, and *friendly clinicians are more likely to have satisfied patients*.[4] An important exception to the use of nondental topics to establish rapport involves the patient who immediately initiates conversation about dental-related issues associated with his or her fear. Failing to respond to such an initiative may suggest to the

patient that the clinician is avoiding the topic of fear or lacks compassion.

The clinician should also be aware of the impression he or she is making when addressing the patient. The use of a first name assumes or implies a familiarity not all patients are comfortable with. Because the manner in which we address each other frequently sets the context for future interactions, dental providers and their staff should be cautious and sensitive to the individual needs of the patient. Addressing the patient as *Mr., Mrs.,* or *Ms.,* unless the patient has expressed a preference for use of his or her first name, demonstrates respect. Older patients and fearful patients may be offended if younger clinicians or staff members address them by their first name. Developing rapport and trust may require additional time and attention with the fearful patient who is already on guard. It is worth the effort, however, because satisfied, formerly fearful patients become excellent ambassadors for the dental practice. Another effective tool with anxious patients is active and engaged listening. In the following paragraphs, the challenge of listening to a distraught patient in a busy practice is discussed.

LISTENING

Although listening is sometimes viewed as analogous to sending an audio signal to a receiver that faithfully reproduces the signal as it was transmitted, listening is not a passive act. Anxious and fearful patients may express their feelings to the clinician or staff in the form of anger and blame. Rather than reacting to the patient's anger, the clinician should exhibit reflective listening. Reflective listening is an effective way to respond to anger, often defusing the exchange regardless of the cause of the anger. When people are angry, one of their primary goals is to convey their feelings to the listener. If a patient is expressing strong emotions, he or she cannot listen very well, so it is best not to offer advice at that moment. Both patients and doctors listen through a filter of biases and prejudices that influence their interpretation of what is being said. In this kind of interaction, it is especially important that the clinician not assume he or she understands what the patient is saying or how the patient "feels." Clinicians should encourage the patient to explain expressed fear with statements such as, "It sounds like you have very strong feelings about what happened. I want to be sure that I understand. Please go on." This gives the patient an opportunity to clarify, and the clinician has demonstrated that the emotional content or tone of the concern is being heard.

Strong feelings do not vanish by being ignored; they do diminish in intensity and lose their sharp edges when the listener accepts them with respect and understanding and allows the patient to express these feelings. Often the best initial step for either the clinician or the staff member is to *LISTEN!* Once the nature of the problem is clarified, and the patient's strong emotions have diminished, the usual techniques for effective communication can be employed using open-ended questions with appropriate follow-up questions based on the content and tone of the message. ***Developing a dialogue of trust between the clinician and the patient is necessary and cannot be delegated to a staff member (see also Chapter 1).***

BUILDING EMPATHY

Fearful patients are sensitive to any communication that can be interpreted as belittling or disrespectful. This includes dental jargon the patient does not understand or terms the clinician or staff members do not clearly explain. Fearful patients may be insulted by a statement such as "There is no reason for you to be afraid," when the patient is convinced there are abundant reasons for fear. The more empathetic the clinician can be, the more likely it is that the fearful patient will accept treatment. The term *empathy* refers to the capacity and willingness to understand a situation from the other person's point of view and communicate that understanding to the person.[20] This is not the same as sympathizing, which can widen the gap between patient and provider and has been shown to be counterproductive in establishing a therapeutic alliance.[53] Instead, reflecting back but not parroting what the patient has said can help the clinician show empathy. For example, if the patient says that he or she hates going to the dentist, a reflective statement might be, "Sounds like you have had some unpleasant experiences with dentists in the past." The patient may elaborate, and at the appropriate time, the clinician can offer reassurance by saying that he or she will do whatever can be done to make the treatment as comfortable as possible. Once a clinician has developed a good rapport with the patient, the rest of the patient's visit has the potential to go more smoothly. The clinician will also find that a good rapport with the patient facilitates a smooth standard interview and future treatment. After a trusting relationship has been established, the patient is more likely to accept the moments in which the clinician is distracted as a forgivable event and not take it as a personal insult or lack of interest.

Demonstrating clinical empathy can be more of a challenge in a diverse society. Clinicians frequently treat patients from ethnic, racial, and cultural groups different than their own. It is unreasonable to expect that clinicians can identify, understand, or adopt what it is like to be from another ethnoracial cultural group. It is still possible, however, to demonstrate clinical empathy if empathy is understood as a feedback loop much like hypothesis testing.[20] Successive cycles of conversation establishing what the patient believes about the nature of dental disease and what needs to be done can allow the patient and clinician to move closer to a shared understanding about an acceptable course of treatment. If nothing else, the clinician's honest attempt to understand the patient's perspective will facilitate trust. Trust cannot be earned if the patient feels there is a lack of concern from the clinician.

Using A Standard Interview Protocol

The use of a standard interview protocol facilitates the dialogue with distressed patients. Not infrequently, the anxious patient will become "sidetracked" with the emotion-driven recollection of past dental experience, and the response to questions in the patient history will meander, lacking logic and clarity. To keep the interview on track and in professional focus, the clinician may need to gently, smoothly, and efficiently return to the standard protocol and format for the information-gathering process. This may be accomplished by using a statement such as, "I am very interested in that part of your experience, but to be sure we have enough time, please tell me about…. Remind me later, and we will return to what you were starting to tell me." Similarly, it may become necessary to pause and deal with the patient's fear in the middle of the interview.

The use of a standard set of questions allows the clinician to concentrate on the patient and the response to each verbal

question, confident that all relevant information has been gathered. Depending on the patient's comfort level and curiosity, it is often useful for the clinician to provide a rationale for particular questions or requests for specific information. The rationale need not be long or detailed but should clearly establish in lay language why obtaining the information is in the patient's best interest. Stressed or fearful patients are frequently not attentive to the details of a message, so it is a good practice for the clinician to verify clarity and understanding by summarizing each phase of the interview. The clinician may wish to say, "Sometimes my statements are pretty confusing. (A little personal joke such as a reference to when I tell my teenager what time to come home can help make the point.) Since much of what we are going to talk about is important if I am to provide optimum care for you, I may ask you to repeat what you think I said just to reassure myself that I am being clear." Patients usually respond positively to such an approach.

Another helpful portion of the standard interview protocol is a question already established on most patient medical/dental health history questionnaires, which asks: "Are you anxious about receiving dental treatment?" The question provides two benefits for the patient: It allows the patient to verbalize his or her anxieties, and it also reassures the patient that the clinician is aware he or she may be anxious about the visit. The answer to the question also provides a benefit to the clinician: If the patient responds positively, a series of follow-up questions regarding the patient's perception of the cause(s) of his or her anxiety can lead to fruitful revelation of specific averse issues, materials, and techniques. This knowledge can then be very helpful in strategizing how treatment will be planned and carried out to mitigate the patient's aversion and anxiety.

The type of questions the clinician uses in talking with a fearful patient can influence the degree of satisfaction with the interaction for both. For example, if the fearful patient is not talkative, the clinician should consider whether responses could be encouraged through use of more open-ended questions. If the patient is talking excessively, closed questions will help the clinician control the interview. Incomplete or inaccurate information may result from questions that lead patients to an answer they believe the clinician is seeking. For example, "I don't suppose there have been any changes in your medications," may suggest to the patient that the clinician does not want to be bothered with any new information. A mix of open and closed questions produces the most effective interview and facilitates an ongoing dialogue. Effective communication, however, is not based solely on words. Nonverbal communication can be an effective strategy in building an empathetic and effective relationship with a patient. The following section describes an approach many clinicians find helpful, beginning with silence, which is rarely thought of as an important communication tool.

Using Nonverbal Strategies

There is a strong tendency in the commercial model of health care to think that giving advice and providing treatment is the sole task of the clinician. Periods of silence are often avoided, but silence can be a useful tool when listening to any patient, especially a frightened one. Conversely, good care cannot be provided without spending the time to build a trusting relationship between the patient and the clinician. The silence may feel a bit clumsy or uncomfortable, but patients often report that they are not given adequate time to respond to the clinician's questions. This is especially true with older patients who may need a bit more time to understand what is being said or asked of them. Giving the patient adequate time to collect his or her thoughts and avoiding the tendency to comment too quickly gives the impression that the patient is the focus of the attention at that moment. It also helps if eye contact is maintained with the patient; a nod of the head shows that the message is being heard and is important. Permitting the silence to continue may encourage the patient to provide additional relevant information that would have otherwise been missed. Within limits, the clinician should encourage the fearful patient to talk more rather than less.

The clinician's physical orientation toward the patient also provides important messages about the level of interest in what the patient is saying. It is unlikely the patient will continue talking if the clinician appears not to care about what is being said. Making direct eye contact and nodding as the patient speaks can be affirming and serve as encouragement for more conversation. During the interview, it is most effective for the clinician to face the patient, with the chair at about the same level as the patient's chair. These initial moments are often the time when the fearful patient assesses the clinician's trustworthiness and the extent to which expressed concerns are being taken seriously.

In Western culture, eye contact is the principal means of demonstrating involvement with another human being. Eye contact should be steady and frequent (without staring). Glancing elsewhere is acceptable, but the patient's face should be the focus of the clinician's attention. The clinician may take notes, but it is important to reestablish eye contact after each note is taken to convey the impression that what the patient is saying is important. Showing care in this way is one avenue of demonstrating clinical empathy. Patients are very sensitive to discordant messages between our words of caring and aspects of nonverbal communication such as eye contact. Maintaining eye contact until the patient has stopped speaking provides a powerful statement of respect and concern.

The fearful patient is best served if the context in which care is received is based on mutual respect and concern. Many fearful patients have not received routine preventive care and may have extensive treatment needs, including some requiring complex, invasive treatment. If so, the patient will need reassurance that the clinician will make every effort to provide comfortable treatment.

No promises should be made that the treatment will be painless or free of discomfort. Pain-free dentistry is not a promise that can always be kept. It is also important to acknowledge the patient's feelings. Acknowledgment does not represent endorsement; it simply confirms that what the patient said was heard. During treatment, frequently expressing sincere interest in the patient's level of comfort and keeping the patient informed of progress helps relieve anxiety. The expression of concern should be sincere, not automatic.

As part of the framework for care of a fearful patient, the clinician should work quickly and systematically without appearing hurried. Planning ahead and informing the patient about the next step can be reassuring. Keeping promises made to the patient will maintain the patient's trust. Such promises may include the length of the appointment or the frequency

of breaks. Being honest about what is and is not realistic helps both the clinician and the patient. Fearful patients appreciate a frequent review of what has been accomplished, what remains to be completed, and any unanticipated deviations from the original plan. Setting a context of predictability is important to most patients, but with fearful patients, the appearance of predictability projects organization and control.[23] The basis of trust often rests in the patient's sense of personal control.

Research has shown that fear about dental care increases when the fearful patient wants control during treatment and believes he or she will not have it.[57] A sense of personal control can be provided through information, predictable sequences, and choices about the treatment and the treatment process. One strategy that returns some level of control to the patient involves inviting the individual to raise a hand when he or she would like to take a "time out." It should not be surprising if a patient tests the clinician's willingness to give up control during the treatment by frequently raising a hand. Other options may include giving patients a choice of music to listen to during treatment, which implies control over the environment.[3,40] (See de Jongh for a review of individualized dental anxiety management strategies.[23,56])

Patients who manage their apprehension about dental treatment often have identified coping strategies that have worked well for them in the past. Fearful patients may not have such well-defined strategies. Asking about preferred coping strategies and helping the patient identify one that usually works has proven useful in reducing anxiety.[55] Dental anxiety can also be managed with conscious sedation techniques,[67] but it is important to remember that these agents do not treat anxiety, they only facilitate treatment. When conscious sedation techniques are used, they are most effective when combined with behavioral interventions.[43,54] (See de Jongh for a review of individualized dental anxiety management strategies.[23])

In short, if anxiety reduction is to be possible, a trusting relationship needs to be in place whereby (1) the patient's feelings of anxiety are acknowledged, (2) a safe and secure environment is in place, and (3) the patient believes that nothing will happen that the patient and doctor have not agreed on.[23] In addition to the strategies described before, numerous other behavioral interventions are available. Although no one strategy has emerged as "best," most have shown that dental anxiety is treatable, and the effects of the behavioral treatment are long lasting.[51] Next, four interventions with particular relevance to dental care are highlighted in somewhat greater detail.

Behavioral Interventions

Distraction

Distraction as an anxiety-reducing strategy has broad appeal because of the ease of use. Music represents one of the simplest distraction techniques to use and is particularly effective if the patient selects the music and listens over individual headphones. Regardless of the patient's anxiety level, patients often report that they prefer to have music in the background because music makes them more comfortable.[4] In a randomized clinical study, patients who listened to music during dental treatment reported less pain, less discomfort, and a greater sense of personal control.[3] Thus music can be both distracting and, under certain conditions of choice, provide the patient with a sense of control.

Portions of the office décor can also divert a patient's attention. It has often been reported that interesting artwork, décor, or tropical fish tanks are useful in distracting the patient from feared stimuli.[4] Some clinicians have used video games or a television set in the operatory as an effective and comforting distraction for anxious patients.[17,33] Manual stimulating distraction devices have also been used during dental anesthesia injection to reduce dental anxiety.[89] The clinician should be aware that simple distraction techniques may be ineffective if the perceived intensity of dental pain is too high.[6] Distraction is largely effective in the short-term management of anxiety but less effective for long-term behavior change.

Relaxation

The goal of relaxation is to achieve both muscular and mental relaxation. Research shows that relaxation is an effective method of reducing patient anxiety.[18,19] Deep breathing coupled with muscle relaxation can be effective in stress reduction. Many fearful adults tend to hold their breath during basic procedures such as applying a rubber dam, giving injections, or forming impressions. When the person's blood becomes poorly oxygenated because of an insufficient amount of fresh air entering the lungs, states of anxiety, depression, and fatigue arise, contributing to the already stressful situation. Deep breathing exercises help to reduce this unwanted stress can consist of as little as 2 to 4 minutes of breathing in deeply, holding the breath, and then exhaling completely. By demonstrating for patients that deep breathing is something they can do on their own, a new sense of control is provided in addition to the calming effects from the breathing techniques. It may even be helpful to attach a heart rate monitor so that both clinician and patient can assess this aspect of stress arousal and success in controlling it.

Pausing during the procedure and suggesting that the patient briefly repeat the deep breathing techniques can be helpful. Muscle relaxation is also very useful in calming the patient. This method includes repeated tensing and relaxing of specific muscle groups in the body. Breathing and muscle techniques can be combined by tensing the muscles while breathing in and relaxing them while breathing out. Practicing this rhythmic coordination of relaxation techniques will quickly and effectively improve the patient's ability to relax.[69] Periodic reinforcement of muscle relaxation during treatment helps the patient regain composure. Pausing during the procedure and suggesting that the patient take several slow, deep breaths can also be useful. For some fearful patients, the mere act of deeply inhaling and exhaling completely can help dispel negative reactions to receiving care. Some caution should be used in attempting to combine music and relaxation therapy, because some types of music may have unanticipated effects on the patient and may actually increase autonomic arousal.

Hypnosis and Guided Imagery

Hypnosis is a guided, self-controlled state of mind in which concentration and focus is directed inward. An altered level of consciousness is reached, similar to "zoning out" while daydreaming or reading a book.[44] Guided imagery is a form of mild hypnosis that can be useful with fearful patients.[7] It produces a light trance from which patients easily awaken, and the

procedure is less time consuming for the clinician than guiding patients into a deep hypnotic state. Asking the patient to focus on a place in which he or she feels very relaxed, comfortable, or safe is a good starting point for guided imagery and can be effectively combined with relaxation training.[79] Information about appropriate images can be gathered during the examination process. Current research shows that patients have reduced pain and distress when they themselves choose the place to be imagined. The patient should be asked to choose imagery that is associated with little movement so that movements will not interfere with the provision of care. During guided imagery, the patient achieves an altered state similar to daydreaming or focused attention. By focusing on a calm and safe scene, positive emotions are elicited that can block or mitigate the anxiety arising from the dental treatment. An analysis of imagery topics chosen by patients shows that the topics were highly individual and further supports the efficacy of guiding patients to a "safe and comfortable place" of their own choosing.[28,54] Guided imagery is effective in managing pain during outpatient procedures and can be delivered by the dental team without disrupting the workflow in the patient care setting.[7,52]

In the past, the success of hypnosis was believed to depend on the hypnotizability of the subject and was associated with a specific "phobic" portion of the population.[39] More recently, researchers have shown that nearly all patients are equally able to engage in imagery during invasive outpatient procedures, and the imagery has resulted in reduced pain and anxiety.[52] Although nearly all patients are equally susceptible to hypnotism, their attitudes, motivations, and fears from common misconceptions may interfere with or impede their willingness to engage in a hypnotic state.[28] The most successful conditions involving hypnotism in the clinical setting include a well-trained hypnotherapist and a patient who is highly motivated to overcome a problem.[2,15] *For most mildly or moderately anxious patients, the most effective management strategy for the clinician is taking time, actively listening to the patient's concerns and fears, and emphasizing the building of a trusting relationship between the patient and the clinician.* For more serious cases, deep-breathing techniques and hypnosis/guided imagery are among the most useful. The effectiveness of hypnosis in treating dental fear has been demonstrated.[39] Hypnosis, however, requires specialized training and experience, so a brief "how to" belies the complexity of the strategy. For clinicians who are interested in being trained in hypnosis, resources can be accessed through the Internet[1] or through other printed materials.[69] Information about training in the specific area may be available through the local dental society or mental health center.

Referring to the Mental Health Professional

In extreme cases, refining the dialogue and using previously mentioned strategies are inadequate to reduce the patient's distress and fear. The clinician may want to exercise the option to refer a fearful patient to a mental health worker for professional counseling and therapy. This decision may depend on the clinician's own skills and interests in working with fearful patients. One criterion used for referral is whether the fear imposes a significant barrier to successful completion of care. If this is the case, referral may be warranted. If a therapist's name is not readily available, a call to a county or state psychologic or psychiatric association will yield the names of professionals who specialize in anxiety disorders. If the patient is currently in therapy, it is appropriate to ask the patient's permission to speak with the therapist. If the patient gives permission to contact the therapist, the clinician should consider maintaining an ongoing dialogue with the therapist during the course of dental treatment. Questions the dental provider and the therapist may discuss are:

- Do adjustments need to be made in the sequence of the dental treatment plan?
- Do adjustments need to be made in the anxiety-management strategies as the treatment progresses?
- Should new anxiety treatments be tried?

Based on the conversation with the therapist, the clinician can decide whether further referral is necessary or if the patient is being treated adequately for his or her dental fear. If the patient's dental fear and anxiety do not subside, other measures may be needed, including pharmacotherapy. As with all treatment, careful documentation of the anxiety treatment is important. The dental team should be reminded to assiduously adhere to HIPAA standards in discussing the patient's care among themselves and in sharing information unless directly relevant to provision of dental care.

SUMMARY

Individual patients differ dramatically from each other in how they respond to dental treatment. These differences arise from multiple biologic, psychologic, and social sources, which are influenced by both genetic factors and lifestyle. How successfully a clinician adapts to these differences by tailoring treatment options will depend on the depth of his or her understanding of the way a patient perceives the situation and the person's general state of health. Incorporating this understanding into the clinician-patient dialogue can produce improved clinical outcomes.

THE FUTURE

Dentistry has always been at the forefront of technologic advances in health care. Until recently, those advances came at a steady and moderate rate that allowed the clinician to adapt using a traditional understanding of the laws affecting practice. However, the exponential growth of the Internet and the digitalization of health care systems have required clinicians to revisit their understanding of the laws of dental technology and the resulting changes in the standard of care.[17]

This chapter provides an overview of the nature of the technology and trends in dentistry, the issues that consequently arise, and the applicable laws.

SCOPE OF DENTAL TECHNOLOGY

Recent advances in dental technology have brought about rapid changes in every aspect of the delivery of dental care, including marketing, communications, record keeping, imaging, testing, diagnosis, treatment, education, and billing. Likewise, these advances have increased the capabilities of the dental clinician, and with their growing acceptance in the dental profession, the standard of care also has evolved.

Patient Communications and Marketing

Many homes and businesses in America have Internet access. Patients younger than 30 may have grown up using computers and cell phones as their primary sources of information and communication.[10] Once just the name of another Internet web page, *Google* (www.google.com) has become a de facto verb that defines one of the most common methods of exploring an issue in dentistry, researching a proposed treatment, or even finding a dentist. Patients frequently investigate a dentist by *googling;* they find sites that rate dental offices, or they may go to a state's licensing webpage.[20] After selecting a dentist, the new patient is likely to use *MapQuest* (www.mapquest.com) for directions to the office if the dentist's webpage does not already provide a link to a map page.

Dental Continuing Education

Dentists no longer need to wait for the mail carrier to deliver journals or find the time to attend a convention for an update on recent advances in dentistry. Many clinicians have Internet subscriptions to sites such the American Dental Association's (ADA) (www.ada.org/prof/resources/pubs/adanews/index.asp) that regularly announce developments in dentistry by e-mail and provide links for further investigation. Accordingly, the legal *standard of care,* or the practices expected of a reasonable and prudent dentist, has become a standard that is defined on a national level rather than simply by the care provided in the local community wherein the dentist practices.

Conversion to digital dentistry soon will no longer be optional. It will become necessary because of the elevation of the standards of care, patient demands, and the requirements of the marketplace in general. At all major dental conventions, most trade exhibitors now market some form of digital

dentistry. Also, clinicians increasingly are seeking patients by offering "high-tech" dentistry.

SCOPE OF THE ISSUES

In the 21st century, dental technology affects every aspect of the delivery of dental care at an ever-increasing rate. At the same time, learning curves are flattening, and costs are dropping. State licensing boards and traditional dental societies are finding it difficult to keep up with the advances in dental technology. U.S. lawmakers and courts also are finding it difficult to keep pace; therefore they have taken laws designed for other technology industries and adapted them to meet medical and dental care issues.

In addition, the law has recognized the impact on privacy of the digital communications age and the ability to transfer electronic patient information instantly. The Health Insurance Portability and Accountability Act (HIPAA), passed in 1996, sets forth strict guidelines on confidentiality standards for patient data.[2]

Barriers to Adoption of Dental Technology

Traditional barriers to the adoption of technologic advances in dentistry have included investment limitations, slow approval by the U.S. Food and Drug Administration (FDA), office design issues, conversion costs, and resistance from clinicians who were very comfortable and reasonably productive with conventional dental systems. The old ways were simple, they worked, and they were cheap, but those barriers are falling. With greater community acceptance, the production of technologic devices has increased, lowering the cost of digital dentistry. Adaptation of technologies from other health care industries has increased the rate of regulatory approval for digital dentistry. A reasonable understanding of the laws of dental technology can help remove the last barrier: clinician resistance.

LEGAL EXPOSURE

Traditional Avenues of Exposure

Traditional legal exposures for the dental practice included *malpractice* (negligence or substandard care), *general liability* (also known as *premises liability*), employment claims, and licensure issues. Typical claims against dental offices involve bad results or ineffective treatment arising from poor planning and execution. In many cases, they can be directly traced to poor record-keeping or to communication gaps between dentists and patients and/or between general dentists and specialists. These weaknesses often are readily spotted by lawyers. Particularly by those who specialize in dental malpractice cases.[7]

Digital dentistry, when used correctly, can reduce traditional legal exposures by increasing record-keeping capability, providing twice as much data at half the input time and eliminating legibility problems. E-mail and faxes provide instant, traceable forms of communication, record sharing, and data gathering; as a result, the clinician is better informed and better able to provide ideal treatment.

New Avenues of Exposure

Although digital dentistry has the potential to reduce the risks associated with certain traditional areas of exposure, it has created some new avenues of potential exposure. Misuse of technology, inadequate maintenance of equipment, warranties, and confidentiality of records are emerging areas of potential liability exposure.

Misuse of Technology

The nature of health care, and particularly of dentistry, is such that maximization of production often is the primary business focus. Dentistry has always been creative in finding ways to provide treatment in less time and with less discomfort and fewer complications for the patient. However, that inventiveness may prompt clinicians to use technology for unapproved, or *off-label,* purposes and to take short cuts. In such cases, the guidelines issued by the manufacturer of a specific technology can be used as a statement of the standard of care. Examples include the *Physician's Desk Reference* (www.pdr.net) for medications, the instruction booklet for endodontic electronic apex locators, template overlays for sizing dental implants, the user guides for virtual impressions, and the owner's manual for electric high-speed handpieces.

In the event of a complication or bad result, the patient's attorney may offer the manufacturer's guidelines as evidence the jury should consider in deciding whether a problem suffered by a patient was the result of substandard care for which damages can be awarded. A particular manufacturer's guide or standard that was not followed by a defendant dentist, projected in bold print on an 8 × 8-foot screen, tends to have a very powerful impact on a jury that is trying to decide whether a treatment complication was merely a bad result or evidence of substandard care.

In contrast, evidence of strict adherence to a manufacturer's guidelines may be used by the attorney defending a dental malpractice suit. It may serve as powerful evidence that the complication or problem was not the result of substandard care but rather a risk of the procedure.

Inadequate Maintenance of Equipment

Manufacturers of dental technology can become targets of personal injury suits if a treatment complication or bad result can be traced to a failure or breakdown of the technology. For example, defective bearings in a high-speed handpiece may cause overheating, resulting in a burn on the patient's lip, or an endodontic file can break in a canal during treatment. Therefore manufacturers of dental equipment have issued specific guidelines for the maintenance of dental devices. If those guidelines are not strictly followed, liability for an injury shifts from the manufacturer to the health care provider, even if the patient's injury was caused by a manufacturing failure. The prudent clinician strictly follows the guidelines for maintaining equipment and, more important, documents adherence to those instructions. This policy should include regular and scheduled testing if such is required by the manufacturer. With regard to the example of the overheating handpiece, some manufacturers have issued revised guidelines calling for shorter and shorter recall cycles and for more frequent testing by the dentist. Failure to keep up to date on those changes could expose the user to liability for an equipment breakdown.

Warranties

Breach of warranty presents a different type of legal exposure than breach of the standard of care. Failure to meet the stan-

dard of care is a form of dental negligence, which usually is determined by comparing the testimony of the defendant with the testimony of expert witnesses retained by both parties.

A *warranty* is a statement or promise of a specific result or, in dentistry, a promise of a specific outcome. In the event of a bad result or complication, the patient need not prove substandard or negligent care; the person need only show that he or she received something other than the promised result. Such representations must be avoided.

Dental high tech equipment, such as computer projections of potential treatment results, can create a warranty and the attendant exposure for less than the projected result. The prudent clinician therefore makes sure to have patients review and acknowledge disclaimers notifying the patient that such projections are merely estimates, that no specific result or outcome can be guaranteed, and that individual outcomes may vary. These disclaimers must be charted and also must become part of the informed consent process and the case documentation.

Some clinicians may think it acceptable to offer an expressly stated but limited warranty for dental treatment. In such cases, no evidence of substandard care is required; merely a failed or unsuccessful result, and the dentist who issued the warranty is required to pay for retreatment.[15]

Standards of Care

The traditional standards of care have evolved to include reasonable standards of dental technology, which is subject to specific state and federal laws. A dentist may become liable for failure to suggest the option of a new form of dental therapy and for not allowing the patient to make an informed decision on options, regardless of whether insurance coverage is available for the ideal treatment or test.

The law has embraced a doctrine of *informed refusal,* which specifically requires discussion of the risks of refusing a recommended treatment or test. For example, the clinician would be required to discuss advanced endodontic treatment modalities, cone beam volumetric tomography (see also online Chapter 29), or dental implants, regardless of the patient's insurance coverage. The prudent clinician documents such discussions with the patient. Such documentation should include a mention of the options discussed and states that the risks, benefits, and alternatives (RB&As) were discussed and the specific option was selected by the patient. If the patient chooses an inferior option (higher failure rate, more complications) because of financial limitations, the clinician should specifically document the informed refusal.

Many dental risk management and professional liability companies now provide *informed refusal* forms for patient acknowledgment and documentation.[9]

Webpage Issues

Internet webpages have become a major business tool throughout the world and particularly in America (see also online Chapter 28). They are the new marketplace, post office, and meeting center—and a new potential for liability for the uninformed dentist. Therefore when planning a webpage, dentists should consider the legal issues as well as style and content.

Webpages are created by blending text with images and *links* (click-on pointers that can direct the viewer to another webpage), all of which are separate files that can be copied and downloaded to make another webpage. Such techniques are commonly used by webpage builders, but the material, text, and images are subject to copyright laws in the same fashion as text and pictures in a book. As such, the use of images and text taken from other webpages may subject the owner (dentist) of the recipient data to liability for copyright infringement. The prudent clinician makes sure that permission has been obtained and documented before using images taken from the Internet, unless the material is considered *public domain* and is so marked or labeled. This proviso also applies to links that use the logo of another company or person. Dentists cannot assume that buying a product or endorsing a company constitutes permission to put the company's logo or trademark on the dentist's webpage. Again, *documentation by way of a confirming letter or e-mail should be obtained before such proprietary images or links are used on a webpage.*[18]

Interactive webpages, created through the use of special programs and e-mail connectivity, present another potential legal issue: the remote and electronic practice of dentistry. Patients can submit questions, send digital photographs or scanned radiographs, and request an opinion through the website. However, responding to such an inquiry may be considered the practice of dentistry in the state where the patient resides, which may not be the same state where the dentist holds a license. The courts have seen several cases of prosecution of doctors for giving advice over the Internet to patients in states other than the state where the doctor is licensed. Also, charges have been brought against insurance company consultants for evaluating out-of-state claims for benefits.[13]

Although currently the subject of considerable discussion, nationwide licensure by credential would appear to be years away. Therefore the practice of dentistry is limited to the licensing of individual states (and nation) in which a dentist maintains a license. To avoid potential liability, a dentist with interactive webpages should use disclaimers specifically stating that the communication is to be considered only as data for informational purposes, *not advice or diagnosis,* and in all cases it is not a substitute for a consultation with a dentist in the community where the patient lives.

Confidentiality and Security

All dental health care providers have a basic understanding of the need to maintain the confidentiality of patient records and the information included in them. However, with the advent of paperless digital dental records and imaging, the potential for rapid and widespread distribution of a patient's inadvertently disclosed confidential information has become a significant issue. The problem has increased with the growth of the Internet and the use of computer consultants with remote access. These matters have come to the attention of lawmakers and the courts. Laws have been passed to address such concerns.

Even if a dentist reasonably believes that he or she is not subject to HIPAA, almost all states have laws requiring that reasonable efforts be made to secure patient records and maintain their confidentiality. Coincidentally, many of those requirements mirror the regulations set forth by HIPAA.[4] The following checklist for confidentiality compliance is useful for all clinicians, whether HIPAA qualified or not.

- *Recall cards.* An unsealed, postcard-type communication from a dental office to a patient should not disclose any

information about a patient's health history. It may only indicate the patient's name and a general statement of the need for an appointment (without specifics as to why) or may merely confirm the date of a recall appointment. Information about the need for premedication or other special preparations or specific treatments to be performed should not be included on an unsealed postcard.

- *Records.* Dentists are required to make reasonable efforts to maintain the confidentiality of records. Protocols should be established for record organization, placement, and storage to prevent inadvertent disclosure of patient information. The jackets of dental charts should not have any markings, writing, or indications of the patient's illness specific health status. Stickers warning of a patient's particular medical condition should not be used. Reception desk protocols should prevent a patient's chart from being left open and visible when staff members are speaking with another patient. This rule should be followed in all areas of the office. Day sheets should not include any information other than the patient's name and the time allotted for the appointment, or they should be positioned so that they are not visible to patients (e.g., under a cover sheet or an inbox).
- *Communication.* Reasonable communication protocols should be established that (1) prohibit easily over heard conversations in the reception area between staff and patients regarding a patient's medical condition; (2) prohibit loud conversation between staff members when discussing the medical history or specific treatments of patients; (3) offer patients the opportunity to go to the dentist's private office to discuss sensitive aspects of a medical history.
- *Computers.* In offices with computer screens that might be viewed by patients, protocols should be established to minimize the potential for inadvertent viewing of information about another patient. Such protocols might include something as simple as turning the computer screen away from patient paths of travel or using polarizing filters over the screen that narrow the viewing angle to 15 degrees.

LAW OF COMPUTER RECORDS

Although the laws of individual states may vary, certain basic requirements apply to computer records in health care settings.[1]

Off-Site Backup

All computer systems should have an off-site backup data storage system. Daily or weekly backups of the computer files must be removed from the office and stored at another site; this prevents loss of the backup data in the office as a result of an event such as a flood or fire.

Protection Against Alteration

A valid digital record-keeping system must include programming that prevents alteration of the data after input. Any digital record-keeping system that allows postinput changes to the entries without maintaining evidence of the change may be challenged in court. The same rules apply to digital imaging such as radiographs and photographs.

Signature

The digital record must also note the identity of the person inputting the data, either by a login system or by a designation at the end of each recorded entry.[8]

Confidentiality

The law requires offices with Internet access to use reasonable security methods such as computer firewalls and antivirus programs. In addition, computer consultants with access to digital files should provide written acknowledgment of their obligation to maintain confidentiality.

In the transition from paper to digital records, paper charts can be converted to digital records by scanning the documents into an Adobe portable document format (PDF) file,[3] a graphic file that cannot be easily altered. It is important to remember that after a file has been converted into digital form, the paper records, radiographs, and photographs must be destroyed in a manner that maintains confidentiality (e.g., shredding). The law considers trash and paper given up for recycling to be similar to public property and readily accessible to anyone. Simply tossing old records into the trash is a violation of the laws that require maintenance of patient confidentiality.

The statute of limitations for bringing a lawsuit against a dentist for malpractice is 2 years in most states. However, various exceptions to that law exist, such as when the patient is a minor or is found to be legally incompetent. Because of these exceptions, most risk managers recommend that records, whether paper or digital, be maintained for at least 10 years after the patient's last visit. After that, the records can be discarded, but this must be done in a manner that maintains patient confidentiality. **Tip:** As more health care facilities and offices go digital, be on the lookout for states to increase the time dental offices are required to keep records.

IMAGING

The prudent clinician recognizes that as the quality of digital radiographs improves and the cost decreases, digital imaging will become a standard of care. There are several reasons for this. Digital radiographs expose the patient to less radiation, are not subject to the same processing problems as conventional films (underdeveloping, poor fixation), can be downloaded to the chart and instantly sent to other dental offices, and ultimately will be required for online insurance submissions. In the not-too-distant future, clinicians may see the end of the darkroom and the passage of laws that ban or severely restrict the use of the chemicals required to process radiographs, because of toxicity concerns.

These same issues will apply to digital photography versus conventional photography, because of the digital mode's easier storage, transmission, and submission to insurance companies. As digital photography becomes more popular with the public, patients will expect that photographs taken by the dentist will be readily and easily transmitted to other health care providers or the patient.

Perhaps the single most dramatic change in the standard of care has come with the advent of cone-beam three-dimensional (3D) imaging, described in Chapter 29.[12] This imaging system provides the clinician with virtually complete anatomy of a tooth and surrounding structures—information that can be used in planning, evaluating, and performing

endodontics.[12,21] The data obtained can display conditions such as root curvature, sinus anatomy, and instrument location to the point that treatment is more predictable and reliable and complications more avoidable.[16] The prudent clinician must consider giving patients the option of 3D cone-beam imaging if such data would enable better treatment planning, reduce risks and complications, and foster greater success. If a patient declines the use of such imaging, the clinician—after educating the patient about the risks, benefits and alternatives—should obtain and document informed refusal.

INSURANCE SUBMISSIONS

Materials, postage, and labor constitute a significant part of the costs incurred by insurance companies for processing dental insurance claims. In the not-too-distant future, insurance carriers will forbid or add a surcharge for claims submitted as paper documentation, using plastic radiographs, and paper photographs. Other industries already require digital submissions. Airlines now add a surcharge for paper tickets, and banks charge a fee for maintaining and returning canceled paper checks. Some courts, such as the Federal District Court of Northern California, strictly prohibit the submission of paper documents (all filings must be submitted over the Internet as Adobe PDFs). Insurance companies will easily find judicial favor when they start to require digital submission of claims for dental treatment and begin charging a fee to process paper submissions.[5]

Office Technology Policies

As dental practices begin to use online computer services such as e-mail and Internet access, as well as digital record storage, the office should establish and enforce staff management policies regarding the use of those technologic aids.

E-Mail and Internet Access

E-mails and Internet surfing are two common sources of computer viruses, spam, and spyware. Computer viruses can damage or destroy data. They typically and unknowingly are sent by a friend who is sharing a joke or photograph that has been passed around by other computer users. While surfing the Internet, users can unknowingly download computer spyware programs; these programs secretly take up residence on a computer system and then silently begin transmitting information about the user's computer over the Internet to outside individuals and companies. The use of e-mail and the Internet also can result in a person's e-mail address being sent or sold to spam companies and businesses that mass produce millions of unwanted e-mail marketing messages per day.

In most states, the law holds that employee use of e-mail, in the absence of a specific policy to the contrary, is considered private, similar to the use of a telephone, and employers may not access such communications without an employee's permission, just as tapping a phone call is illegal. For these reasons, offices providing employee access to e-mail and the Internet should have written policies that specify the restrictions and violation warning (Box 27-1).

Communications

Some clinicians have considered documenting their patient consultations by recording them with video or audio devices.

BOX 27-1

Sample Written Policy for Employees With E-Mail and/or Internet Access

1. *Use of, and access to, e-mail and the Internet at the offices of _____ is restricted and limited to business purposes only. Personal, nonbusiness use is prohibited.*
2. *Use of e-mail and the Internet is not to be considered private, and _____ reserves the right to, and may at any time, audit, record, trace, and/or monitor employees' use of e-mail or the Internet.*
3. *In order to protect the office computer systems and patient privacy, this office will use various security systems such as antivirus and antispyware programs, as well as spam filters. Employees will be expected to assist, as indicated by their assigned job duties, in the routine application of such security systems.*

Violation of these policies may subject an employee to termination of employment.

Recent developments in digital recording make it possible to record and store huge amounts of video and audio data on relatively compact systems. DVDs can record and store up to 6 hours of video/audio on a single disk, which currently costs less than $2. Devices with hard drives can record and store more than 80 hours of video and audio data.

The laws of most states prohibit the recording of conversations conducted over the phone or in person when anyone in the conversation could have a *reasonable expectation of privacy.* Hidden microphones or cameras are illegal recordings and subject the user to both criminal and civil penalties. However, the law allows recording of a conversation and/or the patient's image if the patient gives expressed consent to the recording.

If the clinician decides to record a consultation (video, audio, or both), the patient's permission should be obtained before recording begins. After this permission has been obtained, the patient's consent to being recorded should be stated, including the time and date, at the beginning of the recording and again at the end of the recording. The fact that the consultation was recorded should be noted in the patient's chart.

Patient Education

Digital systems are available for patient education. The fact that a patient viewed educational material about a proposed treatment option or a diagnosis, whether the material is in the form of a booklet or an audio or video program, should be recorded in the patient's chart. The prudent clinician documents what, where, and when the patient was provided educational material, as well as the fact that the dentist and patient had an opportunity to discuss the material.

Even the education of dental students has gone digital; at some schools, all textbooks are provided to students through laptops rather than on paper.[11]

THE FUTURE

Dental technology is growing at an accelerated rate, and the digitalization of all aspects of dental care is on the near horizon. The process began with electronic records, moved to digital

imaging, and is progressing to digital treatments, such as endodontic electronic apex locators, automatic periodontal probes, virtual impressions, computer-fabricated restorations, and in-office testing ("laboratory-on-a-chip" systems) to evaluate a patient's blood sugar, perform microbial assays, and monitor a patient's stress level. Patients have come to expect complete treatment in one session, such as single-visit root canal therapy (indicated in most cases), preparation and placement of crowns, and same-day surgical placement and restoration of implants.[6] One of the present challenges for clinicians considering endodontics is the growing school of thought that removing the tooth and replacing it with an implant may be the better long-term treatment in cases where saving a tooth with endodontics would also involve a post, build-up, pins, crown lengthening, and a crown. In such cases, the prudent clinician should advise the patient of both options, regardless of financial issues, and allow the patient to decide. If the patient chooses the lesser of two options (say, because of insurance coverage), informed refusal should be obtained and documented.[19]

In the near future, after a patient chooses a dental clinician, the individual will have his or her computer's scheduling program contact the dental office's computer over the Internet to schedule an appointment. At the same time, the patient will authorize a HIPAA-qualified release of digital records and imaging from other health care providers, and the information will be downloaded to the dentist's database patient health history profile, which will place appropriate tags for the staff and dentist to review before the first consultation. The dentist's office will have no darkroom, no record storage area (paper or models or imaging), no laboratory, and in some cases, no waiting room because no paperwork would need to be filled out, and patients who might be at the mall next door could be paged on their cell phones just before an appointment. Sound futuristic? It's already here; some dental service companies are completely digital and provide standard-of-care dentistry in a two- or three-operatory recreational vehicle (RV).[14]

SUMMARY

Dental technology is raising the bar for the standard of care. Very soon, some aspects of conventional methods of record keeping, image gathering, and patient treatment will become substandard. The prudent clinician considers and, when appropriate, adapts to new dental technologies but only with an appreciation of the legal issues involved.

- Consulting and Support
- Pharmacology Reference Software
- Patient Education Software

Endodontic offices rely on words, numbers, and images to communicate with patients, assess patient status, evaluate treatment options, and determine treatment outcomes. Many dental offices already use computer-based programs to manage patient demographic and financial information; the electronic oral health record[23] (EOHR) is the next logical step in the journey to the paperless office.

Although EOHRs are now widely available, integration of this information with an electronic health record (EHR) to create a unified, scalable, searchable, and secure patient database documenting the current health status and lifetime medical history of each patient is still elusive. In a broader sense, the real challenge is to understand dental informatics and the ways the collective efforts of the profession can be applied to improve patients' health care. Two experts in dental informatics observed that[79] "application of computer and information sciences to improve dental practice, research, education, and management" is the holy grail of dental informatics.[34,80]

The goals of this chapter are (1) to improve the dental care delivery organization's understanding of dental informatics and (2) to devise a strategic plan to help design office systems that use the latest computer, digital-radiographic, photographic, charting, and management tools to document vital information. Once this strategic guide has been implemented, continual upgrading based on best-recommended practices is important to ensure continued success.

In the early 1990s, the American Dental Association (ADA) initiated the development of technical reports, guidelines, and standards on electronic technologies used in dental practices. A task group was established to promote the concept of a computerized dental clinical workstation and to allow the integration of different software and hardware components into one system to accommodate all a clinician's information needs. Establishment of interoperability standards for these modules eliminates the need for multiple stand-alone systems in the dental office and provides a seamless information exchange throughout all facets of health care. The American National Standards Institute (ANSI) recognized the ADA as an accredited standards developer in 2000[4]; the ADA is working to ensure that common conventions have worldwide acceptance.[43]

The U.S. government has already begun using the Government Computer-Based Patient Record (GCPR) in federal health care agencies. The advantages of the EOHR were highlighted in a recent study[46] that compared an EHR with manual record

keeping. The study's findings were favorable to the EHR: improved understandability (89.2% versus 69.9%), better legibility (100% versus 64.3%), and the benefits of having at least one diagnosis recorded (48.2% versus 33.2%). Additional findings included improved prescription writing (86.6% versus 66.2%) and improved ability to recall advice given to patients (38.6% versus 26.8%).

COMPREHENSIVE TECHNOLOGY PLAN

Information technology (IT) systems are changing every day and at an ever-increasing rate. Deciding what equipment to purchase for patient use in the reception area, as well as for clinical, front desk, administrative, and clinician needs, can be daunting. Upgrading older office systems, especially while an office is in operation, complicates this process.

Clinicians should begin by establishing clear goals for the systems they want to implement. Generally, such technology planning can be divided into three areas: (1) the strategic plan, (2) the operational plan, and (3) measurement of success.

Strategic Plan

The strategic plan should be based on a list of goals for the seamless integration of all computer functions in the office. Clinicians should focus on what is necessary to provide the best service to patients and establish clear priorities. The more sophisticated the system, the more customization that can be done to provide exactly what patients and clinicians value most.

Dental practice systems are meant to assist the human user. These systems are *work multipliers*—that is, the technology replaces human effort, making tasks the clinician and staff members do easier and more error free and in some cases making possible new tasks that otherwise would be too costly in terms of expense or time. The bottom line for these systems is the value provided in terms of labor savings and quality of services compared with the total cost of acquisition and use. If the value the system produces is greater than the cost of buying and using it, the clinician and the practice benefit.

At its most detailed, or *granular,* level, dental care is delivered differently across the United States. Although many commonalities exist, and best practices generally are agreed upon, the goal of achieving the best outcome for the patient often means tailoring the dental arts and sciences to what works best in the hands of a specific clinician. Clinicians build or modify their practice environments to fit the nature of their practice; the workflow is tailored to allow the clinician to operate at the highest level of excellence in the clinical process.

Clinical and practice management systems are most beneficial when technology helps to make activities in the clinical process more efficient, more economic, and less subject to error. As noted in 1996 in a concept model for the electronic dental record published by the ADA, the fundamental activities in the clinical process are[2]:

- Examination
- Diagnosis
- Treatment planning
- Clinical care delivery

Table 28-1 presents the usual types of computer support available for these activities.

TABLE 28-1

Typical Computer Support for the Clinical Process

Procedure	Task	Typical Automation Support
Examination	Data acquisition	Automated charting, note taking, digital radiography
Diagnosis	Data analysis	Clinical decision support, automated real-time consultation
Treatment	Service planning	Decision support: case planning, automated presentation, documentation of informed selection and consent
Care delivery	Service delivery	Documentation of services provided; digital radiography of completed services

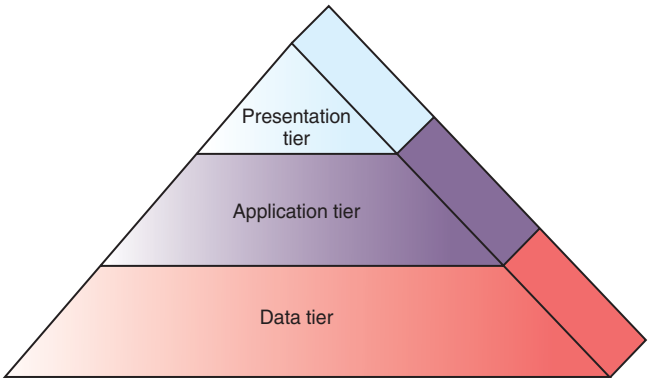

FIG. 28-1 Three basic layers of an integrated office computer system.

The systems that provide this type of support typically are composed of several layers, or *tiers,* that correspond to the basic functions provided by computer technology (Fig. 28-1). Each tier provides the dental practice system with a capability, and for best use, each tier must be configured to support the nature of the practice and its workflow. The tiers usually are categorized as follows:

- *Data tier:* The form and physical storage of data; in clinical practice, this often is the EHR and a variety of clinical and administrative reference data.
- *Application tier:* The internals of the system, which provide logic, calculation, and help with decision-making functions.
- *Presentation tier:* The part of the overall computer system that interacts with people and the outside environment, including other computer systems.

At the data tier, the heart of the clinical system is the EHR. ANSI/ADA Specification No. 1000 provides a data blueprint for digital representation of clinical and support data for an individual human patient.[4] This standard is the only model-based, data-level specification of clinical data for building an

EHR database. In such an EHR data system, not only the individual patient but also family members and significant others are identified. Often this capability is expanded to identify individuals who may provide health care services to the patient. Administrative data such as personal characteristics, employment, and similar information frequently are included in the EHR. The digital structures used to build the dental chart (but not the graphic chart per se) are maintained in the data tier. Also in the data tier, but outside the scope of the EHR, are the reference tables and rules sets for clinical decision support, lists of pharmaceutical items in a formulary database, and code sets for anatomic location, diagnosis, procedures, and so forth. The data tier is the foundation of the practice system.

The application tier is the functional heart of the practice system. All processing of data occurs in this tier, such as clinical decision support whereby the computer acts on rules to alert the clinician to a potential problem with a particular therapeutic agent in the case at hand. The application tier can operate on the data specific to a case, the reference codes, and notations and construct the graphic dental chart for a particular patient. It also operates on any signals from automated diagnostic devices, such as digital periodontal probes, cardiac monitoring devices or root canal depth gauges, converting these into human-understandable measurements that can be displayed to the clinician by the presentation tier.

The presentation tier provides the face of the dental practice system. The application and data tiers usually are neither seen nor heard by the clinician and staff; the presentation tier is by far the most interesting aspect of the computer system because it is the point where the clinician and staff interact with the system. The presentation tier is where the dental chart takes form, where the clinician can watch as its graphic features are recorded, and where the clinician can key in any special notes required. It also is where the clinician receives any patient care advisories, enabling patient safety features such as alerts to prevent adverse events. The presentation tier is where the electronic prescription is sent to a pharmacy. Finally, the presentation tier is the realm of digital radiography, regarded by many as one of the most beneficial aspects of automation in dentistry.[19]

The core of the office IT infrastructure is the central information store (CIS) (Fig. 28-2). The CIS is the "center of the universe" of the IT system, comprising the server and its attendant software and hardware; it also may include data generated in the office or imported from the Internet. The CIS should be located in a secure area and have an always-on connection to the Internet to increase functionality. The establishment of a local area network (LAN) now is considered essential for dealing with the heterogeneous information generated in each physical location and for integrating a wide area network (WAN) to connect several practice locations.

A comprehensive strategic technology plan should address all the information generated and processed in the practice and the ways it will be handled. The clinician must be prepared to manage information from patients and referring clinicians and to document and communicate all pretreatment, treatment, and posttreatment information via LAN, WAN, mail, fax, e-mail, and the web. An ideal system that handles this mix of data and gives all members of the office team what they want integrates the CIS with the reception, clinical, front desk, administrative, and clinician's office components.

FIG. 28-2 Relationship of the central information store (CIS) to functional areas in the office local area network (LAN).

Operational Plan

The newest concept in dental office management is *front-desklessness*. The central tenet of this concept is to minimize office interactions that traditionally take place at the front desk and shift them to the operatories (e.g., procedure code and fee posting, prescription writing, and all associated communications). Some programs now available to endodontists allow pending or posting of all relevant data from any computer in the office, including the generation of postoperative forms, instruction sheets, patient treatment reports, and e-mail correspondence. Advantages of this system include improved workflow and accuracy, because significant office revenues can be lost through posting inaccuracies that are never discovered.[58]

The operational strategy covers the planning and day-to-day practices that ensure a smoothly running IT system. Training and cross-training of staff are essential elements of a complete plan. To begin, at least one staff member must be knowledgeable about basic computer operations, especially word processing. End-user training courses are available online (e.g., globalknowledge.com) and nationwide to teach these basic skills. Books and video self-study materials can augment classroom training. The purchase of most clinical and front desk software systems should include ample opportunity for initial training.

Once initial training has been accomplished, a second training session, preferably on site, is advisable. This second visit, which should be scheduled several months after the initial installation, allows the clinician and the office staff to fine-tune the program by customizing certain preferences and double-checking that all the program's features are used to full advantage. In addition, to get the most out of the software, staff members should periodically review the program's training manual to discover features and shortcuts that may have been overlooked.

All computer workstation environments should be designed with ergonomic considerations in mind, such as work surface, keying, seating (Fig. 28-3), acoustics, lighting, and ventilation (Box 28-1).[42] Special care should be taken to design each area of the office so that employees, patients, and clinicians are comfortable, and all personal health information (PHI) is protected.

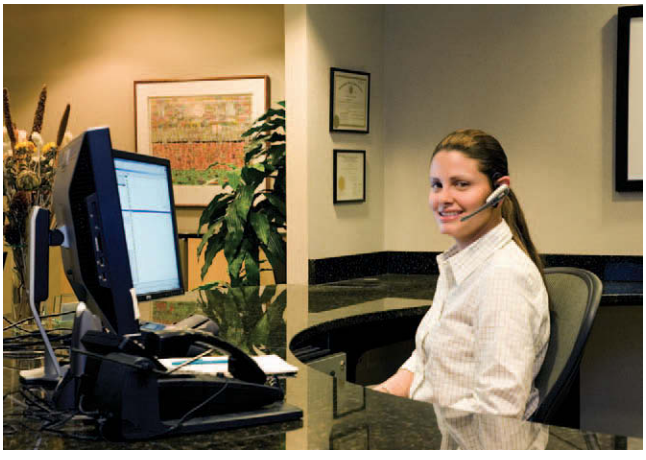

FIG. 28-3 The front desk computer workstation has dual high-resolution 24-inch flat panel monitors, ergonomic seating, and wrist-neutral positioning of the keyboard and pointing devices.

Management of database security is another important aspect of a good operational plan. The security standards mandated by the Health Insurance Portability and Accountability Act (HIPAA) now apply to all covered entities (see also Chapters 11 and 27). Practices are required to (1) perform a risk analysis to safeguard all electronic protected health information (E-PHI); (2) use technical, administrative, and physical safeguards to protect E-PHI; and (3) institute ongoing risk management. Security standards require that each employee have an individual password to access the electronic medical records system. Even in offices that are not covered entities, prudence dictates that clinicians use software that provides multiple levels of protection to reduce the chance of malicious tampering with data. For example, control over deletion of files should be protected to allow only senior staff members and/or the clinician to make changes. Compliance with the security standards requires a framework for ongoing compliance, including the designation of a security official and continual analysis of security needs as office systems change.

The purchase and continuation of hardware and software maintenance contracts are another area where diligence is important. The clinician should create a system for monitoring the status of the maintenance plans for key elements of the IT system, especially digital radiography and front desk software. Establishing insurance coverage for computer hardware, software, and data also requires special attention. General office insurance policies often limit computer coverage; therefore clinicians should discuss policies with a knowledgeable insurance agent. In addition, staff members should keep a file of purchase invoices, including digital photographs of all equipment, to document purchases for insurance purposes.

Marketing the practice is another way in which an IT system can prove invaluable. Referral and educational materials should be upgraded continually. The production of newsletters, e-newsletters, informational mailings, patient education handouts, and management of sponsored study clubs and meetings can be handled with the help of an up-to-date word processing and practice management system (see Fig. 28-1). Marketing is most effective if it is customized, frequent, and consistent.

Measuring Success

Once various technologic systems have been implemented, clinicians should learn how to measure their progress toward achieving strategic goals. For example, if premedication instructions are included in a "welcome kit" sent to new patients or on an Internet "welcome" page, staff members should see a quantifiable improvement in compliance with these instructions. Enhanced communication with patients and referrers should lead to improved satisfaction and increased engagement. Other ways to measure success with regard to operational strategies include surveying patients and referring doctors on the effectiveness of communication materials. A proactive approach to these procedural issues is the hallmark of a well-managed office.

Trend analysis is another key method of evaluating the success of office programs. The ability to better track referral patterns and follow up on collections, treatment efficiency,

BOX 28-1

HEALTH AND SAFETY FACTORS FOR EMPLOYEES

In the past, worker safety primarily involved preventing accidental injury or death from hazards in the factory or other industrial environment. Because the office now is the most common work setting, attention is turning toward subtler but still serious health problems associated with office work, especially cumulative trauma disorders (CTDs) and vision disorders. The incidence of these disorders is growing.

CTDs of the muscles, tendons, or nerves can be caused by repetitive movements of the body. As the frequency and duration of a repetitive task increase, so does the likelihood that a CTD will develop. Although most CTDs can occur in any part of the body, the term usually refers to disorders of the hands, wrists, arms, or shoulders. Carpal tunnel syndrome is one example of a CTD. Typical symptoms of CTDs include pain, swelling, tingling, numbness, or heat around the affected area during both work and rest. These disorders differ from simple fatigue, which disappears after rest. With a CTD, a person may still experience symptoms after days or even weeks of inactivity.

Ergonomists often note that computers themselves are not really to blame; repetitive, unvarying work is the cause of most CTDs. Individual physiology plays a big part in whether a person develops a CTD. However, experts recognize the importance of workstation design and layout in the prevention of CTDs. For example, a work surface's height and forearm support and work process issues (e.g., a company's break policy) affect the incidence of CTDs. For a worker involved in repetitive motion, frequent breaks, even short ones of 30 seconds every 10 minutes, help reduce the probability of a CTD developing. Task variety is also important. Therefore clinicians should design their office duties to allow clerical workers to alternate among different types of work (some of it computer based and some of it not) or to alternate computing tasks that require different motions and muscle groups.

Front Desk, Administrative, and Clinician Computer Workstations: General Specifications

Work Surface

A desktop height of 28.3 inches (71.9 cm), with a keyboard tray below the work surface that places the hands and wrists in a wrist-neutral position, is a good compromise height for front desk and administrative workstations. A bullnose (i.e., curved) edge can be placed on countertops to eliminate sharp corners. CRT monitors should be positioned far enough from the user to reduce extremely low frequency (ELF) radiation exposure.

Keying

Positioning the elbows at 90 degrees and keeping the arms and hands parallel to the floor can help prevent CTDs. With use of Microsoft's "Natural Keyboard" wrist rests,[93] locating mouse and writing platforms in the primary reach zone may also contribute to a more comfortable work environment. Work surface space must allow for efficient organization of documents, papers, and other materials. Peripheral equipment should be easy to reach.

Seating

Seat height should be adjustable to allow for positioning in the range of 16 to 20½ inches (41 to 52 cm) above the floor. The seat should have a "waterfall" or gradually curved contour just behind the user's knee and the underside of the thigh to prevent excessive pressure in this area. A seat back rest and lumbar support should also be provided.

Acoustics and Lighting

Ambient or background noise (i.e., white noise) is desirable at a level that does not interfere with task performance (40 to 55 dB). Experts agree that open-plan acoustics are subject to three main problems: sound level, speech intelligibility, and sound paths.[44]

Lighting sources should be designed and located to minimize glare and provide luminance in the range of 200 to 500 lux in the work area. Task or local lighting may be needed for reading documents. A combination of indirect overhead, natural, and task lighting is preferable. For close-up work, light should be directed sideways onto documents to avoid glare on the monitor; this helps prevent eye fatigue and headaches. Eyestrain is the leading complaint among computer users, according to the American Optometric Association.[7] Computer users should take frequent breaks and have their vision checked, and the work space should be designed so as to reduce visual stress.

Modern LCD monitors are designed to operate at their "native" resolution and a 60 to 70 Hz refresh rate to reduce monitor-induced eye strain. Further improvement can be realized by turning on "ClearType," imbedded in Microsoft Windows XP, Vista, and Windows 7 operating systems. ClearType provides improved font display quality over traditional forms of font smoothing or anti-aliasing. Glare can be reduced by replacing fluorescent lighting diffusers with grids that break up the light pattern. Office color schemes should be neutral and pleasing to the eye.

Ventilation

Proper ventilation requires about two air exchanges per hour. The temperature and humidity level should be kept constant, with temperature range adjustable from 68° F to 75° F (20° C to 24° C).

outcomes, and uncompleted treatments is one of the benefits of a well-designed software program. For example, generating reports that analyze fading referrals can be an important measure of referral satisfaction. Once these data are evaluated, an action plan and global strategy can be devised to address issues that need attention.

TRACKING BITS AND BYTES THROUGH THE "PATIENT LOOP"

The *patient loop* begins when a patient is informed that he or she needs an endodontic procedure and ends with the postoperative check-up visit (Box 28-2). This process begins the

BOX 28-2

THE VIRTUAL OFFICE: READY NOW

The new paradigm for exceptional patient care calls for sophisticated communication and customization that can be accomplished most efficiently in the integrated digital office. The following steps outline the process, or patient loop, from introduction of endodontic treatment to the last follow-up visit.

1. The process begins when patients need an endodontic or implant procedure. The endodontic office should make the following options available:
   - A website for patient education, contact information, referral materials, and patient registration forms
   - A *referral kit* for referring doctors that contains a brochure, a map to the office, customized referral forms, past newsletters, introductory information on the office website, and business reply envelopes
   - Informational meetings with referring clinicians to enhance communication and discuss expectations
2. When patients call for an appointment, the office should be ready to do the following:
   - Preregister patients using the practice management software
   - Set up an appointment
   - Refer patients to the office website, where they can read a welcome letter and complete the patient registration forms using a HIPAA compliant security protocol
   - Mail, fax, or e-mail a *welcome kit* with a welcome letter, brochure, explanation of the procedure, map, biography of the treating endodontist, and statement of the fee policy
3. When patients arrive for their first visit, they can also fill out the personal information sheets on a reception area computer kiosk connected to the network, or they can watch educational material while waiting. Any film-based radiographs can be scanned into the patient database. The patient's status can be indicated in the endodontic time and patient tracking module so that every member of the dental team knows the status of all patients from their presentation visit until they are discharged.
4. When patients are seated in the operatory, an assistant can perform indicated radiographic studies and capture a visible light (VL) image of any teeth or area in question, using an intraoral camera. The assistant then can enter the chief complaint, history of the current illness, list of medications, and medical history into the digital chart and check for drug interactions on the chairside computer workstation. The clinician performs pulp tests and records the endodontic findings in the charting module, followed by an oral and written consent and vital signs check. Treatment then can be started, and each step of the procedure can be recorded by mouse and keyboard input or voice command. If desired, subsequent appointments can be made for patients while they are still in the operatory, treatment reports can be generated, and their insurance information can be sent to the office financial coordinator or directly to the insurance company.
5. Patients are discharged at the front desk departure station, with all pertinent information already entered into the computer. This is an opportunity for patients to receive customized information about their treatment, next appointment, follow-up care, and any medications prescribed or dispensed.
6. Patient treatment reports and other correspondence can be created by the front desk or assisting staff; reviewed by the clinician at a computer terminal; forwarded to the print queue; and sent by mail, fax, or e-mail.
7. When patients return for follow-up visits, digital radiographs can be exposed, and comparisons of immediate postoperative and check-up radiographs can be made side by side on the same screen to assess healing. Reports can then be generated.

patient's journey through different operational steps that result in the successful management of endodontic treatment and completion of the EOHR.

Central Information Store

Creation and management of the EOHR and all its components is the job of the CIS. A CIS requires a single, robust central computer, called a *server,* that links all the computers in the practice. When computer systems are connected in this way, they most often are referred to as a *client/server network*. The server is designed to administer the network efficiently, taking care of management functions such as backup, file sharing, print processing, and web and e-mail tasks.

A server-based system has four primary benefits:

1. It saves time and effort because all information can be stored for instant access by any team member. As files are updated, all the new information is available instantly.
2. Security is better because all data are centrally stored and (normally) automatically backed up.
3. Each user can be better monitored, because each workstation can be uniquely identified at every transaction.
4. Remote access to the entire database is possible, so records can be reviewed from outside the office and more easily maintained.

The Microsoft Windows Server System allows the creation of a single point of contact with the Internet, which improves security as well as security settings that allow for appropriate remote access levels for employees or vendors.

Software

Servers have evolved into microprocessor-based machines dedicated to running certain software applications. Two basic types of software can be purchased to run on a server:

- *Network operating system (NOS)*. Most LANs and WANs in endodontic practices use a Microsoft NOS, which is based on the Microsoft Windows Server System. These sophisticated, stable systems are ubiquitous, and many servers come configured with base installations of the software.
- *Database engine*. One of the most robust and commonly used database management technologies is the structured query language (SQL), an ANSI standard computer language that uses SQL statements for obtaining and manipulating data. SQL is a technology, not a product,

and many vendors offer versions of SQL (e.g., SQL Anywhere, SQL Base, and DB2).

Hardware

Two basic hardware recommendations can be made to ensure a reliable network that can handle both digital imaging and practice management databases:

- *Redundant arrays of inexpensive disks (RAID Level 5)*. To reduce the chance of hardware failure and subsequent data loss, RAID 5 uses an array of multiple hard disk drives that behave like a single storage disk but have increased capacity and improved fault tolerance and performance.
- *Serial computer systems interface (SAS)*. More advanced than the IDE/ATA interface, SAS[82] is really a system-level bus with intelligent controllers that allow hard drives and other peripherals to operate with unmatched performance, expandability, and compatibility. Newer serial ATA (SATA) drives and IDE RAID are not considered as reliable as SAS and should not be used for critical hardware.[49]

Data Security

All data in the office are subject to security threats. Network attacks can interrupt office operations and cause loss of patient data, leading to legal liability. Whether a disgruntled employee decides to delete information, a disk with an infected Word file is brought from home and uploaded on an office computer, or an Internet connection allows unauthorized access, client and server tiers of the network are vulnerable to attack. Scalable security approaches are emerging to address these new challenges in three basic data security categories: integrated security, data backup, and archiving.

INTEGRATED SECURITY

Symantec (Mountain View, CA) and McAfee (Santa Clare, CA) are two leading vendors of enterprise-wide security suites that address malicious code attacks, denial of service attacks, unauthorized network entry, and blended threats.[90] Single-source enterprise protection can automatically update the office server and each client every day via the Internet. This includes:

1. Protection against viruses, worms, and Trojans
2. Software firewall protection to prevent unauthorized access to the network
3. Content filtering to eliminate unwanted materials
4. Connection security for any virtual private networks (VPNs). VPNs are constructed by using public wires (i.e., the Internet) to connect nodes and provide encryption and other security mechanisms.

DATA BACKUP

Data backup is the process of transferring data from the office server to a separate storage medium such as a tape drive or another hard drive. Because data are only as good as the last backup, it is imperative that a consistent backup and recovery protocol be followed. Data loss can be attributed to hard drive failure, data corruption, or physical damage to the server because of fire, flood, or theft. Although many backup strategies exist, even solo clinicians using periapical, panoramic and CBCT digital radiography modalities, and visible light imaging can generate 500 gigabytes of data per year. This means that backing up with CDs and DVDs is not a practical solution. Removable hard drive storage is also not recommended as a primary backup method because it does not allow regression to a previous configuration if an application failure is not evident for several days. Instead, a recommended scheme is a nightly tape backup with a 20-business-day rotation (1 business month) using a different tape for each of 20 days, replacing all tapes at manufacturer's suggested intervals or at least yearly.[12]

All backups should be full backups, rather than incremental or differential backups, to improve efficiency if reinstallation is required. Use of backup-to-disk functions and universal service bus (USB) hard drives can also be useful if multiple point-in-time backups are necessary. A full backup before any software upgrade must always be performed. Backup media should be tested periodically and backup logs examined to make sure the system can be properly restored. Other backup schemes that automatically upload encrypted data to a dedicated Web vendor nightly, ideally SAS 70 Type II certified, and store the data at a minimum of two geo-separate remote sites are available and can also provide a high level of security.

ARCHIVING

An *archive* is a permanent data backup that usually is stored off site. All computer data are subject to loss, and merely making a daily backup of the data does not provide sufficient protection if the data are corrupted because of a previously unknown virus, worm, or Trojan. Removing one tape from the normal backup tape rotation on a monthly basis and placing it in fireproof off-site storage usually ensures that a valid data set is available if a catastrophic event causes data corruption or loss. Another advantage is that this tape can be archived at a local medical records storage facility and logged in and out to ensure that the tape is not altered if required during litigation.

Equipment Protection

The server should be located in a secure area of the office, preferably a computer "closet" with locked access (HIPAA-covered entities are required to provide physical security of E-PHI). Designing lockable front and rear access to the server system or rack, if applicable, enhances access to the CIS when maintenance of upgrades are performed. Although rack-mount systems offer better space efficiency, there is a cost premium for this kind of equipment. All server installations must have adequate cooling, another factor that must be considered when planning the practice's air conditioning and heating systems.

Privacy

Security considerations are recommended for ensuring that data are reliable and safe and for meeting the requirements of Title II of HIPAA. The server and all software, including the wired and wireless LAN and WAN if any, should be protected by a system of individual passwords that allow different levels of security. Server log-in, remote access to the server via the Internet, program security, and especially the practice management system and digital imaging software must be password protected from unauthorized deletions and changes. The server password should be difficult to decipher (e.g., #eio9$kej**) to reduce the chance that the password will be decoded if the server is stolen from the office.

FIG. 28-4 The reception area computer kiosk allows patients to complete registration forms, view educational material, and surf the Internet.

Reception Area

Placement of a computer kiosk in the reception area with Internet-only access can be a convenience for patients who want to complete their registration materials online (Fig. 28-4). A computer installation in the reception area is often overlooked, but this is an ideal place to market the practice, educate patients, and introduce the "high-tech" office. The clinician should plan the location of the kiosk to follow HIPAA guidelines for ensuring patient privacy.

Operationally, this computer can run an Internet kiosk program that prevents users from manipulating the operating system or tampering with the office LAN. The system can serve the following three purposes:

1. The computer can provide new patients with a link to the practice's website, allowing patient registration forms to be completed and sent via the Internet to the office for upload into the office's practice management software, if applicable. This software should use secure file transfer protocol (SFTP) technology to ensure that E-PHI is sent with high-level encryption to maintain privacy.
2. The computer can also be used by patients as a convenience to allow free Internet access if an appointment is delayed.
3. The computer kiosk or a stand-alone computer system can be used to run a PowerPoint or Web-enabled patient education module to help familiarize the patient with services offered by the office and to provide information about the practice and office team members.

Front Desk

In a small office, the computer setup at the front desk is used primarily to process patient accounting and insurance, manage scheduling, and in some cases generate patient treatment reports. Another strategy, especially in multiple clinician practices, is to have separate computer workstations for patient intake and checkout. The addition of Internet functionality is another area where the intake computer can prove valuable.

Production of a customized "welcome letter" sent directly to the patient by mail, e-mail, or fax can help introduce patients to the practice, better inform patients about the office, and set expectations about treatment and billing practices. More offices are now creating websites that offer patient education modules and enhanced functionality; this allows tight integration of the Web materials and office software, as follows:

1. Patients can complete Web forms that transmit demographic data and E-PHI via a HIPAA-compliant protocol directly to the intake computer.
2. TruForm (PBHS, Santa Rosa, CA, and Henry Schein, Inc., Melville, NY) allows a patient to access the office website, complete the registration forms, and transmit them to the office by means of a remote host computer. The data can then populate the preregistration fields in the practice management software automatically.
3. More flexibility can be added with new software program modules that permit greater frontdesklessness. WebConnect, an integrated product by PBHS, allows patients to log on to the practice website, view and change future appointments, review financial information, pay bills online, and communicate automatically by e-mail.

Larger offices, especially in multiple-clinician practices with two or more front desk personnel, may benefit from configuring the front desk with a separate departure area and computer. This computer can be linked to a shared multidrawer laser printer so that both front desk computer stations print to a central printer, with each unit able to print specific documents or envelopes on demand.

Software

Practice management software for an endodontist has some of the same features as software for the generalist. Specialty markets, especially endodontics, have several key requirements. Considerations for hardware and networking, as well as product features (e.g., scheduling, referral tracking, preregistration, advanced reporting, and analysis), have poor analogs in general practice management software and require the selection of a product written specifically for the endodontic specialist.

Another important factor in the selection of software has to do with the recent consolidation trends in the dental software industry.[57] Careful investigation of software companies should include a look at the parent companies in an attempt to determine which ones will survive. When purchasing software, the clinician also should give careful consideration to the basic language and robustness of the program's database engine.

Great software, like a great building, is constructed on a solid foundation. Although there are many techniques for building software, some are superior.

The 2000s saw the delivery of incredible power to the desktop. A client/server model now exists that eclipses all others. Put simply, it features a powerful database engine run on a central computer (i.e., a dedicated server) that controls access to data requested by client workstations. The standard in databases for this model is SQL,[102] which delivers data faster than any other database system and does so with far greater efficiency, safety, and simplicity. Unlike other systems that move data back and forth between the network server and client workstations, client/server systems produce less network

traffic and greater performance. This is because in an SQL system, virtually all data manipulation is done at the server. This also reduces the chance of the data becoming corrupt, because data never leave the server, and the SQL engine actively controls access to the data.

In previous models, each client workstation read data from the server, manipulated it, and then wrote it back. Because no client was aware of the activity of any other client, and the network operated more or less like multiple independent systems, two or more workstations writing data to the server at the same moment was commonplace. In addition, older models looked at data one row at a time, whereas SQL engines grab chunks of data in response to queries issued by the client and send these *result sets* in their entirety to the client. The resulting performance increases in terms of speed are significant, especially with remote offices. Therefore a true 32-bit client/server product with an SQL database is recommended as a minimum requirement.

Hardware

A well-designed front desk workstation includes a computer equipped with a dual monitor card and two large-screen liquid crystal display (LCD) monitors, label printer, and high-speed Internet connection.

Operatory

The core function of an endodontic office is to provide the best clinical care for patients, yet only about 25% of dental offices today use a chairside computer workstation.[81] The chairside clinical workstation (Fig. 28-5) is the natural place to begin the most important gathering of data.

Software

The EOHR begins with thorough documentation of care at an individual site (e.g., a practice or hospital) and eventually becomes part of an individual patient's cradle-to-grave EHR.

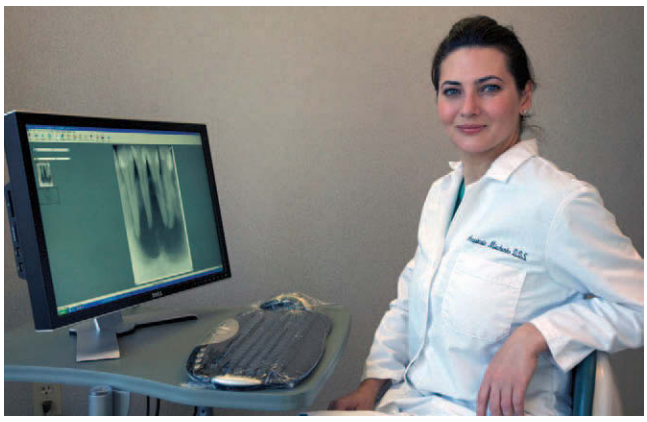

FIG. 28-5 The computer chairside workstation is the information center for today's office. A barrier-protected wireless Bluetooth keyboard and mouse improve asepsis, and the 24-inch flat panel monitor economically supports high-resolution images at 1920 × 1200 dpi with 12-bit internal processing, enabling 1.07 billion colors and improved very low grayscale tones. The remotely positioned operatory central processing unit (CPU) controls three monitors in this configuration.

Electronic charting does everything paper systems do and much more. Numerous systems are available specifically for endodontists.

Electronic charting serves three purposes: (1) accurately and legibly recording diagnostic and treatment data for individual patients,[46] (2) automating many aspects of record taking, and (3) indicating trends by allowing analysis of patient records based on user-defined queries.

An electronic charting system can include the following:

1. Integration with the general practice management software
2. Extensive trend analysis and reporting
3. Voice integration (i.e., the ability of the computer to understand natural speech and record findings)
4. Comprehensive, easy-to-use interface with pick-lists and drop-down boxes that automate entries, many of which are customizable. (Note that any fields that allow customization may not be easily data-mined for groups of users at a later time.)
5. Macroautomation (i.e., the ability of the program to automate common functions by playing back a series of recorded actions)
6. Scanner integration, which allows the user to scan in supporting documents, radiographs, and other paper records

An EOHR for endodontic visits should have the following information, arranged in a logical sequence:

1. General demographic and medical information (integrated with online pharmacologic and medical databases to allow quick lookup of medications and diseases on the Internet in real time)
2. Chief complaint and history of present illness
   a. Chief complaint (which contains a notes field for recording, in the patient's words, what prompted the trip to the office)
   b. History of present illness (notes field for recording the history of the current illness in the patient's words)
3. Clinical examination (describes findings by tooth numbers)
4. Radiographic examination (includes radiographic analysis, which is essential to measurement of treatment outcomes)
5. Etiology (list of causative factors)
6. Diagnosis and treatment plan
7. Treatment notes, which are based on user-defined criteria and include the following information:
   a. Patient's vital signs, (blood pressure, pulse, respiration and temperature)
   b. Tooth number
   c. File lengths
   d. Type of injection, gauge and length of needle, type and amount of anesthetic
   e. Dental dam clamp
   f. Number and names of canals
   g. Trial length, actual length, reference point, measurement methodology, and final instrument size
   h. Instrumentation technique, irrigants
   i. Obturation material and technique, including sealer
   j. Detailed record of restorative treatment
   k. Prescribed medications (may include over-the-counter drugs)
   l. Temporization method, post-and-core procedures and materials
   m. Recommended posttreatment instructions

8. Postoperative report generator
   a. Patient treatment reports can be created automatically and sent to referring clinicians by hard copy or e-mail (using a HIPAA-compliant protocol) (Fig. 28-6)
   b. Documentation of oral and written instructions and a reevaluation plan
   c. Contact log

In keeping with the concept of frontdesklessness introduced earlier, to reduce congestion at the front desk, a customized screen can allow the dental team to post the treatment information in the operatory to generate billing, prescription, customized instruction sheets, and patient treatment reports with a few mouse clicks or the touch of an input pen. The information then can be posted at the front desk or in the operatory, and instructions, prescriptions, and reports can be directed to the appropriate printer for hard copy production or e-mail distribution to any referrers or co-therapists.

Reference software is another area where the Internet-connected concept can prove invaluable. With each chairside computer workstation connected to the Internet, the clinician can subscribe to an online pharmacologic reference that gives specific information about pharmaceuticals as they pertain to dental treatment. One example of such a service is Lexi-Comp Online (Lexi-Comp, Hudson, OH), a site that offers information on medications that are indexed alphabetically and by disease, with specific reference to dental considerations and dental vasoconstrictor precautions.

Hardware

The computer chairside workstation is the "center of the universe" for the endodontic clinician. The central processing unit (CPU) should be placed in a location that allows easy access to connections so that upgrades can be made without major disruption. This computer should be equipped with a dual monitor card to allow two or more monitors to operate simultaneously, as follows: (1) a monitor to display the current schedule, visible only to the clinician and staff; (2) a second output that is then further split by an amplified video splitter to two monitors in "clone" configuration, allowing the clinician and staff to have identical screen views and input tools (Fig. 28-7). This HIPAA-compliant arrangement conceals the schedule and other patients' E-PHI from the view of patients in the dental chair.

In endodontics, clinical input systems represent a very broad category that can be divided into two groups: input devices and charting software. Input devices can be subclassified further into radiographic and photographic or VL imaging equipment.

Imaging

MICROSCOPIC IMAGING

Microscopic imaging has evolved over the past several years to include many choices for high-resolution image capture.

- Medical-grade, single-frame digital cameras are available from several manufacturers that can produce superior images and allow capture directly to the chairside clinical workstation via the USB[95] or the FireWire (IEEE 1394) port or a memory card. Many cameras let the clinician preview an image on the camera's integral display so that images can be quickly retaken if not satisfactory. The cameras attach to the microscope by means of a beam splitter and camera adapter. Professional-grade digital photography has replaced the 35-mm film format for medical and scientific use. It allows an instant picture with image resolution that approximates that of film-based photography.
- Solid-state analog video cameras also can be purchased for microscopic videography (Fig. 28-8). These cameras produce an analog output (either a *composite* signal or an *S-Video* signal). Composite signals with images of 280 lines of resolution usually are less expensive than S-Video models, but the images have inadequate resolution (Box 28-3). Cameras capable of S-Video output can produce images in the range of 480 lines and are preferred for microscopic imaging. They can be connected either to video capture cards for incorporation into imaging databases or to a video splitter to provide several S-Video outputs. One output can be connected to the chairside computer workstation, a second to an LCD flat screen monitor with S-Video inputs, and a third to a videocassette recorder. This arrangement allows legacy systems to operate in a multiscreen mode, but it has been supplanted for the most part by a mostly digital imaging chain. Even more sophisticated cameras with three charged-coupled devices (CCDs) and *component* outputs are available for the highest-level resolution, but they are not necessary for routine clinical documentation.
- A hybrid system that uses the newest consumer-grade video/still cameras with solid state memory allows nonlinear editing, a 16 × 9 recording ratio for widescreen playback, and instant viewing or copying. Many of these cameras can be connected directly to the computer by means of a USB or FireWire and can take credible still images in addition to 30 fps (frames per second) video.

INTRAORAL CAMERAS

Intraoral cameras that can photograph a single tooth, a group of teeth, or a patient's full face are available in digital format, using a USB interface with plug-and-play setup. These cameras are very useful for recording the condition of soft and hard

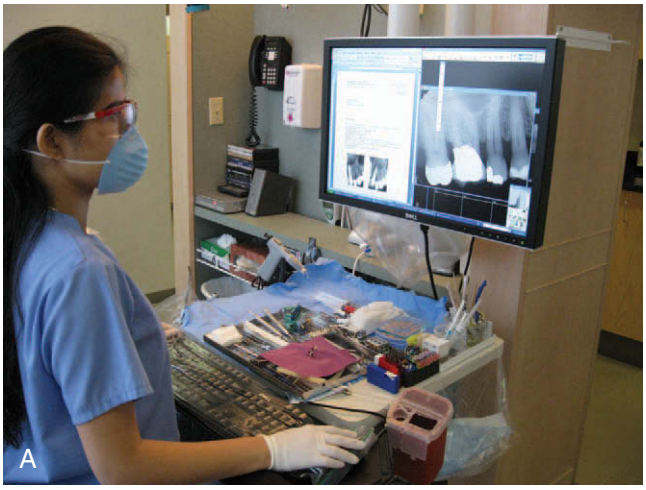

FIG. 28-6 A, Producing patient treatment reports at chairside, shown here, can lead to improved workflow.

Philip Jones, MD
1234 Second Street NW, Suite 306
Washington, DC 20036-7689

Dear Dr. Jones:

Thank you for the referral of Ms. Wendy Patient for endodontic evaluation of her maxillary right dentition. If we can be of further assistance, please let us know.
Patient date of birth: 04/11/1948; **Patient gender:** Female
Patient home phone number: 202-333-5555 **Patient office number:** 202-444-6666
Tooth/teeth number/numbers: UR
Date of treatment: 05/14/2009
Diagnosis: necrosis with internal resorption; acute periradicular abscess
Medical history/medications: 05/14/09: NKDA; Synthroid 50 mg, Lipitor 10 mg, clindamycin 300 mg q6h (for current dental infection)
CC/HPI: "Abscess. I have swelling and off-and-on fever. It has been a problem for a few days. I am traveling to Africa tomorrow."
Comments: The patient's oral temperature was 99.4; indurated swelling maxillary right alveolus, extended between teeth #s 2 and 4. Two buccal fistulae were present (a). A periapical radiograph (b) and a focused field CBCT were exposed. See orthogonal CBCT images below: (c), axial; (d), cross sectional; (e), curved planar; and (f), 3D reconstruction. Tooth #2 shows a unilocular radiolucency at the mesio-buccal root that appears to be continuous with the periapical radiolucency at #3 and extends to the periapcial radiolucency at tooth #4 (20.4 mm). An internal resorptive lesion (green arrow) on the palatal root of tooth #3 and two draining sinus tracts to the cortical plate (yellow arrows, one in the axial view of this section) were noted. Teeth #s 2 and 4 were vital.
Plan: Referred to Dr. Oral Surgeon for extraction and biopsy.
Attending endodontist: Martin D. Levin, DMD, Diplomate, American Board of Endodontics
Cc: Dr. Oral Surgeon

05/14/2009

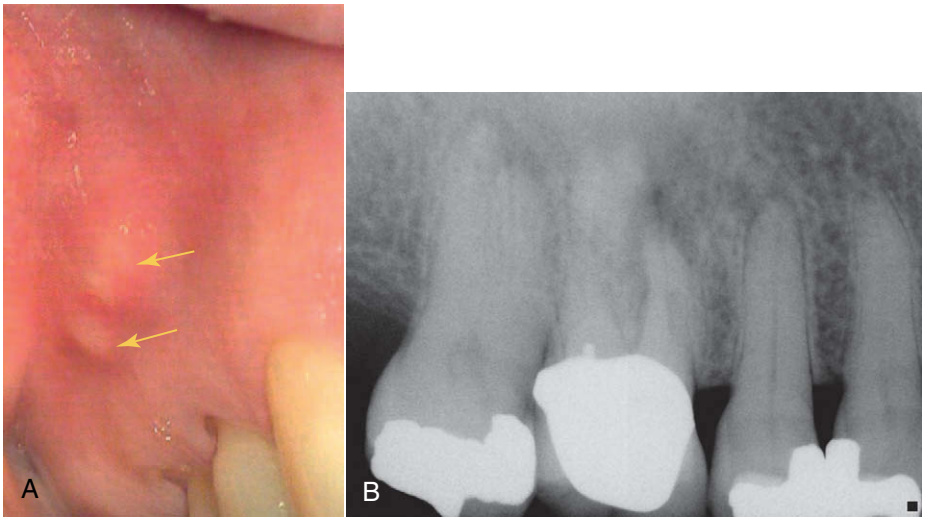

FIG. 28-6, cont'd B, Preformatted patient treatment reports can be automatically created and printed in the office on a variety of printers using a wide array of software. This patient treatment report can be sent by e-mail from a preformatted template using a Health Insurance Portability and Accountability Act (HIPAA) compliant pick-list.[16]

Continued

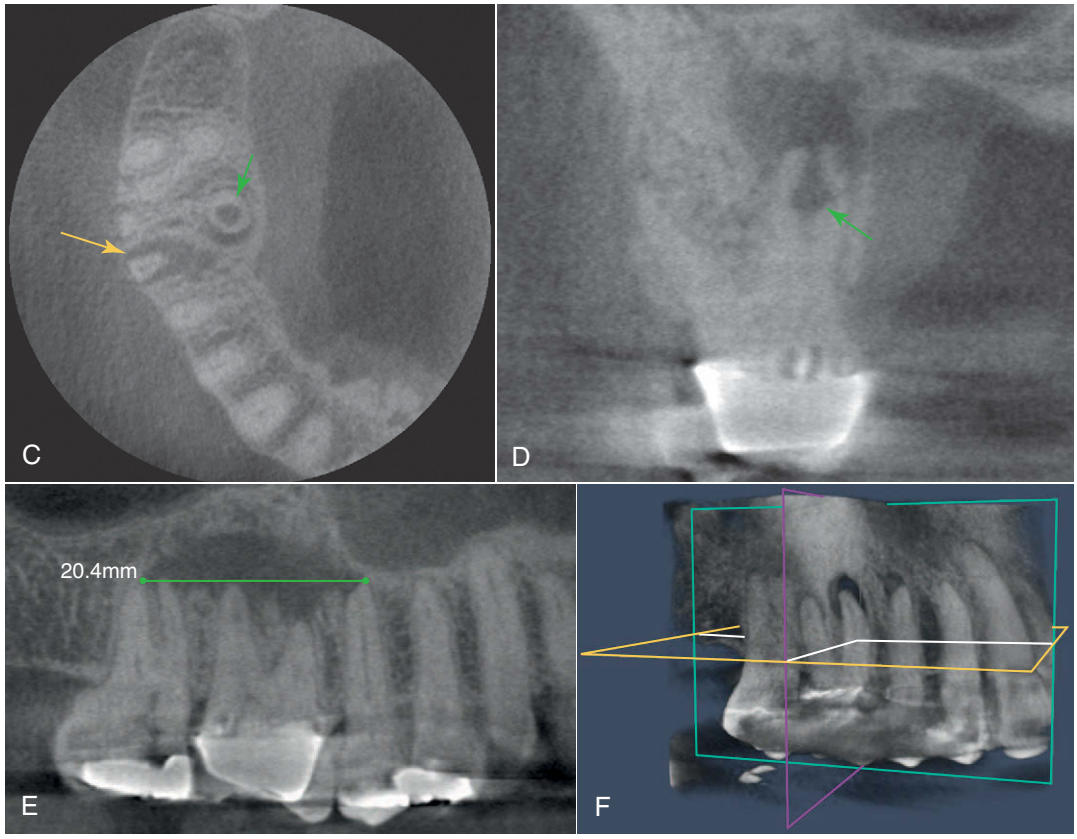

FIG. 28-6, cont'd

FIG. 28-7 This operatory is equipped with four flat panel monitors. This arrangement allows input from the clinician and assistant to any screen. The assistant and schedule screens are located to the rear of the patient in compliance with Health Insurance Portability and Accountability Act (HIPAA) guidelines. The doctor's chairside workstation screen and the ceiling-mounted entertainment/patient education screens are in full view of the patient. The entertainment/patient education screen are able to show music or movie DVDs and VL images from the microscope via a switch.

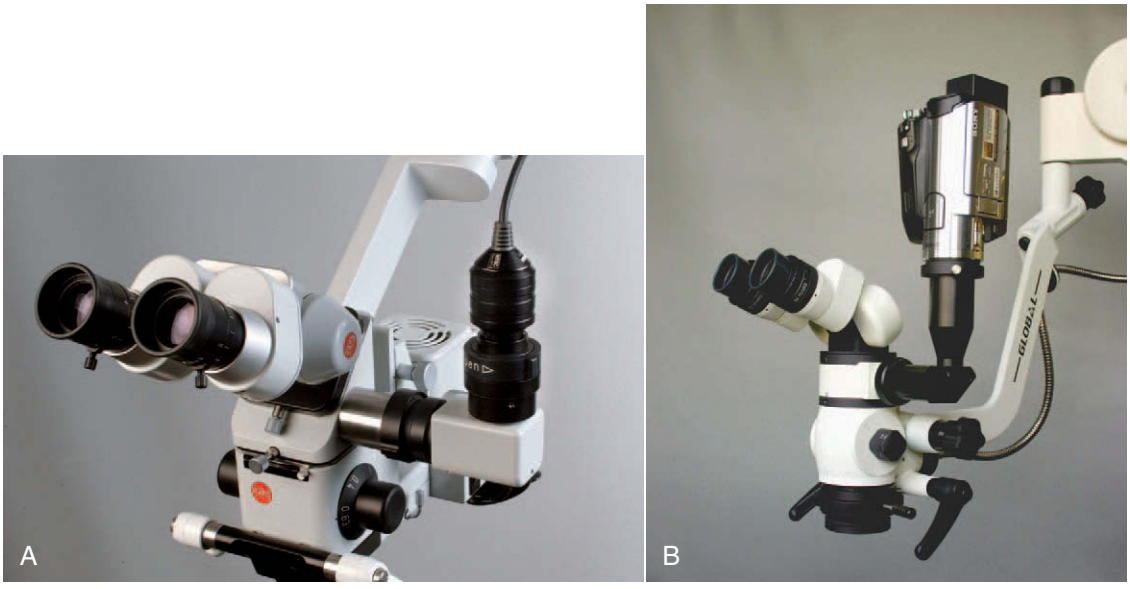

FIG. 28-8 A, This microscope incorporates a miniature analog solid-state camera (Y/C format, 480 lines) into the beam splitter. **B,** A solid-state video camera captures either still images or video at 30 fps (frames per second) in high-definition (HD) format. BOX 28-3

Short Primer on Video Signals

Visible light (VL) imaging is one of the most powerful documentation tools available to the clinician for recording the patient's dental condition. Most operating microscopes can accommodate a wide range of analog and digital VL imaging equipment. Although analog cameras are still popular for microscopic documentation, digital technology is increasingly competitive, especially as the consumer video market converts to digital equipment.

Video cameras generate red, green, and blue (RGB) signals to create video images. If the RGB signals were sent as three separate signals, huge storage and bandwidth capacities would be required. Instead, it is possible to take advantage of the human visual system to reduce storage requirements. This is done by transforming the RGB signals into new video signals that can be band limited with minimal loss of perceived picture quality. In Europe, the dominant television standards are PAL and SECAM. The United States uses three common National Television Standards Committee (NTSC) analog signal formats:

- *Composite video* (single 75-ohm cable terminated at each end with RCA connectors). With composite video, the red, blue, and green signals are mixed together. This architecture is present on almost all contemporary home video equipment; when modulated with audio onto a radio frequency (RF) carrier, it is used by over-the-air digital broadcast stations or on coaxial wire by cable TV systems. These systems have the lowest-quality signals.
- *S-Video*, or super-video (looks like a single cable but internally has two 75-ohm coax or twisted pair cables terminating at each end in a four-pin DIN connector). S-Video involves the transmission of video signals over a cable through division of the video information into two separate signals, one for color (i.e., chrominance) and the other for brightness (i.e., luminance). Professionals refer to this as *Y/C video*, rather than S-Video, because the former is more descriptive of the signal format. These systems produce midrange quality signals.
- *Component video* (analog component video uses three 75-ohm coax cables that terminate at each end in RCA connectors, usually color coded and bundled together). Component video reduces artifacts and color errors by minimizing the number of video-signal format conversions between the source and the display device; it transmits its video signal by dividing the Y, R-Y, and B-Y signals separately. These component video signals produce the highest quality signals.

In professional and industrial video equipment, impedance-matched 75-ohm BNC connectors are used for all these signal formats. Also, each of these analog signal formats can be stored, processed, and transported in the digital domain in professional applications. Digital home satellite systems receive MPEG compressed digital component signals and provide component, S-video, HDMI outputs. The digital versatile disk (DVD) format, and the newer "Blu-Ray" format, also based on MPEG technology, is available with analog component video and HDMI interfaces for the highest possible picture quality.

Computer monitors, on the other hand, are designed for RGB signals. Most digital video devices (e.g., digital cameras and game machines) produce video in the RGB format, so the images look best when shown on a computer monitor. When seen on a television, however, these images look better in S-video format than in composite format. To use S-video, the sending and receiving devices and the interconnect cable must be S-video compatible. The newest connections between computers and monitors is the DisplayPort interface standard, which supports both RGB and component encoding formats. DisplayPort connections are interoperable (capable of supporting analog and digital interfaces), can drive display panels directly, eliminating scaling and control circuits that allow cheaper and thinner displays.

tissues for documentation and for patient education and "co-diagnosis" (allowing the patient to visualize problem areas and participate in the evaluation). When VL images from the intraoral cameras are transmitted directly to a clinical chairside workstation, they can be stored along with radiographic images in the patient's imaging database for easy retrieval. This type of camera can be a valuable adjunct to the microscope-mounted camera because of its lower overall cost. Another advantage of intraoral cameras is the ease with which they can be positioned (Fig. 28-9), especially by dental auxiliaries; a microscope, on the other hand, can be somewhat difficult to position and use with mirrors. Intraoral cameras are available with barrier sheaths to prevent cross-contamination.

A new intraoral camera (Fig. 28-10, *A*) is now available for endodontic offices and features a unique liquid lens technology that instantaneously focuses like the human eye. It features a CMOS sensor that captures still images (1024 × 768) and video (640 × 480) with the highest resolution currently available, and supports a focus range from 1 mm to infinity (Fig. 28-10, *B*). The video output includes the following options: USB 2.0, TV-NTSC, TV-PAL, S-Video, and VGA. Using eight light-

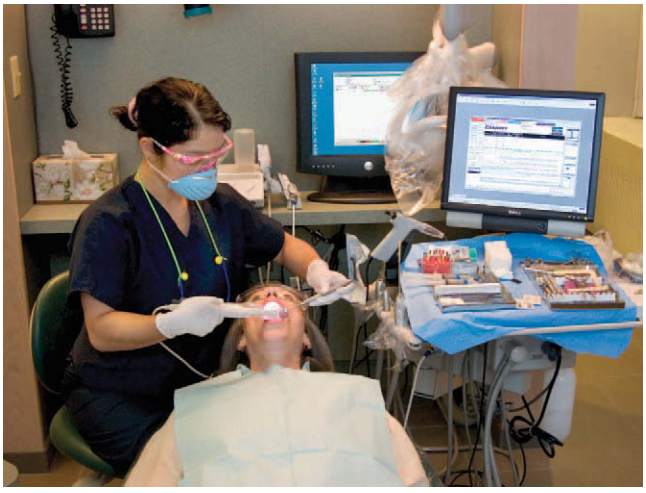

FIG. 28-9 Intraoral cameras can be used efficiently by the staff to deliver images directly to the universal serial bus (USB) port of the chairside computer workstation. *(Courtesy Schick Technologies, Inc., Long Island City, NY.)*

FIG. 28-10 A, The Kodak 1500 wireless intraoral camera captures still images and video using a new liquid lens technology. Coupled with its "WiFi"-enabled docking station, the new camera can transmit high-resolution images anywhere in the office. **B,** An occlusal preoperative image of the mandibular right first molar showing a defective amalgam; buccal, lingual, and distal marginal ridge fractures; and significant occlusal wear. *(Courtesy PracticeWorks, LLC, Atlanta, GA.)*

emitting diodes (LEDs) to provide illumination, the system automatically adjusts to lighting conditions to optimize illumination and contrast levels. The intraoral camera provides the advantages of auto-focus of still images and video, elimination of undesired light reflection by using a unique polarization filter, and automatic adjustment to lighting conditions.

This camera can substitute for microscope-mounted VL imaging hardware. Unlike older wireless technologies, this camera uses "Wi-Fi" connectivity, which enables reliable wireless performance and easy integration with and without a computer. The small docking and charging station allows the camera to be used anywhere in the practice, encouraging camera sharing across multiple operatories.

FIBEROPTIC IMAGING

The introduction of *fiberoptic* and *rod-lens endoscopes* specifically for use in the oral cavity has taken endodontic imaging into the root canal and periapical space.[9,10] Both the fiberoptic and the rod-lens endoscope works in conjunction with a camera, light source, and monitor. The clinician views the treatment field on the monitor, which allows the entire treatment team to see the site. A documentation device can be added to the endoscope's visual system to record the endodontic procedure.

The fiberoptic endoscope is used for intracanal visualization (Fig. 28-11, *A*). The device is composed of 10K flexible fibers that transmit light to a treatment field and images back to the camera. The fiberoptic scope's lens has a diameter of 0.8 mm with 0 degrees of angulation.

Two types of rod-lens endoscopes are used for endodontic procedures (Fig. 28-11, *B*). The model that is 4 cm long and has a lens 4 mm in diameter with 30 degrees of angulation can be used for both conventional and surgical endodontic visualization. Another model, which is 3 cm long and has a lens diameter of 2.7 mm with 70 degrees of angulation, is used primarily for endodontic surgical procedures.

DIGITAL PHOTOGRAPHY

Intraoral and perioral digital imaging provide valuable documentation tools for clinicians. Many clinicians routinely take images of their patients for identification purposes with consumer-grade digital cameras. However, a dedicated model with specific features is recommended for documenting the patient's intraoral and perioral condition for patient education purposes, consultation with colleagues, teaching, and other professional uses.

The following criteria should be considered when purchasing a digital camera:

1. High resolution is important to ensure good image clarity. Although the size of the camera's image sensor and monitor quality are constantly improving, cameras that can produce an image of at least 1600 × 1200 pixels are recommended.
2. The camera should have macro capability (i.e., should be adjustable from about 2 inches [5 cm] to infinity) to ensure that oral and full-face images are distortion free and in focus.

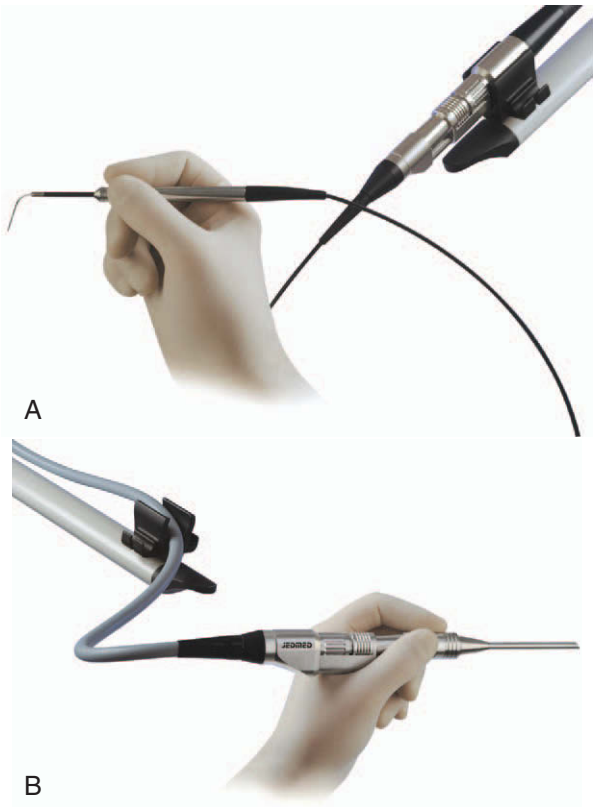

FIG. 28-11 A, Fiberoptic endoscope used for intracanal visualization. *(Courtesy JEDMED Instrument Co, St Louis, MO.)* **B,** Rod-lens endoscope used for conventional and surgical endodontic visualization. *(Courtesy JEDMED Instrument Co, St Louis, MO.)*

3. Lighting is an important consideration in the selection of a digital camera. For this reason, either a flash diffuser or a ring flash is advised to ensure consistent illumination, make sure color values are accurate, and prevent shadows and highlights that are too bright (Fig. 28-12).

The advantages of a digital camera include savings on the cost of film and processing, absolute archiveability, instantaneous evaluation of the image, and the ability to catalog and search the image database. In addition, the clinician can print multiple, identical, inexpensive high-quality copies in just a few minutes. The standard methods of image transfer in the industry are direct wiring via the USB or FireWire port and use of small memory cards. Any TWAIN-compliant[94] (standard software protocol and applications programming interface that regulates communication between software applications and imaging devices) digital radiography or image organizational software allows the clinician to store these images directly in the patient database.

RADIOGRAPHIC IMAGING

The value of digital radiography in dental and medical diagnosis is well known, especially during operative procedures where time to image is important. Key advantages of digital radiography are: reduction in radiation dose to the patient; patient education; image optimization and computer-aided feature extraction;[96a] workflow improvement; the avoidance of shipping, darkroom, or chemical processing errors; environmental

FIG. 28-12 Specially configured digital cameras can record oral and perioral conditions. Cameras can transfer images via USB and memory cards. *(Courtesy PhotoMed International, Van Nuys, CA.)*

waste reduction; improved electronic communications[68]; image archiving; and projecting a technologically advanced practice image.[21,68] Solid-state digital imaging using CCD or complementary metal oxide semiconductor (CMOS) detectors has become an increasingly popular technology for intraoral and extraoral dental radiography. Three methods of producing digital images are available: direct solid-state detectors (e.g., CCD/CMOS detectors[35,77]), indirect photostimulable phosphor plates,[97] and indirect secondary capture of conventional film by scanning.[27] The most useful technology for endodontic practice is the direct model, because digital detectors can produce an image in seconds, often at a lower radiation dose than film.[13]

A CMOS detector is literally a camera on a chip (Fig. 28-13, *A*). Because it has a full digital interface, the analog signals from the scintillator are translated to digital signals by the chip. Simply stated, CCD systems require many supporting components (e.g., timing generators, shuttering and signal-processing chips), whereas CMOS detectors integrate all these functions in a single chip. Any computer with a USB port can accept this detector, and a separate processing board is not needed. Several manufacturers produce CMOS detectors of x-radiation, integrate the radiographic image, and initiate the readout of the pixel data.

Taking this technology a step farther, Schick Technologies (Long Island City, NY) manufactures a wireless sensor, the CDR Wireless (see Fig. 28-13, *B*). This device sends a radio frequency signal to a nearby remote receiver on the 2.4 GHz band that produces an image with the same quality as the wired version. Unlike the CCD, the CMOS chip requires very little electrical energy; therefore no external power supply is needed to support USB utilization, and wireless applications are feasible.

Storage phosphor plate technology allows indirect production of radiographic images using a semiflexible, phosphor-coated plate. With the DenOptix system (Gendex, Des Plaines, IL), plates are loaded into a sheath, exposed, mounted in a carousel, and then placed in the scanner. As many as eight intraoral images are ready for viewing in about 1 minute if the lowest-resolution scan is used. The plates are available in periapical, panoramic, and cephalometric sizes, and they support a wide range of exposure settings. The advantages of this

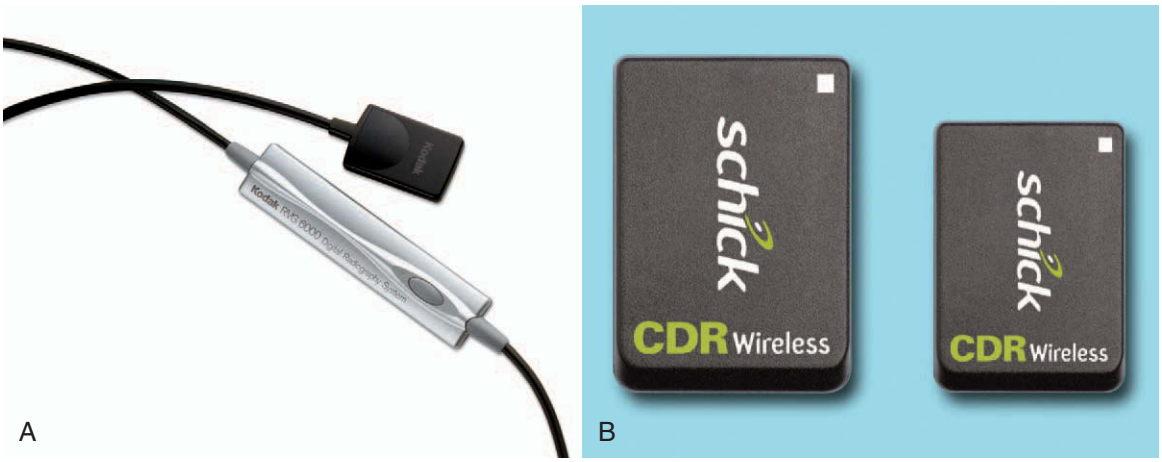

FIG. 28-13 A, Complementary metal oxide semiconductor (CMOS) direct sensor technology is literally a camera on a chip that connects to the chairside workstation via the USB port, thereby eliminating the processing board. **B,** Wireless CMOS sensor transmits images to the chairside workstation by 2.4 GHz radio frequency. *(**A** Courtesy PracticeWorks LLC, Atlanta, GA; **B** courtesy Schick Technologies, Inc., Long Island City, NY.)*

system are that very thin plates are equivalent to film in size, and placement characteristics are very similar to those of film because there is no wire on the plate. The main disadvantages are longer processing times (compared with only seconds for CCD/CMOS sensors), light sensitivity during transfer to the scanner, and the additional handling steps of erasing and sheathing the individual plates between uses. For individual intraoral images, the Air Techniques Scan-X processor (Air Techniques, Hicksville, NY) can process the initial image in less than 20 seconds and subsequent images in about 4 seconds. New intraoral plates have a surface protective layer but can still degrade as a result of scratching during use.

For the truly paperless office, a film scanner (Box 28-4) is necessary because it allows input of historical, film-based radiographic images. Both dedicated film scanners and flatbed scanners are available for digitizing radiographs. The ScanRite dedicated film scanner (ScanRite Systems, Fremont, CA) provides a single image in about 10 seconds (Fig. 28-14). This high-resolution image can be enhanced and imported into any TWAIN-compliant software through the USB port on the computer.

Consumer-level flatbed scanners can be used to scan film-based images, but these require transparency adapters. Flatbed scanners also can be used to scan paper documents and append them to the patient's digital chart. Nevertheless, a dedicated single-purpose scanner with a document feeder is recommended for paper documents.

The value of instant digital imaging in the modern dental office is well known, especially for endodontic and implant procedures. Many researchers have concluded that digital x-ray sensors equal analog film for diagnostic tasks, with the added benefits of immediate image production, image feature enhancement and the increased security of offsite archiving.[24] Conventional film provides a finer grade of detail through continuous shades of grayscale images, rather than the discrete pixels of individual gray levels used by digital systems. Advances in digital imaging continue, such as improved resolution, enhanced digital subtraction radiography,[72] and active surfaces approaching those of film, and in the not-too-distant future, digital image quality may surpass that of film.

FIG. 28-14 The ScanRite (ScanRite Systems, Fremont, CA), a dedicated film scanner, can improve workflow because it is optimized to scan film-based images and automatically correct for brightness, contrast, and color.

To produce the highest quality digital radiographic image, consideration must be given to the entire "imaging chain" (i.e., the x-ray generator, subject, sensor, computer interface, and monitor). *The quality of a digital image depends on each step of the process, and the weakest link degrades the final result.* The following sections discuss basic considerations for a better understanding of digital imaging.

IMAGE QUALITY

One of the most critical and most misunderstood issues concerning digital representation of image data is clinical performance. Computer screen selection, ambient lighting,[52] and image compression all affect the image; however, for the purchasing decision, the most compelling issue should be the image quality of dental structures as perceived by the clinician.

Clinical performance depends on numerous interrelated factors and can be expressed as detective quantum efficiency (DQE), the measure of noise and contrast expressed as a func-

BOX 28-4

Dental Film Scanning

A scanner can be used as a complement or an alternative to a sensor-based or phosphor plate–based digital radiography system. Scanned film images can be saved in digital radiography system software, patient management software, or third-party imaging software (such as that included in the Windows XP and Vista operating software).

Complementary System

To complement a sensor- or phosphor-based digital radiography system, both the scanner and the system software must be TWAIN compliant. This allows images to be scanned directly into the electronic oral health record (EOHR). Some system software even names the file automatically to simplify the process.

Alternative System

Scanners can be used as an alternative to a sensor- or phosphor-based digital radiography system because the investment cost is lower, and the image quality can be excellent. If the office is networked or is wired for monitors in the operatories, the image can be scanned at any location and shown on any computer linked to the network. Two major classes of scanners are of interest to the dental clinician: (1) the relatively inexpensive *flatbed scanner* and (2) the more expensive *dedicated film scanner*.

Flatbed Scanners

Certain models of flatbed scanners offer a transparency adapter to allow scanning of radiographic film. Flatbed scanners typically are best used for documents, photographs, panoramic films, and cephalometric films. Flatbed scanners usually are slow to preview and slow to scan, and their image quality and resolution are inferior to those of dedicated film scanners.

Film Scanners

Dedicated film scanners typically are best used for film-based images. The ScanRite (see Fig. 28-14) is a fast, high-quality film scanner specifically designed to input periapical and bite-wing films, mounted 35-mm color slides, and 35-mm color film. The primary considerations in choosing a dental film scanner are resolution, levels of gray scanned, speed, software, and convenience. Scanner resolution typically is quantified as dots per inch (dpi). Higher resolutions result in better clarity when images are enlarged. *Optical resolution* describes the capability of the hardware. *Interpolated resolution* is the ability of the scanner software to place additional dots among the data scanned. Image quality can be adversely affected by "noise" during image processing of either a scanned or direct digital image.

The levels of gray or number of colors scanned is important because each scanned dot is assigned a "color." The more grays or colors scanned, the better the image quality. With fewer grays or colors, images are "blotchy." This can be demonstrated by adjusting the computer monitor settings to a low color palette or depth while viewing a digital image.

The scanning speed depends on many factors. Better scanners have a built-in buffer memory so that the data do not have to be sent in multiple "bursts" to the computer. Better scanners scan in one pass without stopping. Scanning speed also depends on the resolution selected, the physical size of the original, whether color or grayscale is used, the speed of the microprocessor, and the amount of random access memory (RAM) in the computer.

The better scanners include software with the capability to change the color, select film calibrations, sharpen the image, rotate the image, scale the output, match the output (i.e., gamma level) to other software applications, invert colors or grayscale levels, and save settings for various types of originals. Most scanner software allows an image to be previewed before it is saved to disk; however, this small preview image makes it difficult to make image enhancements accurately. Dedicated film scanners save time by automatically optimizing the brightness, contrast, and color for each scanned image.

tion of object detail. Noise is an inevitable product of the digital imaging chain and is reflected in the signal-to-noise ratio (SNR). Systems with a high SNR produce the best image quality. Compensating for poor SNR is possible—to a point—with increased radiation, but this increasing dose negates one of the key advantages of digital systems. Moreover, excessive dosage can lead to detector saturation and reduced image contrast. *Contrast performance* is the ability of the system to display the actual contrast of an object, and the ability to make window and level adjustments is potentially one of the true benefits of digital radiography over film. Digital detectors generally have a wide dynamic range, with thousands of shades of gray; therefore they might depict areas that might be overexposed or underexposed on film. Window and level adjustments are needed to display all the subtle contrast variations in a digital image, just as a bright light might be used to evaluate an overly dense analog film's radiographic detail.

The ideal is to produce a high DQE by combining low noise and high contrast so that small low-contrast objects can be detected. Another potentially significant advantage of a high DQE is that digital systems can produce better small, low-contrast object detection than film with the same radiation dose. In the future, improving the DQE (high DQE results in low-noise images with high object detectability) coupled with advanced image processing algorithms and other postprocessing improvements will lead to enhanced visualization.[31,40] According to one expert,[28] "DQE is useful when it comes to accurate measurement for endodontic purposes"; however, the DQE is largely theoretical because few dental studies have actually used it.

Simple comparisons of limiting spatial resolution (LSR), the spatial frequency at which the observer can no longer detect a high-contrast test pattern under laboratory conditions, and digital detectors are problematic because there is a point of diminishing returns. The amount of signal captured per pixel is reduced as pixel size becomes smaller, although the amount of noise remains relatively constant for each system. Increasing the number of pixels can result in a lower SNR at each pixel, which limits small object detection. Even though sensors may have LSRs as high as 20 to 22 line pairs per millimeter (lp/mm) when measured using high-contrast lead grids, the smallest object that can be detected is usually larger

in clinical circumstances. In addition, noise and contrast combined with limitations of human vision's poor response to high spatial frequencies limit small object visibility. Nevertheless, the latter problem is somewhat obviated by the ability to zoom-enlarge digital image details. Unfortunately, as low-contrast details such as lateral root canals become even thinner in dimension, there might not be sufficient contrast to detect them, regardless of the system's spatial resolution. There is no free ride. A low DQE, even with a high LSR resulting from high noise and low contrast, may remain a limiting factor.

Furthermore, the quality of many film-based images may be compromised by operational problems such as chemical and film freshness, developing inconsistencies, light leaks, and shipment handling. Gross and moderate caries can be detected with both conventional film and digital imaging systems with a great degree of surety. Studies[50,101] showed relative equality between digital and film-based radiographs for caries detection. Another study[91] compared the accuracy of caries detection in film-based, storage phosphor, and CCD sensors. They found that the diagnostic accuracy of film was comparable to that of digital systems. The study also noted that the dentist's ability to evaluate the radiographs accurately was the most significant variable in radiographic diagnosis. Unfortunately, the presence of caries is always more extensive than depicted by either digital or film systems. Incipient caries and some periapical lesions continue to present a challenge for both film and digital-based systems.

Caries detection on interproximal surfaces has been further refined with the development of smart software that uses a software algorithm approved by the U.S. Food and Drug Administration (FDA), originally developed for the defense industry. This predictive software, the Logicon Caries Detector (PracticeWorks, LLC, Atlanta, GA), produces three types of diagnostic aids to improve caries detection by up to 20%.[38]

In the detection of periapical bone lesions created in cortical and trabecular bone, some have stated that no difference was seen among E-speed film, CCD, and CMOS sensors.[74] Furthermore, the study noted that "cortical bone lesions were detected with significantly higher accuracy once the junction of the cortical plate was involved or perforated."[6] However, caution must be exercised when evaluations are made using artificially created lesions.

Digital detectors produce images with a dynamic range of 8 to 16 bits. A typical 12-bit system records 4096 shades of gray. Because most computer monitors can display only 8 bits, or 256 shades of gray, some of the data are lost in the transformation. If these data are processed linearly instead of by sophisticated algorithms, some useful data are discarded.[26] These types of algorithms are commonly used in most modern digital systems to maintain the clinical usefulness of the images produced.

RADIATION

Silver-halide film records the interaction of x-ray photons with electrons in the film emulsion.[30] The photons are either attenuated (absorbed or scattered) or transmitted (along with some scatter) and reach the film emulsion to create a latent image. This image is then chemically processed to reveal the viewable radiograph. Film images are characterized by continuous shades of gray between the extremes of black and white.[76] However, film requires a relatively high dose of x-radiation to achieve the same result as a direct digital detector. According to van der Stelt,[96] "the primary principles of radiation protection in diagnostic radiology are justification (the patient will experience more benefit than harm from the exposure) and the 'as low as reasonably achievable' (ALARA) principle." Despite the fact that radiation exposure can be reduced by using thyroid shields, the highest-speed films, and rectangular collimation, studies consistently demonstrate that radiation hygiene is not practiced by dentists to its fullest benefit. In 2006, medical x-rays, especially medical CT and nuclear medicine imaging, constituted nearly half of the total radiation exposure of the U.S. population from all sources (Fig. 28-15). New guidelines issued in 2003 by the National Council on Radiation Protection (NCRP) in its Report No. 145 supersedes the previous report published in 1970.[68b]

If the states adopt the newest NCRP recommendations (Box 28-5), as is commonly done, most dental offices would not be in compliance. Two terms used in the report have been specifically defined. The terms *shall* or *shall not* indicate that adherence to the recommendation would be in compliance to the standards of radiation safety. The terms *should* or *should*

BOX 28-5

National Council on Radiation Protection Recommendations

1. Dentists must examine their patients prior to ordering or prescribing x-ray images (this is not a new guideline).
2. The use of leaded aprons on patients shall not be required if all other recommendations in this report are rigorously followed (read full report #145).
3. Thyroid shielding shall be used for children and should be provided for adults, when it will not interfere with the examination (e.g., panoramic imaging).
4. Rectangular collimation of the beam, which has been recommended for years, shall be routinely used for periapical radiographs. Each dimension of the beam, measured in the plane of the image receptor, should not exceed the dimension of the image receptor by more than 2% of the source-to-image receptor distance. Similar collimation should be used, when feasible, for bitewing radiographs.
5. Image receptors of speeds slower than ANSI speed Group E films shall not be used for intraoral radiography. Faster receptors should be evaluated and adopted if found acceptable. For extraoral radiography high-speed (400 or greater) rare earth screen-film systems or digital-imaging systems of equivalent or greater speed shall be used.
6. Dental radiographic films shall be developed according to the film manufacturer's instructions using the time-temperature method. In practical application, this means that sight development (reading wet x-ray films at the time of the procedure) shall not be used.
7. Radiographic techniques for digital imaging shall be adjusted for the minimum patient dose required to produce a signal-to-noise ratio sufficient to provide image quality to meet the purpose of the examination.
8. Clinicians designing new offices or remodeling existing locations will need shield protection to be provided by a qualified expert.

From the National Council on Radiation Protection and Measurements: Radiation protection in dentistry, Report #145, Bethesda, MD, 2003, NCRP. Available at <ncrponline.org/Publications/145press.html>. Accessed July 17, 2009.

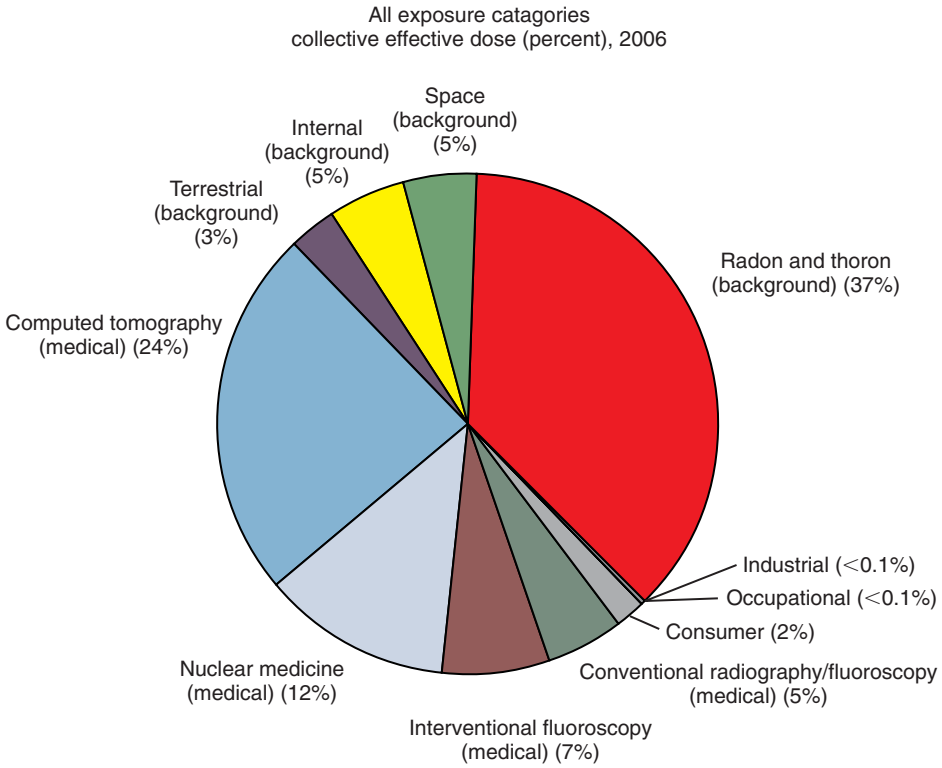

FIG. 28-15 Natural and manmade sources of radiation. *(From National Council on Radiation Protection and Measurements (NCRP) Report No.160, Ionizing Radiation Exposure of the Population of the United States, 2009.)*

not indicate prudent practice and acknowledge that exceptions may be made in certain circumstances. In addition, there are also nine new recommendations for image processing of conventional film in the NCRP report. A strong argument can be made for clinicians to switch to a direct digital radiography system to avoid all the drastic changes necessary to assure compliance with the new recommendations.

Digital intraoral imaging generally requires less radiation than film-based systems, a key public health benefit. According to the ADA Council on Scientific Affairs, digital imaging reduces radiation exposure by 50% to 90%.[5] Film scanning provides no reduction in radiation, because a conventional film image must first be produced.

Although digital radiography promises to reduce radiation for each image exposure, the real radiation a patient receives in relation to the diagnostic information gained remains controversial. In studies by Versteeg et al. and Sommers, technique errors for digital detectors were higher than film-based systems.[87,98] The most common difficulty, according to focus-group studies, was found to be sensor positioning. These findings dramatically point out the need for careful and ongoing training of dental technicians in the art of taking radiographs with digital sensors—a critical step in taking full advantage of the benefits of reduced radiation for each image exposed.

Placement errors aside, most CCD and CMOS-APS detectors have a similar range or exposure latitude to counteract under- or overexposure. Direct digital detectors take about 100 times more exposure to produce a black image than a light gray image, or a 100:1 ratio. In comparison, film has about a 1000:1 ratio, and PSPs have a range of 10,000:1.[99] Although the benefit of PSPs' wider range of exposure latitude may "save" an occasional overexposed image, PSPs can lead to inadvertent excessive radiation exposure, because overexposure will less likely produce poor image quality as a warning.[11] Strict adherence to preset exposure settings will continue to require diligence to reduce radiation exposure. Additional reduction in radiation to special-needs patients (e.g., patients with developmental disabilities or are severely mentally handicapped) may also be realized because of the advantages of digital detectors.[29]

Common dental projections rarely if ever deliver a measurable absorbed dose to an embryo or fetus, but any radiologic procedure on a pregnant patient should be conducted so as to minimize the radiation dose to the pelvic region.[47] This procedure should be conducted only if x-ray exposure is required for adequate diagnosis and treatment. If dental care is to be delayed until after delivery, exposure should also be delayed. Also, usual and customary radiographic selection criteria should be applied for patients who are trying to get pregnant, breastfeeding, or have received radiation therapy to the head and neck for medical purposes (the radiation dose from dental radiography is insignificant when compared to therapeutic dosing).[39,64]

Even though restriction of an intraoral dental x-ray beam is mandated by federal law to be a circle no greater than 7 cm, rectangular collimation has proven to significantly reduce radiation dose to the patient. The ADA Council on Scientific Affairs states that the "tissue area exposed to the primary x-ray beam should not exceed the minimum coverage consistent with meeting diagnostic requirements and clinical feasibility. For periapical and bitewing radiography, rectangular collimation should be used whenever possible because a round field beam used with a rectangular image receptor produces…

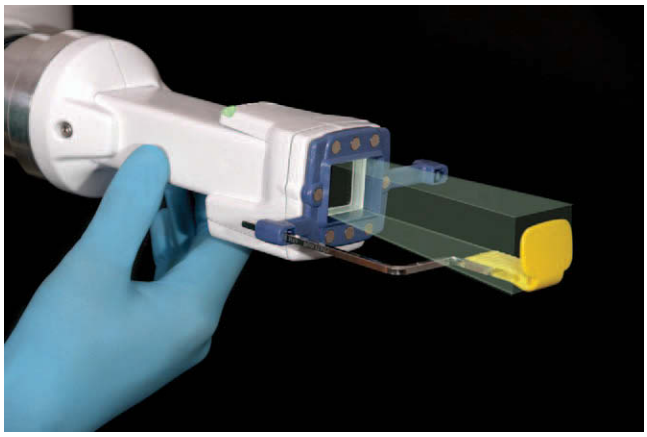

FIG. 28-16 In compliance with the recommendations of the National Council of Radiation Protection and Measurements (NCRP) guidelines, reducing radiation for periapical and bitewing radiographs can be accomplished by using a rectangular collimation device to assure that only productive ionizing radiation reaches the patient. When compared to conventional round collimation, the Tru-Align system restricts the beam size to approximately the size of a #2 periapical film or digital sensor, thereby reducing skin surface–area dose by a factor of 5 and overall radiation to patients by as much as 65% to 70%. *(Courtesy Interactive Diagnostic Imaging Inc, Atlanta, GA.)*

unnecessary radiation exposure to the patient."[5] In a recent study by Seltzer et al.[83] comparing a new rectangular collimation system, Tru-Align (Interactive Diagnostic Imaging Inc, Atlanta, GA), with conventional round collimation, the rectangular collimator (Fig. 28-16) reduced skin surface–area dose by a factor of almost 5. The Tru-Align system, deemed easy to use, generally gave perfect alignment with only occasional cone-cuts.

Personnel monitoring is required in all states to assure compliance with established ionizing radiation limits. According to the Maryland Department of the Environment guidelines,[88] monthly badges are required for the first 6 months of employment to document that radiation will not exceed 10% of the legal radiation limit set by the state. Ionizing radiation dose limits for Maryland of 5000 millirem for workers, 500 millirem in 9 months for pregnant women,[47] and 100 millirem for the general public are mandated by state regulation. All dosimetry badge reports must be maintained at the office for review as proof of minimal radiation exposure. Variations of these requirements are found in each state, so familiarity with the controlling laws is mandatory.

QUALITY ASSURANCE

Clinicians should ensure that their practices take all necessary steps to produce consistently high-quality radiographs with minimal ionizing radiation exposure to patients and staff. Dental office quality assurance involves periodic evaluation of the entire imaging chain, including the x-ray generator, film procurement and storage, developer,[30] darkroom, view boxes, and protective aprons. Administration of quality assurance requires assigning responsibility, training, evaluating results of testing, and taking corrective action.[53] Ohio, for example, requires each registrant to maintain a site-specific written quality assurance program with published requirements for how often x-ray generators need to be tested and calibrated and so on.[73]

FIG. 28-17 Using large interactive displays improves the patient's understanding of their condition, leading to a better treatment experience. Here the clinician is explaining a periradicular lesion shown by focused-field cone-beam computed tomography.

PATIENT EDUCATION

Most people of college age and older are visual learners, and presentations that include both visual and auditory modalities are superior to visual or auditory modalities alone.[32] Consider the educational value for the patient able to view a large, high-resolution radiograph in conjunction with the clinician's diagnostic explanation (Fig. 28-17). Once the patient understands their dental condition (e.g., caries, periradicular pathosis), treatment acceptance becomes more assured, and the patient experience is enhanced.

WORKFLOW IMPROVEMENT: A WORK MULTIPLIER

Digital radiography is a work multiplier; it replaces human effort, making tasks the practitioner and staff members perform easier and more error free. In some cases, it makes new tasks possible.[19] DDR images take less time to expose, duplicate, retake, and transmit, all with less radiation and environmental impact. With solid-state systems, any operative procedure, such as endodontic therapy and implant placement, can be performed in less time. The diagnostic yield of digital imaging systems will improve as enhancements are made to image acquisition, but also to our understanding of human vision and cognition. Image processing can improve diagnostic outcomes by defining diagnostic issues and designing tools to achieve specific goals.[68a] Also, visual information such as digital radiography and visible light images (i.e., intraoral photography, microscopy) is easier to access than film-based images and improves office operations by increasing efficiency. PSP plates take at least 8 seconds to process after the detector is transported to the developing site and unwrapped, whereas CCD/CMOS-APS detectors are virtually instant, with "paint times" usually just a few seconds. Some workflow advantages are shown in the following comparisons.[73a]

OPTIMIZATION

All digital radiographic systems allow for some image optimization (Fig. 28-18, *A*). Postexposure image processing routines differ among manufacturers. Some produce a raw image for which automatic enhancement routines can be turned on and off, whereas others produce images that are filtered automatically. Most software features the ability to change contrast and brightness to view images that are underexposed or overex-

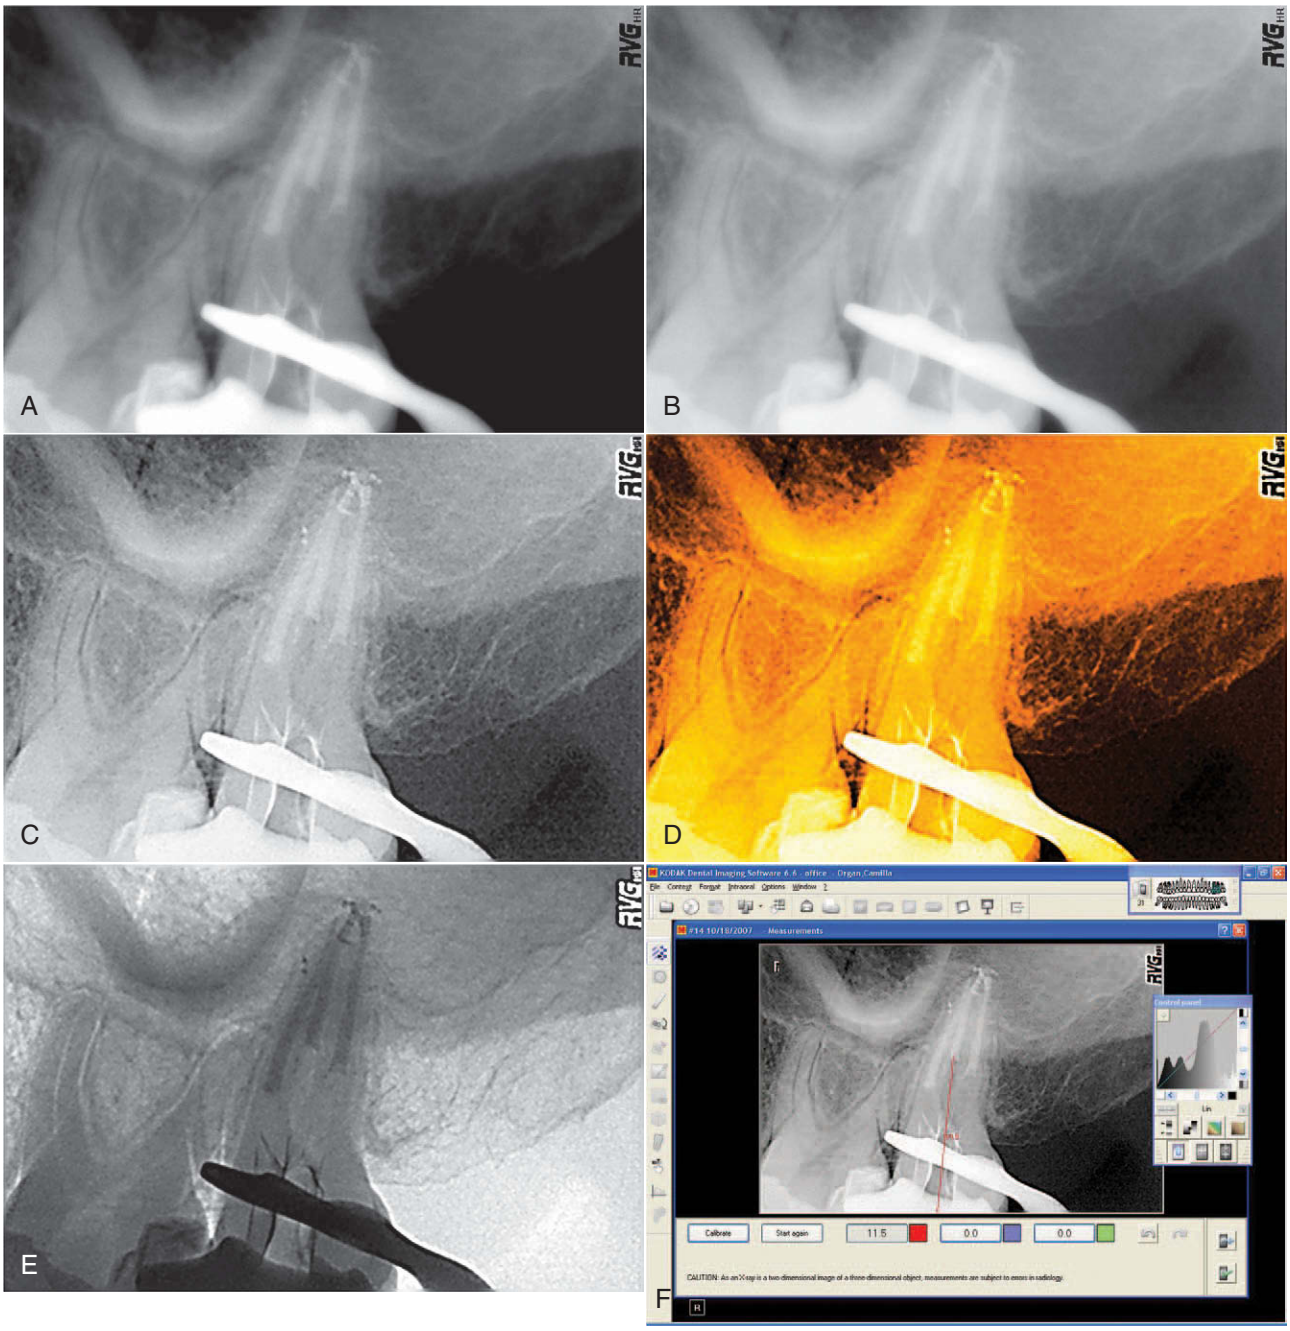

FIG. 28-18 Optimization of digital radiographs. **A,** Raw periapical image. **B,** Window and level adjustments, similar to contrast and brightness, have been used to reduce the effects of overexposure. **C,** A filter has been applied to enhance readability. **D,** The image has been colorized to further differentiate the elements of the radiograph. **E,** Image reversal can sometimes improve readability. **F,** Once calibrated, the measuring tool can be helpful for measuring root lengths and distances to anatomic sites, but accuracy is not assured because of parallax error.

posed, as well as to equalize density, magnify (see Fig. 28-18, B), create an inverse image (see Fig. 28-18, E), and allow for image rotation and mirror imaging. Another enhancement, pseudocoloring, ascribes false colors based on the brightness of pixels and can help with patient visualization of images.[54] A number of systems also have algorithms that can sharpen and enhance caries imaging, and the future promises even more improvements.[70]

Filtering tools are available in all commercially available software, but comparison is difficult because proprietary names do not reveal the underlying algorithms. Investigators[55] studied the functionality of 13 software programs and suggested more standardization of filtering tools to improve exchange, enhancement, processing, and analysis. They further suggested that public-domain image processing and analysis software, similar to software adopted for medicine by the National Institutes

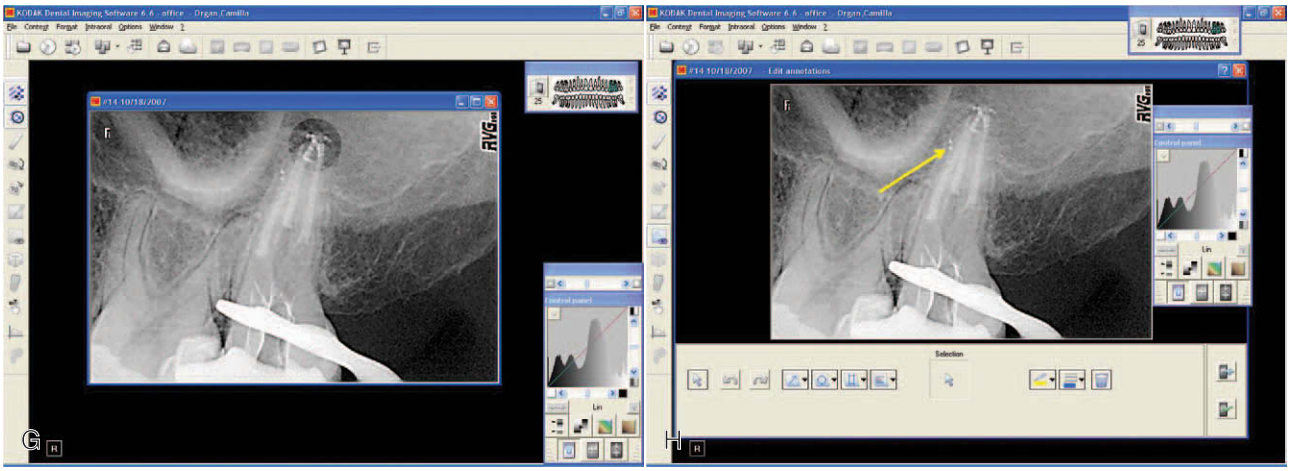

FIG. 28-18, cont'd G, Certain regions of interest (ROI) can be highlighted with a preset contrast tool that can be moved around the image to highlight specific areas. **H,** ROI can be annotated with arrows and drawing tools. *(Courtesy Dr. John D. West, Tacoma, WA, and PracticeWorks, LLC, Atlanta, GA.)*

of Health (NIH), may provide the basis for more standardization.[70]

MEASUREMENT

The three types of measurement generally available with digital imaging software are (1) linear measurement, the distance between two points in millimeters (see Fig. 28-18, *F*); (2) angle measurement, the angle between two lines; and (3) area measurement, the area of the image or a segment of the image.

Because magnification and distortion error play a significant role in all two-dimensional radiographic measurement accuracy, both film and digital systems are subject to parallax error. However, a study[22] that compared endodontic file length images of human teeth taken with a custom jig suggested that "measurement error was significantly less for the digital images than the film-based images." This was true even though, as the authors pointed out, the measurement differences may not be clinically significant. Sophisticated calibration algorithms are under development, and accurate measurement of parallel images should be more feasible in the future.[13]

SECURITY

Although film-based images can easily be produced in duplicate, each subsequent rendition of the image is reduced in quality. Digital images, on the other hand, can be reproduced in unlimited number because the images can be stored and produced without any loss of detail. Furthermore, digital images can be stored on and off site and on many types of media, which helps prevent permanent loss from theft, fire, or other causes.

Paradoxically, the ease with which digital images can be reproduced and stored allows for alteration of radiographs without a trace.[25,100] Of course, this has always been possible with duplicated analog film images, but the issue has not been commonly addressed. The ease of producing an altered image is controversial, but most digital vendors on the market have safeguards that greatly minimize the possibility of this occurring. In addition, standards such as Digital Imaging and Communications in Medicine (DICOM; discussed later in the chapter) help protect image integrity through the use of digital signatures in the form of tagged attributes attached to each image.[25] Archiving radiographic images in a secure site in DICOM format using removable media such as DVD and tape is one of the current solutions to this problem. These types of magnetic and optical media can be stored off site by a third party archivist for extra protection.

These data are also vulnerable when sent via the Internet to a discussion site. Two common technologies, Secure Socket Layer (SSL)[1] and digital certificates (VeriSign, Mountain View, CA), can provide at least 128-bit encryption and virtually eliminate the chance of alteration or fraud. SSL connections to Internet servers can be recognized by the prefix *https://* in the address line. In any event, such material should be carefully secured to fulfill HIPAA requirements regarding privacy.

Another important security consideration is the database engine used to store the files on the server. Among the most robust systems are SQL-based models, which allow for client-server configuration with industry-standard software protocols. Images that are stored and retrieved cannot be deleted, nor can patient identification be changed, without opening a separate administration utility, which can be password protected on the server.

IMAGE STORAGE AND COMPRESSION

All computer-based images are voracious consumers of hard drive space, and various manufacturers have used a number of techniques to reduce image size. For example, Schick Technologies allows acquisition of each image with the advanced compression technology of the JPEG4 codec. Clinicians can also compress selected groups of images between certain dates with up to four different compression schemes, allowing for *lossless* (no visible change in image clarity with approximately 50% to 75% reduction in file size) to *lossy* (significant reduction in file size with some degradation of image resolution) compression. Lossy compression is not recommended for dental grayscale images.

MARKERS

Occasionally, radiographs and VL images need a tag so the clinician can return to them later to assemble teaching or

patient education materials. Most software today allows markers to be placed so that a computer search can call up the images efficiently. These customized tags can be useful in organizing cases that require special follow-up to evaluate postoperative healing. In addition, readily available software enables the clinician to create notes and diagrammatic annotation of important features of an image (see Fig. 28-18, *D*, *F*, and *G*).

COMPUTER INTERFACE

Many digital sensors connect to the chairside computer workstation via the USB port. As of 2004, only Schick Technologies had produced a wireless sensor that transmits the image data by radio frequency to a nearby receiver and thence to the USB port, eliminating any sensor wire. The direct USB connection eliminates any computer interface board, which simplifies installation and maintenance. Laptop configurations add flexibility if the clinician wants to move the equipment between different operatories and office locations or use it for off-site procedures at hospitals and nursing homes. Laptop configurations also benefit from the elimination of special cards for sensor connection. System backup strategies are particularly important for laptops because of the increased risk of theft or of being dropped.

X-RAY GENERATOR

According to Miles, the image chain is only as good as its weakest link, and digital systems work best with a modern x-ray generator.[66] Images from digital detectors are optimized if taken with an x-ray generator that has (1) an extremely accurate timer, especially for short exposures,[51] (2) low mA and kV settings, and (3) a direct current (DC) circuit. Farman,[28] however, contends that the x-ray generator has not been shown to have a significant effect on digital radiographic quality.

FOCUSED FIELD CONE-BEAM COMPUTERIZED TOMOGRAPHY IN ENDODONTICS

Endodontics is an image-guided specialty, and until recently, endodontic radiographic diagnosis relied on two-dimensional radiographic assessment. The introduction of cone-beam computerized tomography (CBCT), and especially recent refinements such as very small field of view (FOV) or focused-field devices, is revolutionizing the visualization of the dentition and the maxillofacial complex (see online Chapter 29).

The shortcomings of panoramic radiography have been well understood for many years. They are flat, two dimensional, superoinferior or posteroanterior images that suffer from superimposition of all structures imaged and distortion and magnification errors. Therefore, measurements of objects on panoramic images are inaccurate. CBCT images, on the other hand, capture anatomic entities in three dimensions (3D) and can be viewed by digital selection of the region of interest (ROI) with great accuracy. In recent research published by Stratemann et al.,[89] linear measurements of skulls comparing calipers and CBCT imaging revealed only a 1% relative error.

According to one source,[41] "these machines are smaller than medical CTs, less expensive to purchase and operate, produce a fraction of the radiation dose, and possess an open architecture that, generally, eliminates patient complaints of claustrophobia." Unlike periapical radiography, CBCT scans enable the visualization of the "true extent of lesions and their spatial relationship to important anatomic landmarks."[15] Comparing periapical radiographs (PAs) of 156 maxillary posterior roots with small field CBCT images prior to surgery, investigators[61] found that these CBCT images showed 34% more lesions than were visible with PAs alone (Fig. 28-19). Numerous papers have demonstrated that CBCT imaging is superior to PA radiography in detection of periradicular lesions. Researchers[37,67] created artificial osseous defects and conclusively demonstrated the improved detection rate of bony defects with CBCT imaging. Other researchers[59] reported that in 70% of cases that were evaluated with both PA and CBCT, CBCTs provided clinically relevant information not visible on PA radiography. Other researchers have reported that CBCT, which can be used to measure the grayscale values of lesions, may provide a better, more accurate, and faster method to differentially diagnose a solid from a fluid-filled lesion or cavity. This may allow the clinician to decide whether or not periradicular surgery is necessary without waiting for a long recall period to see if healing has occurred.[84]

Newly introduced hybrid units like the Kodak 9000 3D extraoral imaging system (PracticeWorks, LLC, Atlanta, GA) have two digital detectors, one for digital panoramic imaging and one for focused-field digital volumetric tomography (Fig. 28-20). Aside from panoramic radiographs, this unit produces 3D images of an area measuring just 37 mm × 50 mm (approximately a quadrant), with less radiation than a standard CBCT and improved readability because of its new higher-resolution detector. Unique to the Kodak 9000 3D system is the highest-resolution sensor available at this time, with a voxel (*vol*ume pix*el*, representing a quantity of 3D data similar to a pixel representation in 2D data) size of just 0.076 mm. While not necessary for use in every case, when appropriate, this technology will improve visualization and ultimately lead to better care. This is because imaging the maxillary posterior region poses unique challenges, where roots of teeth overlap and anatomic structures such as the zygomatic buttress and maxillary sinus are present.

Medical CTs necessitate a significant radiation dose to patients, with a typical scan of the maxilla and mandible of 2.00 millisieverts (mSv), or as much as 345 panoramic images. On the other hand, large FOV CBCTs will image the same area at 0.068 to 1.073 mSv or 3 to 44 panoramic equivalents.[63] The focused-field FOV CBCT will further reduce radiation exposure to 0.005 to 0.038 mSv[62] because of its limited coverage and low mA technique factors (Table 28-2).

Integration of third-party digital radiography and VL imaging products is very important to the modern endodontic practice, especially if the goal is to create a paperless environment. Several open platform applications specific to dentistry are available that allow the clinician to acquire, store, annotate, manipulate, and output many types of images. Comprehensive packages such as ViperSoft (Integra Medical, American Fork, UT), TigerView (Televere Systems, Los Gatos, CA), and Kodak Dental Imaging Software (PracticeWorks, LLC) work with analog and digital still and video cameras, scanners, and digital radiography programs. Once an image has been acquired, these sophisticated software programs allow the clinician to label and annotate the image, transmit it by e-mail, and even simulate the repair and restoration of teeth (i.e., cosmetic imaging). As operatory-based computers become the norm, dental imaging systems are becoming mainstream, allowing secure

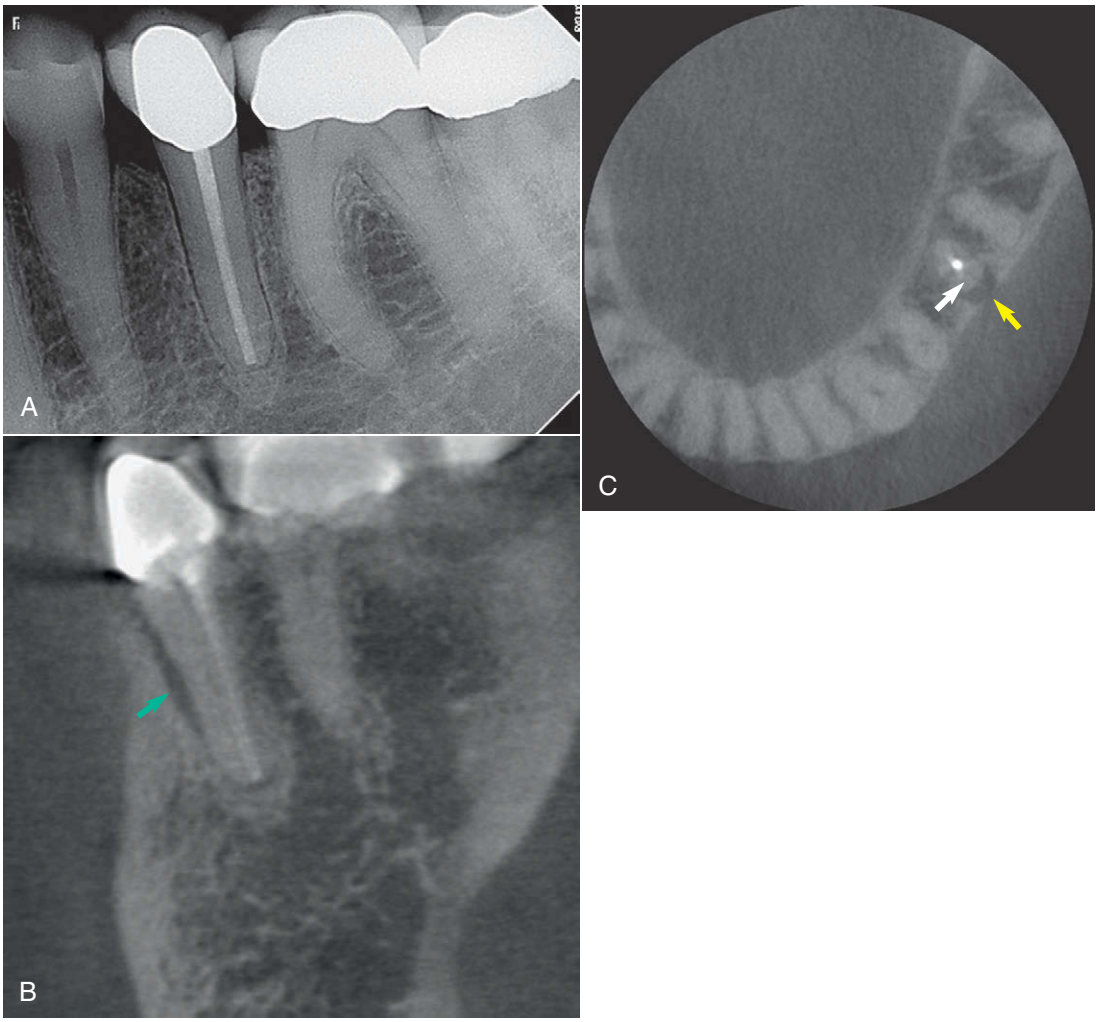

FIG. 28-19 A digital periapical radiograph **(A),** showed previous endodontic treatment, slight widening of the periodontal ligament on the mesial, and a periapical condensing osteitis. Two CBCT images: **B,** sagittal view *(green arrow)* demonstrated significant periradicular widening of the periodontal ligament, which extended to the buccal aspect and appeared to perforate the buccal plate; **C,** axial view *(yellow arrow)*. While the image showed streak artifact on the mesial and distal of tooth #20, a vertical fracture was evident on the direct buccal that extended from the CEJ to the midroot *(white arrow)*. This example demonstrates the improved visualization of periradicular pathosis with 3D technology.

network e-mail transfer of images in several industry standard formats (i.e., DICOM, TIFF, BMP, JPEG, and TGA). Before purchasing any software, including imaging software, the clinician should confirm that it is HIPAA compliant (transaction types, standards, and code sets) and DICOM conformant to the requirements set forth in DICOM Supplement 92 (2004).[18]

Imaging software can be an invaluable aid for cataloging images for easy retrieval, case presentation to other dentists and patients, analysis, and magnification of images for improved diagnosis. Sophisticated practice management software should integrate smoothly with these systems, extending the functionality of the office software and creating a complete EOHR.

Sterilization Area

The computer in the sterilization area can be used to create, print, or transmit patient treatment reports, to order supplies, for general communication duties, and as a backup for the front desk system. One advantage of creating the report in the clinical area is that the staff member who assisted with treatment can individualize the report as necessary. Once a template has been created and the software populates the preset fields, radiographs and VL images can be inserted and then sent to an approval queue to be inspected by the clinician in the private office, or an assigned staff member can print or e-mail it. Some practice management software programs are designed to create these reports at the chairside computer workstation and send them directly to predesignated printers and specific paper trays. Report generation at the chairside promises to further streamline the patient treatment report process.

Administrative Area

The generation of marketing materials; bookkeeping, payroll, and banking functions; bulk scanning; and special projects can be assigned to the administrative computer. Although small offices often use the front desk computer for these tasks, the increased utility of a separate computer for special projects cannot be overemphasized.

FIG. 28-20 The Kodak 9000 3D extraoral imaging system has two digital detectors, one for panoramic imaging and one for focused-field digital volumetric tomography. This DICOM-compliant unit takes 13.5 seconds to capture a CBCT dataset of 461 basis images that are then reconstructed to create a focused-field 3D volume of 37 mm × 50 mm. *(Courtesy PracticeWorks, LLC, Atlanta, GA.)*

Clinician's Office

The clinician's office should be equipped with a workstation that allows entry into all the programs on the network. Ample connections for uploading camera images and digital video sequences, for Internet access, and for a smart phone are also recommended. The smart phone modules available from some vendors allow the clinician to take home a synchronized database of patient and referring clinician information, the appointment schedule, and images (Fig. 28-21). This facilitates after-hours emergency communication and allows notations made to the patient's chart to be synchronized with the office database the next time the smart phone is connected to the LAN.

Real-time video conferencing and collaboration can also be handled from the clinician's office computer. Addition of an Internet camera with audio capability is all that is needed to communicate with a colleague via the Web.

COMPUTER INDUSTRY STANDARDS

Graphics and Imaging

For most clinicians, graphics and imaging is a confusing area. Windows has many graphics standards; it has been difficult to sort out which ones to use, but this is beginning to change. Although some dental imaging software stores graphics data in nonstandard ways, most products support computer industry norms. It is less important that clinicians understand the peculiarities of the different graphics storage categories than which ones to look for in a program. The importance of standards here is simply that if the graphics are stored in a standard manner, clinicians will be able to manipulate an image and drop it directly into the dental software. Some of the common image formats are:

- *Bitmap (BMP):* This is the Microsoft standard for Windows. It is used and understood by almost all imaging software and is the format of most pictures delivered with a Windows computer. Its strengths are universal distribution and very high quality. Its chief weakness is that the files it creates are not compressed and take up more space.

TABLE 28-2

Effective Doses From Various Dental X-Ray Procedures

Radiation Source*	Millisieverts (mSv)	Time Period for Equivalent Effective Dose From Natural Background Radiation (United States is 3 mSv/year)
CBCT (focused FOV)	0.005-0.038	1-5 days
CBCT (large FOV)	0.068-1.073	9-131 days
Panoramic†	0.010-0.026	1.2-3.2 days
Cephalometric	0.026	3.2 days
Full-mouth intraoral (18 F speed films)‡	0.150	18.3 days
Bitewings (4 F speed films)‡	0.038	4.6 days
Intraoral periapical radiograph	0.005	0.61 days
Maxillomandibular CT	2.000	243 days
Maxillary CT	1.400	170 days
Mandibular CT	1.320	160 days
CT abdomen	10.000	3.3 years
Chest (PA film)	0.020	2.4 days
Average galactic radiation in Denver, CO (per year)	0.510	62 days

CBCT, Cone-beam computed tomography; *CT,* computed tomography; *FOV,* field of view; *PA,* posteroanterior.

*Radiation doses vary considerably within and between different brands of equipment.

†With respect to digital panoramic radiographs, there appears to be no dose reduction compared with film-based panoramic images, because there is already a large dose reduction as a result of the use of intensifying screens in the panoramic cassettes.

‡There is approximately a 50% decrease in effective dose when comparing digital imaging and "F" speed film.

Effective doses from various dental x-ray procedures adapted from the Health Physics Society: <http://hps.org/publicinformation/ate/faqs/dentalpatientissuesq&a.html>. Accessed July 17, 2009; American Dental Association: <http://www.ada.org/public/topics/xrays_faq.asp>. FIG. 28-21 Clinicians can take the patient database out of the office with a smart phone linked to the office database. *(Courtesy Henry Schein, Inc., Melville, NY.)*

- *Joint photographic experts group (JPEG or JPG):* This is probably the most popular standard for PCs and the Internet. It has good quality and supports compressed formats (allowing for smaller files). When JPEGs are resaved, they are recompressed; therefore, care must be taken to limit the number of times the image is saved, or it must be saved in a different format (e.g., TIFF). JPEG 2000, the new image coding system, uses wavelet technology that allows improved compression and smaller-sized files.[92]
- *Tagged image file format (TIFF or TIF):* This is also a very popular standard because the images are highly flexible and can be used with many different image processing applications.[6] The images are usually very high quality and typically support minimal compression.
- *Graphic interchange format (GIF):* This is a very compressed format that is most popular on the Internet and online services, but it is not helpful in storing digital images.

Open Database Connectivity

One of the classic problems in the computer industry is that each vendor stores and manipulates its data differently. As a result, data can be read only if tools created by the same company are used. To correct this problem, Microsoft introduced open database connectivity (ODBC). With ODBC in place, software programs connecting to databases first connect to ODBC (another software product, called a *driver*), and ODBC connects to the database. This makes ODBC (and other derivative standards, such as JDBC and OLE DB[36]) a translator between software programs and databases. The advantage of ODBC is that software developers can plug into different databases without changing their program codes. In addition, ODBC-compliant databases are accessible from many programs.

ODBC is helpful to clinicians because it allows them to read and analyze the database from spreadsheet programs, report writers, graphics programs, and other database programs. In today's open-standards world, *it is unwise to purchase any product that is not ODBC compliant*.

Digital Imaging and Communications in Medicine

DICOM is a set of international standards established in 1985 by the American College of Radiology (ACR) and the National Electrical Manufacturers Association[17,69] (NEMA) to address the issue of vendor-independent data formats and data transfers for digital medical images.[75] The ADA has promoted the interoperability of dental images through the efforts of its Working Group 12.1.[26]

DICOM serves as a standard for the transferal of radiologic images and other medical information between computers, allowing digital communication between systems from various manufacturers and across different platforms (e.g., Apple or Windows).[19] The DICOM standard provides for several hundred attribute fields in the record header, which contains information about the image (e.g., pixel density, dimensions, and number of bits per pixel), as well as relevant patient data and medical information. Although earlier versions did not specify the exact order and definition of the header fields, each vendor is required to publish a DICOM conformance statement, which gives the location of pertinent data. The DICOM standard also supports a form of SSL (see section on security) for the transmission of digital output. The big hurdle is to support medical and dental consultations between two or more locations with different imaging software. With DICOM in place, dental clinicians can change vendors and maintain database continuity. Most software vendors are striving to achieve full DICOM compliance, and some have achieved at least partial compliance.

Based on the DICOM model, the ADA Standards Committee on Dental Informatics has identified four basic goals for electronic standards in dentistry: (1) interoperability, (2) electronic health record design, (3) clinical workstation architecture, and (4) electronic dissemination of dental information.[3] The dental profession must continue to promote DICOM compatibility so that proprietary software and file types do not hinder communication and risk making data obsolete.

Systematized Nomenclature of Dentistry

Systematized nomenclature of dentistry (SNODENT) is an ADA-sponsored, comprehensive set of standardized terms for defining dental disease in an electronic environment. SNODENT is part of a larger code set called *systematized nomenclature of medicine* (SNOMED),[86] which was developed by the College of American Pathologists. The codes allow dentists to document a wide range of conditions and risk factors using standard terms to aid communication among dental and medical clinicians. In addition, SNODENT allows dentists and researchers to better assess the long-term benefits of certain treatment protocols by standardizing the measurement of outcomes and the documentation of evidence-based care.[65]

INTERNET

The Internet offers current and prospective patients and referrers an opportunity to learn about the office at their convenience. The Web has consistently proved itself a cost-effective communication and marketing tool in dentistry (Fig. 28-22). The right content mix, one that is unique and well targeted to

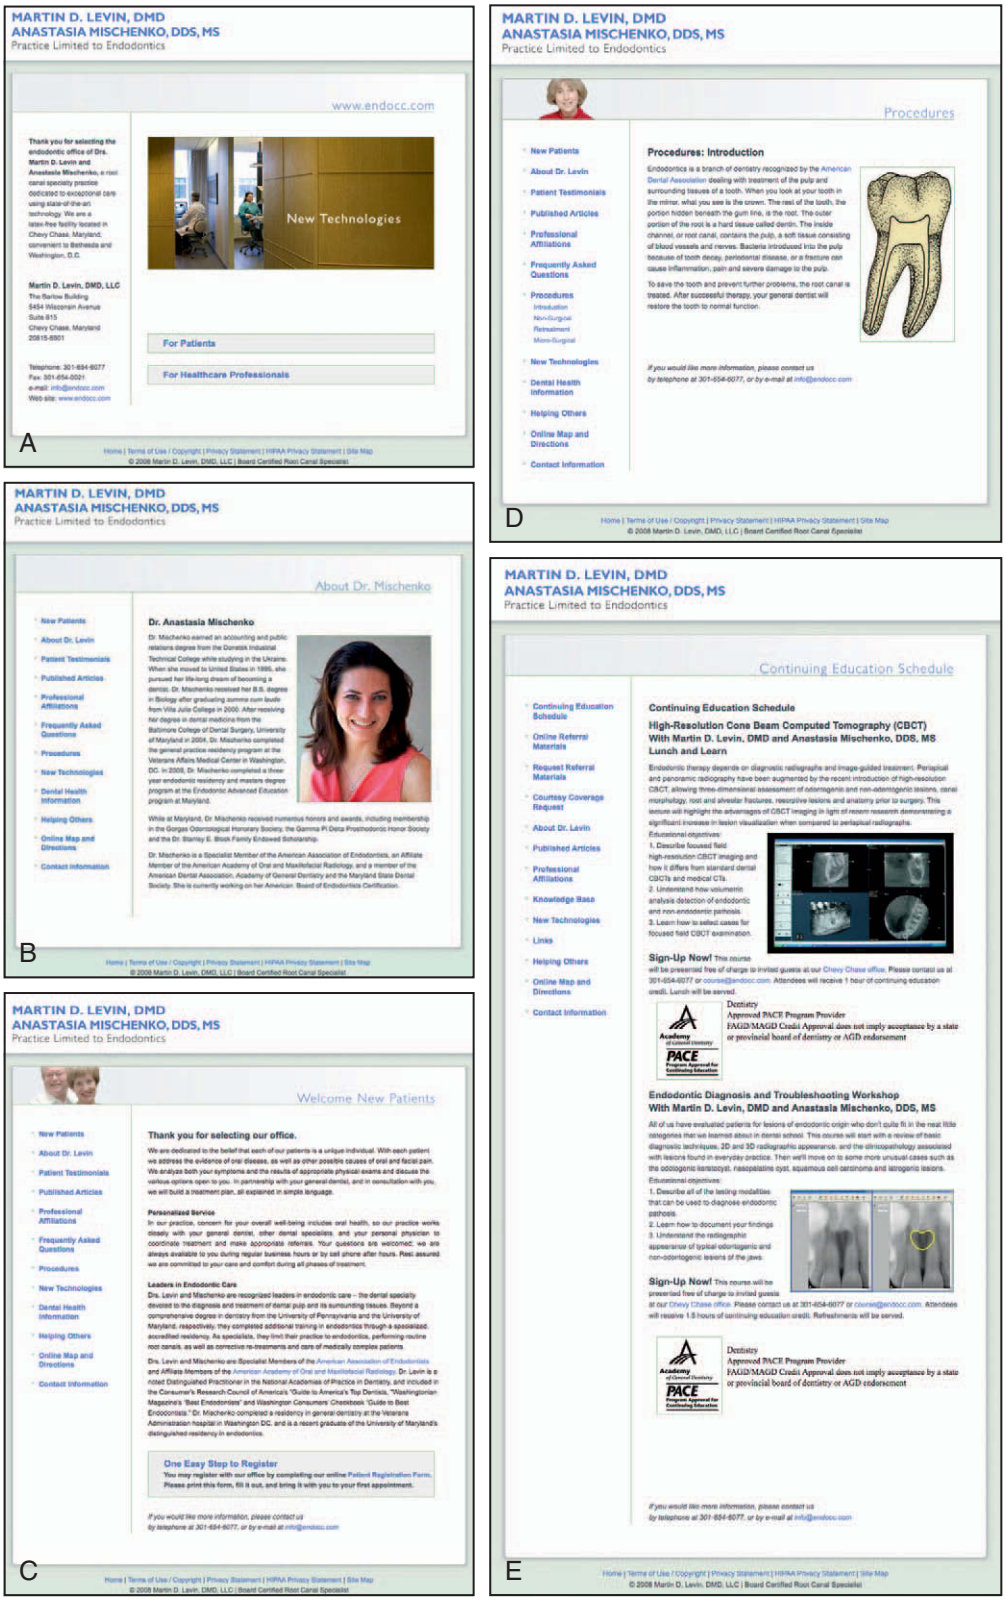

FIG. 28-22 The Internet has revolutionized office communications. **A,** The main index page of www.endocc.com, the author's endodontic office website, shows the esthetic possibilities of a professionally designed site. **B,** This page helps viewers learn about the clinicians, their educational qualifications, and professional accomplishments. **C,** The "Welcome New Patients" page introduces the practice and displays the website navigation bar on the left pane. **D,** Patients can view animated illustrations and video sequences designed to help them understand procedures. Here, the nonsurgical phase of therapy is explained. **E,** "For Healthcare Professionals" module enhances communication with other clinicians by including continuing education offerings, templates for transmission of patient referral materials, professional affiliations, a knowledge base, links to other sites and contact information. *(Courtesy Atlantic Design LLC, Playa del Rey, CA.)*

the needs of prospective and current patients, can improve both the image of the practice and patient satisfaction.

Getting started on a website can be a daunting task, because the possibilities are virtually limitless. The following steps can help the beginner get started:

1. The best way to begin is to visit other medical and dental providers' websites. The clinician should learn how to navigate the sites and should determine the elements that are required and which high-end graphic effects might prove effective. Simple is better, but patients want to see an esthetically pleasing site, and they want to learn something on each visit.
2. The clinician should then decide on a set of goals for the site; for example, should the site generate referrals via Internet search engines or serve as a resource for patients and referrers?
3. A design for the site should then be created. It should project the practice's image or brand and should fulfill patients and referring clinicians' needs. All design elements should be consistent with other marketing materials to further the practice's brand identity.
4. The next step is to outline the proposed site and create a storyboard that includes navigation possibilities for the audience. Each page is designed on a separate piece of paper, and these ideas are tested with friends and selected prospective users.
5. A uniform resource locator (URL) must be chosen so that the site address can be easily remembered and entered in a browser with minimal effort and confusion. Again, the URL should tie in to the practice's desired image.
6. The blanks on the web pages are then filled in with copy, photographs, and an appealing style that projects the practice's vision. Copyright laws apply to most material on the Internet; therefore written permission must be obtained before using protected material.
7. The website must be kept fresh. To draw repeat visitors, it must be updated continually, and all links must be relevant and functional. Some dental Internet vendors allow the clinician to edit the site on an as-needed basis 24 hours a day, 7 days a week, by adding a small applet that allows password-protected entry.

An endodontic office website can contain searchable educational material for study clubs and referrers. Websites can be transformed into a communications center, a scientific reference library, and clinical and business information resource. This can provide fast, convenient access to resources such as MEDLINE, online continuing education courses, product catalogs, practice management information, and pharmacology references.

Many vendors currently provide service for site construction and hosting that include creative patient education modules, maps with customized directions, clinician biographies, and animated procedure descriptions. Some sites also include referral forms that automate attachment of digital radiographs and promote interactive discussions about treatment.

New patients can benefit by submitting forms directly to the practice's management software via an always-on Internet connection. Clinicians can customize referral forms to provide data fields that *require* inclusion of certain information for submission, so that patients can provide more complete registration information.

IMPORTANT SOFTWARE FEATURES

Financial Security

Although fraud in dental offices is not often discussed, even conservative statistics indicate that it is a significant problem. No absolute solution exists; therefore vigilance is the key. However, the clinician should do at least three things[56]:

1. *Become educated.* Clinicians should find out how people embezzle from a dental office. Sometimes this means taking a course or two, hiring a fraud expert to review office systems, or both.
2. *Pay attention to the business.* Too many dental professionals abdicate the function of their front office to trusted "office managers." This dynamic, in which the owner of the business ignores the business, is ill conceived and invites fraud.
3. *Select software with a security log.* The practice should use an office computer system that carefully tracks all deletions, edits, and other potentially suspicious behavior automatically and prevents anyone except the clinician from viewing the security log. In addition, each user is logged on and off the system, so that the software knows when a particular person was on the system; what station the person was using; and which transactions they created, edited, or removed. Most security experts recommend that each financial transaction (i.e., routing slips) be sequentially numbered without the possibility of modification or deletion.

Referral Tracking

Sophisticated referral tracking and trend analysis are crucial to the success of a specialized practice. These capabilities are lacking in software created for the general dentist. Software designed using SQL tracks financial and other statistics associated with referrers in the practice at the moment transactions are posted. Thus the statistics are always current and accurate. Key features of referral tracking include:

1. Real-time statistics. The software should give the clinician up-to-the-second statistics (without the need to run reports) in several key areas:
   - Production
   - Collections
   - Adjustments
   - New patients
   - Patient visits
   - Teeth treated
   - Production/collections ratio (the collections percentage)
2. Real-time ranking of all referrers relative to all others in any of the previously mentioned categories.
3. Sophisticated, flexible reports based on production, collections, procedures, and other factors that can be filtered and sorted.
4. Generation of correspondence, labels, and envelopes to one referrer or a selection of referrers based on queries.
5. Availability of referrer data from the patient screen, the schedule, and other key areas so that the clinician can

make quick decisions and see the juxtaposition of referrer and other system information.
6. Charts and graphs on referrer and patient activity associated with referrers.
7. Tracking of multiple-referrer categories:
   - Referral source (i.e., general dentist, patient, phone book, website, etc.)
   - General dentist (track multiple office locations and group name identity of referring doctor)
   - Dental specialists (i.e., periodontist, oral surgeon, orthodontist, etc.)
8. Collection of the previously mentioned data by multiple facilities of the referrer. In other words, if the referral source has multiple facilities, the clinician should be able to track statistics for each of those facilities and summarize a consolidated set of numbers for all facilities.
9. Collection of the previously mentioned data by practice. If the practice uses several referral sources, this feature allows the clinician to assess statistical data by practice.

Preregistration

Using a specialized system, some software can preregister a patient (i.e., the process of recording information for patients referred but not yet seen by the clinician) at almost any level of detail. The major features associated with preregistration are:

1. The ability to record all pertinent data about a referred patient—including insurance, referral source, and medical conditions—before an appointment is made. Ample notes fields are available for recording comments from both the patient and other clinicians. A direct link to e-mail and home and work phone icons facilitates quick communication. A "welcome letter" and information about the patient's first appointment can be produced automatically and sent out with a brochure.
2. An integrated link to the schedule allows the clinician to easily drag and drop the preregistration record into the appointment book, complete with all the relevant information from preregistration.
3. Automatic correspondence can be sent to the patient after creation of the preregistration record.
4. An integrated link to the registration module means that the system can automatically create both the patient record and the insurance records without reentering the data. Sophisticated algorithms continually update insurance data based on previous cases submitted.

REFERENCE

Infrastructure and Connectivity

Single Locations: Local Area Networking

LANs allow the sharing of data and network-attached devices to improve workflow efficiency. The simplest form of LAN is the peer-to-peer model. Connected by a hub and simple wiring, two or more computers can network to share resources and data. The drawbacks of this type of system are the limited number of workstations that can be adequately supported and the necessity to restart the entire system if a program fault occurs. Peer-to-peer systems are not recommended. A much more robust solution requires a dedicated server connected with cabling to each workstation via a central hub. The utility of a network cannot be underestimated. For example, a central repository of digital radiographs allows clinical chairside workstations in each operatory to call up all patient images so that a patient does not have to be in the same operatory for each subsequent visit. A server-based LAN has several additional advantages. It provides greater reliability and faster overall speed; it allows individual stations to be rebooted without restarting the entire system; it secludes the server in a safe location; and it supports a large number of workstations at one or multiple sites. Addition of enterprise-level virus, Trojan, and worm protection is another benefit of the server. With this feature, the server can go online daily to automatically download the latest virus definitions from the manufacturer and allow client machines to self-update as preset by the clinician.

Multiple Locations: Wide Area Networking

The efficiency of the client/server model also allows practices with multiple facilities to set up high-speed communications between those locations, keeping the database on a single server. Maintaining a single database at one location means that updates to patient and billing data are instantly visible practice-wide, reducing errors and consequent liability. But maintaining a single database also requires high-speed access to that data from all practice and remote (e.g., laptop) locations.

The features, power, and complexity of today's software solutions have forever retired dial-up modem banks as a remote-access option. High-speed access is no longer an option, but a requirement. Interconnected offices have access to various options when it comes to high-speed wide-area connectivity. Typically, there is a trade-off between speed, cost, and reliability. For example, a T1 circuit, which is available in "point-to-point" format or as a conduit to the Ethernet, has moderate speed, is generally highly reliable, and is reasonably expensive. Lower-cost options such as DSL or broadband (cable, FIOS), often targeted more at consumers, offer higher speed but often with less reliability than their more-expensive counterparts. Keep in mind that offices in remote or rural locations will have fewer connectivity options than offices in cosmopolitan, higher-tech areas.

Virtual Private Networks

As part of an office's connectivity package, Internet access is now effectively a requirement. Leveraging the Internet as a communication medium makes data security concerns imperative. This is easily accomplished by implementing firewalls at each internet-connected office location and deploying industry-standard, affordable Virtual Private Networks (VPNs)[48] between these locations (see Fig. 28-23).

VPNs use the Internet as their long-distance backbone, leveraging TCIP/IP 60 internet protocols to effect communication. Essentially, the process looks like this:

1. Each office obtains local internet service, connecting it to an Internet service provider (ISP). A VPN is configured at each office's firewall to encrypt data going to other offices.
2. The ISP passes the signal through the Internet, occasionally through another ISP, to the second office. VPNs are private because the signal that passes through the very

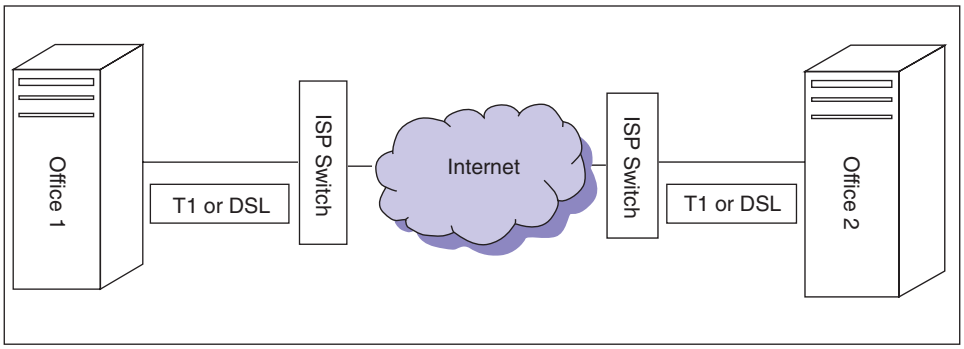

FIG. 28-23 Virtual private networks (VPNs) use wide bandwidth technology to connect two or more locations.

public Internet is encrypted to prevent others from intercepting and reading the traffic. VPN solutions are often packages with Internet routers or firewalls.

Citrix and Windows Terminal Server

Just a few years ago, all networking was wide area, combining mainframe-like servers at one location with remote dumb terminals at other locations using the UNIX platform. The difference between these systems and the current technology is that the old networks are just receiving and transmitting stations and are capable only of displaying text. The advantage of these systems is that they are highly efficient. Because only one central computer is involved, no data moves through the network; only screens and key clicks move between server and terminal. These systems require only low-speed, inexpensive data lines. In addition, UNIX is and always was designed to run high-performance WANs. Even today, almost all Internet servers run on a UNIX platform.

By comparison, Windows-based networks are highly inefficient. Because everything in Windows is an image, all workstations are computers; real data move across the network, and higher-performance communications lines are required to carry the signals. Citrix (Citrix Systems, Ft. Lauderdale, FL), has provided the closest approximation (in the Windows world) of the mainframe model of computing. Citrix software (e.g., Xen Server, Xen App, Xen Desktop) offers leading solutions to maintain all data and programs on a single server. In other words, the client workstations (PCs in most cases) are not running any software; they are simply sending and receiving Windows screens and transmitting keyboard and mouse activity. Because a much smaller amount of data is moving around the network, Citrix systems can perform well with much lower-speed communication lines. Microsoft's Windows server platforms (e.g., Windows 2003 Server, Windows 2008 Server) also offer remote "terminal servers" capability.

No matter which WAN model the clinician chooses, the client/server system is recommended because only a very small amount of real data travels on the network. This is vastly different from other dental software systems, which transmit data to the workstation for change and then transmit the data back for storage. In these non–client/server systems, the server is simply a passive storage system. Client/server systems feature a dynamic, active server that controls access. This can be likened to a busy intersection. A client/server system has "traffic lights" and "police officers" (i.e., the SQL database engine) which control access. No such controls exist in a non–client/server system. Each car (i.e., workstation) entering the intersection makes its own decisions as to when to stop and when to go. As a result, "collisions" and "accidents" (i.e., corrupted data) are more common.

Fat- and Thin-Client Computing and the Internet

Software written for PCs and Windows often is referred to as a *fat-client model*. This unattractive label signifies that software written for the PC must be installed and run separately from each client computer; only the database is centralized. Each fat-client must be a powerful PC with the software individually installed. Because data must travel to and from the client, the bandwidth of the communications channel must be significant. *Bandwidth* is a term used to specify the speed of a communications channel. For example, a high-speed cable connection offers wide bandwidth because it can transmit 5 megabits of data per second; a T1 connection transmits at 1.544 megabits per second. A 56k modem connection is narrow bandwidth because it can only transmit at speeds up to 56 kilobits per second. A cellular broadband connection may offer 768 kilobits per second. Specialists in communications often refer to bandwidth as "the size of the pipe," with fat pipes being higher speed than small pipes.

Another disadvantage of the fat-client model is the cost of maintaining it. Imagine for a moment that you worked in a large law office with 200 desktop computers, all running the same software. If the company making the law office's software released an update, the practice would have to install the update separately on each workstation. In addition, each of those 200 workstations would have to be powerful PCs, which produces its own maintenance headaches.

The thin-client model[85] is much simpler. This is not a new model; UNIX networks have always been thin, and most mainframe networks are thin. In fact, the fat-client model is a product of the PC age. The Internet, the ultimate thin-client network, has become so pervasive that thin-client computing has again become the preferred model. Within the next few years, developers of software for endodontists probably will reengineer their software and hardware to run on the Internet as a thin-client solution, with imaging, charting, and patient demographic data stored and archived remotely, and running on a simple Internet browser (e.g., Internet Explorer or Firefox).

The Internet represents a great deal more than just a different place to run office software. Remarkable innovations available now to clinicians include (to name just a few):

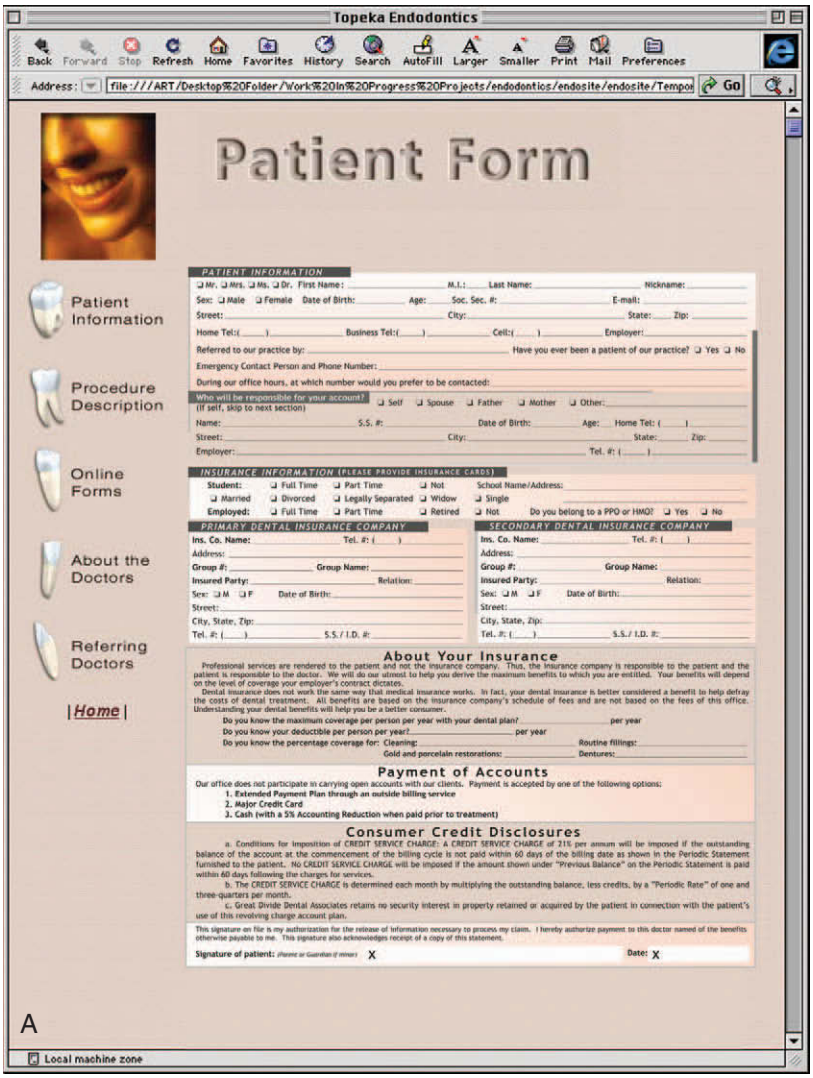

FIG. 28-24 A, Patients can receive pretreatment instructions or a "Welcome Letter" and complete their preregistration forms on the office website in this fictitious example.

- *Automated preregistration over the Internet.* Several vendors provide online patient registration forms (Fig. 28-24, *A*), which can securely transfer information over the Internet directly into an endodontic software database (see Fig. 28-24, *B*).
- *Multiprovider networks.* Multiprovider networks allow clinicians to send patient records and images to colleagues in a secure area on the Internet.
- *Online scheduling.* Patients can have limited use of the schedule online, 24 hours a day, 7 days a week. For example, patients can enter their name and appointment date, and the website will allow cancellation of the appointment and selection of preferences for a new appointment (i.e., specific days of the week and time of day).
- *Online payments.* Patients can pay their bills online.
- *Data backup.* With this feature, which is offered by numerous vendors, data can be automatically transferred at night to geo-separate servers at different locations.
- *Online ordering.* Clinicians can order most supplies over the Internet.
- *Data analysis.* In the future, clinicians may provide anonymous data to data banks that will analyze the information and report statistics regarding their practices.

Early PCs and mainframe computers were isolated and therefore limited islands of information storage. Later, networked systems with some sharing of data allowed exchanges within each business entity only. Today, using software protocols such as HTTP and HTML, the Internet has revolutionized interconnectivity between millions of computer networks, allowing cross-platform connectivity. Software is now the chief driver of distributed computing, characterized by technologic advances such as extensible markup language (XML), a system of small applications that can be connected for specific functions to enhance Web services. With XML, information now can travel to and from different systems regardless of hardware and location. The integration across many platforms provides numerous benefits, including better connections among offices, patients, referrers, and vendors. Finding ways to allow patients, referrers, and vendors to conduct exchanges that remain private and secure, however, has been a continuing challenge. Microsoft.NET is the software tech-

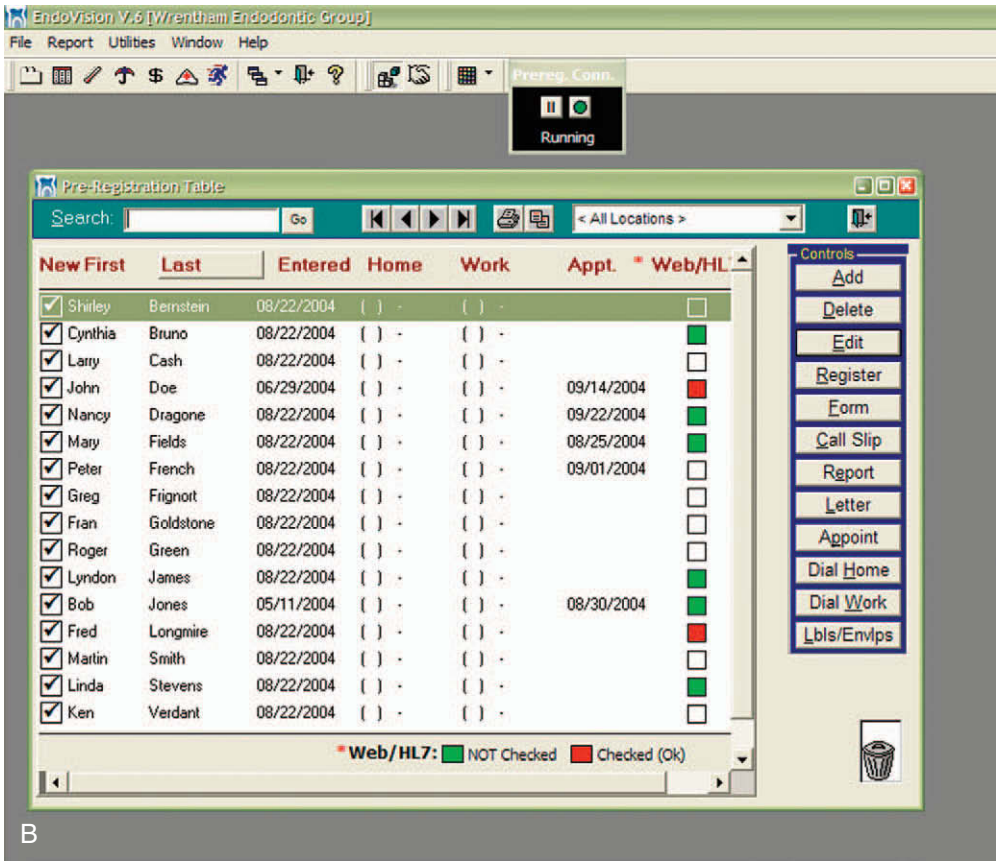

FIG. 28-24, cont'd B, When submitted by the patient, the forms are transmitted to the office computer via a web server and are automatically entered into the practice management software (green square under Web/HL7). (***A** courtesy PBHS, Santa Rosa, CA. **B** courtesy Henry Schein, Inc., Melville, NY.)*

nology for connecting disparate systems and the watchword for the next generation of software platforms. That said, the IT plan for endodontic offices should include provision for each computer workstation to be connected to the Internet to improve functionality.

Power, Cabling, and Wireless

Power

All computers, especially the server, should be protected from voltage sags, interruptions, and surges in power and should allow for an orderly shut-down and saving of all open files if a power aberration occurs. Although many uninterruptible power supply (UPS) topologies are available for small business applications, the *line interactive UPS* is especially well suited for servers. In this scheme, the battery to AC power inverter is always on, and the battery is charged when input AC power is normal, and the inverter is operated in reverse. This design provides power filtering and reduced power transients compared with the *standby UPS* topology recommended for workstations[8] (Table 28-3). Because the primary cause of hard drive failure is power spikes and sags, dedicated and properly specified UPS equipment is highly recommended.

The computer and monitor must be plugged into only the surge/battery backup–protected sockets. Laser printers should not be plugged into the battery positions, just the surge suppression sockets, because they draw too much current. Any system that receives telephone service also should be protected from "back door" lightning strikes that can destroy the office's system and data.

Cabling and Wireless

Wall jacks for power and Ethernet,[71] a LAN technology that transmits information between computers at speeds of 1000 Mbps (million bits per second), should be placed near the computer workstations. A double duplex power outlet should be installed at each location, along with a combination wall plate containing an Ethernet and a telephone jack. Internal wiring for the Ethernet should be run with copper unshielded twisted-pair (UTP) Cat 6 wire terminated in RJ 45 blocks. Cabling used inside walls is different from that used in patch cords. Wall cabling is much more susceptible to breakage and therefore should be terminated in a fixed block mounted on the wall (i.e., a wall jack) and not run out of the wall directly to the CPU. The Cat 6 can operate at a bandwidth of 1000 MHz and carry voice and data at rates of up to 1 Gbps.

Wireless networks are becoming more common, but they can be somewhat problematic because of sometimes inconsistent reception. Some wireless capability is necessary if tablet or slate PCs are part of the practice's computer hardware. Wireless networks must be carefully configured so that security features effectively shield against hacking. Before installation, the clinician should fully understand the advantages and disadvantages of a wireless LAN.

TABLE 28-3

Examples of Uninterruptible Power Supply (UPS) Systems Commonly Used by Small Businesses

UPS Type	APC Product Name	Benefits	Recommendations
Standby	Back-UPS	Low cost, high efficiency, compact	Best value for workstations
Line interactive	Smart-UPS, Back-UPS Pro, and Matrix	High reliability, high efficiency, good voltage conditioning	Most popular type of UPS because of its high reliability; ideal for servers and harsh power environments

Modified from APC Corp: *White Paper #1, The Different Types of UPS Systems*, www.apcmedia.com/salestools/SADE-5TNM3Y_R5_EN.pdf. Accessed Nov 21, 2009.

Central Processing Unit

Two kinds of CPUs are commonly used in dental offices: the standard desktop, or minitower, and the laptop. CPUs designed for businesses, such as Dell's OptiPlex line (Dell, Austin, TX), are network-optimized for improved manageability and reliability. These units also support multiple monitor configurations, which increases available "desktop" space for displaying multiple application windows to improve productivity.

Desktop CPUs can be used in almost any area or for almost any task, and the clinician should choose one of the fastest processors available. It should have enough random access memory (RAM) to allow several programs to be run at once and should include at least two internal expansion slots and one drive bay for additional peripherals. As a general rule, a faster processor adds to a machine's useful life, and upgrading the system's RAM to at least one level more than required to run the computer's operating system (OS) is advisable. Increasing RAM to at least 4 GB (gigabytes) improves speed for today's graphic-intensive software. Savings are often available on RAM, and it is well worth the additional investment.

Software applications, the OS, and the data created by the office are stored on the hard drive. As hard drive capacity increases and the price per megabyte declines, it becomes easier to choose a large hard drive that is adequate for most purposes. Because data are stored on the server in the CIS, the office generally does not need to buy individual workstation CPUs with ultralarge-capacity hard drives.

Monitors

The monitor's size and image quality are critical to image resolution. Clinicians should invest in the highest quality unit they can afford. In all likelihood, the monitor will last well past any single CPU. LCDs are free from geometric image distortions, flicker, and screen brightness variations, which may reduce the incidence of Computer Vision syndrome (eyestrain, headaches, etc.).

LCD screens require little in the way of maintenance. The clinician should make sure that all equipment in clinical areas is protected from cross-contamination with disposable barrier techniques, if applicable, and that manufacturer's recommendations are followed regarding ventilation, electrical and shock hazards (all clinical equipment should be powered through hospital-grade electrical connections), and cleaning. Many vendors make cleaning solutions, wipes, and cloths specifically for LCD computer screens.

LCD Screens

The gold standard for administrative, front desk, and imaging applications in the operatory are LCD[20] screens with high-resolution characteristics. All flat screens are not created equal. The following tips can aid the clinician in selecting a screen:

1. The screen should have the Video Electronics Standards Association's (VESA) mounting hole pattern on the back so that it can be attached to an industry-standard mounting arm. This mounting hole pattern is square and measures 3 × 3 inches (75 × 75 mm) or 4 × 4 inches (100 × 100 mm).
2. LCD monitors are measured by the size of the viewable area. A flat panel screen of 20 to 24 inches is recommended. Most screens list horizontal and vertical viewing angles of at least 140 degrees. The ideal horizontal and vertical viewing angle is 160 degrees or more.
3. LCD is a transmissive technology. A fixed-intensity fluorescent or light-emitting diode (LED) backlight is filtered by the liquid crystals arranged between two finely grooved surfaces. These new LEDs produce greater dynamic contrast, are thinner, consume 40% less power, have a wider color gamut, but cost more than fluorescents at this time. Organic light-emitting diodes (OLED), another new monitor technology, are composed of a film of organic compounds, are the thinnest technology, and do not require a backlight to function, providing deep black levels. The screen purchased should have a 3-year warranty on the backlight. Most LCD fluorescent screens last for about 60,000 hours (6.8 years) of continuous use.
4. An LCD panel can display only one resolution at full screen size, because each pixel is hard wired (e.g., a 1280 × 1024 panel has 1,310,720 hard-wired pixels in its native mode). A minimum dot pitch of 0.26 mm is recommended. If an LCD panel has a native resolution of 1280 × 1024 pixels, it can display at a resolution of 640 × 480 by using less of the screen area. Most LCD screens can rescale a lower-resolution image using rathiomatic expansion, which works adequately for photographs but not very well for text or images with fine detail. Objects become jagged, and artifacts fill the extra pixels. When resampling is done for scaling the image up, antialiasing fills the extra pixels, resulting in better results. For the clinician, the bottom line is to choose a screen with a clear understanding of the native resolution and plan to use it as specified.

5. Only LCD monitors that support digital (binary pulse) signal inputs (i.e., DVI) should be purchased for general office use. Because LCD screens process information digitally, fluttering and ghosting can result if digital information from the computer must be sent to the video card, converted to analog, sent on to the LCD screen, and then converted back into a digital signal. Currently, LCD units that include both analog video and digital inputs such as high definition multimedia interface (HDMI), digital visual interface–digital (DVI-D) with high definition content protection (HDCP), DisplayPort, video graphics array (VGA), component video, S-video, and composite video are recommended for certain applications.
6. The refresh rate (i.e., how quickly the screen paints the image) is an important indicator of how well the screen will depict moving images. A refresh rate of 6 msec is a minimum standard.
7. Special attention should be paid to contrast ratios, to ensure that the screen depicts a large range of light and dark tones. A contrast ratio of at least 80,000:1 should help paint an image with excellent appearance quality.
8. Integral stereo speakers are a nice feature on any monitor. Although most speakers do not take up much room, built-in speakers reduce clutter and make the computer system easier to move.

Printers

Dental offices strive to run compliant, cost-effective operations that minimize cost and maximize productivity. Printers are available in a dizzying array of formats and output types; therefore careful selection for each use is recommended. Although increasingly popular multifunction products (MFP) promise "significant advances in the areas of document distribution and management, security, wired and wireless connectivity, and color,"[45] most dental offices use single-function machines. Because most MFP devices use proprietary software drivers, the prospective buyer must make sure that the machines are compatible with all the software used in the office. Selection of the right printers is crucial to the usefulness of the entire computer system.

Monochrome and Color Laser Printers

The front desk, administrative, and clinician's office computers should be linked to a monochrome or color laser printer for printing of patient instructions, insurance materials, receipts, and general word processing tasks. Clinicians who follow the frontdesklessness concept should consider a multidrawer printer model so that stationery, plain paper, and envelopes are all preloaded. For example, EndoVision software (Henry Schein, Inc., Melville, NY) allows the clinician to use a "rapid post" module to select tasks that can be directed to multiple individual and networked printers and specific drawers.

Label Printers

Sterilization area and front desk computers benefit from dedicated label printers for printing chart labels and mailing labels for general mailing duties. Although the use of industry-standard window envelopes can greatly reduce the need for envelope printing, label printers are often a useful adjunct, especially for larger items.

Inkjet Printers

Production of patient treatment reports and radiographs are the primary functions of the inkjet printer. A high-quality printer with individual archival inks that use a variety of paper formats can produce stunning reports that can improve communication with co-therapists. Epson's (Epson America Inc, Long Beach, CA) new pigment-based inks with resin-coated 0.1-µm particle size and long-lasting permanence ratings are the gold standard for professional image printing.

Document Scanners

Scanning of documents improves dental processes by increasing security and efficiency and reducing storage space. Scanners can transmit documents in a variety of formats, so careful attention should be given to compatibility with dental management software. Documents should be scanned into a patient's individual file so that all the documents for that particular patient are easily accessible. Accounting and other miscellaneous office documents can be scanned into a file on the server or client workstation for easy retrieval. Recommended scanners include native support for Adobe portable document format (PDF). The PDF file format has become the document exchange standard because of its wide industry acceptance. PDF files can be read independently from other application software and can be viewed as thumbnails in Microsoft Office application software; each document can be password protected.

Portable Document Format

Unlike TIFF and JPEG image formats, PDF encapsulates other compression formats so that documents become application independent. These files have embedded metadata, or data within the image, that can authenticate the document. As an open specification, PDF also maintains documents in a consistent format, which makes it the best choice for long-term archiving and for preserving the original appearance.

Security

PDF files improve security through digital signatures and document encryption features that improve HIPAA compliance and address general business security demands. All PDF files can be password protected to limit access to only those authorized to view the contents.

Versatility

PDF files can be viewed on every major computing platform, including Microsoft Windows, Mac OS, and UNIX.

Searchable Images

PDF creates image files that can be searched and indexed by optical character recognition (OCR). Processing a document with OCR produces a searchable bitmap that is hidden behind the image while preserving the look of the original image.

Input Devices

With pointing devices and keyboards, location and ease of use should be considered along with infection control. In the operatory, clinicians should choose wireless keyboards and optical mice that can be protected by barriers to eliminate cross-contamination. Logitech manufactures a wide range of wireless

input devices, including Bluetooth models with wireless hub/battery charger, keyboard, and rechargeable mouse that allows a range of up to 30 feet (9 m) using the 2.4 GHz ISM band. Care must be taken with the addition of any radio frequency (RF) wireless devices to guard against interference with other wireless equipment, such as the wireless radiographic sensors, tablet and slate computers, and wireless telephones.

Graphic tablets are also useful adjuncts that allow annotation of drawings in the patient's chart. Graphic tablets can be purchased in several sizes and usually require a USB interface. The pen, or stylus, can be wired or wireless, although batteries add to the weight of the pen. Another solution to graphic input, albeit a more expensive one, is a wireless tablet PC, which has all of the functionality of a PC with wireless RF capability and true tablet functionality. These devices can operate as a laptop and, with "digital ink" technology, can input hand-written notes and graphics into any enabled application.

Consulting and Support

IT systems require thorough planning and careful implementation to ensure trouble-free installation. Clinicians should begin planning with local vendors in close cooperation with the practice management vendor. Because technology changes constantly, clinicians need someone who can update the system's hardware and software, upload "patches" and "firmware updates," and generally be available for help with equipment purchase decisions. These vendors usually work on an hourly basis and may offer blocks of time per month or per quarter at discounted rates and guaranteed response times.

Pharmacology Reference Software

Many programs are available that can serve as clinical pharmacology references. As mentioned previously, Lexi-Comp Online is a Web-enabled or installable product that features extensive indexing, cross-referencing, and linking of drugs for optimum quick search functions. For example, the clinician simply types in the name of the drug, and the program calls up every reference to it in the compendium. The search can be done by alphabetic listings, a main index of drug classifications, product identification (by description of the drug), adverse reactions, disease description, drug interactions, and other parameters. This product contains clinically oriented monographs on all drugs used in the United States and allows for quick, accurate identification of drug interactions and contraindications. The program also promotes a quick search of dental and dental vasoconstrictor implications for each drug listed.

Patient Education Software

Patient education is an important part of modern dental practice. One study[14] found a positive statistical correlation between patient education and their endodontic treatment experience. To this end, several vendors have created informational software programs for the Web and local computer use. The patient can access these programs on the Internet, at a computer kiosk in the reception area, or at the clinical chairside workstation.

Health Insurance Portability and Accountability Act

Confusion about transmission of protected health information by electronic means has created the myth that clinicians cannot communicate by e-mail or the Internet. The U.S. Department of Health and Human Services has stated[16]:

> *The Privacy Rule allows covered health care providers to share protected health information for treatment purposes without patient authorization, as long as they use reasonable safeguards when doing so. These treatment communications may occur orally or in writing, by phone, fax, e-mail, or otherwise.*

SUMMARY

Creation of the EOHR is the next logical step in the journey to the paperless office. Integration of this information with an EHR to create a unified patient database that documents the current health status and lifetime medical history for each patient is the pot of gold at the end of the rainbow. As the functionality of digital systems improves, every dental care delivery organization should consider incorporating at least some of these advances. However, technology is not a substitute for treatment excellence, and clinicians must continue to strive to provide quality treatment for patients regardless of the equipment they use.

CHAPTER 29

Cone Beam Imaging for Endodontic Procedures

DALE A. MILES and THOMAS V. McCLAMMY

CHAPTER OUTLINE

PRINCIPLES OF CONE BEAM VOLUMETRIC TOMOGRAPHY
- Voxels and Voxel Sizes
- Field of View

IMAGING TASKS IMPROVED OR SIMPLIFIED BY CONE BEAM VOLUMETRIC TOMOGRAPHY
- Apical Morphology and Suspected Lesions of Endodontic Origin
- Root Canal System Morphology
- Presurgical Visualization
- Suspected Root Fractures and Trauma
- Internal and External Root Resorption

Although at first glance, it may seem that cone beam volumetric tomography (CBVT), also known as *cone beam computed tomography* (CBCT), may be "overkill" for diagnostic evaluation of endodontically compromised teeth, the interest and adoption of this advanced imaging modality is now becoming very popular with clinicians performing endodontic procedures—and for good reason. Two-dimensional (2D) grayscale images, whether they are conventional film or digital images, cannot accurately depict the full three-dimensional (3D) representation of the teeth and supporting structures. In fact, traditional images are very poor representations of even the pulpal anatomy. They grossly underestimate canal structure and often cannot accurately visualize periapical changes, especially where there is thick cortical bone, as in the presence of anatomic obstructions (Fig. 29-1, *A*).

On the other hand, CBVT allows the clinician to view the tooth and pulpal structures in thin slices in all three anatomic planes: axial, sagittal, and coronal. This capability alone allows visualization of periapical pathology and root morphology previously impossible (see Fig. 29-1, *B*).

Several tools available in CBVT, such as changing the vertical or horizontal angulation of the image "on the fly" or in real time, as well as thin-slice, grayscale data of 0.1 mm thickness, will never be available for conventional or even digital radiographic assessment.[1] In addition, the ability to use CBVT data to view the region of interest in three anatomic planes of section at very low x-ray doses was never as easy or accessible as it is today. Most clinicians probably never even anticipated that such a precise imaging solution would be introduced to the dental profession during their careers.

This chapter will address the principles, applications, imaging attributes, image artifacts, and potential liability of adopting CBVT technology for endodontic procedures. Given this information, the student of endodontics will begin to realize the significant advantages and improved diagnostic and treatment-planning capabilities of this extraordinary radiographic imaging technology.

PRINCIPLES OF CONE BEAM VOLUMETRIC TOMOGRAPHY

Three important parameters of cone-beam imaging are described in the following sections:

1. Voxel size
2. Field of view (FOV)
3. Slice thickness/measurement accuracy

Voxels and Voxel Sizes

Unlike medical computed tomography (CT) scanning, cone-beam scanning machines acquire their x-ray information using low kV and low mA exposure parameters in a single pass from 180 to 360 degrees of rotation. Medical scanners use kilovoltages of 120 kV or more and milliamperages of about 400 mA. The highest exposure factors for any dental cone-beam scanner is the Imaging Sciences i-CAT (Imaging Sciences International, Hatfield, PA) (Fig. 29-2), which uses 120 kV and 24 mA. In contrast, dental scanners like the Planmeca Promax® (Planmeca Oy, Helsinki, Finland) (Fig. 29-3, *A*) or Veraviewepocs 3D (J. Morita Corporation, Kyoto, Japan) (Fig. 29-3, *B*) use typical dental exposure factors of about 5 to 7 mA and 70 to 80 kV. The x-ray dose for all cone-beam machines is significantly lower than the dose received from a medical computed axial tomography (CAT) scan.

Besides lower exposure factors, the image data in cone-beam imaging is reconstructed from isometric voxels; that is, the images are constructed from pixels that are cubic and have

FIG. 29-1 A, A well-angulated periapical radiograph of tooth #3 taken during diagnostic appointment for endodontic evaluation in maxillary right quadrant. At first glance, there is little radiographic evidence of significant periapical and/or periradicular change. **B,** Cone beam volumetric tomography of same tooth at same appointment gives an entirely different perspective; periapical changes are visible on all three roots in all three anatomic planes of section. (***B,*** *Image taken with J. Morita Veraviewepocs 3D [J. Morita, Osaka, Japan].*)

FIG. 29-2 The Imaging Sciences i-CAT. (*Courtesy Imaging Sciences International, Hatfield, PA.*)

the same dimensions for length, width, and depth. These voxel sizes are as small as 0.1 to 0.6 mm.[1] By comparison, medical CAT scan slice data is 1 mm to 1 cm. Fig. 29-4 illustrates the difference between a pixel and a voxel, the difference between an ***anisometric pixel*** of medical CT and an ***isometric pixel (voxel)*** of CBVT, and how the pixel data is acquired from both modalities.

A patient in a medical CT scanner is moved in the scanner as little as 1 mm at a time as the image data is acquired. But for each slice acquired, the patient is exposed to ionizing radiation. If it takes 20 or 30 slices to acquire the data for the head region, the patient is exposed during the gathering of each slice. This results in significantly higher absorbed x-ray doses for the patient. A typical CBVT examination would expose the patient to only about 20 to 500 μSv in one rotation, whereas a typical medical examination of the head would approach 2100 μSv[2] because the image data is gathered one section or layer at a time. Consequently, CBVT data has much higher resolution than medical CT data and is acquired at a fraction of the radiation dose. Because of the smaller voxel size, there is also greater image resolution.

Field of View

The FOV ranges from as small as a portion of a dental arch to an area as large as the entire head. Currently, the smallest FOV available is 37 × 50 mm (Fig. 29-5), which may be appropriate for a single arch. The largest, 220 × 220 mm (Fig. 29-6), is probably far larger than an endodontist would require, but many machines with larger FOVs can be collimated down to as little as 40 × 40 mm, making them very suitable for endodontic procedures. The selection of the FOV depends on several factors. Among the most important are:

1. Diagnostic task
2. Type of patient
3. Spatial resolution requirements
4. Clinician's confidence interpreting the acquired data volume

Diagnostic Task

Since patients may have more than one tooth requiring an endodontic procedure, it may be desirable to have a machine capable of acquiring a CBVT volume greater than 40 × 40 mm.

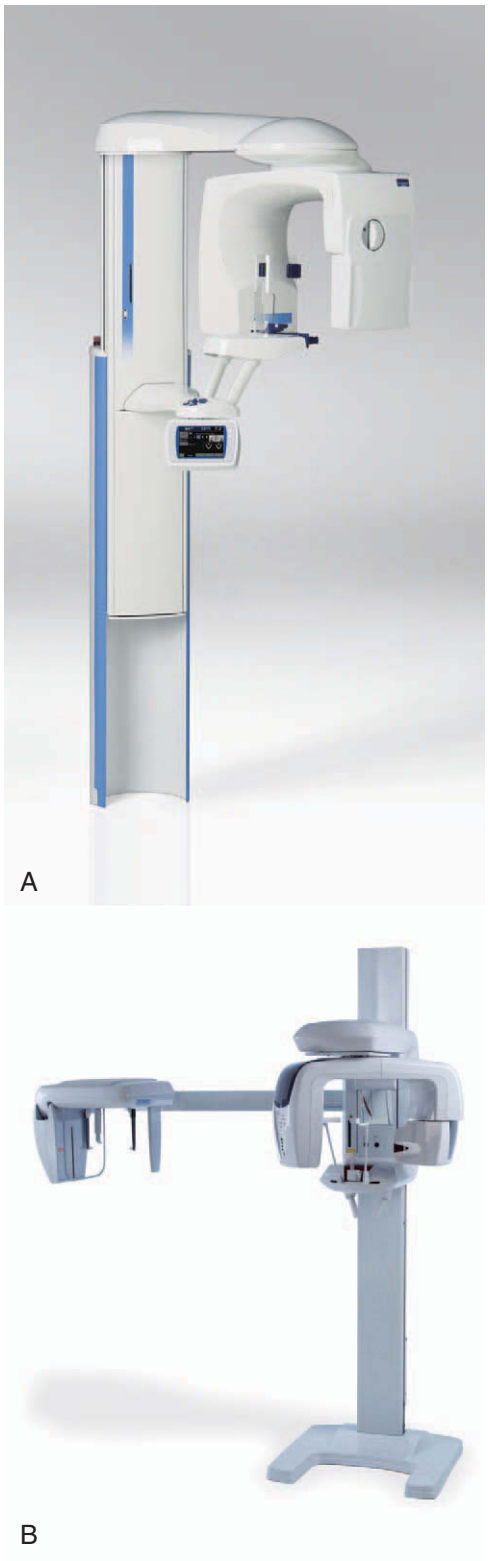

FIG. 29-3 A, The Planmeca ProMax 3D. **B,** The J. Morita Veraview-epocs 3D. (***A,*** *Courtesy Planmeca Oy, Helsinki, Finland.* ***B,*** *Courtesy J. Morita Corp, Osaka, Japan.)*

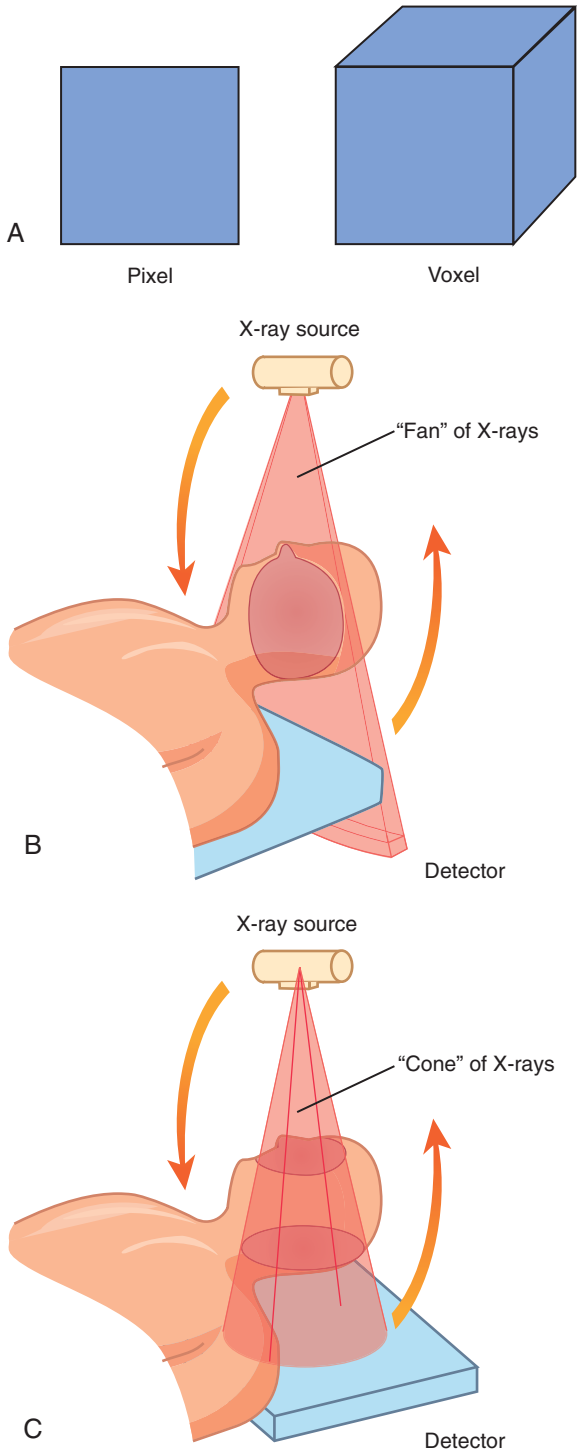

FIG. 29-4 A, Drawing on the left represents a *pixel* (picture element), the image capture and display element of any traditional digital image displayed on the computer. Shades of gray or color will be displayed in these pixels to represent a 2D image. Drawing on the right represents a *voxel* (volume element). Voxels are isometric pixels having the same dimension or length on all sides. They are very small (from 0.10 to 0.60 microns) and are the capture element for cone beam imaging devices. They too can have gray shades or colors in them (displayed on the computer in pixels, but with image-reconstruction software and postprocessing, can be made to look 3D in grayscale or color images. Principles of conventional fan beam **(B)** and cone beam **(C)** tomography. (***B-C*** *from Babbush et al:* Dental implants: the art and science, *ed 2, St Louis, Elsevier/Saunders, 2011.)*

TABLE 29-1

Details of Machines Currently on the Market (October 2009)

Machine	Type of Image			Smallest Cone Beam FOV (cm)	Largest Cone Beam FOV (cm)	Native Voxel Size (microns)
	"True" Panoramic	Bitewing	Periapical			
Planmeca: ProMax 3D	Yes	Yes	Yes*	4 × 4	13 × 17	0.16
Soredex: Scanora 3D	Yes	No	No	6 × 6	7.5 × 14.5	0.15
Carestream: Kodak 9000	Yes	No	No	3.7 × 5	3.7 × 5	0.076
J. Morita: Veraviewepocs 3D	Yes	No	No	4 × 4	8 × 8	0.12
PreXion: PreXion 3D	?	No	No	7.62 × 8.12800 (cm) (3 × 3.2 inches)	7.62 × 8.12800 (3 × 3.2 inches)	0.2
Gendex: GXCB-500	No; reconstructed	No	No	4 × 4	13 × 13	0.125

3D, Three-dimensional; *FOV,* field of view.

*Bitewing mode also depicts periapical regions of teeth in all quadrants from canine to third molar.

In addition, many clinicians may prefer more than one imaging modality to more fully evaluate their patients' needs. There are several multifunctional cone beam machines available that will allow the clinician to acquire several image types with only one machine. Table 29-1 details the machines currently available that allow several types of images to be reconstructed from the data set. Fig. 29-7 illustrates the advantages of using multiple image types for an endodontic case.

Type of Patient

Just because you own a cone beam machine does NOT mean that every patient will require a cone-beam scan.[2] More importantly, some patients requiring an endodontic procedure may be children or adolescents in whom the need to minimize the absorbed x-ray dose is more critical. Cone-beam machines with smaller FOVs can somewhat limit the radiation dose to critical organs and tissues of the head and neck in these cases.

Spatial Resolution Requirements

All endodontic imaging procedures require high spatial resolution. Assessment of canal structure, canal length, and lesions of endodontic origin (LEOs)[3] exhibiting apical change are all important tasks requiring minute detail. If CBVT is employed, the data acquisition should be performed at the smallest voxel size. The smaller the voxel size, the higher the spatial resolution. Many of the larger stand-alone cone-beam machines,

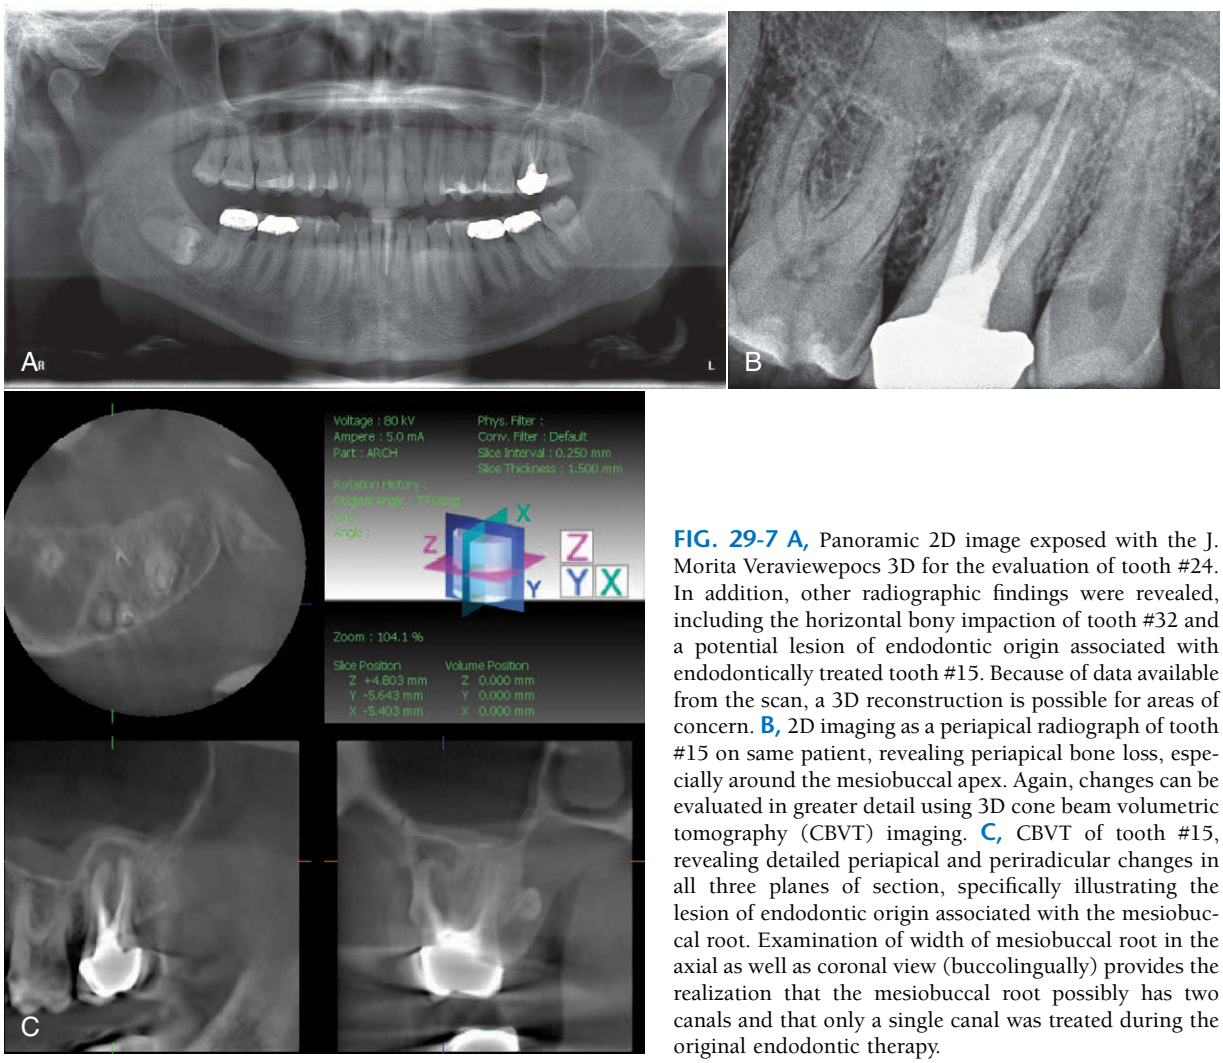

FIG. 29-7 A, Panoramic 2D image exposed with the J. Morita Veraviewepocs 3D for the evaluation of tooth #24. In addition, other radiographic findings were revealed, including the horizontal bony impaction of tooth #32 and a potential lesion of endodontic origin associated with endodontically treated tooth #15. Because of data available from the scan, a 3D reconstruction is possible for areas of concern. **B,** 2D imaging as a periapical radiograph of tooth #15 on same patient, revealing periapical bone loss, especially around the mesiobuccal apex. Again, changes can be evaluated in greater detail using 3D cone beam volumetric tomography (CBVT) imaging. **C,** CBVT of tooth #15, revealing detailed periapical and periradicular changes in all three planes of section, specifically illustrating the lesion of endodontic origin associated with the mesiobuccal root. Examination of width of mesiobuccal root in the axial as well as coronal view (buccolingually) provides the realization that the mesiobuccal root possibly has two canals and that only a single canal was treated during the original endodontic therapy.

such as the Imaging Sciences i-CAT, set their voxel size defaults to 0.4 mm. This voxel size is inadequate for high spatial detail. However, these same machines often have a voxel size selection program that allows smaller voxel size during the image acquisition. The absolute minimum voxel size for endodontic imaging should be 0.2 mm. Machines such as those cited in Table 29-1 typically use voxel sizes of 0.076 to 0.16 mm for their native image capture. *Fig. 29-8* shows two images taken at the axial slice level of the mental foramen. Fig. 29-8, *A* shows a slice using a voxel size during capture of 0.4 mm. Fig. 29-8, *B* shows an axial slice at the same level using a voxel size of 0.16 mm.

Clinician's Confidence Interpreting the Acquired Data Volume

As previously stated, endodontic imaging procedures can be appropriately performed with small volume data sets. Unless there are multiple teeth in different quadrants requiring endodontic diagnostics or procedures, a small FOV is probably sufficient. This also reduces the diagnostic responsibility for occult pathology outside the region of interest (ROI). Large-FOV machines will capture structures like the paranasal sinuses, airway, and vertebral column, so the clinician has an ethical and legal responsibility to examine these structures for potential pathoses.[4,5] To ignore these non-odontogenic regions would be considered negligence. Clinicians have the option to perform the radiographic evaluation themselves or refer the data volume to a qualified specialist such as an oral and maxillofacial radiologist or medical radiologist.[5,6]

For endodontists, and indeed most general clinicians, a CBVT scanner with a smaller FOV may be more appropriate.

IMAGING TASKS IMPROVED OR SIMPLIFIED BY CONE BEAM VOLUMETRIC TOMOGRAPHY

For endodontic treatment and assessments, there are at least five primary imaging tasks whereby CBVT scans have a distinct advantage over traditional 2D radiographs. These include evaluation of the following:

1. Apical morphology and suspected lesions of endodontic origin

FIG. 29-8 A, Axial slice from data gathered with a 0.4-mm voxel size. Compare the trabecular pattern and outline of the mental foramina to the same location using 0.16-mm voxel size in Part B. **B,** Axial slice from data gathered with a 0.16-mm voxel size.

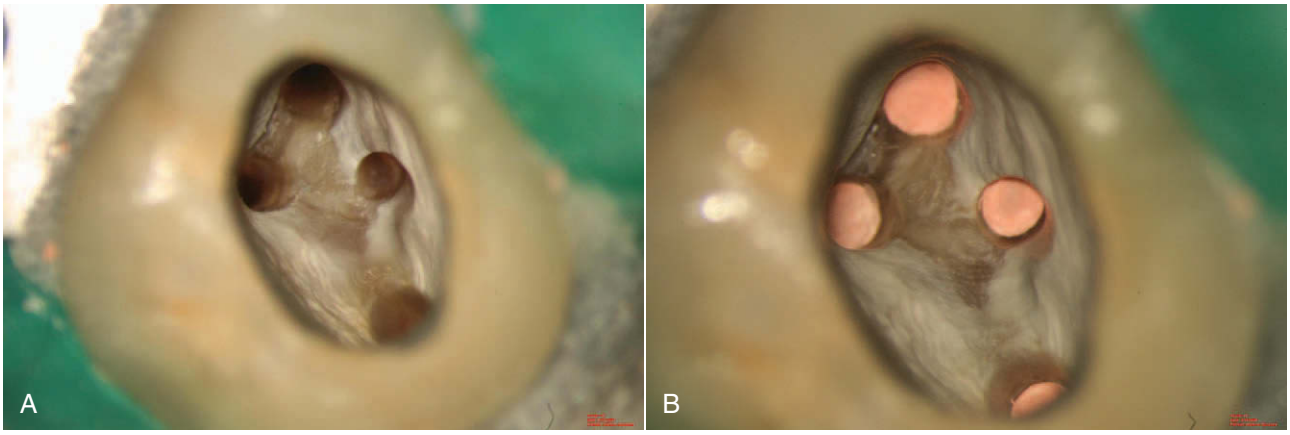

FIG. 29-9 Tooth #15 was endodontically retreated nonsurgically. As suspected, the original treatment did not access and treat the entire root canal system. Seen here are images taken of the access cavity just prior to **(A)** and after **(B)** final obturation of the entire system, including the missed mesial buccal canal.

2. Root canal system morphology
3. Presurgical visualization
4. Suspected root fractures and trauma
5. Internal and external root resorption

Apical Morphology and Suspected Lesions of Endodontic Origin

The precise location and visualization of root morphology is vastly improved with cone-beam data. Root curvature, root path, and anomalies within the canals themselves (e.g., obstructions, narrowing, bifurcation) are made more apparent when all three anatomic planes of section are available for review, especially with the capability of narrowing the slice thickness to as little as 0.1 mm (Fig. 29-9). Visual obstruction from anatomic features such as buccal bone and the malar process over the apices of maxillary roots simply "disappear" when you can scroll through the slices of the bone from facial to palatal in 0.1-mm sections while also changing axial orientations.

Additional benefits of some CBVT imaging software include allowing the clinician to create a pseudopanoramic image—that is, a thin-slice grayscale image of the mandible, maxilla, or both. Conventional panoramic machines, though not commonly employed by endodontists, use the mandible to select the focal trough, or zone of sharpness. This means that the palatal roots of the maxillary posterior teeth may not be centered in the focal trough. With CBVT imaging software, a central plane through the maxilla or mandible can be drawn so that the structures of interest can always be centered. This facilitates apical lesion assessment, even with a panoramic image (Fig. 29-10).

Radiographically, it is fundamental to understand that lesions of endodontic origin arise secondary to pulpal breakdown products and form adjacent to canal portals of exit.[7,8] These lesions can and do form three-dimensionally anywhere along root surface anatomy.[9] Prior to CBVT, clinicians were unable to visualize the specific location and extensiveness of periapical bone loss.

Fig. 29-11, *A* is a 2D periapical radiograph of the previous endodontic treatment of tooth #30, revealing no objective radiographic pathosis. The patient reported that tooth # 30 had

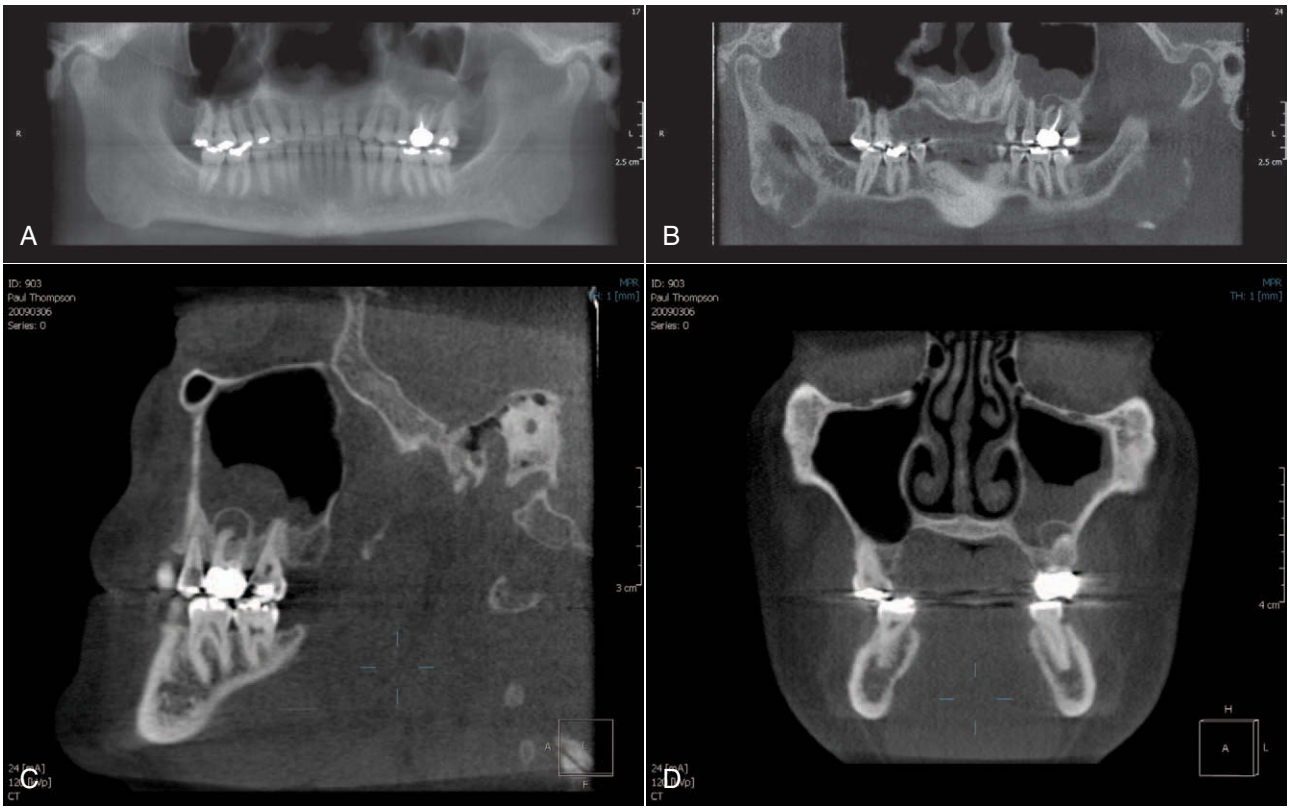

FIG. 29-10 A, Even though this is a reconstructed panoramic from the CBVT data, it approximates the view one would see on a conventional panoramic radiograph. It is somewhat difficult to see the lesion on tooth #14. **B,** This image is a thin slice pseudopanoramic image which shows the lesion more precisely because it is a very thin slice (0.10 mm). **C-D,** These slices of tooth #14 show the lesion in sagittal **(C)** and coronal **(D)** views, confirming the pseudopanoramic view.

been treated by an endodontist 5 years ago. The patient had returned to the treating clinician numerous times over the last 5 years complaining of tooth pain in this area. The patient was last advised that the area "had not enough time to heal." However, an additional radiograph exposed with a different angulation revealed that only one of the two mesial canals were cleaned and obturated (Fig. 29-11, *B*). Using available CBVT technology, additional radiographs would not be necessary to elucidate this information (Fig. 29-11, *C-D*).

Fig. 29-11, *E* shows multiplanar views of tooth #30 taken with a contemporary CBVT machine. This image set reveals:

1. A very high probability of a missed ML canal
2. A lesion of endodontic origin developing on the mid-furcation side of the mesial root (large white arrows)
3. Early periapical and periradicular changes of tooth # 31 (small white arrow)

Tooth #30 was sensitive to percussion and buccal alveolar bone palpation. While it can be concluded from the information available for the CBVT image that tooth #30 is the source of the patients' pain, the clinician can also inform the patient that tooth #31 may also need endodontic therapy and that a further evaluation of this tooth is necessary.

Root Canal System Morphology

As the adage goes, nature seldom makes a straight line and never makes two of the same. This statement is dramatically illustrated when evaluating root canal system morphology. With ever-present unusual and atypical root shapes and numbers, there is a need to look further than what a clinician can see or imagine with 2D radiography (Fig. 29-12).

Presurgical Visualization

Surgical endodontic treatment is often performed in cases of endodontic nonhealing when nonsurgical retreatment is not possible. In the past, conventional and digital 2D periapical radiographs have been the only way to assess the apical region. Unfortunately, the information available from these images may not adequately prepare the clinician to surgically resolve the pathosis. For example, the clinician may be unable to observe whether the lesion has perforated the buccal and/or palatal cortical plates, as in the example that follows, or even observe which root or roots are involved. Presurgical confusion is resolved with cone-beam imaging. Multiplanar views allow the clinician to see the defect and suspected causes from the axial, sagittal, and coronal aspects; 3D grayscale or color imaging helps to visualize the entire defect before the incision is created. This is an immense improvement over conventional imaging (Fig. 29-13).

Suspected Root Fractures and Trauma

Fig. 29-14 shows 2D and 3D images of the endodontic and restorative treatment of tooth #30. The 2D periapical

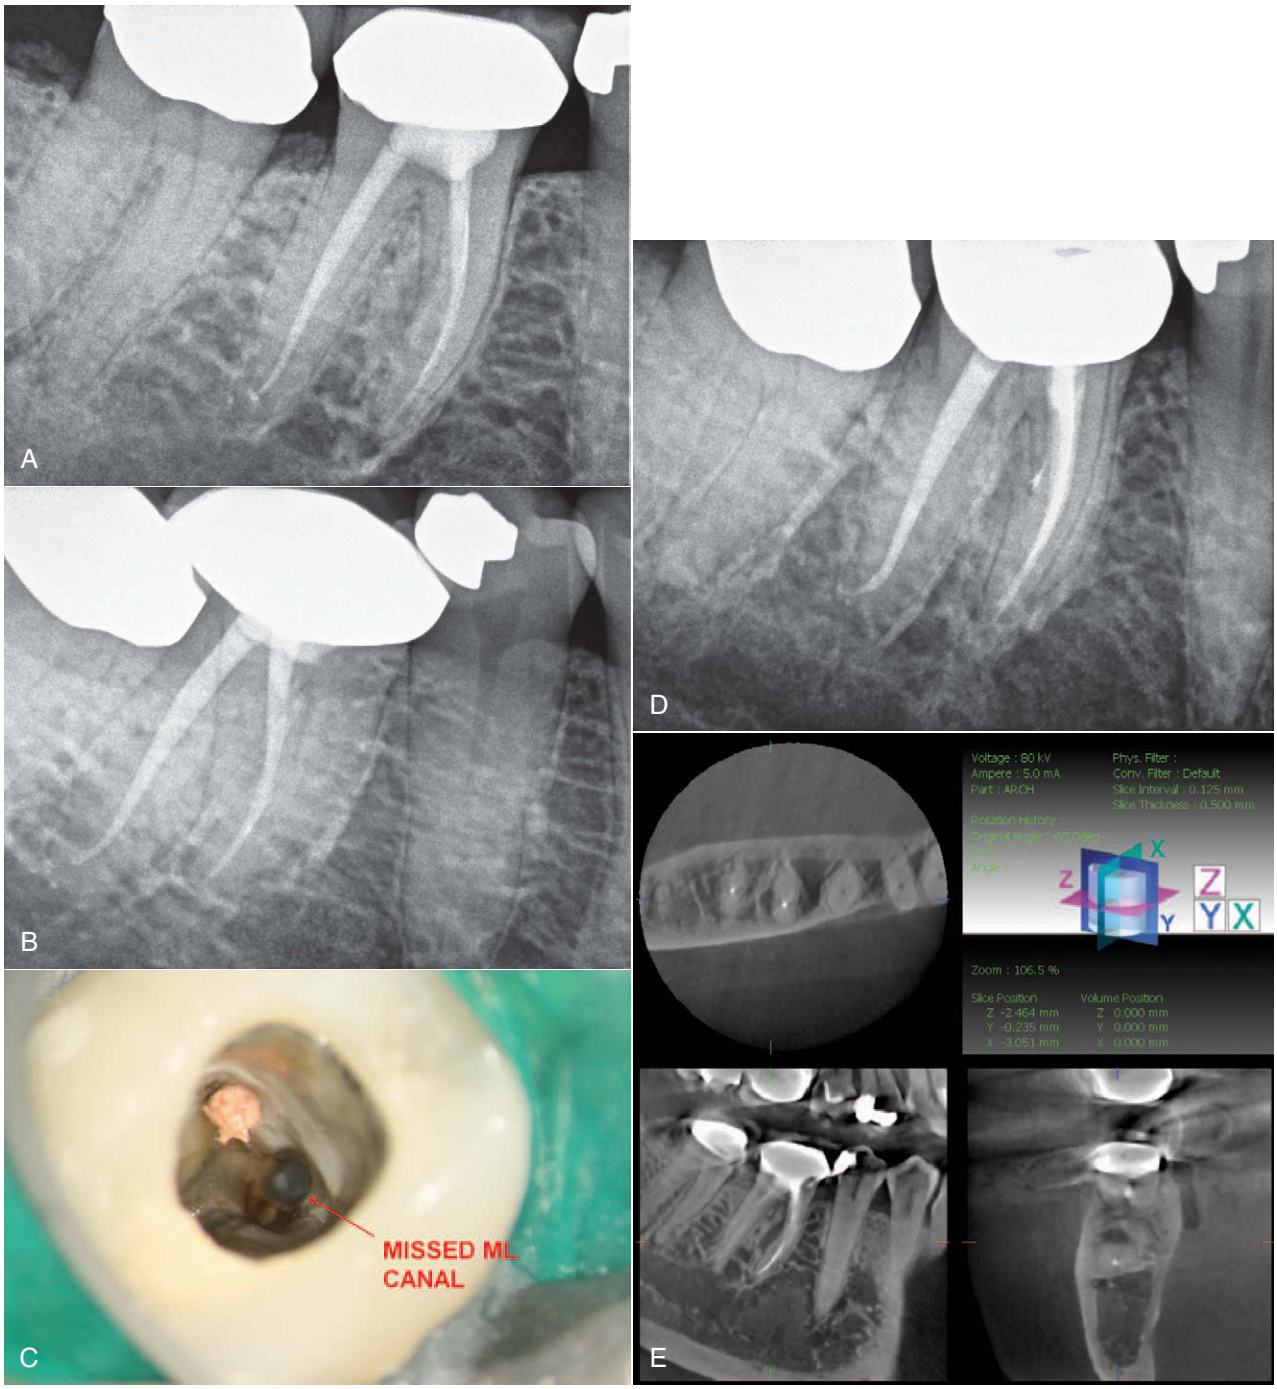

FIG. 29-11 A, Tooth #30. **B,** Exposure of tooth #30 with a different angulation, confirming that original root canal therapy for tooth #30 only addressed a single mesial canal. **C-D,** Initial access for nonsurgical retreatment provided visual confirmation that original endodontic therapy did not address the mesial lingual canal **(C).** Part **D** illustrates a posttreatment radiograph that addresses cleaning and obturation of entire root canal system. **E,** Multiplanar views of tooth #30.

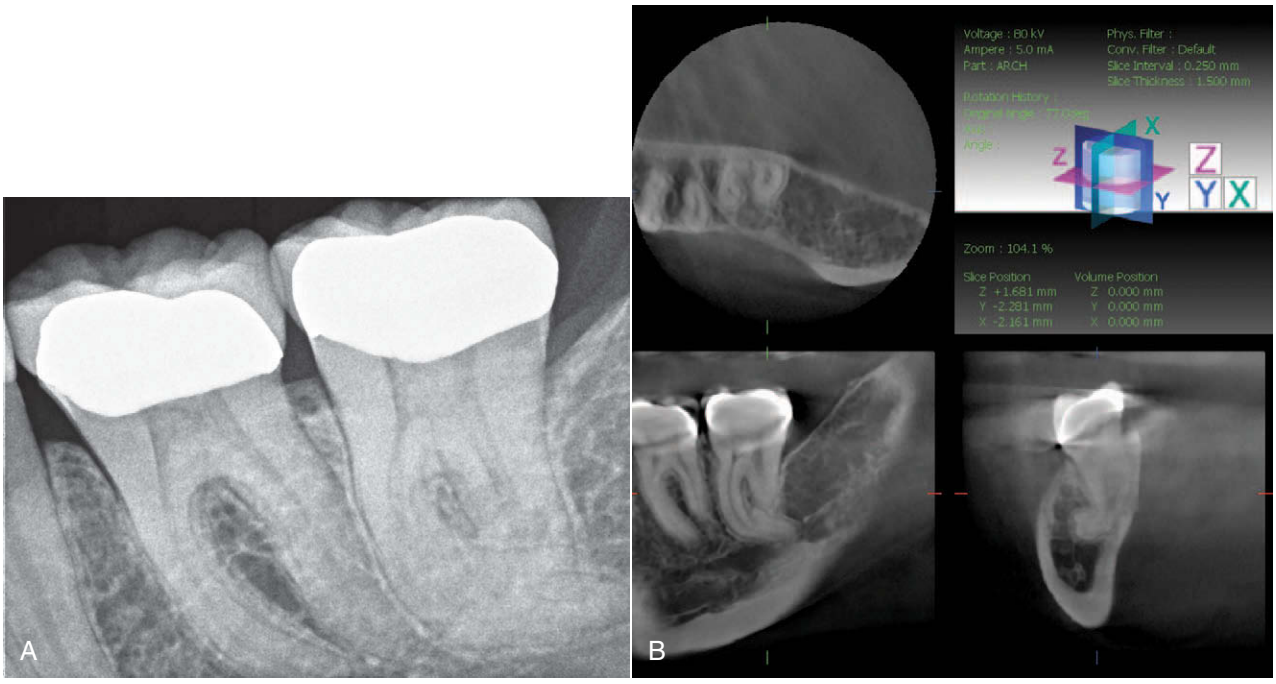

FIG. 29-12 A, Tooth #18, referred for endodontic evaluation and potential treatment. This 2D radiograph reveals significant pulp stones and canal calcification developing not only in coronal aspect of root canal system but extending down the visible distal canal. Apical third of the canal system appears unusual and dilacerated. Cone beam volumetric tomography (CBVT) imaging would be beneficial in visualizing root canal anatomy prior to creating ideal endodontic access. **B,** Single slice of the CBVT for tooth #18. Information regarding direction of root canal anatomy is provided in all three planes of section, axial, coronal, and sagittal. It is interesting to note that axial slice shows that the mesial lingual root actually traverses buccally as it approaches its terminal extent. This is valuable information for the clinician, available prior to cleaning and shaping of entire root canal system, permitting a higher degree of treatment predictability.

FIG. 29-13 Axial slice **(A)** and sagittal slice **(B)** reveal that there may not be any cortical bone perforation. This is because these slices are very thin (0.10 mm), and it depends which level or section of the slice is being viewed; lesion is observed to have spread palatally.

Continued

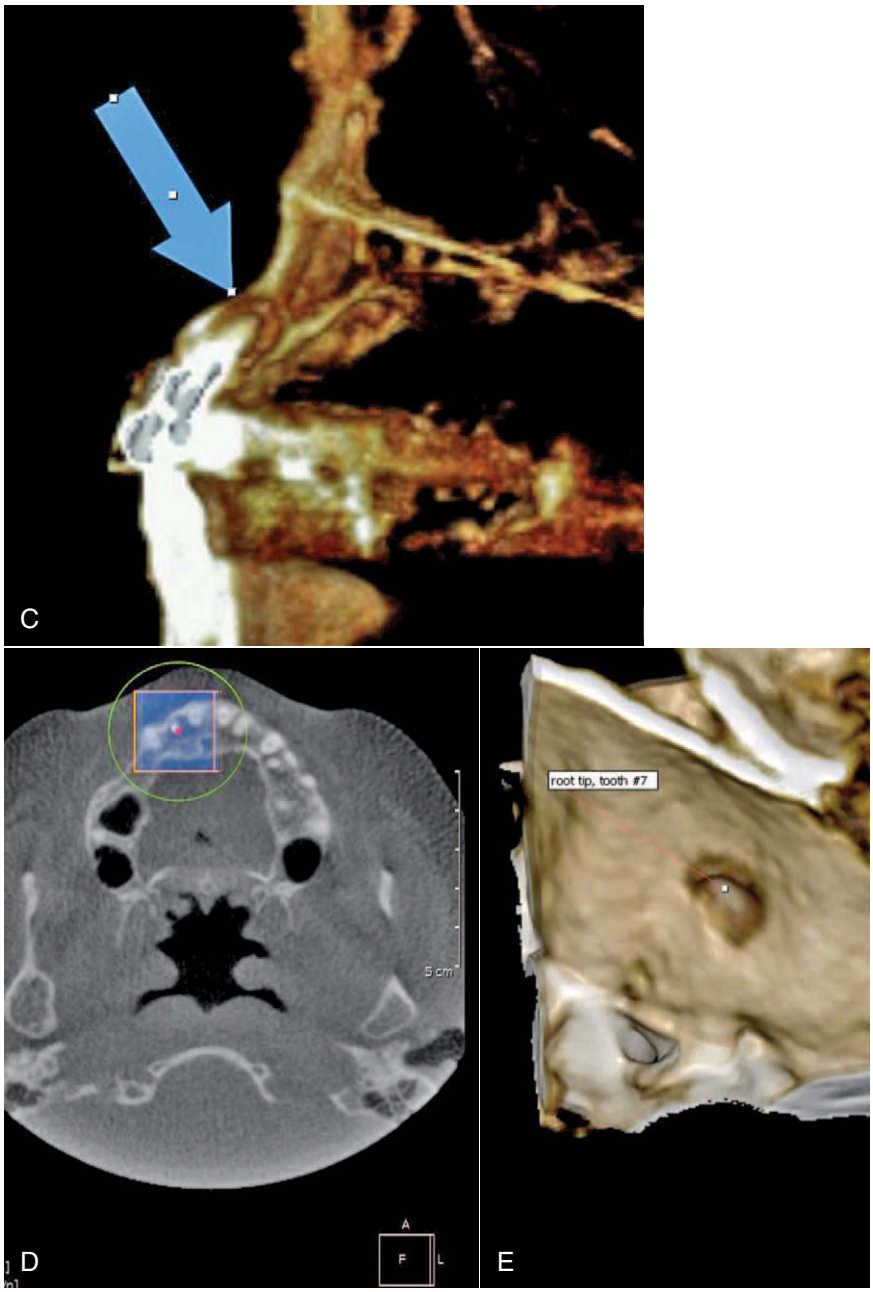

FIG. 29-13, cont'd C, When an oblique-slice tool (found in OnDemand 3D, CyberMed International, Seoul, Korea) is used and the slice thickness thickened, a 3D color image reveals a buccal cortical bone perforation (*arrow*). **D-E,** Using another tool called a *cube tool* and rotating the image to look from the top down on the lesion, the clinician can actually visualize the root apex of tooth #7 through the lesion perforation.

radiograph illustrates incomplete distal canal obturation, with associated periapical bone loss in the area of the apical third of the distal root. The CBVT image reveals a horizontal root fracture in the distal root at the apical extent of the post. Without this valuable information, the clinician may have attempted nonsurgical retreatment or an apicoectomy. Instead the patient can be informed of a hopeless prognosis, and valuable treatment time, expenses, and patient and clinician frustration can be avoided because of the enhanced information provided from the CBVT imaging.

Internal and External Root Resorption

Most clinicians are aware—and ideally communicate to their patients—that the long-term prognosis for teeth with extensive root resorption may be unpredictable. Endodontic treatment can often resolve these defects, with early diagnosis and treatment typically providing an improved prognosis. CBVT imaging of these resorption lesions provides the clinician with enhanced information so that more appropriate treatment-planning options are available (Fig. 29-15).

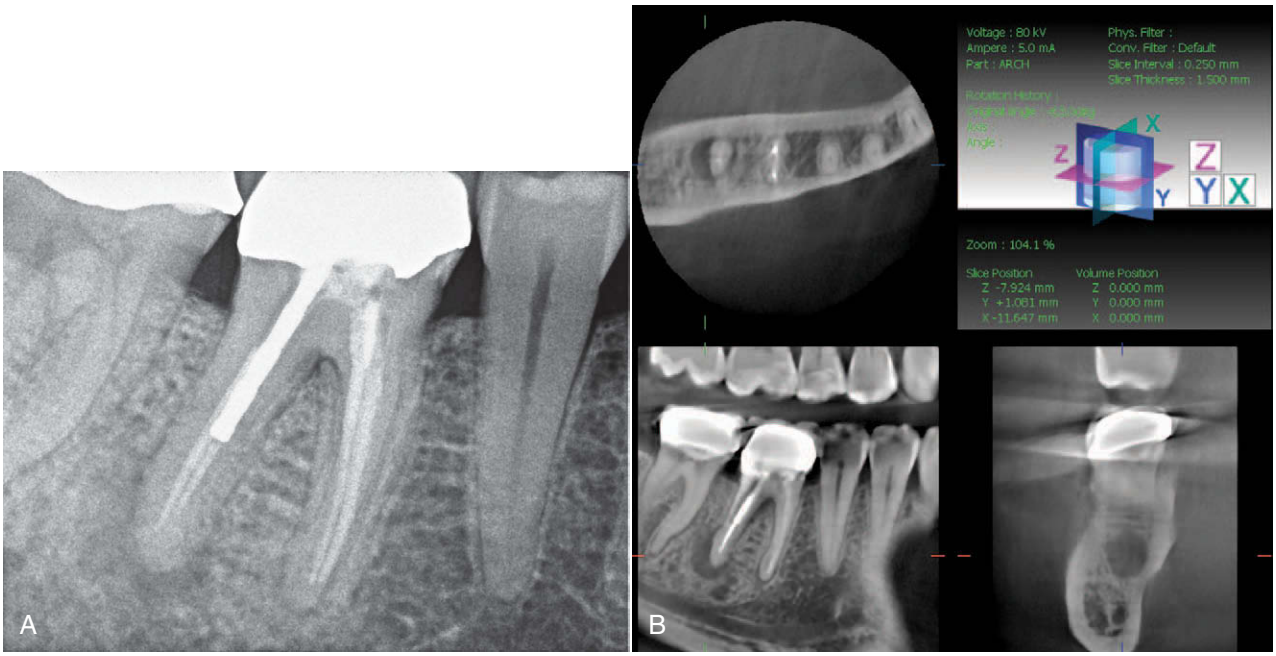

FIG. 29-14 A, Incomplete obturation of distal root canal complex. **B,** CBVT slice of tooth #30 shows the lesion of endodontic origin (LEO) on the distal root more dramatically than the PA. While axial and coronal views do not provide significant information, sagittal view reveals a horizontal root fracture at the apical extent of the post.

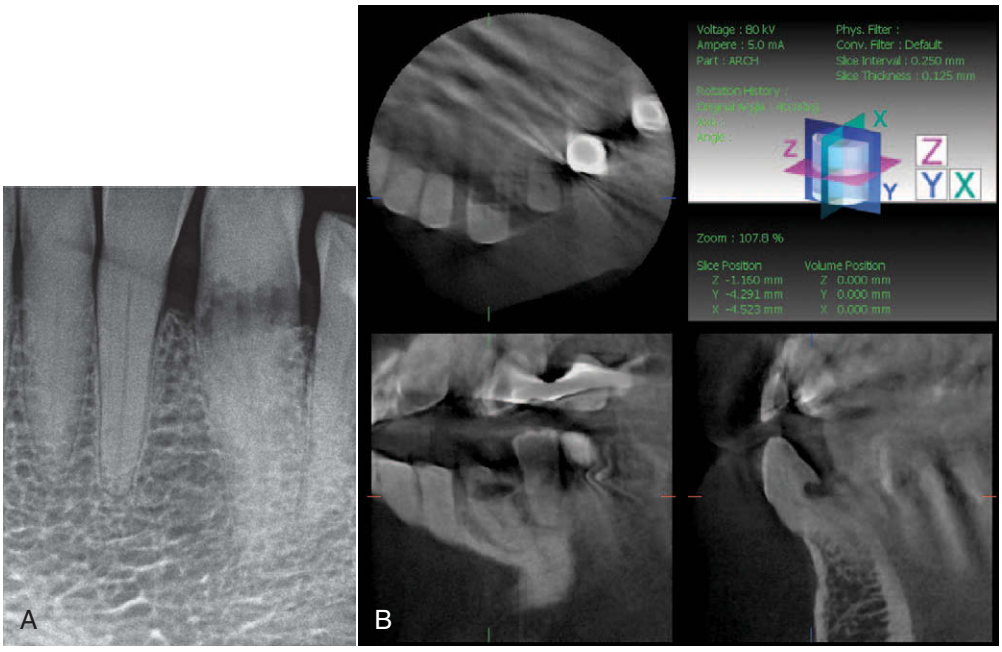

FIG. 29-15 A, Patient referred for evaluation and potential treatment of tooth #22. The periapical (PA) image reveals some significant cervical resorption. Tooth is asymptomatic, and patient was unaware of the problem until clinician discovered the defect upon routine clinical examination. Clinically, the resorptive defect appears primarily on lingual aspect of tooth but extends both to the mesial and distal aspects of tooth and slightly subgingival towards the level of crestal bone. **B,** CBVT slice confirms that resorption defect is significant and congruent with findings of the pretreatment PA images. The defect does communicate with the pulp of the tooth. Endodontic therapy may be indicated, but CBVT imaging suggests a questionable endodontic and restorative prognosis.

- Scheduling
- Customer Service

MARKETING
- Endodontic Referral Marketing

LEADERSHIP
- The Endodontic Leader

Operating a successful endodontic practice requires both excellent clinical *and* management skills (Fig. 30-1). Endodontists are extremely well trained in their clinical specialty, but most do not receive extensive business training prior to becoming a practice owner. This scenario is beginning to change as more in the dental profession recognize the value of practice management skills and the role they play in an endodontist's ability to have a successful and rewarding career.

Endodontists who possess management skills are better positioned to handle the demands of operating an endodontic practice—a business that can generate significant revenue. Historically, there was a time when endodontists could enter practice without strong business skills and enjoy a long, prosperous career, but the business side of endodontics has become more complicated in recent years.

Young endodontists are leaving dental school and residency with far more debt than even a decade ago. The cost of purchasing or opening an endodontic practice continues to rise. In addition, endodontists face increased competition from other clinicians who perform root canal treatments. The success of endodontic practices can also be affected by the development of new clinical techniques or services. For example, some clinicians believe that dental implants are a better treatment choice than root canals, depending on the difficulty of saving the infected tooth. As dental implant procedures become easier and more common, this trend may continue to grow.

To meet these and other challenges, endodontists need to supplement their clinical expertise with the necessary practice management skills. *Practice management* involves the use of documented systems to achieve superior business results. Effective practice management allows endodontists to provide optimal patient care while creating a highly productive, low-stress office environment. The design and implementation of effective practice management and marketing systems enables endodontists to operate their practices as successful businesses with steady growth and maximum efficiency. Endodontists who can combine excellent clinical skills with strong practice management skills will experience greater practice success (see Fig. 30-1).

ENDODONTIC MANAGEMENT SYSTEMS

Written, documented systems are the basic foundation for all successful operations within an endodontic practice. Step-by-step, reproducible systems enable a practice to operate successfully as both a provider of patient care and a business enterprise. Documented systems reduce unnecessary stress and allow endodontists to remain chairside so they can focus on providing exceptional quality of care. As each system is established, every step in that system must be clearly documented and then implemented. Many endodontists fail to establish efficient systems in the early years of a new practice, and inefficient systems can hinder the practice's growth, increasing stress for the doctor and team.

Endodontists should begin their careers by developing and implementing effective practice systems. This way, when a practice begins to grow, the office has a solid management foundation in place to allow for the achievement of more challenging goals. If the practice waits until it gets busier, there is less time to design effective systems, and the endodontist often becomes less motivated to do so owing to a higher level of "busyness" and other responsibilities in life.

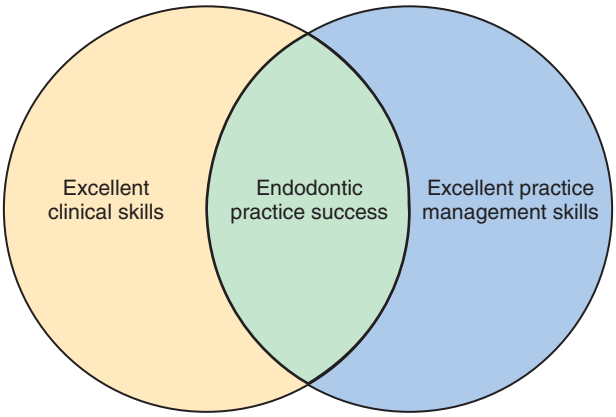

FIG. 30-1 The keys to achieving practice management success.

Systems Design

New practice owners have an excellent opportunity to design systems when capacity is available. This type of foresight sets the stage for practice growth in the years to come. However, systems should be evaluated and updated throughout an endodontist's career. It will be necessary to replace most major endodontic practice systems on a 5- to 7-year cycle to maintain growth and profitability. The reason is that practices regularly outgrow their systems as a result of changes in staff, equipment, technologies, referral relationships, and the economy.

Systems should be designed based on the specific characteristics of each practice. Areas to be considered include:

- Days of operation
- Hours of operation
- Number of staff
- Number of patients
- Number of emergencies
- Average daily patient flow
- Types of procedures offered
- Number of chairs

For example, a practice that sees a higher volume of patients will probably need more staff than a practice that sees a lower number of patients. The same would be true for a practice that participates heavily with insurance companies versus a fee-for-service practice.

Effective management systems can make the difference between a successful endodontic practice and a *highly* successful endodontic practice. Many endodontists cannot fathom how they could see any more patients, produce any more revenue, or work any harder. Yet, there exist similar practices that have much higher production in the same number of days per week with the same number of staff. It is always interesting to reflect on why one endodontic practice can be so much more financially successful than another practice in a similar situation.

Assuming a sufficient patient flow, the answer always comes down to management systems. It is not about working harder or faster, but creating systems that allow the practice to operate at a specific production and profitability level in a low-stress environment. Key systems and principles for effective endodontic management and marketing include:

1. Vision
2. Mission
3. Goal setting
4. Key performance indicators
5. Staff training and development
6. Scheduling
7. Customer service

MANAGEMENT

Vision

The first question endodontists should answer before opening or purchasing an endodontic practice is "What kind of endodontic practice do I want to have?" This question requires the endodontist to take some time and identify a vision, which is a description of where the doctor wants the practice to be in 3 to 5 years. Whereas some vision statements may reflect a longer period, this shorter timeframe works well for most endodontists because it is difficult to predict changes in dentistry, the economy, and other events more than 5 years into the future. In addition, after 3 to 5 years, it is time for the clinician to review what has been accomplished and possibly establish a new vision for the practice.

To create a vision statement, the following questions should be answered:

- What location is most suitable for the practice?
- What size should the practice be in 3 to 5 years?
- Does the doctor want to be in solo practice or group practice?
- What days and hours will be satisfactory for the practice?
- What services will the practice provide?
- Is the intent to have only one practice or to have more than one location?

These are just a sampling of questions that can stimulate the design of a vision statement.

A vision statement clearly articulates where the practice is going. The length of a vision statement can vary between a short, single paragraph and several paragraphs. It is probably counterproductive to have a multipage vision statement; it will be difficult for both the endodontist and staff to fully grasp such a lengthy and complex vision.

The vision guides the long-term development and growth of the endodontic practice. Once the vision statement has been created, it should be shared with the endodontic staff on a regular basis. Good leaders always communicate their vision to their staff. When team members understand where the practice is headed, they are empowered to help the endodontist achieve his or her vision. Sharing the vision inspires commitment and participation in achieving the vision. The following are two examples of vision statements:

Short Vision Statement

In 5 years, we will be the leading endodontic practice in the area. We will be known for exceptional quality of care and outstanding customer service. We will grow by 20% per year. Our staff is motivated and committed to continuously improving our management systems and to a lifelong learning process. We strive to meet or exceed our goals in a low-stress work environment.

Long Vision Statement

In 5 years, we will be known in the community for being the most comprehensive and skilled endodontic practice in

the area, offering our patients an atmosphere of compassion and comfort.

Our excellent management skills create an environment that is low stress and productive. We consistently meet our production goals without creating a rushed or late atmosphere, and our days are fulfilling.

We provide exceptional customer service that consistently generates spontaneous, positive comments. Team members have a clear understanding of their roles and responsibilities. We have developed practice systems that foster a sense of fulfillment and accomplishment for all. In year 5, we will engage an associate doctor.

Mission

Once the vision statement has been created, the next step is the development of a mission statement.

While the vision statement is about where the practice will be in the future, the mission statement is focused on where the practice is today.

Once again, a strong leader has a clear practice mission and shares it with the team. Because of the similar services provided by endodontic practices, many mission statements resemble one another—they talk about quality, patient care, practice services, and customer satisfaction. It is not important to have a mission that differentiates one practice from another, but it *is* essential to have a mission that reflects the doctor's true vision. Here is an example of a mission statement:

Our endodontic practice is dedicated to delivering quality care to meet the endodontic needs of our patients and referring doctors. We provide exceptional clinical care and customer service in a comfortable, relaxed environment.

One way to keep the mission statement top of mind is to display it prominently in several places throughout the office, as well as on the practice's website. The most powerful reason for displaying the mission statement is to reinforce to the team that the mission is a living document that guides the practice. An added bonus of displaying the mission statement is the opportunity to let patients know of their importance to the practice.

The endodontist should reference the mission statement on a regular basis. Reinforcing the mission during meetings helps staff members focus on why the practice exists and the difference the team is trying to make in the lives of patients.

Goal Setting

Goal setting is one of the most important business activities for endodontists. It is critical to achieving success in a doctor's professional and personal life. Once a vision and mission are established, annual goals are the method to make the vision and mission a reality. Goal setting is a step-by-step methodology that leads to the achievement of the overall vision. To be effective as a goal, it must be:

1. Written
2. Deadline-driven
3. Measurable

Goals that lack these three characteristics cannot be considered goals and are much less likely to be achieved. Be sure that all of the goals are aligned with the practice's vision and mission to achieve the desired results.

The hectic pace of today's endodontic practice obliges many doctors to focus on day-to-day operations and fail to step back and see the big picture until many years have gone by. Goal setting and regular goal review can help endodontists manage their practice instead of being managed by it.

Far more than just a motivational concept, goal setting acts as a timeline, benchmark, and directional process to achieve the vision and mission. A vision or mission without specific goals is merely an idea. Endodontists who set goals are much more likely to achieve their goals and ultimately make their practice vision and mission a reality.

Key Performance Indicators

Without data, an endodontic practice cannot be well managed. To obtain a clear picture of current and potential practice performance, practice goals must be monitored and measured. Key performance indicators (KPIs) provide an accurate assessment of the practice's most critical functions, including:

- Production
- Collections
- Profit
- Overhead
- New patients
- Account receivables
- Case acceptance
- Average production per patient
- Number of re-treats versus initial root canal treatment
- Insurance percentages
- Production per hour

These KPIs offer endodontists a starting point for analyzing their practices. Once the information has been collected, weekly measurement and analysis are necessary. Although this may sound arduous, a weekly review should take only a few minutes. Such frequency of analysis can bring substantial benefits to the practice.

Evaluating KPIs every week allows endodontists to rapidly identify trends or performance deviations that may be difficult to discern otherwise. With accurate practice data, endodontists are then able to take appropriate actions.

Staff Training and Development

Establishing practice systems will only be effective if the team understands their roles in making those systems work. Training the endodontic team begins with the development of job descriptions that list the skills, responsibilities, and accountabilities needed to perform each staff position. Bear in mind that the majority of endodontic staff will be hired without previous endodontic or dental experience and must be trained on the job.

Training is specific to each position so that all team members can perform their duties and responsibilities as independently and effectively as possible. During training, it is critical that practices document training policies and procedures. When policies and protocols are documented, they can be clearly communicated to new staff and regularly reinforced by current team members.

One frequent problem is that many team members fail to fully understand their job responsibilities and are not held accountable for their performance, which means the endodon-

tist will continue to handle numerous responsibilities that should be performed by other team members.

Although this type of behavior may be common in the early stages of an endodontic practice, endodontists who become effective leaders learn how to delegate appropriate tasks to the endodontic team. The goal for every endodontist should be to spend 98% of their workday involved in direct patient care or communication with referring doctors. To reach this goal, it is recommended that endodontists make a list of all activities they will perform and all responsibilities that will be assigned to the endodontic staff. This exercise will allow the endodontist to clearly identify which activities should be handled by the doctor only and which can and should be delegated to the team.

Delegation empowers the team to take ownership of their roles in contributing to practice success. The concept involves giving responsibilities to staff members so that endodontists can concentrate on what they do best. Without delegation, endodontists often carry out numerous responsibilities that can be performed by others. To spend more time in direct patient care, endodontists must delegate appropriate responsibilities to specific staff members. In addition, the team should be cross-trained on systems to cover for any illnesses, vacations, or turnover.

Once all team members have achieved a high level of expertise and independence, the practice can operate at peak performance. Efficiency, professional satisfaction, and quality of care steadily climb to maximum levels. At this stage, endodontists trust their teams to effectively perform their duties with minimal oversight. Best of all, doctors can focus on providing exceptional patient care without distractions and unnecessary stress.

In successful endodontic practices, the doctor focuses 98% of working hours strictly on patient care, interdisciplinary treatment, and referring-doctor communication. These practices will typically reach 90% to 100% of the practice production potential.

Scheduling

Making changes in the area of practice management should begin with a thorough evaluation of the schedule because of its impact on all other major systems. If the schedule is integrated properly with all other endodontic management systems, the practice has the best opportunity to achieve the endodontist's goals.

Schedules are created to achieve specific practice production in a low-stress environment. This means that an endodontic practice must establish a target for its annual production and design the schedule accordingly. Each year, endodontic practices should complete an exercise of determining the desired level of growth and create a schedule that allows for that growth. The greatest challenge to increasing production is scheduling limitations that make it all but impossible for the practice to grow.

The following principles are essential when designing the ideal schedule for any individual endodontic office.

Schedule for Production

Design the schedule to achieve a specific production goal. Endodontic practices are typically capable of growing between 5% and 15% annually. Less than 4% growth represents moving into a plateau. There are endodontic practices that can grow by as much as 25% to 30% in a single year as optimal systems are implemented.

Scheduling is a quantitative and mathematical activity because time is quantitative and therefore measurable. The schedule should answer questions like: *How many of each service will we need to perform this year? Will those numbers allow for the production goal to be achieved?* Benchmark these production goals against the hours and days per week the practice is available for patient care, and adjust the schedule accordingly.

Set the Daily Production Goal

Setting the daily goal is a reflection of the annual production goal. To determine the daily goal, simply take the annual production goal and divide it by the number of days the practice will be operating that year. Then build the schedule around this key number. Front desk personnel should become aware that the top practice management priority is to achieve the daily goal. By implementing an excellent scheduling system, they will have a far greater chance of successfully accomplishing this task.

Perform Procedural Time Studies

Many practices are unrealistic about how much time they actually need for procedures. One common example is for root canals to simply be scheduled at one per hour, even though the practice is becoming more stressed and rarely runs on time. Performing "procedural time studies" to determine the exact amount of time needed for each procedure is recommended.

During procedural time studies, each type of treatment performed by the office should be measured approximately 10 times to develop an average procedure time. Once these studies are performed and the schedule is updated, most endodontists will usually be able to increase their endodontic workload by using time more efficiently.

Young endodontists should perform procedural time studies once a year for the first 5 years they are in practice. After that, studies can be conducted at less frequent intervals (every 3 to 5 years) to evaluate whether the endodontist has become faster or more efficient, either by experience, technique, or the use of new technologies in the practice. Procedural time studies play a critical role in building an effective and accurate schedule, which directly affects the success of the endodontic practice.

Create the Ideal Day

The schedule should be designed to perform larger and more complex cases in the morning whenever possible. This can be extremely challenging owing to the number of emergencies seen by endodontists during a normal day. By scheduling larger procedures in the morning, practices can avoid the fatigue factor that occurs later in the day for both the endodontist and the team. Of course, emergencies will continue to occur, but effectively managing other appointments will better position the practice to handle end-of-day emergencies. Other recommendations for creating the ideal day include:

- Handle minor to moderate types of cases in the early afternoon.
- Perform consults and diagnoses in the midafternoon.

- Schedule all minor procedures for the end of the day. These include post-ops, quick checks, and the like.

Basically, this means that the more difficult or larger cases will occur in the morning when the doctor and team are fresh. As the day goes forward, the doctor and staff have the opportunity to work on less complex cases, such as second visits and patient consultations, with all minor procedures at the end of the day. A highly organized schedule will allow for increased productivity and higher profitability while decreasing stress for the endodontist and the team throughout the day.

Manage Emergencies

No discussion of endodontic scheduling would be complete without a focus on emergency management. Emergency procedures are a frequent occurrence in endodontic practices. Managing emergencies well requires a combination of referring-doctor management, setting patient expectations, and effective scheduling. The result will be a highly productive, enjoyable environment for any endodontic practice.

The first step in managing emergencies is to develop a schedule that allows some flexibility throughout the day. It does not benefit the practice to create a schedule that is 100% maximized without accounting for emergencies. Instead, analyze how many emergencies occur on an average day, and then leave time for that number of emergencies in the schedule. Many high-level endodontic practices will often schedule only 80% of their day, leaving time slots for emergencies. The key is to not ignore the time slots and invite every emergency patient to visit the office immediately, but to manage each situation appropriately.

For example, a patient who is in mild discomfort calls at 10 AM. The practice does not have an opening until 12 noon. If the patient is allowed to come in immediately, the office feels a need to work the patient into the schedule, not only causing stress for the doctor and team but possibly forcing already-scheduled patients to wait longer than expected. If the practice manages the emergency patient during an emergency time slot, the opportunity to create an excellent flow for the day and a positive customer service experience for every patient seen is maximized. The main point is to provide optimal care and exceptional customer service without disrupting the daily schedule.

The keys to effective emergency management are:

- Evaluate each call from a patient or referring office to determine the level of emergency. Many calls are not true emergencies, and these patients do not need to be seen immediately. Scripting and training can help staff members elicit specific information from patients about the level of discomfort (mild tenderness versus extreme pain) while providing excellent customer service.
- If it is a true emergency, bring the patient in immediately, but still evaluate the schedule to facilitate the overall process. Highly systemized endodontic practices use trained staff to evaluate emergency situations as much as possible, including preliminary assessment and x-rays.
- If the emergency call does not constitute a true emergency, it is important to use proper scripting to move the patient into an emergency time slot that will prevent the appointment from disrupting the entire schedule. This approach can be used with either a referring office or a patient.
- If the practice notices ongoing disruptions from emergencies, it should reevaluate the emergency policy and scripting to create a more effective methodology. Many practices tell every emergency patient to come in immediately. The problem arises in mistaking high-level customer service with providing immediate treatment. It is much more effective to manage the emergency patient into a time slot reserved for emergencies, unless the patient is experiencing an endodontic problem that necessitates immediate treatment. Staff training is critical for effectively managing emergencies while providing a high level of customer service.

Scheduling is the single most important system, because it integrates with all other systems. When an effective scheduling system has been established and properly implemented, the practice will immediately see an increase in productivity and a decrease in stress. Most stress in endodontic practices is based on poor scheduling methods that overwhelm the doctor and team while lowering customer service. This same type of stress is indicative of inefficient practice systems, which means that even though the endodontist is actually working harder, profitability will be lower. An efficient schedule enables the endodontist to provide a high level of care and customer service to all patients.

Customer Service

Customer service is much more than just "being nice" to patients. It is a system focused on managing the patient experience from the initial referral to treatment to postoperative care. Outstanding customer service is critical to exceeding patient expectations and building strong relationships with referring doctors.

The vast majority of endodontic patients are referred to the practice by general dentists. The growth of the endodontic practice depends on the satisfaction and confidence of referring doctors. General dentists want to know that their patients' expectations, as well as their own, are being met. When patients receive excellent clinical treatment and superior customer service, they are likely to provide positive feedback when returning to their general dentist. Positive feedback from patients reinforces the dentist's confidence in the endodontist and leads to continuing referrals.

Developing a customer service system is more complex than simply telling the staff to be nice to patients and referral sources. A customer service system requires that patients consistently receive the same level of responsiveness, caring, and concern from every member of the practice. Consistency and quality are at the core of a practice's customer service system.

Although the patient's time in the endodontic practice may be limited, the endodontist must realize that the patient will be returning to the referral source and sharing his or her experience with the referring doctor and/or the clinician's staff. The patient will also share information about the experience with family, friends, and others. Negative word-of-mouth descriptions about the office will obviously hurt the endodontic practice's reputation within the community.

Patients want to believe they are the practice's *only* priority when they come in for their appointments. Endodontic practices with excellent customer service strive to meet this expectation. If a practice fails to return phone calls in a timely fashion, is running late when the patient arrives, or does not

seem prepared for the appointment, patient confidence and trust disappears, as does their perception of quality care.

Practices should manage expectations by making everything about the patient's treatment plan value based. Do patients fully understand the value of their treatment plans? Do they know exactly what the treatment entails, what the fees are, and why the treatment must be done? Does the patient know the projected outcome? All these questions must be satisfactorily answered before treatment starts.

Endodontic practices have an opportunity to exceed expectations when:

- There is complete understanding about why, how, and when endodontic treatment will take place.
- Patients have realistic expectations of outcomes.
- Patients and referring doctors receive accurate and timely information about the treatment process.
- The practice has timely follow-up posttreatment communication with patients.

MARKETING

Endodontic Referral Marketing

The business model of an endodontic practice is based on receiving referrals from general dentists and other doctors. There will certainly be the occasional patient who selects an endodontic practice through the Yellow Pages, Internet, or recommendation from a friend, but the majority of endodontic patients will be referred by other clinicians. For endodontic practices to reach their true production and profitability potential, a referral marketing program should be in place. The major challenges with implementing a referral marketing program are:

Expertise

Referral marketing is a specialized form of marketing. Endodontists are trained clinicians with little to no experience or expertise in this type of marketing; most endodontists typically learn about referral marketing through trial and error. This process can be time consuming and costly in terms of missed opportunities.

Time

Endodontists are extremely busy. They are not only the main producer in the practice but often the only producer. It is not unusual for an endodontist to work 8 hours a day highly focused on providing patient care and managing the practice and have little time to think about referral marketing. This is problematic because effective referral marketing is not a few isolated activities but a complete program that must be carried out in a systemized manner to achieve desired results.

Consistency

Perhaps the chief reason referral marketing programs fail is inconsistency. Inconsistent referral marketing leads to inconsistent referrals. The typical pattern is that if the practice has slowed down, the endodontist will attempt to increase referral marketing until positive results are generated. Once referrals increase, then referral marketing slows down or ceases altogether. This stop-and-start type of marketing leaves practices more susceptible to the effects of economic conditions, increased competition, and a host of other factors. A consistent referral marketing program is the solution to numerous challenges that face endodontic practices.

Referral marketing should be viewed as a mandatory part of the practice's systems. Referral marketing has two major components:

1. Establishing strong relationships with referring doctors (Fig. 30-2)
2. Designing a consistent marketing program that reaches the doctor's targeted demographic

ESTABLISHING STRONG RELATIONSHIPS WITH REFERRING DOCTORS

Referral marketing differs from traditional marketing in that it is relationship driven. A successful referral marketing program requires positive and consistent contact with referring doctors and offices. It is an investment in time and energy, but when done correctly, it can generate a steady influx of referred patients from dentists and other doctors. Communication is critical to establishing and maintaining strong relationships with referring dentists and their practices. Sharing information about mutual patients throughout the treatment process creates a sense of partnership and teamwork that is essential to relationship-building. To strengthen relationships with their referral base, endodontists should meet regularly (e.g., quarterly) with their referring doctors. These meetings can be formal or informal occasions, but they provide an opportunity to enhance both the treatment process and the referral relationship.

DESIGNING A CONSISTENT MARKETING PROGRAM

Building a strong relationship with referring doctors requires more than one or two conversations or meetings a year. By implementing a series of consistent, ongoing marketing strategies that reach referring doctors, endodontists create greater awareness for their practices and services while building and maintaining referral relationships. Referral marketing strategies are selected from areas such as professional relationship, clinical education, social activities, and patient satisfaction. For example, hosting a practice management seminar is a "professional relationship" strategy, and going to a sporting event with a referring doctor is considered a "social activity" strategy. An effective referral marketing program encompasses multiple strategies, resulting in stronger relationships with referring doctors and their teams. The more referrals an endodontist receives, the greater potential for long-term growth and practice success.

LEADERSHIP

Leaders possess many skills, qualities, and attributes that are the result of learning, experience, and self-motivation. Many people have great ideas or vision, but true leaders are able to implement those ideas or carry out the steps necessary to achieve predetermined goals. They have the ability to inspire others to do their best. The most successful endodontic practices are guided by strong leaders.

Becoming an excellent leader starts with the desire to have an outstanding practice. Most endodontists are highly motivated to be excellent clinicians. Endodontic continuing education is focused mainly on clinical topics, which is extremely appropriate, given that doctors have an obligation to provide

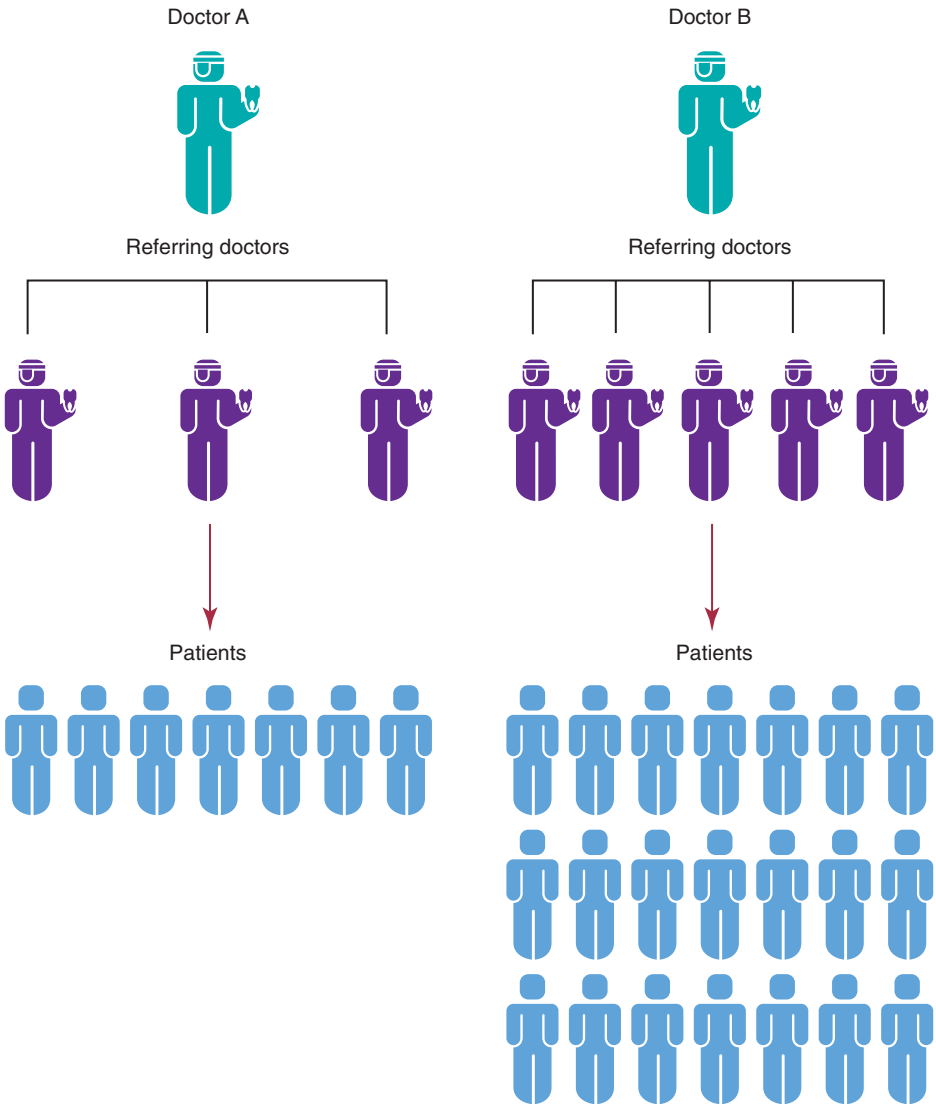

FIG. 30-2 The impact of referral marketing. *Doctor A* does *not* have a formal referral marketing program in place. *Doctor B* does have a formal referral marketing program in place. The results are dramatic. *Doctor B* has many more referring doctors, who refer more patients for treatment.

the best possible care to patients. This makes it even more important for endodontists to seek out opportunities to develop leadership, business management, and marketing skills.

The Endodontic Leader

As practice owners, endodontists are automatically viewed as leaders by team members. The more leadership skills an endodontist can master, the better leader he or she will become. Though not an exhaustive list, the following leadership skills are critical for endodontists:

Interpersonal Communication

Interpersonal skills are the foundation of leadership. Endodontists work with a small group of people in a fairly limited space. Good interpersonal skills are essential for a smoothly functioning office environment. In business, there are many successful "tough" bosses. Even though they may be disliked, they are respected. Unfortunately, being tough or inflexible is not always the best strategy, especially in dentistry. Few endodontists can be tough leaders and still expect to have happy team members and a successful practice. The best practice leaders can motivate their staffs, accomplish goals, and are well respected by their teams. Regular morning meetings and monthly staff meetings provide excellent opportunities to communicate with the team, increase awareness of practice challenges and goals, and build stronger interpersonal relationships with team members.

Decision Making

As the CEO of the practice, endodontists must make business decisions. There are many people who do not progress in business simply because they teeter between two ideas and fail to make a decision in a timely manner. No matter what the issue, excellent leaders make decisions and trust their instincts, based on analysis, education, and experience. Why? Strong leaders believe in themselves and their knowledge base. They

are confident and have the ability to make decisions that are in their best interest and that of their teams.

Motivation

Motivation is one of the most important skills for a leader. The endodontic leader is able to bring together a team of individuals to achieve shared goals and move toward the practice vision. Many people are not self-motivated. Instead, some external force motivates them. In this case, the external force is the practice leader. It is easier to motivate others and work as a team if the leader is trusted and respected.

Pursuit of Knowledge

Practice leaders are usually in constant pursuit of knowledge. They want to excel in the management of the endodontic practice and will read, listen, and learn as much as possible about the subject of practice management. Leaders are typically lifelong learners who do not learn sporadically but tend to seek out opportunities to learn new ideas and strategies on an ongoing basis.

Teamwork

Endodontic leaders never work on their own. They rely on their team to help achieve practice goals. However, many people mistake the concept of being a leader with being a "ruler." The "ruler" approach is not an effective one when working closely with a team whose performance is tied to the ultimate success of the practice. Therefore, endodontic leaders must remember that they are part of a group dynamic. In fact, the practice leader is like the coach of a basketball or football team. He or she creates a game plan, guides the team, and facilitates teamwork.

Time Management

Time is one of the leader's most important assets. Endodontic leaders must not only manage their own schedule but their team's as well. However, good leaders do not micromanage their team. They educate staff members, provide guidance, set expectations, and hold the team accountable for the results.

Successful leaders effectively and efficiently use their time, creating positive outcomes for themselves, their teams, and their practices. Good leaders also eliminate extraneous items from their lives that take time away from achieving their goals.

Leading By Example

The best way to earn the team's respect is to "talk the talk and walk the walk." The way the endodontist behaves will have a significant effect on how the team acts. The professionalism exhibited toward patients, the doctor's attitude and interactions with individual staff members—all of these behaviors send messages to the team. The team is looking to the endodontist for leadership guidance, and the best strategy is to serve as an effective role model. If the team is expected to show up on time, the endodontist cannot stroll in 15 minutes late every day without causing resentment. Good leaders adhere to the rules others are expected to follow.

Leadership is a way of thinking and acting based on desire, skills, training, and specific behaviors. Endodontists who are willing to develop leadership skills will inevitably build better teams with lower turnover and higher efficiency.

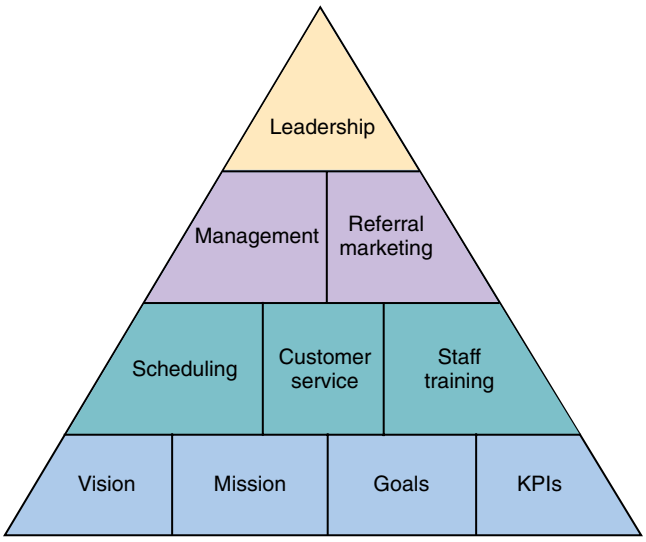

FIG. 30-3 Key principles of endodontic practice management.

CONCLUSION

Effective practice management involves management systems and referral marketing that allows an endodontic practice to provide outstanding patient care while operating as a successful business enterprise (Fig. 30-3). The #1 source of practice stress is the lack of efficient systems. When an endodontic practice operates year after year without strong systems, the endodontist experiences increased stress and frustration. On the other hand, endodontists who implement documented, high-performance systems enjoy greater satisfaction (and profitability) throughout their careers.

Endodontics is a challenging and rewarding profession. With the right systems, team training, and leadership skills, endodontists can achieve their vision and create a highly successful practice.

  in patients on chemotherapy/radiation therapy, 74–75
  sealer leakage, 364f
  soft tissue, 723–726
    clot formation, 724
    endothelial cells/angiogenesis, 725–726
    epithelium, 726
    fibroblasts/fibroplasia, 725
    inflammatory phase, 723–725
    macrophage organization, 725
wound healing *(Continued)*
    polymorphonuclear neutrophil organization, 724–725
    proliferative phase, 725–726
  systemic medications for, 727–728
    bisphosphonates, 727
    cyclooxygenase-2 (COX-2) inhibitors, 728
    glucocorticoids, 727–728
    nonsteroidal antiinflammatory drugs (NSAIDs), 728
  from ultrasound, 911f
woven bone formation, 726
wrong tooth errors, 177f

X

xenografts, 764t
xenon-133 radioisotopes, 226
x-ray exposure, 988
x-ray generators, 992
x-rays. *See* radiography
X-Tip system, 708f–709f, 709–710
xylene, 911–912, 912f

Y

Yamikoglu's and Kartal's canal configurations, 144f
Young modulus, 777

Z

zinc-oxide-Eugenol (ZOE) formula, 263–264, 269, 359–362, 359b–360b, 518, 753, 811, 825f, 834f–835f, 835–836, 837f–839f, 838
zinc phosphate cements, 786
zirconia-based crowns/inlays, 155
zirconium posts, 784, 905
zone of H_hl, 809
