VASCULAR SUPPLY
- Regulation of Pulpal Blood Flow
- Circulation in the Inflamed Pulp

PULPAL REPAIR

PULPAL CALCIFICATIONS

AGE CHANGES

From many perspectives, the pulp is a unique tissue. It is a soft tissue of mesenchymal origin with specialized cells, the odontoblasts, arranged peripherally in direct contact with dentin matrix. The close relationship between odontoblasts and dentin, sometimes referred to as the *dentin-pulp complex*,[115,278,342] is one of several reasons dentin and pulp should be considered as a functional entity made up of histologically distinct elements. In particular, several unique properties are imposed on the pulp by the rigid mineralized dentin in which it is enclosed. It is situated within a low-compliance environment that limits its ability to expand during episodes of vasodilation and increased filtration. Because the pulp is relatively incompressible, the total volume within the pulp chamber cannot be greatly increased (although reciprocal volume changes can occur among arterioles, venules, lymphatics, and extravascular tissue). *As a consequence, inflammatory reactions result in an increase in tissue pressure due to a limited increase in fluid volume.*[141,143] In the pulp, therefore, careful regulation of blood flow is of critical importance.

*The authors acknowledge the outstanding work of Drs. Henry Trowbridge, Syngcuk Kim, Hideaki Suda, David H. Pashley, and Fredrick R. Liewehr in previous editions of this text. The present chapter is built on their foundational work.

The dental pulp is in many ways similar to other connective tissues of the body, but its special characteristics deserve serious consideration. Even the mature pulp bears a resemblance to embryonic connective tissue and is therefore a relatively rich source of stem cells (see also Chapter 16). The pulp houses a number of tissue elements, including axons, vascular tissue, connective tissue fibers, ground substance, interstitial fluid, odontoblasts, fibroblasts, immunocompetent cells, and other cellular components. These components respond dynamically to developmental, physiologic (e.g., orthodontic or masticatory forces) or pathologic stimuli. The overall dynamic response pattern plays a key role in whether pulp tissue adapts or undergoes tissue necrosis to these stimuli (see also Chapter 13).

The pulp is supported by a microcirculatory system, and its largest vascular components are arterioles and venules. Unlike most tissues, the pulp lacks a true collateral system and is dependent on relatively few arterioles entering through the apical foramina. The vascular system of the pulp decreases progressively with age.[24]

The tooth pulp is a unique sensory organ. Because it is encased in a protective layer of dentin, which in turn is covered with enamel, it might be expected to be quite unresponsive to stimulation. However, despite the low thermal conductivity of dentin, the pulp is undeniably sensitive to thermal stimuli, such as ice cream and hot drinks. The unusual mechanism that allows the dentin-pulp complex[115,278,342] to function as an exquisitely responsive sensory system is discussed later in the chapter.

After tooth development, the pulp retains its ability to form dentin throughout life. This enables the vital pulp to partially compensate for the loss of enamel or dentin caused by mechanical trauma or disease. How well it serves this function depends on many factors, but the potential for regeneration and repair is as much a reality in the pulp as in other connective tissues of the body.

This chapter brings together what is known about the development, structure, and function of the dentin-pulp complex in the hope that this knowledge will provide a firm biologic basis for clinical decision making.

DEVELOPMENT

Embryologic studies have shown that the pulp is derived from the cephalic neural crest. Neural crest cells arise from the ectoderm along the lateral margins of the neural plate and migrate extensively. Those that travel down the sides of the head into the maxilla and mandible contribute to the formation of the tooth germs. The dental papilla, from which the mature pulp arises, starts to develop as ectomesenchymal cells proliferate and condense adjacent to the dental lamina epithelium (Fig. 12-1). It is important to remember this migratory potential of ectomesenchymal cells later in the chapter when reviewing the ability of pulp cells to move into areas of injury and replace destroyed odontoblasts.

During the sixth week of embryonic life, tooth formation begins as a localized thickening of ectoderm associated with the maxillary and mandibular processes. This activity results in the formation of two horseshoe-shaped structures, one on each process. These structures are termed the *primary dental laminae*. Each primary dental lamina splits into a vestibular and a dental lamina (Fig. 12-2).

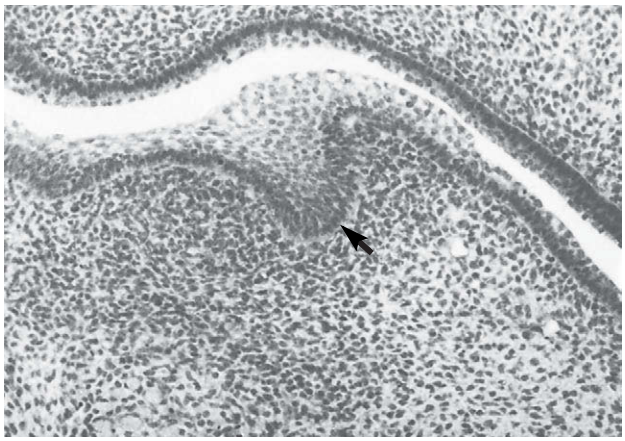

FIG. 12-1 Dental lamina *(arrow)* arising from the oral ectoderm.

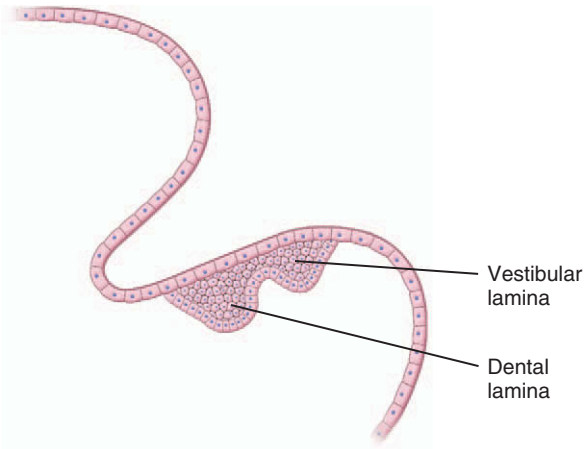

FIG. 12-2 Diagram showing formation of the vestibular and dental lamina from oral ectoderm.

Numerous studies have indicated that the embryonic development of any tissue is promoted by interaction with an adjacent tissue. The complex epithelial-mesenchymal interactions during tooth development have been studied extensively. Cell-to-cell and cell-to-extracellular matrix (ECM) interactions direct the differentiation of ameloblasts and odontoblasts by causing these cells to change gene expression.

Growth factors, often termed *signaling molecules,* are polypeptides that promote proliferation, migration, and differentiation of a variety of cells. It can be assumed that growth factors are involved in signaling during those epithelial-mesenchymal interactions that regulate tooth initiation, morphogenesis, and cell differentiation.[294,298-300,319-321]

From the onset of tooth formation, a dental basement membrane (DBM) exists between the inner dental epithelium and the dental mesenchyme. The DBM consists of a thin basal lamina, which is formed by the epithelial cells, and a layer of ECM derived from the dental mesenchyme. The basal lamina is made up of an elastic network composed of type IV collagen, which has binding sites for other basement membrane constituents such as laminin, fibronectin, and heparan sulfate proteoglycans. Laminin binds to type IV collagen and also to receptors on the surface of preameloblasts and ameloblasts.

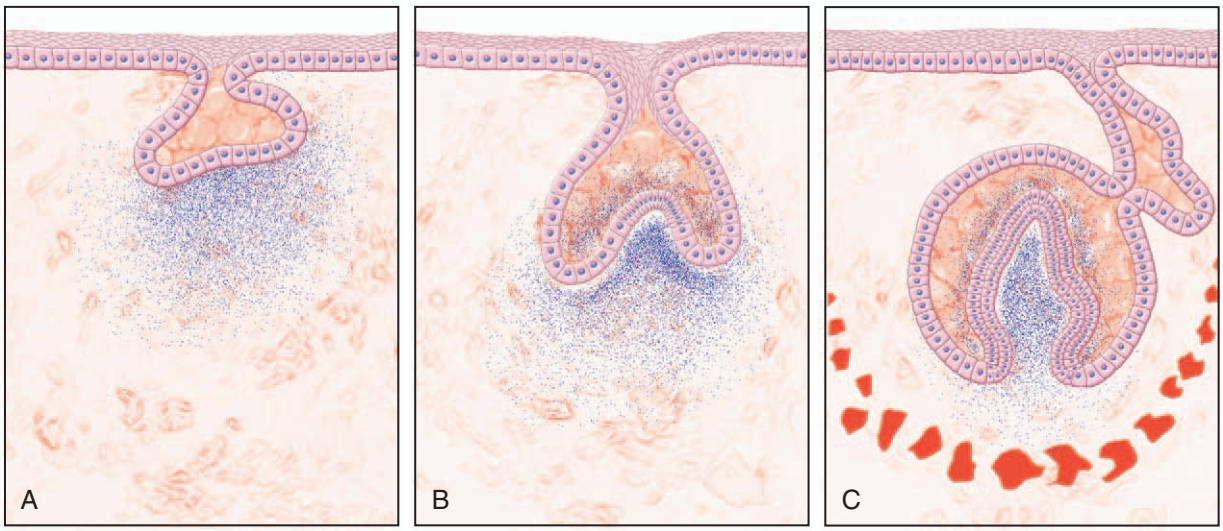

FIG. 12-3 Diagrammatic representation of **(A),** the bud, **(B),** the cap, and **(C)** the bell stages of tooth development.

The DBM also contains mesenchyme-derived type I and type III collagen, hyaluronate, heparan sulfate, and chondroitin 4- and 6-sulfates. Certain proteoglycans expressed on the cell surface of the odontoblast function as receptors for these matrix molecules. This permits signals from components of the matrix to influence the migration and differentiation of odontoblasts. The composition of the DBM changes during tooth development, and these alterations appear to modulate the successive steps in odontogenesis. With the differentiation of odontoblasts, type III collagen disappears from the predentin matrix, and fibronectin, which surrounds preodontoblasts, is restricted to the apical pole of mature odontoblasts.[196]

The initial stage of development of the dental papilla is characterized by proliferative activity beneath the dental lamina at sites corresponding to the positions of the prospective primary teeth. Even before the dental lamina begins to form the enamel organ, a capillary vascular network develops within the ectomesenchyme, presumably to support the increased metabolic activity of the developing tooth buds.

Stages of Development

Although formation of the tooth is a continuous process, as a matter of convenience tooth morphogenesis has been divided into three stages: (1) bud, (2) cap, and (3) bell (Fig. 12-3).[186] In the *bud stage* the epithelial cells of the dental lamina proliferate and produce a budlike projection into the adjacent ectomesenchyme. The *cap stage* is reached when the cells of the dental lamina have proliferated to form a concavity with a caplike appearance. The outer cells of the cap are cuboidal and constitute the outer enamel epithelium. The cells on the inner or concave aspect of the cap are somewhat elongated and represent the inner enamel epithelium. Between the outer and inner epithelia is a network of cells termed the *stellate reticulum* because of the branched reticular arrangement of the cellular elements. The rim of the enamel organ (i.e., where the outer and inner enamel epithelia are joined) is termed the *cervical loop*. As the cells forming the loop continue to proliferate, there is further invagination of the enamel organ into the mesenchyme. During this time, the organ assumes a bell shape, and tooth development then enters the *bell stage* (Fig. 12-4). During the bell stage, the ectomesenchyme of the dental papilla becomes partially enclosed by the invaginating epithelium.

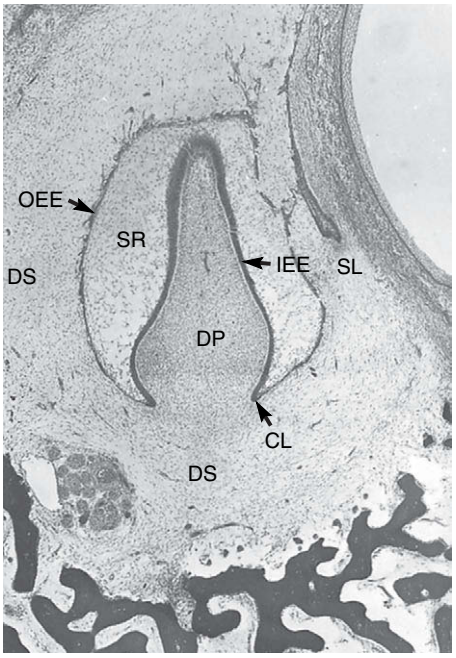

FIG. 12-4 Bell stage of tooth development showing the outer enamel epithelium (OEE), stellate reticulum (SR), inner enamel epithelium (IEE), dental papilla (DP), cervical loop (CL), successional lamina (SL), and dental sac (DS).

The condensed ectomesenchyme surrounding the enamel organ and dental papilla complex forms the dental sac and ultimately develops into the periodontal ligament (see Fig. 12-4). During the bell stage, the primary dental lamina degen-

erates and is invaded and replaced by mesenchymal tissue. In this way the epithelial connection between the enamel organ and the oral epithelium is severed. The free end of the dental lamina associated with each of the primary teeth continues to grow and forms the successional (secondary) dental lamina. It is from this structure that the tooth germ of the succedaneous tooth arises. As the maxillary and mandibular processes increase in size, the permanent first molar arises from posterior extensions of the dental lamina. After birth, the second and third molar primordia appear as the dental laminae proliferate into the underlying mesenchyme.

The morphogenesis (shape) of the crown is controlled by specialized signaling centers called *epithelial enamel knots* (EK). The enamel knots are transient clusters of nonproliferative epithelial cells located in the dental epithelium.[159,215,353] They express members of molecules belonging to key conserved fibroblast growth factor (Fgf), bone morphogenetic protein (Bmp), Hedgehog (Hh), and Wnt families that are well known to be essential for embryo and organ formation.[332] The signaling activity of the enamel knot and expressed molecules such as Fgf4 and Bmp4 regulate cellular processes of the surrounding epithelial and mesenchymal cells, leading to altered proliferation and expression of genes essential for tooth formation, such as transcription factors Mxs1 and Pax9.[172,354] The first appearing primary enamel knot (PEK) is present at the tip of the epithelial bud at the bud stage.[159] At the cap stage, the PEK is located in the middle part of the anterior-posterior axis of the enamel organ.[159,353] The secondary enamel knots (SEK), which appear later at the site of cusp tips, regulate the formation and number of the cusps of the multicusped teeth.[159] The recently found tertiary enamel knot (TEK) in turn prevents enamel formation by the underlying ameloblasts and thus controls the formation of the enamel-free areas in animals having these areas, such as mice.[215]

Development of the Tooth Nerve Supply

Peripheral innervation serves significant roles in pulp biology. The initial innervation of the tooth originates from the sensory trigeminal ganglia. The nerve fibers innervate specific sites in the adult tooth, and as a consequence, the development of dental innervation is not a random event but instead is a strictly spatiotemporally controlled process that is tightly linked to the advancing tooth morphogenesis and dental cell differentiation[173,209] (Fig. 12-5). In the well-analyzed mouse mandibular molar, the molar nerve[209] from the inferior alveolar nerve branch reaches the tooth at the early bud stage. The nerve follows a narrow mesenchymal pathway under the tooth germ, where it divides into the buccal and lingual branches.[173,209,243] During the cap and bell stages, nerve fibers establish a nerve plexus beneath the primary apical foramina. Nerve fibers wait here before they are allowed to enter the dental papilla. This takes place only after the crown shape is being defined by both dentin and enamel appearance in the crown.[237,238] The nerve fibers enter the papilla at both the mesial and distal ends, which are the sites of the future mesial and distal root of the molar tooth germ. The nerve fibers innervate the subodontoblastic region, the coronal odontoblast layer, and predentin layer with some fibers terminating in the dentin. The nerve fibers of the nerve plexus also contribute to the innervation of the periodontium.[146] Pioneer sympathetic innervation of the dental pulp follows the sensory one.[237]

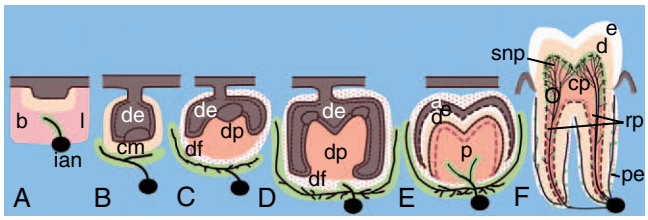

FIG. 12-5 Growth of the sensory trigeminal axons to the dental target areas during tooth formation. The schematic illustration is based on studies on the localization of nerve fibers in the developing mouse molar **(A-F).**[173,237,238] Pioneer dental axons follow a restricted mesenchymal pathway (*marked green in **B***) and grow around the developing tooth germ, termed the *mesenchymal dental follicle target field* (*green in **C-F***). Nerve fibers penetrate into the dental pulp (p) right after the onset of enamel formation **(E)** and innervate the major pulp-dentin border target area (*marked green in **F***). *a,* ameloblasts; *b,* buccal; *cm,* condensed dental mesenchyme; *cp,* coronal pulp; *d,* dentin; *de,* dental epithelium; *df,* dental follicle; *dm,* dental mesenchyme; *dp,* dental papilla; *e,* enamel; *ian,* inferior alveolar nerve; *l,* lingual; *o,* odontoblaster; *p,* dental pulp; *pe,* periodontium; *rp,* radicular pulp; *snp,* subodontoblastic nerve plexus; nerve fibers are marked in black. (*Modified from Kenntunen P, et al: Regularing av utvikling av tannens form og sensorisk nerveforsying er samordent. Nor Tannlaegeforen Tid 119:162–166, 2009.*)

Molecular Control of Trigeminal Axon Navigation

There is increasing evidence that the navigation of the growing dental axons involves concerted, redundant signaling activity by molecules of different families. The molecules exerting positive attractive effect on axon guidance or survival are expressed in the mesenchymal pathway or target areas around and within the tooth germ.[214] The molecules include neurotrophic factors, which promote survival, differentiation, and maintenance of neurons in developing and adult vertebrate nervous systems. NGF (nerve growth factor), which is essential for dental pulp nerve supply, and GDNF (glial cell line-derived neurotrophic factor) are expressed in the major target area of the developing tooth, namely the dental follicle and pulp-dentin border target areas. In addition, many other molecular families, such as laminins, neuregulin/ErbB, Ephs and Ncam are implicated in the development of the tooth nerve supply.[100,214]

Repulsive axon guidance molecules in turn, are produced in the areas next to the axon pathways. They control axon navigation by preventing nerve fibers from entering areas that should be avoided. The secreted chemorepellant, semaphorin3A (Sema3A), which is expressed in mesenchymal restriction areas,[173] controls dental trigeminal axon fasciculation as well as the timing and patterning of tooth innervation.[173] In addition, Sema3A appears to control the site of the nerve fiber penetration to the dental pulp (i.e., through the future roots).[216] Because Sema3A expression in mesenchymal restriction areas is controlled by signaling from the dental epithelium, this indicates that tooth innervation development, like the formation of the tooth germ proper, is controlled by local tissue interactions. Of note, Fgfr2b, which is essential to tooth morphogenesis by regulating epithelial proliferation and function of the enamel knot, also controls Sema3A expression and

therefore dental axon navigation. Thus, Fgf2b acts as a molecule that integrates tooth morphogenesis and dental trigeminal axon patterning.[197]

Differentiation of Odontoblasts

Differentiation of epithelial and mesenchymal cells into ameloblasts and odontoblasts, respectively, occurs during the bell stage of tooth development. This differentiation starts in the region where the cusp tip will develop and proceeds towards the cervical loop. The preameloblasts lining the dental papilla induce differentiation of odontoblasts. Consequently, odontoblast-secreted dentin matrix induces enamel secretion by ameloblasts.

During the bell stage of development, there is still mitotic activity among the relatively immature cells of the inner enamel epithelium in the region of the cervical loop. As they commence to mature into ameloblasts, mitotic activity ceases, and the cells elongate and display the characteristics of active protein synthesis (i.e., an abundance of rough endoplasmic reticulum [RER], a well-developed Golgi complex, and numerous mitochondria).

As the ameloblasts undergo differentiation, changes are taking place across the basement membrane in the adjacent dental papilla because of a coordinated exchange of growth factors and other soluble mediators. Before differentiation of odontoblasts, the dental papilla consists of sparsely distributed polymorphic mesenchymal stem cells with wide intercellular spaces (Fig. 12-6). With the onset of differentiation, a single layer of cells, the presumptive odontoblasts (i.e., preodontoblasts) align themselves along the basement membrane separating the inner enamel epithelium from the dental papilla. These cells stop dividing and elongate into short columnar cells with basally situated nuclei (Fig. 12-7). Several cytoplasmic projections from each of these cells extend toward the basal lamina. At this stage, the preodontoblasts are still relatively undifferentiated.

As the odontoblasts continue to differentiate, they become progressively more elongated and take on the ultrastructural characteristics of protein-secreting cells. Cytoplasmic processes from these cells extend through the DBM toward the basal lamina, and more and more collagen fibrils appear within the ECM. The first formed collagen fibers pass between the preodontoblasts and extend toward the basal lamina to form large, fan-shaped bundles 100 to 200 nm in diameter, often referred to as *von Korff fibers*. These fibers stain with silver stains and are associated with a high content of proteoglycans. Some smaller collagen fibers, approximately 50 nm in diameter, also pass between the odontoblasts and are thought to arise in the dental papilla subjacent to the odontoblasts.[29]

A study on collagen gene expression during rat molar tooth development found both types I and III collagen messenger

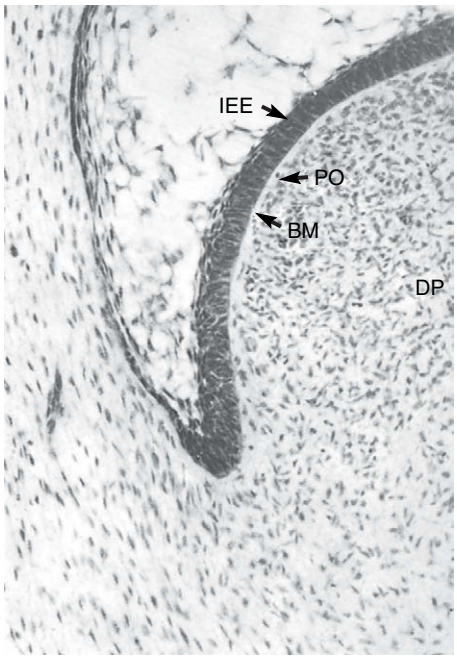

FIG. 12-6 Bell stage shows preodontoblasts (PO) aligned along the basement membrane (BM) separating the inner enamel epithelium (IEE) from the dental papilla (DP).

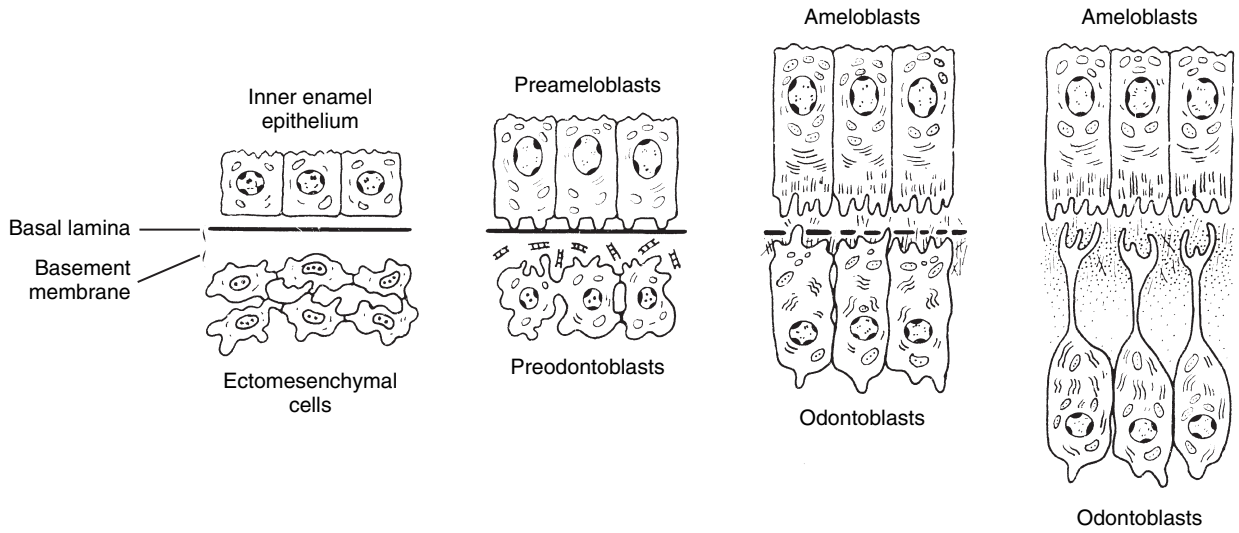

FIG. 12-7 Diagrammatic representation of the stages of odontoblast differentiation.

ribonucleic acid (mRNA) in developing odontoblasts.[75] Levels of type I collagen mRNA increased with the progression of odontoblast differentiation, whereas type III collagen gene expression decreased as dentinogenesis proceeded. Both type I and type III collagen mRNA were detected in dental pulp mesenchymal cells.

Dentinogenesis first occurs in the developing tooth at sites where the cusp tips or incisal edge will be formed. It is in this region that odontoblasts first reach full maturity and become tall columnar cells, at times attaining a height of about 50 µm (see Fig. 12-7). The width of these cells remains fairly constant at approximately 7 µm. Production of the initial dentin matrix involves the formation, organization, and maturation of collagen fibrils and proteoglycans. As predentin is formed, the odontoblasts commence to move toward the central pulp, depositing predentin at a rate of approximately 4 to 8 µm per day in their wake during early tooth development. Within predentin, a process from each odontoblast becomes accentuated and remains to form the odontoblast process. The dentinal tubules are formed around these cellular processes. Similar to tooth initiation and morphogenesis, dentinogenesis is controlled by epithelial-mesenchymal interactions that are mediated by a combination of EMC and signaling molecules of different families such as BMP and Tgf-β1.[197]

Root Development

Root development commences after the completion of enamel formation, when the cervical loop does not exist. The stellate reticulum and stratum intermedium cells disappear, and the inner and outer enamel epithelium in the distal part of the cervical loop forms Hertwig's epithelial root sheath (HERS), composed of two cell layers, the inner and outer enamel epithelium (Fig. 12-8). HERS determines the size and shape of the root or roots of the tooth. As in the formation of the crown, the cells of the inner enamel epithelium induce the adjacent mesenchymal stem cells in the pulp to differentiate into preodontoblasts and odontoblasts. As soon as the layer of dentin matrix mineralizes, gaps appear within the HERS-derived Malassez epithelium, allowing mesenchymal cells from the dental sac to move into contact with the newly formed dentin. These mesenchymal stem cells thereafter differentiate into cementoblasts and deposit cementum matrix on the root dentin. Some cells of the Malassez epithelium persist within the periodontal ligament and are known as the *epithelial cell rests of Malassez*. These clusters of epithelial cells surrounded by basement membrane appear as a meshlike network around the root. Although the number of these rests gradually decreases with age, it has been shown that at least some of them retain the ability to undergo cell division[347] (Fig. 12-9). In later life, if a chronic inflammatory lesion develops within the periapical tissues as a result of pulp disease, proliferation of the epithelial rests may produce a periapical (radicular) cyst.

Accessory Canals in the Root

Occasionally during formation of the root sheath, a break develops in the continuity of the sheath, producing a small gap. When this occurs, dentinogenesis does not take place adjacent to the defect. The result is a small "accessory" canal between the dental sac and the pulp. An accessory canal can become established anywhere along the root, creating a periodontal-endodontic pathway of communication and a possible portal of entry into the pulp if the periodontal tissues

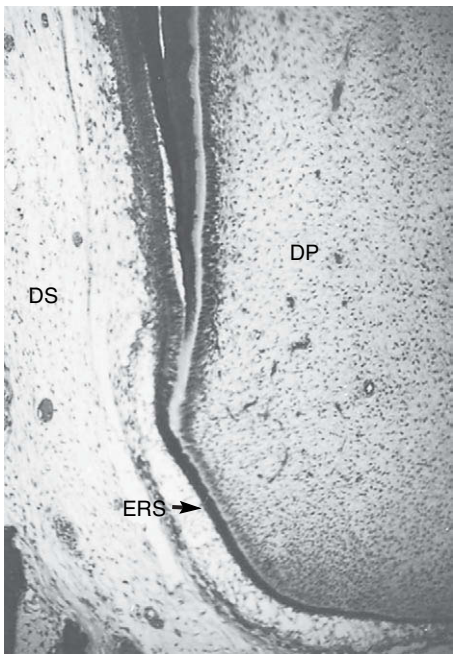

FIG. 12-8 Root development showing dental pulp (DP), dental sac (DS), and epithelial root sheath (ERS).

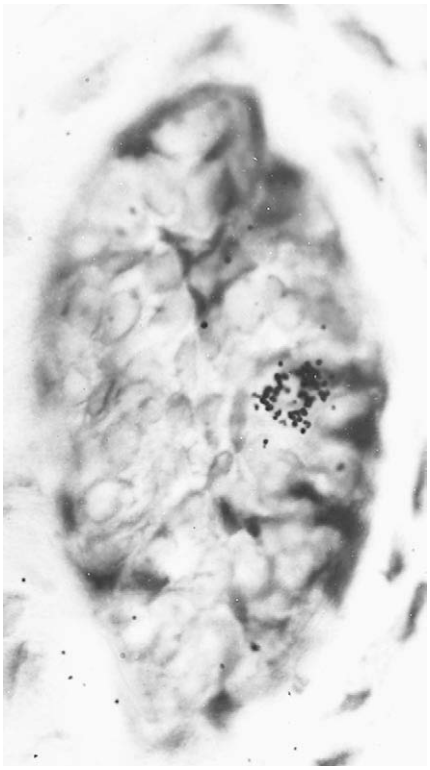

FIG. 12-9 Autoradiograph of an epithelial rest cell showing ^{3}H-thymidine labeling of the nucleus, indicating that the cell is preparing to divide. (*From Trowbridge HO, Shibata F: Mitotic activity in epithelial rests of Malassez.* Periodontics *5:109, 1967.*)

lose their integrity. In periodontal disease, the development of a periodontal pocket may expose an accessory canal and allow microorganisms or their metabolic products to gain access to the pulp. Conversely, in the case of teeth with infected, necrotic pulps, the inability to cleanse, shape, and obturate these canals could result in periodontitis (see also Chapter 18).

DENTIN

Fully mature dentin is composed of approximately 70% inorganic material, 20% organic material, and 10% water on a weight basis. The main inorganic component of dentin is calcium hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$.[204] Organic matrix consists of proteins, the most common of which is type I collagen; there is a minor component of type V collagen.[43] The most common noncollagenous proteins include dentin phosphoprotein (DPP), dentin matrix protein 1 (DMP1), dentin sialoprotein (DSP), osteopontin (OPN), osteocalcin, and bone sialoprotein (BSP).[43] In addition, dentin contains proteoglycans, small amounts of phospholipids, and numerous growth factors, including bone morphogenetic proteins (BMP), insulin-like growth factors (IGFs), and transforming growth factor beta (TGF-β). These growth factors have significance during demineralization of dentin since they may locally stimulate subsequent stem cell differentiation (see later and Chapter 16). The elasticity of dentin provides flexibility for the overlying brittle enamel and allows the impact of mastication to occur without fracturing enamel.[183,184,369] From an engineering perspective, the collagen can be thought of as steel rebar, and the mineralized crystals act as cement; the resulting composite structure has great tensile strength, particularly given its small size. Additionally, the enamel-dentin junction (EDJ) between dentin and enamel is an uneven scalloped border that increases contact and adherence between dentin and enamel, keeping the two hard tissues together during mastication.

Primary, Secondary, and Tertiary Dentin

Primary dentin is produced during tooth development until the teeth have erupted into the oral cavity. It is classified as *orthodentin,* the tubular form of dentin lacking of cells found in the teeth of all dentate mammals.[204] The primary dentin is secreted at a relatively high rate and constitutes the major part of the dentin in the tooth. It is regular in structure and contains dentin tubules that form an S-shaped primary curvature as a result of the directional movement of odontoblasts, which have a cell process that extends from a broad peripheral border towards a narrow, centrally located cell layer. After tooth eruption, the odontoblasts continue to lay down dentin but slightly change their direction, which contributes to bending of the dentinal tubules. It is referred to as *secondary dentin* and is synthesized at a much lower rate and is less regular in structure than primary dentin. Secondary dentin is deposited during the rest of the tooth's life. Unlike primary and secondary dentin, *tertiary dentin,* or reparative or reactionary dentin, is deposited as a result of a pathologic process such caries or occlusal abrasion. Tertiary dentin has been suggested to be secreted by original odontoblasts or in case of their death, by newly differentiated replacement odontoblasts originating from nearby mesenchymal stem cells. The function of the tertiary dentin is to protect the pulp from noxious influences. Tertiary dentin is disorganized in structure compared to primary and secondary dentin.

Mantle Dentin

The first layer of the primary dentin to be deposited is mantle dentin. It is produced by odontoblasts that are not yet fully differentiated. In the adult tooth, mantle dentin is the oldest dentin and is produced adjacent to the enamel in the crown. Odontoblasts first produce the collagen components, which are organized in a collagen fibril network. Electron microscopic analyses have shown that odontoblasts produce small membrane-closed matrix vesicles where precipitation of minerals starts.[33] After the rupture of the matrix vesicles, the crystals spread within the collagen matrix and are assumed to act as starting points for the growth of the apatite crystals. In addition to the crown, mantle dentin is also found in the root between cementum and Tomes granular layer. However, this is a controversial finding, and opposing data suggest that a hyaline layer or enameloid is found in the root instead of mantle dentin.

Later during the mineralization of the circumpulpal dentin, the matrix vesicles are no longer detected.[205] Mantle dentin can be recognized by the characteristic thick, fan-shaped collagen fibers deposited immediately subjacent to the basal lamina in histologic sections. These fibers run roughly perpendicular to the DEJ. Spaces between the fibers are occupied by smaller collagen fibrils lying more or less parallel with the DEJ or CDJ. Mantle dentin is only 150 µm thick and is slightly less mineralized (about 4% less mineral) than underlying dentin[139] and is therefore softer.[369] The mineralization of the mantle dentin may differ from mineralization of the rest of the dentin additionally, since dentinphosphoprotein (DPP), which regulates crystal growth in the circumpulpal dentin, does not appear to be present in mantle dentin.[246]

Circumpulpal Dentin

Circumpulpal dentin is formed after the layer of mantle dentin has been deposited, and it constitutes the major part of primary and secondary dentin. The odontoblasts first deposit the organic matrix, which is composed mainly of collagen fibrils approximately 500 nm in diameter, oriented at right angles to the long axis of the dentinal tubules. These collagen fibrils are closely packed together and form an interwoven network that will be embedded by the subsequent mineral crystals. Calcium is actively transported from the blood vessels by the odontoblasts into the collagen fibril template/network. There is evidence that mineralization of the dentin is under control of dentinphosphoprotein (DPP). DPP is able to bind calcium, since it is highly anionic. Conformational changes of DPP enable it to bind large numbers of calcium ions, which allows the formation and growth of mineral crystals in the collagen matrix network. By regulating the release and concentration of DPP, the odontoblasts may regulate the initiation and speed of dentin mineralization. Hydroxyapatite crystals are deposited on the surface and within the fibrils and continue to grow as mineralization proceeds, resulting in an increased mineral content of the dentin. The circumpulpal dentin is mineralized through calcospherites in the mineralization front between predentin and mineralizing dentin. The mineral crystals are organized in a radiating pattern in calcospherites, the size of which may vary in size and shape in different regions of dentin.

As the calcospherites enlarge, they fuse with adjacent calcospherites until the dentin matrix is completely mineralized.

Predentin

Predentin is a 15- to 20-μm unmineralized organic matrix layer of dentin situated between the odontoblast layer and the mineralized dentin.[204] Its prime protein constituents include type I and type II collagens.[42] Noncollagenous elements consist of several proteoglycans (i.e., dermatan sulfate, heparan sulfate, hyaluronate, keratin sulfate, chondroitin 4-sulfate, chondroitin 6-sulfate),[40,117] glycoproteins, glycosaminoglycans (GAGs),[83] Gla proteins, and dentin phosphoprotein (DPP)[42] DPP is a highly phosphorylated protein that is exclusively found in bone and dentin.[290] In dentin, DPP is produced by the odontoblasts and transported to the mineralization front. It is thought to bind to calcium and play a role in mineralization.[109,359] Growth factors such as TGF-β, insulin-like growth factor, platelet-derived growth factor, and angiogenic growth factor have also been identified in dentin.[294] The presence of growth factors in dentin may have profound clinical significance because resorption of dentin conceivably releases these growth factors into pulp, where they alter biologic functions of this tissue. Dentinal resorption may stimulate formation of tertiary dentin.

TABLE 12-1

Mean Number and Diameter per Square Millimeter of Dentinal Tubules at Various Distances from the Pulp in Human Teeth

Distance from Pulp (mm)	Number of Tubules (1000/mm²)		Tubule Diameter (μm)	
	Mean	Range	Mean	Range
Pulpal wall	45	30–52	2.5	2.0–3.2
0.1–0.5	43	22–59	1.9	1.0–2.3
0.6–1.0	38	16–47	1.6	1.0–1.6

(From Garberoglio R, Brännström M: Scanning electron microscopic investigation of human dentinal tubules. *Arch Oral Biol* 21:355, 1976.)

Dentinal Tubules

A characteristic of human dentin is the presence of tubules that occupy from 1% (superficial dentin) to 30% (deep dentin) of the volume of intact dentin.[107,277] The diameter of tubules vary from 1 μ to 2.5 μm and traverse the entire thickness of dentin from the DEJ or CDJ to the pulp. They are slightly tapered, with the wider portion situated toward the pulp. This tapering is the result of the progressive formation of up to 1 μm of peritubular dentin, which leads to a continuous decrease in the diameter of the lumen of the tubules to a final diameter of about 1 mm.[107] No peritubular dentin is present when the tubules reach the predentin and pulp chamber.

In coronal dentin, the tubules have a gentle S shape as they extend from the DEJ to the pulp. The S-shaped curvature is presumably a result of the crowding of odontoblasts as they migrate toward the center of the pulp. As they approach the pulp, the tubules converge because the surface of the pulp chamber has a much smaller area than the surface of dentin along the DEJ. This results in a progressive increase in dentin permeability (discussed later).[275-277,279]

The number and diameter of the tubules has been determined and varies depending on the location in the tooth (Table 12-1).[107] The number and diameter of dentinal tubules are similar among rats, cats, dogs, monkeys, and humans, demonstrating a remarkable consistency in mammalian orthodentin.[4]

Lateral microtubules containing branches of the main odontoblastic processes have been demonstrated by other researchers,[167,236] who suggested that they form pathways for the movement of materials between the main processes and the more distant matrix. It is also possible that the direction of the branches influences the orientation of the collagen fibrils in the intertubular dentin.

Near the DEJ, the dentinal tubules ramify into one or more terminal branches[236] (Fig. 12-10). This occurs because during the initial stage of dentinogenesis, the differentiating odontoblasts extended several small cytoplasmic processes toward the DEJ, but as the odontoblasts migrated, their processes converged into one major process (see Fig. 12-7).

Intertubular Dentin

Intertubular dentin is located between the dentin tubules and constitutes the bulk of dentin (Fig. 12-11). Its organic matrix consists mainly of collagen fibrils having diameters of 50 to 100 nm. These fibrils are oriented approximately at right angles to the dentinal tubules. They are well mineralized and provide tensile strength to dentin.[184] Intertubular dentin is found between the DEJ and the mineralization front.[204]

Intratubular Dentin

Dentin lining the inner walls of tubules is termed *intratubular* or *peritubular dentin* (see Fig. 12-11). Intratubular dentin represents a specialized form of orthodentin not found in all mammals. The matrix of peritubular dentin differs from that of intertubular dentin by having relatively fewer collagen fibrils and a higher proportion of sulfated proteoglycans and mineral. Because of its lower content of collagen,[183,374] peritubular dentin is harder than intertubular dentin and therefore is more quickly dissolved in acid than intertubular dentin. By preferentially removing peritubular dentin, acid-etching agents used during dental restorative procedures and ethylenediaminetetraacetic acid (EDTA) used in endodontic treatment enlarge the openings of the dentinal tubules, making the dentin more permeable. The absence of intrafibrillar mineral in patients with dentinogenesis imperfecta type II may be responsible for their softer dentin.[185]

Dentinal Sclerosis

Partial or complete obturation of dentinal tubules may occur as a result of aging or develop in response to persistent stimuli such as attrition of the tooth surface or dental caries. When

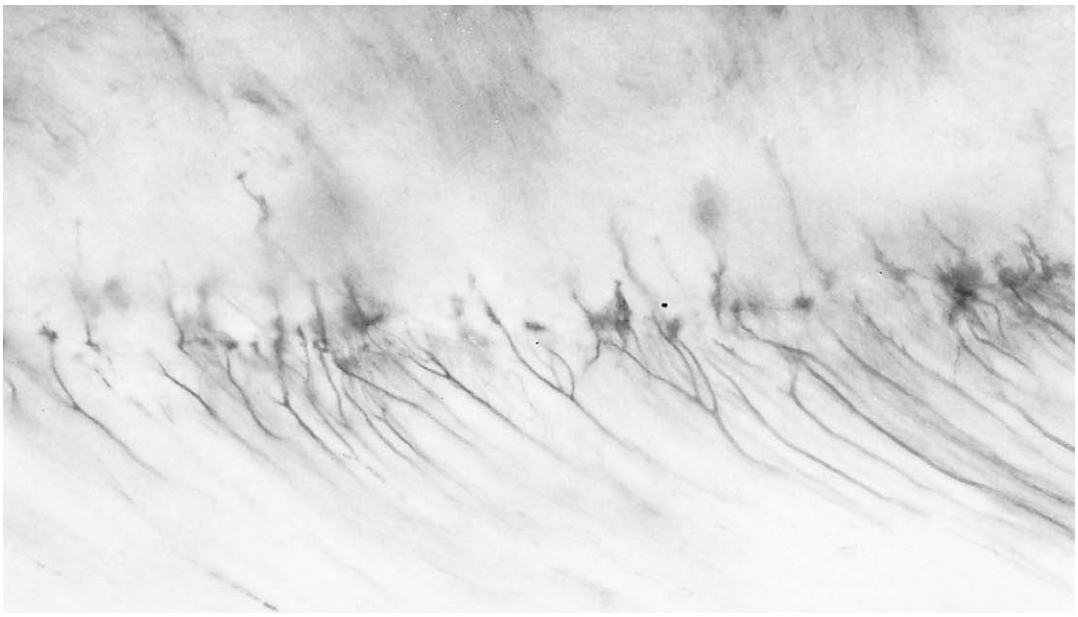

FIG. 12-10 Ground section of a tooth demonstrating branching of the dentinal tubules near the dentin and enamel junction (DEJ). This branching may account for the increased clinical sensitivity at the DEJ.

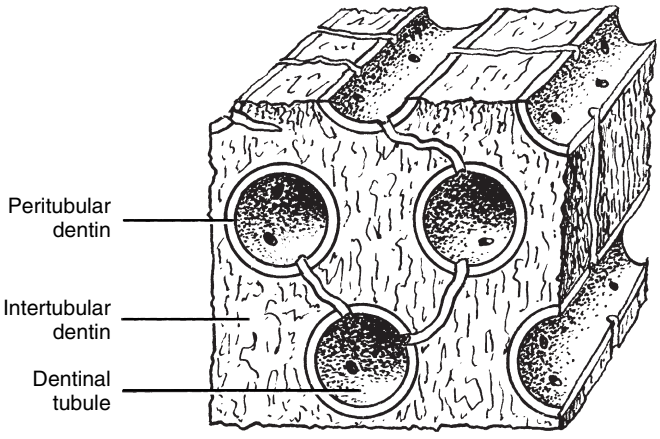

FIG. 12-11 Diagram illustrating peritubular and intertubular dentin. *(From Trowbridge HO: Dentin today: research reveals new information about the complexity of dentin.* Dentistry *2:22–29, 1982.)*

tubules become filled with mineral deposits, the dentin is termed *sclerotic*. Dentinal sclerosis is easily recognized in histologic ground sections because of its translucency (due to homogeneity of the dentin). Studies using dyes, solvents, and radioactive ions have shown that sclerosis results in decreased permeability of dentin,[92,276,328] so by limiting the diffusion of noxious substances through the dentin, dentinal sclerosis helps shield the pulp from irritation.

One form of dentinal sclerosis is thought to represent an acceleration of intratubular dentin formation. This form appears to be a physiologic process, and in the apical third of the root it develops as a function of age.[323,328] Dentinal tubules can also become blocked by the precipitation of hydroxyapatite and whitlockite crystals within the tubules. This type occurs in the translucent zone of carious dentin and in attrited dentin and has been termed *pathologic sclerosis*.[263,328,371]

Interglobular Dentin

Interglobular dentin refers to dentin that contains organic matrix that is unmineralized because the growing calcospherites failed to coalesce. This occurs most often in the circumpulpal dentin close to the mantle dentin in the crown and close to the Tomes granular layer in the root. In certain dental anomalies (e.g., vitamin D–resistant rickets, hypophosphatasia), large areas of interglobular dentin are a characteristic feature (Fig. 12-12).[108]

Dentinal Fluid

Free fluid occupies 1% of superficial dentin but about 22% of the total volume of deep dentin (i.e., near the pulp).[277] This fluid is an ultrafiltrate of blood from the pulp capillaries, and its composition not surprisingly resembles plasma in many respects.[61] Using calcium ion–specific electrodes, the ionized calcium concentration of dentinal fluid in predentin was two to three times higher than plasma.[212] Although it contains plasma proteins, their concentration is only about 10% that of plasma.[219] The outward fluid flows between the odontoblasts through the dentinal tubules and is blocked peripherally by enamel on the crown and cementum on the root. It has been shown that the tissue pressure of the pulp is approximately 14 cm H_2O (10.3 mm Hg).[67] Consequently, a pressure gradient exists between the pulp and the oral cavity that accounts for the slow outward flow of fluid if any dentin becomes exposed. Exposure of the tubules by tooth fracture or during cavity preparation often results in the outward movement of fluid to the exposed dentin surface in the form of tiny droplets.[157] Dehydrating the surface of the dentin with compressed air, dry heat, or the application of absorbent paper can accelerate this outward movement of fluid.[37-39,274] Rapid flow of fluid through the tubules is thought to be a cause of dentin sensitivity.[230] The slow outward movement of dentinal fluid is not sufficient to activate the mechanoreceptor nerves responsible for dentin

FIG. 12-12 Section showing interglobular dentin (ID) in a deciduous incisor from a 3-year-old boy with childhood hypophosphatasia.

sensitivity. This slow outward fluid flow, about 0.02 ml/sec/mm^2, must increase to 1 to 1.5 ml/sec/mm^2 before these nerves begin to discharge.[230]

Bacterial products or other contaminants may be introduced into the dentinal fluid as a result of dental caries, restorative procedures, or growth of bacterial biofilms beneath restorations.[37,234,284] Dentinal fluid may thus serve as a sink from which injurious agents can diffuse into the pulp, producing an inflammatory response. Conversely, dentinal fluid may serve as a vehicle for the egress of bacteria from a necrotic pulp into the periradicular tissue. This has particular significance in the apical portion of the root canal system in the development or maintenance of apical periodontitis because bacteria are the key etiologic factor (see Chapter 15). Fortunately, the density of dentinal tubules is much lower in the apical portion of the root compared to the cervical portion, and this anatomic feature may contribute to the success of nonsurgical root canal treatment. In addition, endodontic surgical techniques have been modified to reduce exposure of dentinal tubules during apical root resection by reducing the angle of root resection; as the angle of resection approaches 90 degrees to the long axis of the root, a corresponding decrease is seen in dentinal tubules exposed to the periapical tissue (see Chapter 21 for details).

Dentin Permeability

The permeability of dentin has been well characterized.[92,97,274-277,279,282] Dentinal tubules are the major channels for diffusion of material across dentin. Because fluid permeation is proportional to tubule diameter and number, dentin permeability increases as the tubules converge on the pulp (Fig. 12-13). The total tubular surface near the DEJ is approximately 1% of the total surface area of dentin,[274,277] whereas close to the pulp chamber, the total tubular surface may be nearly 45%. From a clinical standpoint, it should be recognized that dentin beneath a deep cavity preparation is much more permeable than dentin underlying a shallow cavity when the formation of sclerotic or reparative dentin is negligible.

One study[97] found that the permeability of radicular dentin is much lower than that of coronal dentin. This was attributed to a decrease in the density of the dentinal tubules from approximately 42,000/mm^2 in cervical dentin to about 8000/mm^2 in radicular dentin. These investigators found that fluid movement through outer radicular dentin was only approximately 2% that of coronal dentin. The low permeability of outer radicular dentin should make it relatively impermeable to toxic substances such as bacterial products emanating from plaque.

Factors modifying dentin permeability include the presence of odontoblast processes in the tubules and the sheathlike lamina limitans that lines the tubules. Collagen fibers have also been observed in most tubules.[71] The functional or physiologic diameter of the tubules is only about 5% to 10% of the actual anatomic diameter (i.e., the diameter seen in microscopic sections).[233] This is small enough to trap and remove bacteria from dentinal fluid,[234] permitting sterile fluid to enter the pulp chamber.

In dental caries, an inflammatory reaction develops in the pulp long before the pulp actually becomes infected with micorganisms.[345] This indicates that bacterial byproducts reach the pulp in advance of the bacteria themselves,[19,284] and the early inflammatory response is elicited by the accumulation of bacterial antigens or byproducts into the pulp, not by the bacteria themselves. Dentinal sclerosis (i.e., reparative dentin formation) beneath a carious lesion reduces permeability[328] by obstructing the tubules, thus decreasing the delivery of irritants into the pulp.

The cutting of dentin during cavity preparation or root canal therapy produces a microcrystalline debris that coats the dentin and clogs the orifices of the dentinal tubules. This layer of debris is termed the *smear layer*. Because of the small size

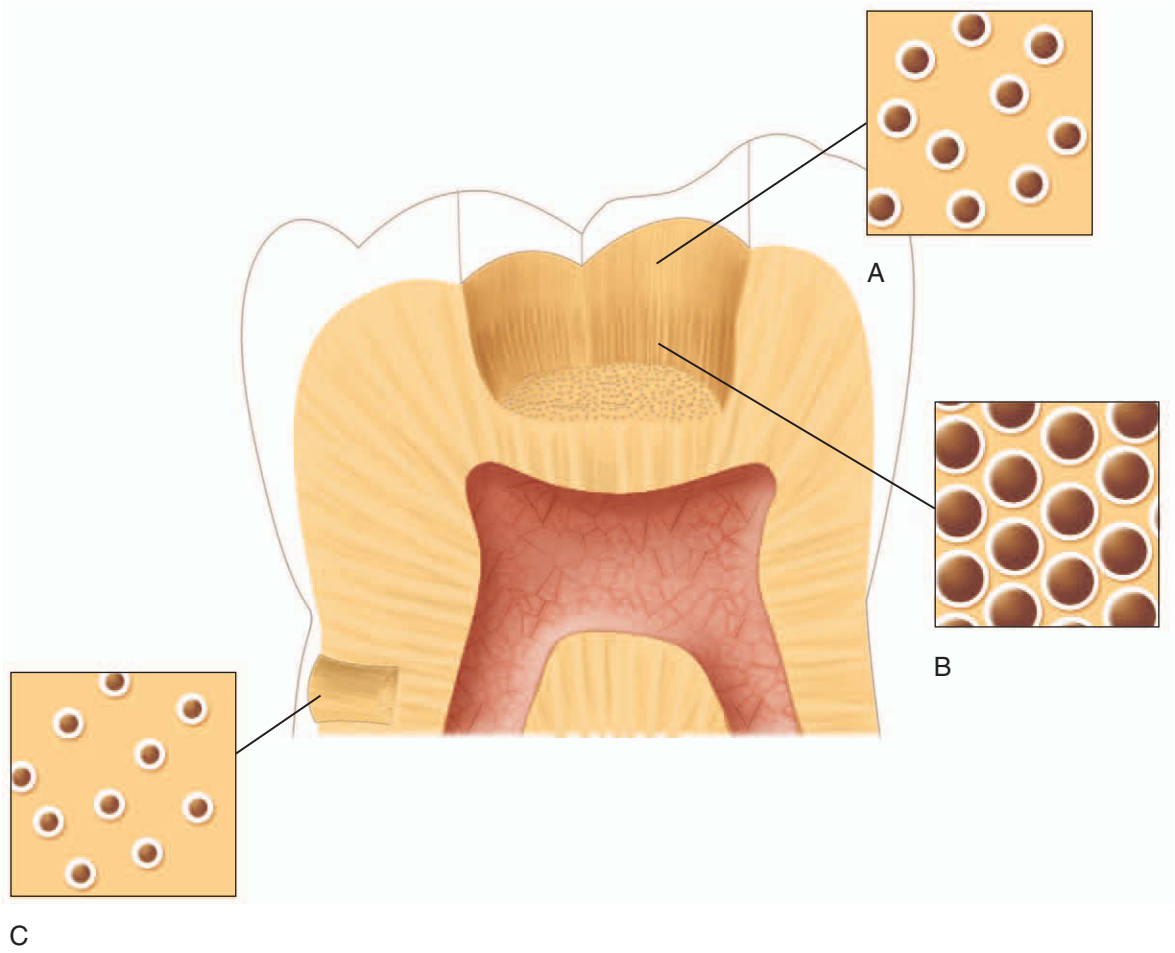

FIG. 12-13 Diagram illustrating the difference in size and density of tubules in the dentinal floor between a shallow **(A)** and a deep **(B)** cavity preparation, in coronal dentin versus **(C)** root dentin. *(Redrawn from Trowbridge HO: Dentin today: research reveals new information about the complexity of dentin.* Dentistry *22:22–29, 1982.)*

of the particles, the smear layer is capable of physically preventing bacteria from penetrating dentin.[234,244] Removal of the debris by acid etching or EDTA greatly increases the permeability of the dentin by widening the orifices of the tubules. Consequently, the incidence of pulpal inflammation may be increased significantly if cavities are treated with an acid cleanser unless a cavity liner, base, or dentin-bonding agent is used. Continued pulpal protection will then depend on the durability of the bond.

When the dentin surface of vital and nonvital teeth was exposed to the oral environment for 150 days, bacterial invasion of dentinal tubules occurred more rapidly in the nonvital teeth.[244] Presumably this was due to the resistance offered by the outward movement of dentinal fluid and the presence of odontoblast processes in the tubules of vital teeth.[280,361,362] Importantly, it has been shown that antibodies or other antimicrobial components are present within the dentinal fluid of teeth with vital pulps.[125]

MECHANICAL PROPERTIES OF ROOT DENTIN

Endodontic therapy has long been criticized for "weakening" teeth, especially roots, possibly making them more prone to fracture. Although some investigators have proposed that endodontically treated root dentin was more "brittle" than normal vital teeth,[80] subsequent punch shear tests of endodontically treated teeth showed only a 14% reduction in dentin toughness compared with vital dentin.[57] The controversy began when the moisture content of pulpless dog teeth was reported to be 9% less than that of vital controls.[137] However, endodontic therapy was shown not to change the Vickers hardness of human root dentin.[199] Much of the increased incidence of coronal fractures of endodontically treated teeth can be attributed to the loss of tooth structure produced by preparing adequate access openings.[152] Similarly, root fractures in endodontically treated teeth are in part due to physical weakening of roots by creation of post spaces.[123,156] In addition, fatigue life studies have shown that dentin from old patients has a much shorter fatigue life than dentin from young teeth.[15] The perceived increased incidence of root fractures in endodontically treated teeth may actually reflect a slow, spontaneous reduction in the fracture toughness of old dentin,[11] regardless of root canal treatment.

Any occlusal stress applied to the coronal dentin is magnified in the root because it has a smaller volume and cross-sectional area. Collagen in the dentin matrix does not turn over metabolically, so it is never repaired and may accumulate microcracks over decades of function. When collagen is

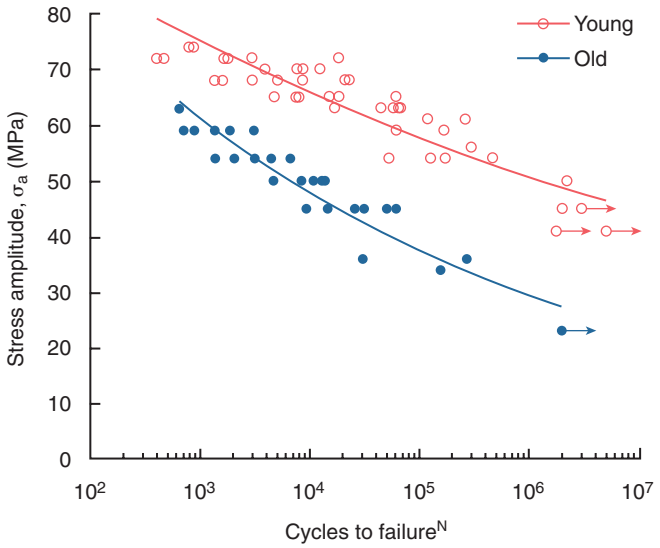

FIG. 12-14 The fatigue life diagram for cyclic loading of coronal dentin using 4-point flexure. The young dentin (average age = 25 years) and old dentin (average age = 62 years) were obtained from fully erupted second and third molars. secreted into the forming dentin matrix, a number of noncollagenous proteins are secreted at the same time, some of which bind to collagen. For instance, dentin sialoprotein (DSP),[42,116] dentin phosphophoryn (DPP),[42,70,75] and matrix metalloproteinases (MMPs)[336] are all known to bind to collagen. MMPs such as gelatinase A have been extracted from dentin in their active form.[225] More recently, both collagenolytic activity and gelatinolytic activity have been measured in mineralized dentin powder.[281] These enzymes may slowly attack the collagenous matrix of dentin, thereby weakening it over many decades. The mineralized dentin surrounding post spaces in roots that had been under function for more than 10 years was shown to be disrupted and fragmented.[89] Functional stresses may cause microcracking of dentin in a manner similar to that seen in cortical bone.[358] Fatiguing of roots over decades[226,247,248] may be responsible for the fractured roots in endodontically treated teeth in older patients. Fatigue life experiments show that old coronal dentin tolerates fewer loading cycles before fracture (Fig. 12-14) than young dentin.[15] If this is confirmed in root dentin, and if the mechanism or mechanisms responsible for this increased susceptibility to fatiguing can be identified, then effective interventions may be developed to increase the fatigue life of roots that have been endodontically treated.

MORPHOLOGIC ZONES OF THE PULP

The Pulp-Dentin Complex

The dental pulp and dentin function as a unit, and the odontoblasts represent a crucial element in this system. The odontoblasts are located in the periphery of the pulp tissue, with extensions into the inner part of dentin. Dentin would not exist unless produced by odontoblasts, and the dental pulp is dependent on the protection provided by the dentin and enamel. Likewise, integrated dynamics of the pulp-dentin complex imply that impacts on dentin may affect the pulpal components, and that disturbances in the dental pulp will in turn affect the quantity and quality of the dentin produced.

Odontoblast Layer

The outermost stratum of cells of the healthy pulp is the odontoblast layer (Figs. 12-15 and 12-16). This layer is located immediately subjacent to the predentin. The odontoblast processes, however, pass on through the predentin into the inner part of dentin. Consequently, the odontoblast layer is actually composed of the cell bodies of odontoblasts. In addition, capillaries, nerve fibers, and dendritic cells may be found among the odontoblasts.

In the coronal portion of a young pulp that is actively secreting collagen, the odontoblasts assume a tall columnar form.[63] The odontoblasts vary in height; consequently, their nuclei are not all at the same level and are aligned in a staggered array, often described as a palisade appearance. This organization makes the layers appear to be three to five cells in thickness even though there is only one actual layer of odontoblasts. Between adjacent odontoblasts there are small intercellular spaces approximately 30 to 40 nm in width. Odontoblast cell bodies are connected by tight and gap junctional complexes.[30,63,149] Gap junctions are formed by connexin proteins[110] that permit cell-to-cell passage of signal molecules.

The odontoblast layer in the coronal pulp contains more cells per unit area than in the radicular pulp.[224] Whereas the odontoblasts of the mature coronal pulp are usually columnar, those in the midportion of the radicular pulp are more cuboidal (Fig. 12-17).[63] Near the apical foramen, the odontoblasts appear as a squamous layer of flattened cells. Because fewer dentinal tubules per unit area are present in the root than in the crown of the tooth, the odontoblast cell bodies are less crowded and are able to spread out laterally.[224] During maturation and aging, there is a continued ongoing crowding in the odontoblast layer, particularly in the coronal pulp, due to narrowing of the pulp space. Apoptosis of odontoblasts seems to adjust for this limited space during development.[235]

There are a series of specialized cell-to-cell junctions (i.e., junctional complexes), including desmosomes (i.e., zonula adherens), gap junctions (i.e., nexuses), and tight junctions (i.e., zonula occludens) that connect adjacent odontoblasts. Spot desmosomes located in the apical part of odontoblast cell bodies mechanically join odontoblasts together. The numerous gap junctions provide permeable pathways through which signal molecules can pass between cells (Fig. 12-18) to synchronize secretory activity that produces relatively uniform predentin layers (see Fig. 12-16). These junctions are most numerous during the formation of primary dentin. Gap junctions and desmosomes have also been observed joining odontoblasts to the processes of fibroblasts in the subodontoblastic area. Tight junctions are found mainly in the apical part of odontoblasts in young teeth. These structures consist of linear ridges and grooves that close off the intercellular space. However, tracer studies suggest direct passage of small elements from subodontoblastic capillaries to predentin and dentin between the odontoblasts.[330] It appears that tight junctions determine the permeability of the odontoblast layer when dentin is covered by enamel or cementum by restricting the

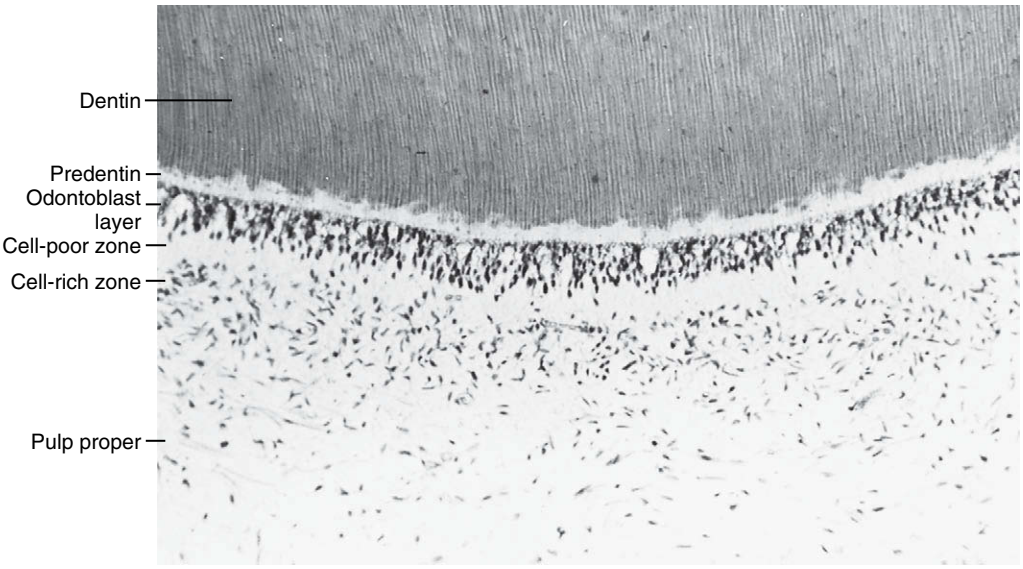

FIG. 12-15 Morphologic zones of the mature pulp.

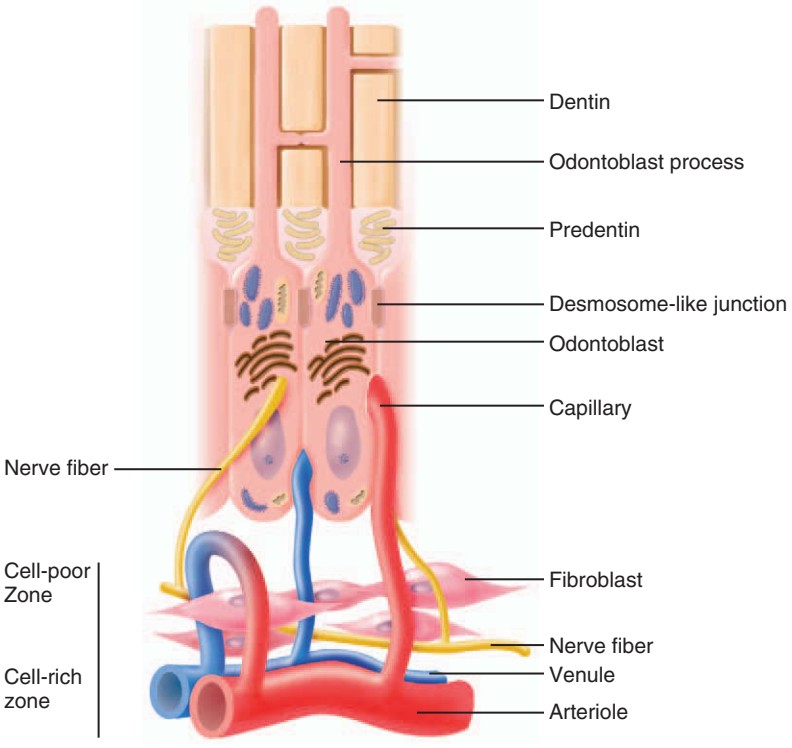

FIG. 12-16 Diagrammatic representation of the odontoblast layer and subodontoblastic region of the pulp.

passage of molecules, ions, and fluid between the extracellular compartments of the pulp and predentin.[30] During cavity preparation, these junctions are disrupted, thereby increasing dentin permeability.[350,351]

Cell-Poor Zone

Immediately subjacent to the odontoblast layer in the coronal pulp, there is often a narrow zone approximately 40 µm in width that is relatively free of cells (see Fig. 12-15) and hence is called the *cell-free layer of Weil*. It is traversed by blood capillaries, unmyelinated nerve fibers, and the slender cytoplasmic processes of fibroblasts (see Fig. 12-16). The presence or absence of the cell-poor zone depends on the functional status of the pulp.[63] It may not be apparent in young pulps, where dentin forms rapidly, or in older pulps, where reparative dentin is being produced.

Cell-Rich Zone

In the subodontoblastic area, there is a stratum containing a relatively high proportion of fibroblasts compared with the

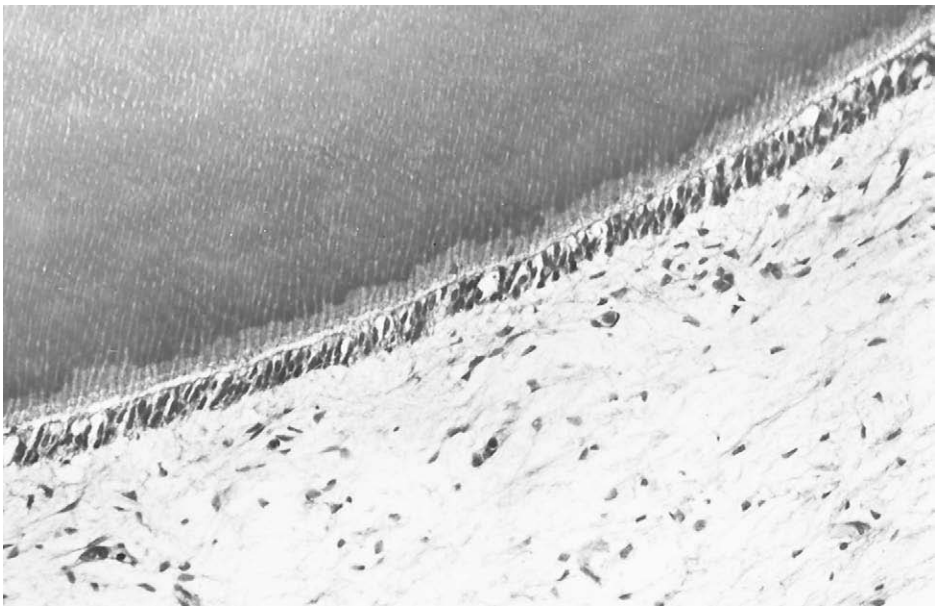

FIG. 12-17 Low columnar odontoblasts of the radicular pulp. The cell-rich zone is inconspicuous.

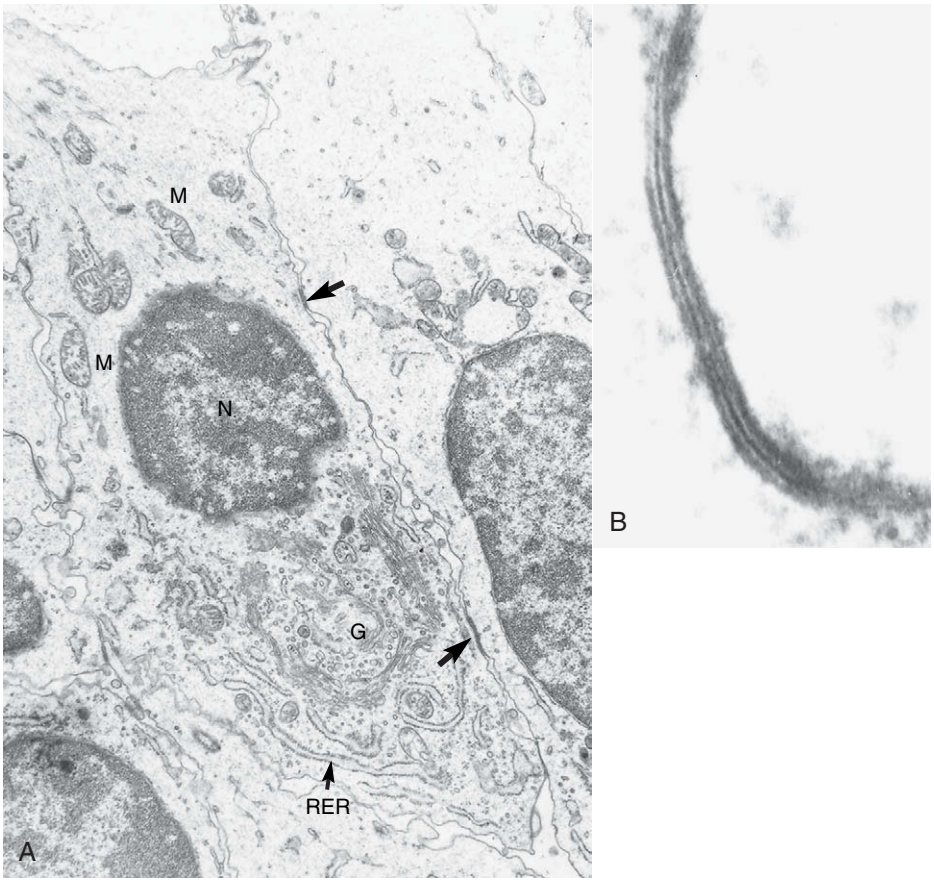

FIG. 12-18 A, Electron micrograph of a mouse molar odontoblast demonstrating gap junctions *(arrows)*, nucleus (N), mitochondria (M), Golgi complex (G), and rough endoplasmic reticulum (RER). **B,** High magnification of a section fixed and stained with lanthanum nitrate to demonstrate a typical gap junction. *(Courtesy Dr. Charles F. Cox, School of Dentistry, University of Alabama.)*

more central region of the pulp (see Fig. 12-15). It is much more prominent in the coronal pulp than in the radicular pulp. Besides fibroblasts, the cell-rich zone may include a variable number of immune cells like macrophages and dendritic cells, but also undifferentiated mesenchymal stem cells.

On the basis of evidence obtained in rat molar teeth, it has been suggested[119] that the cell-rich zone forms as a result of peripheral migration of cells populating the central regions of the pulp, commencing at about the time of tooth eruption. Migration of immunocompetent cells out of and into the cell-rich zone has been demonstrated as a result of antigenic challenge.[388] Although cell division within the cell-rich zone is rare in normal pulps, the death of the odontoblasts triggers a great increase in the rate of mitosis. Because odontoblasts are postmitotic cells, irreversibly injured odontoblasts are replaced by cells that migrate from the cell-rich zone onto the inner surface of the dentin.[96] This mitotic activity is probably the first step in the formation of a new odontoblast layer.[73,240-242,320] Studies implicate stem cells as a source for these replacement odontoblasts.[326]

Pulp Proper

The pulp proper is the central mass of the pulp (see Fig. 12-15). It consists of loose connective tissue and contains the larger blood vessels and nerves. The most prominent cell in this zone is the fibroblast.

CELLS OF THE PULP

Odontoblast

Because odontoblasts are responsible for dentinogenesis, both during tooth development and aging, the odontoblast is the most characteristic and specialized cell of the dentin-pulp complex. During dentinogenesis, the odontoblasts form dentin and the dentinal tubules, and their presence within the tubules makes dentin a living responsive tissue.

Dentinogenesis, osteogenesis, and cementogenesis are in many respects quite similar, and odontoblasts, osteoblasts, and cementoblasts have many characteristics in common. Each of these cells produces a matrix composed of collagen fibrils, noncollagenous proteins, and proteoglycans that are capable of undergoing mineralization. The ultrastructural characteristics of odontoblasts, osteoblasts, and cementoblasts are likewise similar in that each exhibits a highly ordered RER, a prominent Golgi complex, secretory granules, and numerous mitochondria. In addition, these cells are rich in RNA, and their nuclei contain one or more prominent nucleoli. These are the general characteristics of protein-secreting cells.

The most significant differences among odontoblasts, osteoblasts, and cementoblasts are their morphologic characteristics and the anatomic relationship between the cells and the mineralized structures they produce. Whereas osteoblasts and cementoblasts are polygonal to cuboidal in form, the fully developed odontoblast of the coronal pulp is a tall columnar cell.[63,224] In bone and cementum, some of the osteoblasts and cementoblasts become entrapped in the matrix as osteocytes or cementocytes, respectively. The odontoblast, on the other hand, leaves behind a cellular process to form the dentinal tubule, and the cell body resides outside the mineralized tissue. Lateral branches between the major odontoblast processes interconnect[167,236] through canaliculi, just as osteocytes and cementocytes are linked together through the canaliculi in bone and cementum. This provides a pathway for intercellular communication and circulation of fluid and metabolites through the mineralized matrix.

The ultrastructural features of the odontoblast have been the subject of numerous investigations. The cell body of the active odontoblast has a large nucleus that may contain up to four nucleoli (Fig. 12-19). The nucleus is situated at the basal end of the cell and is contained within a nuclear envelope. A well-developed Golgi complex, centrally located in the supranuclear cytoplasm, consists of an assembly of smooth-walled vesicles and cisternae. Numerous mitochondria are evenly distributed throughout the cell body. RER is particularly prominent, consisting of closely stacked cisternae forming parallel arrays that are dispersed diffusely within the cytoplasm. Numerous ribosomes closely associated with the membranes of the cisternae mark the sites of protein synthesis. Within the lumen of the cisternae, filamentous material (probably representing newly synthesized protein) can be observed.

The odontoblast appears to synthesize mainly type I collagen,[196,375] although small amounts of type V collagen have been found in the ECM. In addition to proteoglycans[40,82,117] and collagen,[196,202] the odontoblast secretes dentin sialoprotein[42] and phosphophoryn,[42,70] a highly phosphorylated phosphoprotein involved in extracellular mineralization.[42,75] Phosphophoryn is unique to dentin and is not found in any other mesenchymal cell types.[75] The odontoblast also secretes both acid phosphatase and alkaline phosphatase. The latter enzyme is closely linked to mineralization, but the precise role of alkaline phosphatase in dentinogenesis is not completely understood. Acid phosphatase, a lysosomal enzyme, may be involved in digesting material that has been resorbed from predentin matrix.[85]

In contrast to the active odontoblast, the resting or inactive odontoblast has a decreased number of organelles and may become progressively shorter.[63,224] These changes can begin with the completion of root development and eruption when dentin production shifts from primary to secondary dentin.

Odontoblast Process

A dentinal tubule forms around each of the major odontoblastic processes. The odontoblast process occupies most of the space within the tubule and coordinates the formation of peritubular dentin.

Microtubules and microfilaments are the principal ultrastructural components of the odontoblast process and its lateral branches.[106,150] Microtubules extend from the cell body out into the process.[106,151] These straight structures follow a course that is parallel with the long axis of the cell and impart the impression of rigidity. Although their precise role is unknown, theories as to their functional significance suggest that they may be involved in cytoplasmic extension, transport of materials, or the provision of a structural framework. Occasionally, mitochondria can be found in the process where it passes through the predentin.

The plasma membrane of the odontoblast process closely approximates the wall of the dentinal tubule. Localized constrictions in the process occasionally produce relatively large spaces between the tubule wall and the process. Such spaces may contain collagen fibrils and fine granular material that presumably represents ground substance. The peritubular

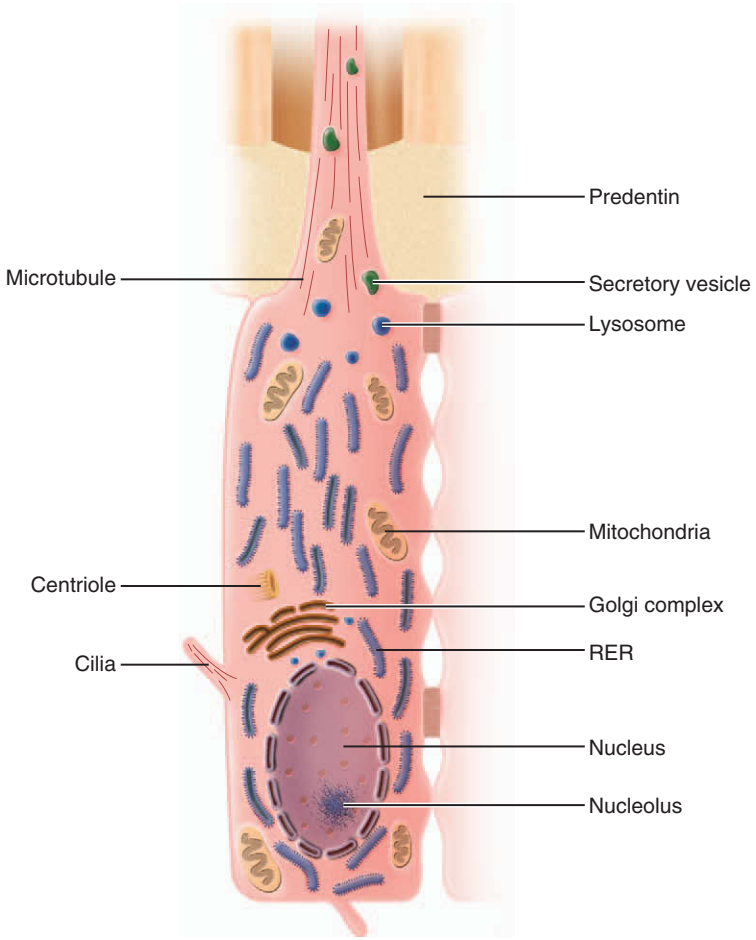

FIG. 12-19 Diagram of a fully differentiated odontoblast. *RER,* Rough endoplasmic reticulum.

dentin matrix within the tubule is lined by an electron-dense limiting membrane called the *lamina limitans*.[244,333,372] A narrow space separates the limiting membrane from the plasma membrane of the odontoblast process, except for the areas where the process is constricted.

In restoring a tooth, the removal of enamel and dentin often disrupts odontoblasts.* It would be of considerable clinical importance to establish the extent of the odontoblast processes in human teeth, because with this knowledge, the clinician would be in a better position to estimate the impact of the restorative procedure on the underlying odontoblasts. However, the extent to which the process penetrates into dentin has been a matter of considerable controversy. It has long been thought that the process is present throughout the full thickness of dentin. Although ultrastructural studies using transmission electron microscopy have described the process as being limited to the inner third of the dentin,[51,107,333,372] it should be noted that this could possibly be the result of shrinkage occurring during fixation and dehydration. Other studies employing scanning electron microscopy have described the process extending further into the tubule, often as far as the DEJ,[121,168,318,381] but it has been suggested that what has been observed in scanning electron micrographs is actually the lamina limitans.[333,334,372]

*References 44, 47, 73, 77, 192, and 241.

In an attempt to resolve this issue, monoclonal antibodies directed against microtubules were used to demonstrate tubulin in the microtubules of the process. Immunoreactivity was observed throughout the dentinal tubule, suggesting that the process extends throughout the entire thickness of dentin.[318] However, a study employing confocal microscopy found that odontoblast processes in rat molars do not extend to the outer dentin or DEJ, except during the early stages of tooth development.[51] It is likely that the walls of tubules contain many proteins originally derived from odontoblasts that no longer remain at that site. Because dentin matrix does not turn over, these antigens remain fixed in place. From a clinical perspective, it is important to remember that these processes in the tubules represent appendages from living odontoblasts in the pulp, which explains why the dentin must be considered a vital tissue, the destruction of which will affect the pulp.

The odontoblast is considered to be a fixed postmitotic cell in that once it has fully differentiated, it apparently cannot undergo further cell division. If this is indeed the case, the lifespan of the odontoblast coincides with the lifespan of the viable pulp. However, its metabolic activity can be dynamically altered (described under the heading, Pulpal Repair).

Relationship of Odontoblast Structure to Secretory Function

Studies using radiolabeled chemicals have shed a great deal of light on the functional significance of the cytoplasmic organ-

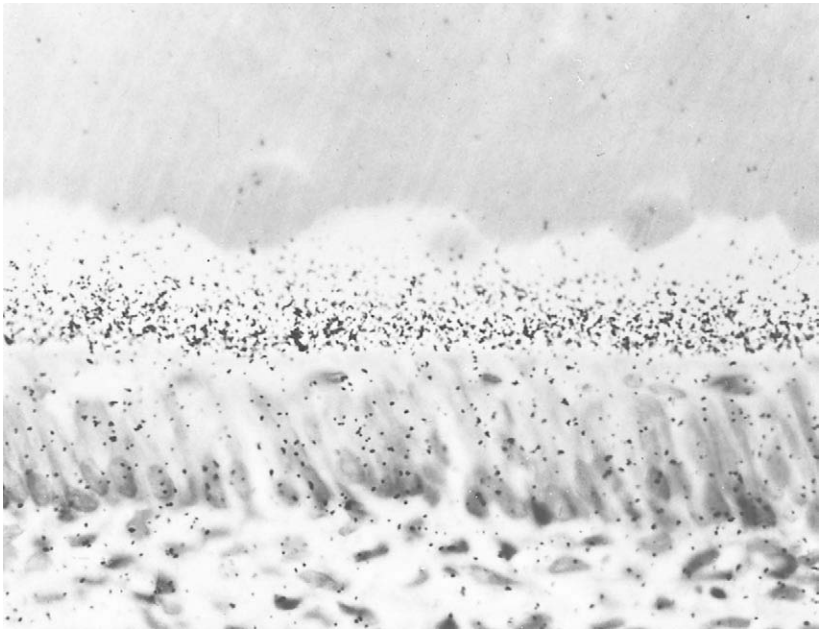

FIG. 12-20 Autoradiograph demonstrating odontoblasts and predentin in a developing rat molar 1 hour after intraperitoneal injection of ^{3}H-proline.

elles of the active odontoblast.[375,376] In experimental animals, intraperitoneal injection of a collagen precursor (e.g., ^{3}H-proline) is followed by autoradiographic labeling of the odontoblasts and predentin matrix[375] (Fig. 12-20). Rapid incorporation of the isotope in the RER soon leads to labeling of the Golgi complex in the area where the procollagen is packed and concentrated into secretory vesicles. Radiolabeled vesicles can then be followed along their migration pathway until they reach the base of the odontoblast process. Here they fuse with the cell membrane and release their tropocollagen molecules into the predentin matrix by the process of exocytosis.

It is now known that collagen fibrils precipitate from a solution of secreted tropocollagen, and that the aggregation of fibrils occurs on the outer surface of the odontoblast plasma membrane. Fibrils are released into the predentin and increase in thickness as they approach the mineralized matrix. Whereas fibrils at the base of the odontoblast process are approximately 15 nm in diameter, fibrils in the region of the calcification front have attained a diameter of about 50 nm.

Similar tracer studies[376] have elucidated the pathway of synthesis, transport, and secretion of the predentin proteoglycans. The protein moiety of these molecules is synthesized by the RER of the odontoblast, whereas sulfation and addition of the GAG moieties to the protein molecules take place in the Golgi complex. Secretory vesicles then transport the proteoglycans to the base of the odontoblast process, where they are secreted into the predentin matrix. Proteoglycans, principally chondroitin sulfate, accumulate near the calcification front. The role of the proteoglycans is speculative, but mounting evidence suggests that they act as inhibitors of calcification by binding calcium. It appears that just before calcification, the proteoglycans are removed, probably by lysosomal enzymes secreted by the odontoblasts.[83]

Pulp Fibroblast

Fibroblasts are the most numerous cells of the pulp. They appear to be tissue-specific cells capable of giving rise to cells that are committed to differentiation (e.g., odontoblast-like cells) if given the proper signal. These cells synthesize types I and III collagen, as well as proteoglycans and GAGs. Thus they produce and maintain the matrix proteins of the ECM. Because they are also able to phagocytose and digest collagen, fibroblasts are responsible for collagen turnover in the pulp.

Although distributed throughout the pulp, fibroblasts are particularly abundant in the cell-rich zone. The early differentiating fibroblasts are polygonal and appear to be widely separated and evenly distributed within the ground substance. Cell-to-cell contacts are established between the multiple processes that extend out from each of the cells. Many of these contacts take the form of gap junctions that provide for electronic coupling or chemical signaling from one cell to another. In terms of ultrastructure, the organelles of the immature fibroblasts are generally in a rudimentary stage of development, with an inconspicuous Golgi complex, numerous free ribosomes, and sparse RER. As they mature, the cells become stellate in form, and the Golgi complex enlarges, the RER proliferates, secretory vesicles appear, and the fibroblasts take on the characteristic appearance of protein-secreting cells. In addition, collagen fibrils accumulate along the outer surface of the cell body. With an increase in the number of blood vessels, nerves, and collagen fibers, there is a relative decrease in the number of fibroblasts in the pulp.

Many fibroblasts of the pulp are characterized by being relatively undifferentiated. A more modern term for undifferentiated cells is *stem cells*. Many pulpal cells do seem to remain in a relatively undifferentiated modality (compared with fibroblasts of most other connective tissues[128]). This perception has been supported by the observation of large numbers of reticulin-like fibers in the pulp. Reticulin fibers have an affinity for silver stains and are similar to the argyrophilic fibers of the pulp. However, in a careful review, it appears that actual reticulin fibers may not be present in the pulp; instead the previously described fibers are actually *argyrophilic collagen fibers*.[17] The fibers apparently acquire a GAG sheath, and it is this

sheath that is impregnated by silver stains. In the young pulp, the nonargyrophilic collagen fibers are sparse, but they progressively increase in number as the pulp ages.

Many experimental models have been developed to study wound healing in the pulp, particularly dentinal bridge formation after pulp exposure or pulpotomy. One study[96] demonstrated that mitotic activity preceding the differentiation of replacement odontoblasts appears to occur primarily among perivascular fibroblasts.

Pulpal fibroblasts seem to take active part in signaling pathways in the dental pulp. For example, fibroblast growth and synthesis is stimulated by neuropeptides; in turn, fibroblasts produce NGF and proinflammatory cytokines during inflammation.[32,380,382] NGF plays an important role not only in development but also in regulating neuronal and possibly odontoblast responses to injury via activation of similar neurotrophin receptors expressed on both cell types (see also Plasticity of Intradental Nerves Fibers in this chapter).[380]

Macrophage

Macrophages are monocytes that have left the bloodstream, entered the tissues, and differentiated into various subpopulations. The different subpopulations can be studied by their antigenic properties in immunohistochemical studies. Many are found in close proximity to blood vessels. A major subpopulation of macrophages is quite active in endocytosis and phagocytosis (Fig. 12-21). Because of their mobility and phagocytic activity, they are able to act as scavengers, removing extravasated red blood cells, dead cells, and foreign bodies from the tissue. Ingested material is destroyed by the action of lysosomal enzymes. Another subset of macrophages participates in immune reactions by processing antigen and presenting it to memory T cells.[265] The processed antigen is bound to class II major histocompatibility complex (MHC) molecules on the macrophage, where it can interact with specific receptors present on naïve or memory T cells.[124] Such interactions are essential for T cell–dependent immunity. Similar to fibroblasts, macrophages take an active part in the signaling pathways in the pulp. When activated by the appropriate inflammatory stimuli, macrophages are capable of producing a large variety of soluble factors, including interleukin 1, tumor necrosis factor, growth factors, and other cytokines. A recent study has shown that a subset of macrophages express lymphatic markers, indicating a link between macrophages and lymphatic function and development.[20]

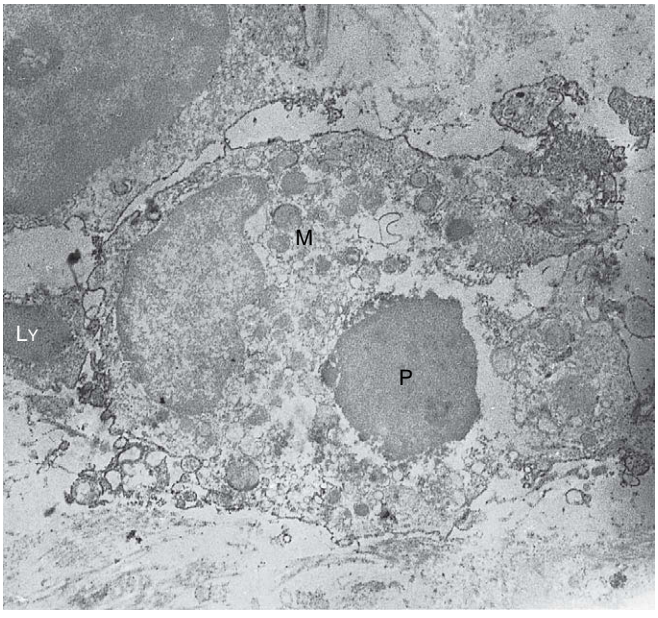

FIG. 12-21 Immunoelectron micrograph of an HLA-DR+ matured macrophage (M) in the human pulp, showing a phagosome (P). *Ly,* Lymphocyte.

Dendritic Cell

Dendritic cells are accessory cells of the immune system. Similar cells are found in the epidermis and mucous membranes, where they are called *Langerhans' cells*.[164,264] Dendritic cells are primarily found in lymphoid tissues, but they are also widely distributed in connective tissues, including the pulp[303] (Fig. 12-22). These cells are termed *antigen-presenting cells* and are characterized by dendritic cytoplasmic processes and the presence of class II MHC complexes on their cell surface (Fig. 12-23). In the normal pulp, they are mostly located in the periphery of the coronal pulp close to the predentin but migrate centrally in the pulp after antigenic challenge.[388] They are known to play a central role in the induction of T cell–dependent immunity. Like antigen-presenting macrophages, dendritic cells engulf protein antigens and then present an assembly of peptide fragments of the antigens and MHC class II molecules. It is this assembly that T cells can recognize. Then the assembly binds to a T-cell receptor and T-cell activation occurs (Fig. 12-24). Fig. 12-25 shows a cell-to-cell contact between a dendritic-like cell and a lymphocyte.

Lymphocyte

Hahn et al.[124] reported finding T lymphocytes in normal pulps from human teeth. T8 (suppressor) lymphocytes were the predominant T-lymphocyte subset present in these samples. Lymphocytes have also been observed in the pulps of impacted teeth.[191] The presence of macrophages, dendritic cells, and T lymphocytes indicates that the pulp is well equipped with cells required for the initiation of immune responses.[164,303] B lymphocytes are scarcely found in the normal pulp.

Mast Cell

Mast cells are widely distributed in connective tissues, where they occur in small groups in relation to blood vessels. Mast cells are seldom found in the normal pulp tissue, although they are routinely found in chronically inflamed pulps.[303] The mast cell has been the subject of considerable attention because of its dramatic role in inflammatory reactions. The granules of mast cells contain heparin, an anticoagulant, and histamine, an important inflammatory mediator, as well as many other chemical factors.

METABOLISM

The metabolic activity of the pulp has been studied by measuring the rate of oxygen consumption and the production of carbon dioxide or lactic acid.[27,93-95,127,304] An investigation employed an oxygen-sensitive microelectrode inserted into a rat incisor pulp with a micromanipulator.[386] The authors

FIG. 12-22 Class II antigen-expressing dendritic cells in the pulp and dentin border zone in normal human pulp, as demonstrated by immunocytochemistry. *D,* Dentin; *OB,* odontoblastic layer.

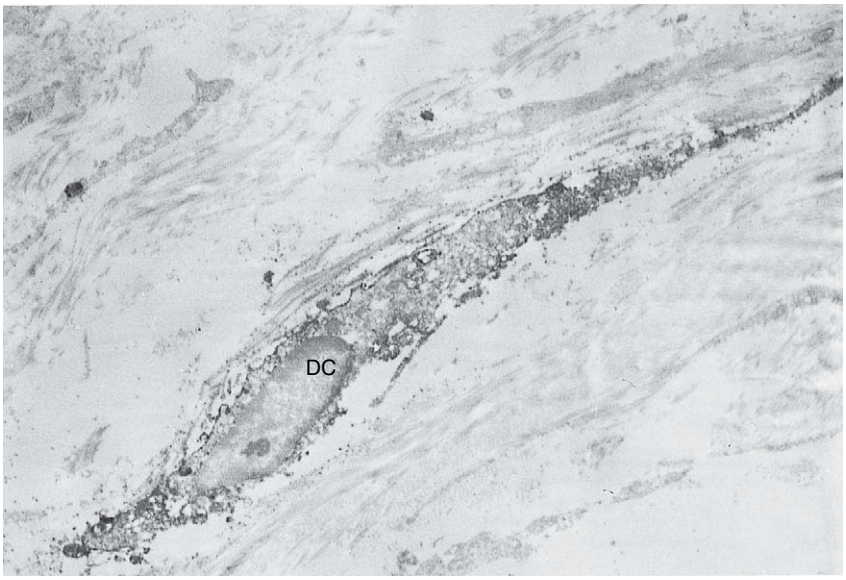

FIG. 12-23 Immunoelectron micrograph of a dendritic-like cell (DC) in the human pulp, showing a dendritic profile with a relatively small amount of lysosomal structures.

reported that odontoblasts consumed O_2 at the rate of 3.2 ± 0.2 ml/min/100 g of pulp tissue.[386]

Because of the relatively sparse cellular composition of the pulp, the rate of oxygen consumption is low in comparison with that of most other tissues. During active dentinogenesis, metabolic activity is much higher than after the crown is completed. As would be anticipated, the greatest metabolic activity is found in the region of the odontoblast layer, and the lowest is found in the central pulp, where most of the nerves and blood vessels are located.[26]

In addition to the usual glycolytic pathway, the pulp has the ability to produce energy through a phosphogluconate (i.e., pentose phosphate) shunt type of carbohydrate metabolism,[95] a metabolic pathway that permits tissues to function under varying degrees of ischemia. This could explain how the pulp manages to withstand periods of low perfusion resulting from vasoconstriction induced by epinephrine-containing infiltration anesthesia.[175]

Several commonly used dental materials (e.g., eugenol, zinc oxide and eugenol, calcium hydroxide, silver amalgam) inhibit oxygen consumption by pulp tissue, indicating that these agents may be capable of depressing the metabolic activity of pulpal cells.[94,163] One study[127] found that application of orthodontic force to human premolars for 3 days resulted in a 27% reduction in respiratory activity in the pulp. This study utilized carbon-14-labeled succinic acid in the medium. As

cells metabolize succinic acid, they produce $^{14}CO_2$ that can be trapped and quantitated by a liquid scintillation counter.[127] This technique requires only a few milligrams of tissue.

THE PULPAL INTERSTITIUM AND GROUND SUBSTANCE

The interstitium consists of the interstitial fluid and the interstitial (extracellular) matrix and occupies the extracellular and extravascular space. It is amorphous and generally regarded as a gel rather than a solid. Its constituents are similar in all tissues, but their relative amount varies. The major structural component of the interstitium is collagen (Fig. 12-26). The network of collagen fibers also supports the other components of the interstitium, the proteoglycans, hyaluronan, and elastic fibers. The two former components represent the glycosaminoglycans of the interstitial matrix.

Because of its content of polyanionic polysaccharides, the interstitium is responsible for the water-holding properties of

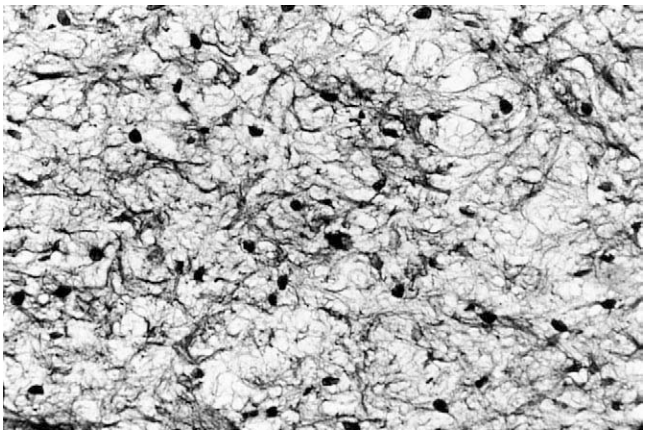

FIG. 12-26 Delicate network of pulpal collagen fibers as demonstrated by the Pearson silver impregnation method.

connective tissues and acts as a molecular "sieve" in regulating the diffusion of substances through this space. The magnitude of the excluded volume has important consequences because the effective protein concentration in the interstitium is higher than the value that would be estimated from fluid volume per se.[378]

Connective tissue consists of cells and fibers, both embedded in ground substance or extracellular matrix (ECM). Cells that produce connective tissue fibers also synthesize the major constituents of the ECM. Whereas the fibers and cells have recognizable shapes, the ECM is described as being amorphous. It is generally regarded as a gel rather than a solid. Because of its content of polyanionic polysaccharides, the ECM is responsible for the water-holding properties of connective tissues.[378]

Nearly all proteins of the ECM are glycoproteins.[221] Proteoglycans are an important subclass of glycoproteins.[117] These molecules support cells, provide tissue turgor, and mediate a variety of cell interactions. They have in common the presence of GAG chains and a protein core to which the chains are linked. Except for heparan sulfate and heparin, the chains are composed of disaccharides. The primary function of GAG chains is to act as adhesive molecules that can bond to cell surfaces and other matrix molecules.

Fibronectin is a major surface glycoprotein that, together with collagen, forms an integrated fibrillary network that influences adhesion, motility, growth, and differentiation of cells. Laminin, an important component of basement membranes, binds to type IV collagen and cell surface receptors.[113] Tenascin is another substrate adhesion glycoprotein.

In the pulp, the principal proteoglycans include hyaluronic acid dermatan sulfate, heparan sulfate, and chondroitin sulfate.[221] The proteoglycan content of pulp tissue decreases approximately 50% with tooth eruption.[202] During active dentinogenesis, chondroitin sulfate is the principal proteoglycan, particularly in the odontoblast and predentin layer, where it is somehow involved with mineralization; with tooth eruption, hyaluronic acid and dermatan sulfate increase, and chondroitin sulfate decreases greatly.

The consistency of a connective tissue (e.g., the pulp) is largely determined by the proteoglycan components of the ground substance. The long GAG chains of the proteoglycan molecules form relatively rigid coils constituting a network that holds water, thus forming a characteristic gel. Hyaluronic acid in particular has a strong affinity for water and is a major component of ground substance in tissues with a large fluid content, such as Wharton's jelly of the umbilical cord. The water content of the young pulp is very high (approximately 90%), so the ground substance forms a cushion capable of protecting cells and vascular components of the tooth.

Ground substance also acts as a molecular sieve in that it excludes large proteins. Cell metabolites, nutrients, and wastes pass through the ground substance between cells and blood vessels. In some ways, ground substance can be likened to an ion exchange resin, because the polyanionic chains of the GAGs bind cations. In addition, osmotic pressures can be altered by excluding osmotically active molecules. Thus proteoglycans can regulate the dispersion of interstitial matrix solutes, colloids, and water, and (in large measure) they determine the physical characteristics of a tissue, such as the pulp.

Degradation of ground substance can occur in certain inflammatory lesions that have a high concentration of macrophage lysosomal enzymes. Proteolytic enzymes, hyaluronidases, and chondroitin sulfatases of lysosomal and bacterial origin are examples of the hydrolytic enzymes that can attack components of the ground substance. The pathways of inflammation and infection are strongly influenced by the state of polymerization of the ground substance components.

Hyaluronan

Another major structural component of the interstitial matrix is hyaluronan. It is an unbranched, random-coil molecule from repeating nonsulfated disaccharide units and is found in the interstitium as free molecules or bound to cells, possibly via the connection to fibronectin.[194] Its large molecular weight together with its protein structure accounts for its unique properties. It has a high viscosity even at low concentration, exhibits exclusion properties, and has a strong affinity for water.

Hyaluronan is one of several types of GAGs in the pulp.[203,221] The hyaluronan receptor-1 is expressed on lymphatic vessels and also on immune cells in the dental pulp.[20] Hyaluronan is removed from the tissue by the lymphatics and metabolized in the lymph nodes[98] and by endothelial cells in the liver.[126,285]

Elastic Fibers

Elastic fibers comprise an elastin core and a surrounding microfibrillar network and provide elasticity to the tissue.[272] The amount of elastin in the interstitial matrix in most tissue is small. There is no evidence for elastic fibers in the matrix in the pulp.[126,285]

The Inflamed Interstitium

Hyaluronidases, and chondroitin sulfatases of lysosomal and bacterial origin are examples of the hydrolytic enzymes that can attack components of the interstitium. During infection and inflammation, the physical properties of the pulp tissue may then be altered due to production of such degrading enzymes.[133,302] In addition to their own damaging effect, they may also pave the way for the deleterious effects of bacterial toxins, increasing the magnitude of the damage.[166]

The pathways of inflammation and infection are strongly influenced by the particular composition of the interstitium in every tissue and its degradation by either host or microbial enzymes.

CONNECTIVE TISSUE FIBERS OF THE PULP

Two types of structural proteins are found in the pulp: collagen and elastin. Elastin fibers are confined to the walls of arterioles and, unlike collagen, are not a part of the ECM.

A single collagen molecule, referred to as *tropocollagen,* consists of three polypeptide chains, designated as either alpha-1 or alpha-2 depending on their amino acid composition and sequence. In the human pulp, the amount of collagen is reported to be 26% to 32% of dry weight in premolars and molars.[355] Type I and type III collagen represent the major subtypes of collagen in the pulp, and type I is found in thick striated fibrils throughout the pulp tissue.[195,317] The different combinations and linkages of chains making up the tropocollagen molecule have allowed collagen fibers and fibrils to be classified into a number of types:

- Type I collagen is found in skin, tendon, bone, dentin, and pulp.
- Type II collagen is found in cartilage.
- Type III collagen is found in most unmineralized connective tissues. It is a fetal form found in the dental papilla and the mature pulp. In bovine pulp, it constitutes 45% of the total pulp collagen during all stages of development.[355]
- Types IV and VII collagen are components of basement membranes.
- Type V collagen is a constituent of interstitial tissues.
- Type VI collagen is a heterotrimer of three distinct chains, alpha 2 (VI) and alpha 3 (VI), and is widely distributed in low concentrations in soft tissues at interfibrillar filaments.

Type I collagen is synthesized by odontoblasts and osteoblasts; fibroblasts synthesize types I, III, V, and VII collagen.

In collagen synthesis, the protein portion of the molecule is formed by the polyribosomes of the RER of connective tissue cells. The proline and lysine residues of the polypeptide chains are hydroxylated in the cisternae of the RER, and the chains are assembled into a triple-helix configuration in the smooth endoplasmic reticulum. The product of this assembly is termed *procollagen,* and it has a terminal unit of amino acids known as the *telopeptide of the procollagen molecule*. When these molecules reach the Golgi complex, they are glycosylated and packaged in secretory vesicles. The vesicles are transported to the plasma membrane and secreted by way of exocytosis into the extracellular milieu, thus releasing the procollagen. Here the terminal telopeptide is cleaved by a hydrolytic enzyme, and the tropocollagen molecules begin aggregating to form collagen fibrils. It is believed that aggregation of tropocollagen is somehow mediated by the GAGs. The conversion of soluble collagen into insoluble fibers occurs as a result of cross linking of tropocollagen molecules. The presence of collagen fibers passing from the dentin matrix between odontoblasts into the dental pulp has been reported in fully erupted teeth.[28] Larger collagen fiber bundles are much more numerous in the radicular pulp than in the coronal pulp. The highest concentration of these larger fiber bundles is usually found near the apex (Fig. 12-27). Pulpectomy procedures should engage the pulp with a barbed broach in the region of the apex, since it generally affords the best opportunity to remove this tissue intact.[342]

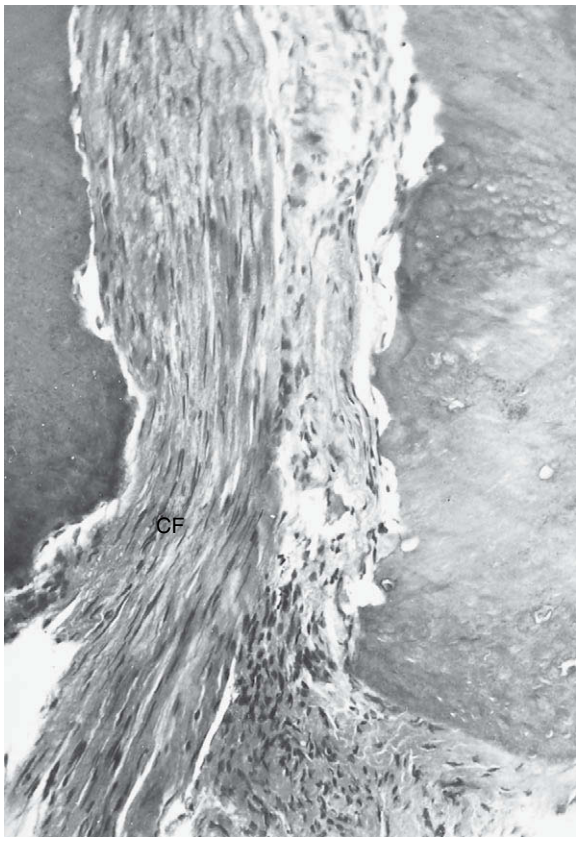

FIG. 12-27 Dense bundles of collagen fibers (CF) in the apical pulp.

INNERVATION

Pain is a subjective phenomenon involving not only sensory physiologic responses but also emotional, conceptual, and motivational aspects of behavior. The existence of peripheral "nociceptive" (pain-detecting) sensory neurons forms the basis for pain, and pain sensations of varying qualities and intensities are evoked by activation of the intradental nerves innervating teeth. Noxious stimuli in teeth are transmitted in primary afferent neurons located in the trigeminal ganglion via second-order neurons in the brainstem to the brain (Fig. 12-28; see also Chapters 3 and 19). Transmission of sensory information consists of a cascade of events involving input, processing, and sensing,[313] so the control of dental pain should be based on an understanding of the origin of pain signals and the complex modulation that may take place locally and at higher levels (see Chapter 19). The sensory system of the pulp appears to be well

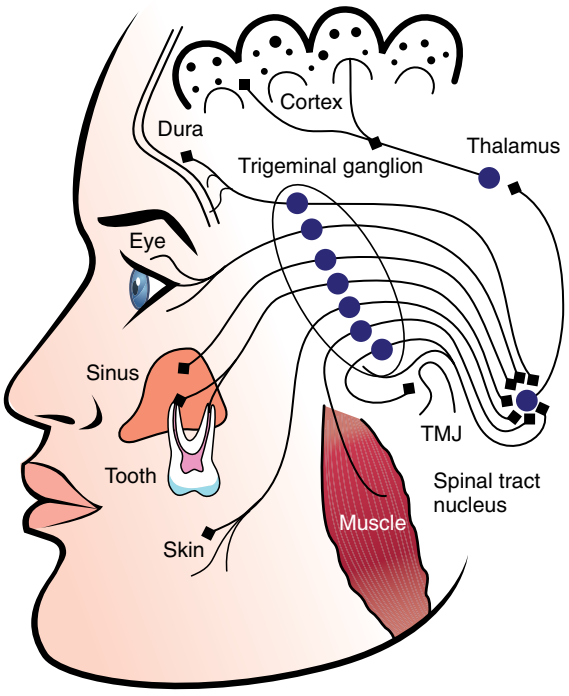

FIG. 12-28 Schematic drawing illustrating the convergence of sensory information from teeth to higher brain centers.

suited for signaling potential damage to the tooth. The tooth is innervated by a large number of myelinated and unmyelinated axons. The number of axons entering a human premolar may reach 2000 or more, and each axon can arborize to form multiple points of innervation.[87,160,161]

Regardless of the nature of the sensory stimulus (i.e., thermal, mechanical, chemical, electric [e.g., pulp tester]), almost all afferent impulses generated from pulp tissue result in the sensation of pain. However, when the pulp is weakly stimulated by an electric pulp tester under carefully controlled experimental conditions, a nonpainful sensation (i.e., prepain) has been reported.[231] Thus not all afferent neurons that innervate the pulp are nociceptors. The innervation of the pulp includes both *afferent neurons,* which conduct sensory impulses, and *autonomic or efferent neurons,*[154] which provide neurogenic modulation of the microcirculation, inflammatory reactions,[136] and perhaps regulate dentinogenesis.[48]

The sympathetic innervation of teeth derives from the superior cervical ganglion (SCG).[10,286] Postganglionic sympathetic nerves travel with the internal carotid nerve, join the trigeminal nerve at the ganglion, and supply teeth and supporting structures via the maxillary and mandibular division of the trigeminal nerve.[223] Sympathetic fibers appear with blood vessels at the time the vascular system is established in the dental papilla.[101] In the adult tooth pulp, sympathetic fibers form plexuses, usually around pulpal arterioles (Fig. 12-29). Stimulation of these fibers results in constriction of the arterioles and a decrease in blood flow.[2,78] The sympathetic neuron terminals contain the classic neurotransmitter, norepinephrine (NE), and neuropeptide Y (NPY) (see Neuropeptides later in this chapter). NPY is synthesized in sympathetic neurons and supplied to terminals by axonal transport. By contrast, NE is mainly produced locally in the terminals. Compared to the sensory nerves, these fibers are most often located in deeper parts of the pulp proper, but fibers have also been found in close relation to odontoblasts.[2,155]

FIG. 12-29 Histologic section, immunohistologically stained for neuropeptide Y (NPY), shows the distribution of sympathetic nerves in the root pulp of a rat molar. NPY fibers are seen associated with blood vessels. *(Courtesy Dr. Inge Fristad, Department of Clinical Dentistry, University of Bergen.)*

The presence of parasympathetic cholinergic nerves in dental tissues has been and is still controversial, although it has been concluded that there is absence of parasympathetic vasodilation in the cat dental pulp.[270,307] It has been reported that the neuropeptide, vasoactive intestinal polypeptide (VIP), is localized in the parasympathetic neurons.[210,211] The origin of these fibers is uncertain insofar as no form of surgical denervation has resulted in complete loss of VIP-containing fibers from the dental pulp.[366]

Sensory nerve fibers are usually classified according to their diameter, conduction velocity, and function as shown in Table 12-2. The pulp contains two types of sensory nerve fibers: myelinated (A fibers) and unmyelinated (C fibers). It has been shown that there is some functional overlap between pulpal A and C fibers, since both fiber types can be nociceptors.[154,160,161,230,252] The A fibers include both A-beta and A-delta fibers. The A-beta fibers may be slightly more sensitive to stimulation than the A-delta fibers, but functionally these fibers are grouped together in the dental pulp, since both innervate the dentinal tubules, and both are stimulated by dentinal fluid movement (Fig. 12-30). Approximately 90% of the A fibers in dental pulp are A-delta fibers.[230] Table 12-3 summarizes the principal characteristics of the main sensory fibers.

During the bell stage of tooth development, "pioneer" nerve fibers enter the dental papilla following the path of blood vessels.[101] Although only unmyelinated fibers are observed in the dental papilla, a proportion of these fibers are probably A fibers that have lost their myelin sheath. Myelinated fibers are the last major structures to appear in the developing human dental pulp.[13] The number of nerve fibers gradually increases, and some branching occurs as the fibers near the dentin. During the bell stage very few fibers enter the predentin.[101]

TABLE 12-2

Classification of Nerve Fibers

Type of Fiber	Function	Diameter (μm)	Conduction Velocity (m/sec)
A-alpha	Motor, proprioception	12–20	70–120
A-beta	Pressure, touch	5–12	30–70
A-gamma	Motor, to muscle spindles	3–6	15–30
A-delta	Pain, temperature, touch	1–5	6–30
B	Preganglionic autonomic	<3	3–15
C dorsal root	Pain	0.4–1.0	0.5–2.0
Sympathetic	Postganglionic sympathetic	0.3–1.3	0.7–2.3

TABLE 12-3

Characteristics of Sensory Fibers

Fiber	Myelination	Location of Terminals	Pain Characteristics	Stimulation Threshold
A-delta	Yes	Principally in region of pulp-dentin junction	Sharp, pricking	Relatively low
C	No	Probably distributed throughout pulp	Burning, aching, less bearable than A-delta fiber sensations	Relatively high, usually associated with tissue injury

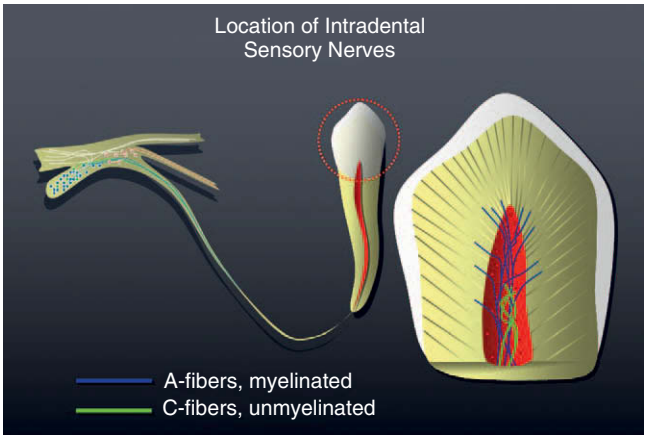

FIG. 12-30 Schematic drawing illustrating the location of A and C fibers in the dental pulp. Myelinated A fibers are located in the periphery of the pulp, penetrating the inner part of dentin. Unmyelinated C fibers are located in the deeper part of the pulp proper.

The sensory nerves of the pulp arise from the trigeminal nerve and pass into the radicular pulp in bundles by way of the foramen in close association with arterioles and venules (Fig. 12-31). Each of the nerves entering the pulp is invested within Schwann cells, and the A fibers acquire their myelin sheath from these cells. With the completion of root development, the myelinated fibers appear grouped in bundles in the central region of the pulp (Fig. 12-32). Most of the unmyelinated C fibers entering the pulp are located within these fiber bundles; the remainder is situated toward the periphery of the pulp (see Fig. 12-30).[292] It should be noted that single neurons have been reported to innervate the pulps of multiple teeth in animal studies.[145] Assuming similar innervation patterns occur in humans, this finding may partially explain why patients often have difficulty localizing pulpal pain to a specific tooth. An alternative explanation to this clinical observation is that the pulp has a relatively low density of proprioceptors, and thus patients have difficulty identifying the inflamed pulp until the inflammation reaches the periradicular tissue, which is highly innervated with proprioceptors. This is discussed in greater detail in Chapters 3 and 19.

In the human premolar, the number of unmyelinated axons entering the tooth at the apex reached a maximal number shortly after tooth eruption.[160] At this stage, an average of 1800 unmyelinated axons and more than 400 myelinated axons were found, although in some teeth fewer than 100 myelinated axons were present. Five years after eruption, the number of A fibers gradually increased to more than 700. The relatively late appearance of A fibers in the pulp may help to explain why the electric pulp test tends to be unreliable in young teeth, since A fibers are more easily electrically stimulated than C fibers.[104]

A quantitative study of axons 1 to 2 mm coronal to the root apex of fully developed human canine and incisor teeth[160] reported a mean of about 360 myelinated axons in canines and incisors, whereas there were 1600 to 2200 unmyelinated axons. However, this does not reflect the actual number of neurons supporting a single tooth, because multiple branching of the axons may occur in the peripheral tissues. Overall, approximately 80% of the axons were unmyelinated fibers.[160,161]

The nerve bundles pass upward through the radicular pulp together with blood vessels (see Fig. 12-31). Once they reach the coronal pulp, they fan out beneath the cell-rich zone, branch into smaller bundles, and finally ramify into a plexus of single-nerve axons known as the *plexus of Raschkow* (Fig. 12-33). Full development of this plexus does not occur until the final stages of root formation.[87] It has been estimated that each axon entering the pulp sends at least eight branches to the plexus of Raschkow. There is prolific branching of the fibers in the plexus, producing a tremendous overlap of receptor fields.[131,252-254,256] It is in the plexus that the A fibers emerge from their encircling Schwann cells and branch repeatedly to form the subodontoblastic plexus. Finally, terminal axons pass between the odontoblasts as free nerve endings (Figs. 12-34 and 12-35). The extent to which dentin is innervated has been the subject of numerous investigations.[45,47,48,52,87,200] With the exception of the innervation of dentinal tubules, discussed later in this chapter, the bulk of dentin is devoid of sensory nerve fibers. This offers an explanation as to why pain-producing agents (e.g., potassium chloride) do not always elicit pain when applied to exposed dentin. Similarly, application of topical anesthetic solutions to dentin does not decrease its sensitivity. A very high concentration of lidocaine solution is needed to block the response of intradental nerves to mechanical stimulation of the dentin.[6]

One investigator[122] studied the distribution and organization of nerve fibers in the dentin-pulp border zone of human teeth. On the basis of their location and pattern of branching, several types of nerve endings were described (Fig. 12-36). Some fibers were found running from the subodontoblastic nerve plexus toward the odontoblast layer. However, these fibers do not reach the predentin; they terminate in extracellular spaces in the cell-rich zone, the cell-poor zone, or the odontoblast layer. Other fibers extend into the predentin and run through a dentinal tubule in close association with an

FIG. 12-35 Unmyelinated nerve fiber (NF) without a Schwann cell covering located between adjacent odontoblasts (O) overlying pulp horn of a mouse molar tooth. Predentin (PD) can be seen at upper right. Within the nerve there are longitudinally oriented fine neurofilaments, microvesicles, and mitochondria. (*From Corpron RE, Avery JK: The ultrastructure of intradental nerves in developing mouse molars. Anat Rec 175:585, 1973.*)

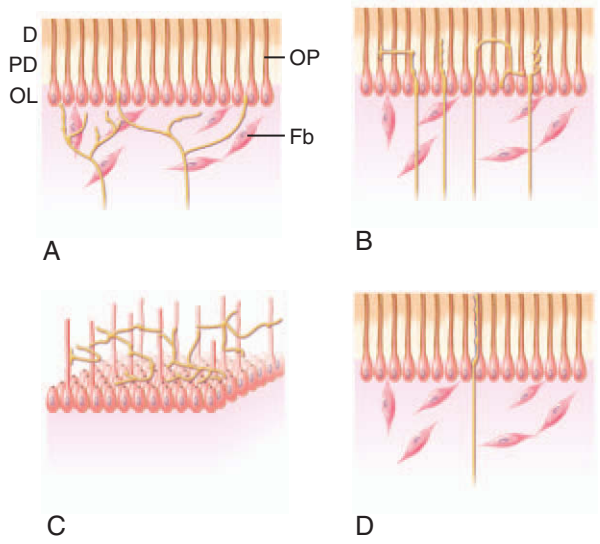

FIG. 12-36 Schematic drawing showing distribution of nerve fibers in the dentin-pulp border zone. **A,** Fibers running from the subodontoblastic plexus to the odontoblast layer. *D,* Dentin; *Fb,* fibroblast; *OL,* odontoblast layer; *OP,* odontoblast process; *PD,* predentin. **B,** Fibers extending into the dentinal tubules in the predentin. **C,** Complex fibers that branch extensively in the predentin. **D,** Intratubular fibers extending into the dentin.

odontoblast process. Most of these intratubular fibers extend into the dentinal tubules for only a few micrometers, but a few may penetrate as far as 100 µm (see Fig. 12-33). The area covered by a single such terminal complex often reaches thousands of square micrometers.[122,253]

Intratubular nerve endings are most numerous in the area of the pulp horns, where as many as 40% of the tubules may contain fibers.[48,200] The number of intratubular fibers decreases in other parts of the dentin, and in root dentin only about 1% of dentinal tubules contain a fiber. This notion has been challenged in a study that stained pulps for protein gene-product 9.5, a specific marker for nerves.[218] In that study, root dentin appeared to be as well innervated as coronal dentin. The anatomic relationship between the odontoblast processes and sensory nerve endings has led to much speculation as to the functional relationships between these structures, if any.[47] When present, nerve fibers lie in a groove or gutter along the surface of the odontoblast process, and toward their terminal ends, they twist around the process like a corkscrew. The cell membranes of the odontoblast process and the nerve fiber are closely approximated and run closely parallel for the length of their proximity but are not synaptically linked.[149]

Although it may be tempting to speculate that the odontoblasts and their associated nerve axons are functionally interrelated and that together they play a role in dentin sensitivity, there is a paucity of evidence supporting this hypothesis. If the odontoblast were acting as a classic receptor cell,* it would have chemical, electric, or mechanical communication with the adjacent nerve fiber. However, researchers have been unable to find classical anatomic structures (e.g., synaptic junctions) that could functionally couple odontoblasts and nerve fibers together. With regard to the membrane properties of odontoblasts, it has been reported that the membrane potential of the odontoblast is low (−24 to −30 mV),[189,212] and that the cell does not respond to electric stimulation.[189,379] It would appear that the odontoblast does not possess the properties of an excitable cell. Further, the sensitivity of dentin is not diminished after disruption of the odontoblast layer.[39,201] It is still possible that odontoblasts could modulate neuronal function via alteration in sodium channel activity or the release of paracrine factors that diffuse to the closely approximated nerve terminal.

Another study showed that a reduction in pulpal blood flow induced by stimulation of sympathetic fibers leading to the pulp results in depressed excitability of pulpal A fibers.[78] The excitability of C fibers is less affected than that of A fibers by a reduction in blood flow.[341]

Of clinical interest is the evidence that nerve fibers of the pulp may be resistant to necrosis[84,239] because their cell bodies are found in ganglia outside the pulp. Since nerve bundles in general are more resistant to autolysis than other tissue ele-

*A receptor cell is a non–nerve cell capable of exciting adjacent afferent nerve fibers. Synaptic junctions connect receptor cells to afferent nerves.

ments, even in degenerating pulps, C fibers might still be able to respond to noxious stimulation. It may be that C fibers remain excitable even after blood flow has been compromised in the diseased pulp, since C fibers are often able to function in the presence of hypoxia.[341] This may offer an explanation as to why instrumentation of the root canals of apparently nonvital teeth sometimes elicits pain. On the other hand, histologic studies on nonvital teeth failed to demonstrate high levels of innervation, leading to the suggestion pain may be due to the transfer of noxious chemicals to terminals located in periapical tissues.[239]

Tissue Injury and Deafferentation

When a peripheral nerve is cut or crushed, an interruption of the afferent input to the CNS occurs, which is called *deafferentation*. It would be logical to assume that the result of deafferentation would be anesthesia of the formerly innervated area, but occasionally other symptoms may occur, which may surprisingly include pain. Following nerve injury, a dramatic shift in transcription of neuropeptides, receptors, and sodium channels has been documented. The bidirectional contact between the nerve cell and the peripheral target tissue is lost, and the neurons change into a state of either regeneration or neuronal cell death. The impact on neurons in the trigeminal ganglion is dependent on the injury site. A peripheral injury has less effect than a more centrally located one. However, even a small pulp exposure induces neuronal changes, both in the trigeminal ganglion and at the second-order neuronal level in the brainstem.[46,367] Because each single-rooted tooth contains about 2000 nerve fibers,[160,161] extirpation of the pulp is shown to cause both neurochemical and degenerative changes of their cell bodies in the gasserian (trigeminal) ganglion.[120,174,315] The central projection of these nerves to the spinal nucleus of the trigeminal nerve are also affected,[343] and there is evidence for transsynaptic changes[314,315] that are reflected in the sensory cortex. Even larger responses would be expected from tooth extraction, where both periodontal ligament and pulpal innervation are destroyed.

When an axon is severed peripherally, a complete degeneration of the cell bodies may not always occur.[368] Attempted regeneration by axonal sprouting may result in altered expression of various receptors, resulting in sensitivity to norepinephrine (via increased adrenergic receptor activity)[261] or acetylcholine (via increased cholinergic receptor activity),[72] sensitizing sensory neurons to autonomic activity. In addition, dorsal horn neurons, deprived of their normal sensory input, may begin to respond to other nearby afferents. Thus normal inhibitory influences are reduced, and a widening of the sensory receptive field is produced, which can produce central sensitization (see Chapter 19). *Phantom tooth pain* is another term often used synonymously with pain following deafferentation. Different reports suggest an incidence of persistent pain following pulpectomy to be in the range of 3% to 6%.[222,360]

Following tissue injury or tissue inflammation, extensive changes occur in the gene expression of sensory ganglion nerves and, by way of transsynaptic mechanisms, in their central projections.[47,253,254,315] One example is the upregulation of inducible gene transcription factors such as c-*fos*[53] and different subsets of sodium channels.[114] This is thought to result in alterations in threshold properties and the size of receptor fields. C-*fos* is not normally expressed in neurons in the brainstem, but chronic pulpitis causes prolonged increases in c-*fos* expression is some brainstem neurons.

If such changes also occur in humans, they may help to explain why certain patients may complain of vague, poorly described pain for months following endodontic treatment. If their pulpitis caused sprouting of periapical nerves,[52-54,182] these nerves may have been due to the transport of peripheral signaling molecules to the cell body by way of retrograde axoplasmic flow.[45,54] This could induce changes in the expression of many genes, resulting in central senstization[8,44] that may require many months to correct.[327] Reports of nerve sprouting in human inflamed pulps have been confirmed in different studies.[296,297,303] Such reactions might contribute to increases in dentin sensitivity as well as expansion of receptive fields.[253,254,256] Sprouting of sympathetic fibers has also been reported,[135] but the timing appears to be different. The functional implications and how this is related to pain mechanisms are unknown, but it has been suggested that these reactions are involved in healing and nociception following pulpal inflammation.[111,135,136]

Pulp Testing

The electric pulp tester delivers a current sufficient to overcome the resistance of enamel and dentin and stimulate the sensory A fibers at the dentin-pulp border zone. Smaller C fibers of the pulp do not respond to the conventional pulp tester because significantly more current is needed to stimulate them.[252] Bender et al.[18] found that in anterior teeth, the optimal placement site of the electrode is the incisal edge, since the response threshold is lowest at that location and increases as the electrode is moved toward the cervical region of the tooth.

Cold tests using carbon dioxide (CO_2) snow or liquid refrigerants and heat tests employing heated gutta-percha or hot water activate hydrodynamic forces within the dentinal tubules, which in turn excite the intradental A fibers. C fibers are generally not activated by these tests unless they produce injury to the pulp. It has been shown that cold tests do not injure the pulp.[104] Heat tests have a greater potential to produce injury, but if the tests are used properly, injury is not likely.

Sensitivity of Dentin

The mechanisms underlying dentin sensitivity have been a subject of interest in recent years. How are stimuli relayed from the peripheral dentin to the sensory terminals located in the region of the dentin-pulp border zone? Converging evidence indicates that movement of fluid in the dentinal tubules is the basic event in the arousal of dentinal pain.[38,39,249,361,363] It now appears that pain-producing stimuli, such as heat, cold, air blasts, and probing with the tip of an explorer, have in common the ability to displace fluid in the tubules.[38,230] This is referred to as the *hydrodynamic mechanism of dentin sensitivity*. The hydrodynamic theory suggests that dentinal pain associated with stimulation of a sensitive tooth ultimately involves mechanotransduction. Recently, classical mechanotransducers have been recognized on pulpal afferents, providing a mechanistic support to this theory.[138] Thus fluid movement in the dentinal tubules is translated into electric signals by receptors located in the axon terminals innervating dentinal tubules. Indeed, there is a positive correlation between rate of fluid flow in the tubules and discharge evoked in intradental nerves,[229,230,363] with outward fluid movements producing a much stronger nerve response than inward movements.[230]

In experiments on humans, brief application of heat or cold to the outer surface of premolar teeth evoked a painful response before the heat or cold could have produced temperature changes capable of activating sensory receptors in the underlying pulp.[250,346] The evoked pain was of short duration: 1 or 2 seconds. The thermal diffusivity of dentin is relatively low; yet the response of the tooth to thermal stimulation is rapid, often less than 1 second. Evidence suggests that thermal stimulation of the tooth results in a rapid movement of fluid into the dentinal tubules. This results in activation of the sensory nerve terminal in the underlying pulp. Presumably, heat expands the fluid within the tubules faster than it expands dentin, causing the fluid to flow toward the pulp, whereas cold causes the fluid to contract more rapidly than dentin, producing an outward flow. It is speculated that the rapid movement of fluid across the cell membrane of the axon terminal activates a mechanosensitive receptor, similar to how fluid movement activates hair cells in the cochlea of the ear. All axon terminals have membrane channels through which charged ions pass, and this initial receptor current, if sufficient, can trigger voltage gated sodium channels to depolarize the cell, leading to a barrage of impulses to the brain. Some ion channels are activated by voltage, some by chemicals, and some by mechanical pressure.[230,249,253] In the case of pulpal nerve fibers that are activated by hydrodynamic forces, pressure would be transduced, gating mechanosensitive ion channels.

The dentinal tubule is a capillary tube with an exceedingly small diameter.*[107] The physical properties of capillarity are significant because fluid force increases as the diameter is reduced. If fluid is removed from the outer end of exposed dentinal tubules by dehydrating the dentinal surface with an air blast or absorbent paper, capillary forces produce a rapid outward movement of fluid in the tubule (Fig. 12-37). According to Brännström,[38] desiccation of dentin can theoretically cause dentinal fluid to flow outward at a rate of 2 to 3 mm/sec. In addition to air blasts, dehydrating solutions containing hyperosmotic concentrations of sucrose or calcium chloride can produce pain if applied to exposed dentin.

Investigators have shown that it is the A fibers rather than the C fibers that are activated by hydrodynamic stimuli (e.g., heat, cold, air blasts) applied to exposed dentin.[251,256] However, if heat is applied long enough to increase the temperature of the dentin-pulp border by several degrees Celsius, then C fibers may respond, particularly if the heat produces injury. It seems that the A fibers are mainly activated by a rapid displacement of the tubular contents.[249] Slow heating of the tooth produced no response until the temperature reached 111° F (43.8° C), at which time C fibers were activated, presumably because of heat-induced injury to the pulp. These C fibers are called *polymodal nociceptors* because they contain numerous receptors that confer the ability to detect and respond to many different types of stimuli.[253,254] Capsaicin, the pungent active ingredient in hot peppers, is known to simulate C fibers and a subset of A-delta fibers.[154] Capsaicin activates transient receptor potential, subtype vanilloid 1, (TRPV1).[59] The TRPV1 receptor is expressed primarily on a major subclass of nociceptors and responds to heat (>110° F [>43° C]), certain inflammatory mediators, and acid (pH < 6). Thus TRPV1 has been considered a molecular integrator of polymodal noxious stimuli.[260] The ability of the TRPV1 antagonist, capsazepine, to inhibit acid-, heat-, and capsaicin-activated trigeminal neurons[206] has led to the development of new drugs (i.e., TRPV1 antagonists) for the treatment of pulpal pain. Eugenol is known to activate and ultimately desensitize TRPV1, and this may explain the anodyne action of zinc oxide eugenol temporary restorations.[384]

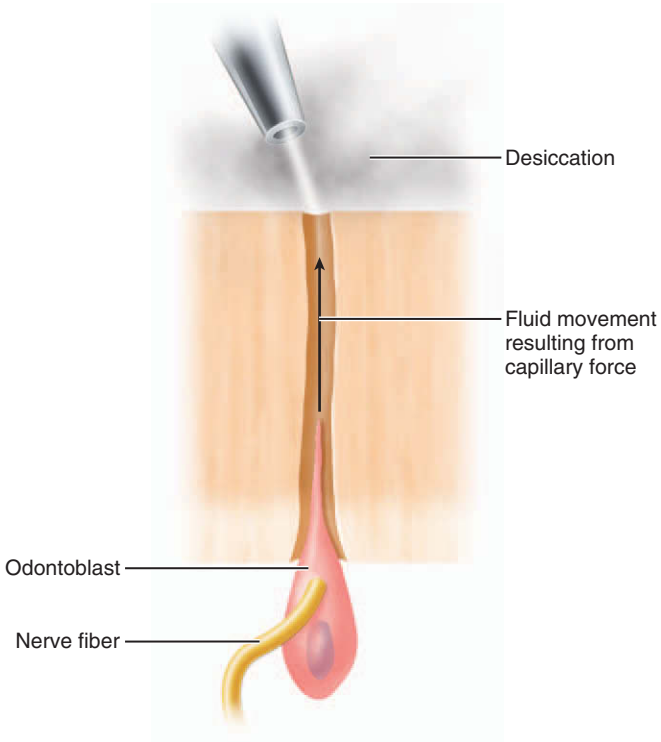

FIG. 12-37 Diagram illustrating movement of fluid in the dentinal tubules resulting from the dehydrating effect of a blast of air from an air syringe.

It has also been shown that pain-producing stimuli are more readily transmitted from the dentin surface when the exposed tubule apertures are open[148,162] and the fluid within the tubules is free to flow outward.[162,230,363] For example, acid treatment of exposed dentin to remove the smear layer opens the tubule orifices and makes the dentin much more responsive to stimuli such as air blasts and probing.[148,254]

Perhaps the most difficult phenomenon to explain is dentinal pain associated with light probing of dentin. Even light pressure of an explorer tip can produce strong forces.* These forces have been shown to mechanically compress dentin and close open tubule orifices with a smear layer that causes sufficient displacement of fluid to excite the sensory receptors in

*To appreciate fully the dimensions of dentin tubules, understand that the diameter of the tubules (about 1 μm) is much smaller than that of red blood cells (about 7 μm). The thickness of coronal dentin is about 3 mm, so each tubule is 3000 μm long but only 1 μm in diameter. Thus each tubule is 3000 diameters long.

*A force of 44 cM (44 g) applied to an explorer having a tip 40 μm in diameter would produce a pressure of 2437 MPa on the dentin.[55] This is far in excess of the compressive strength of dentin, listed as 245 MPa, as evidenced by the shallow grooves lined by smear layers created in dentin using this force.[56]

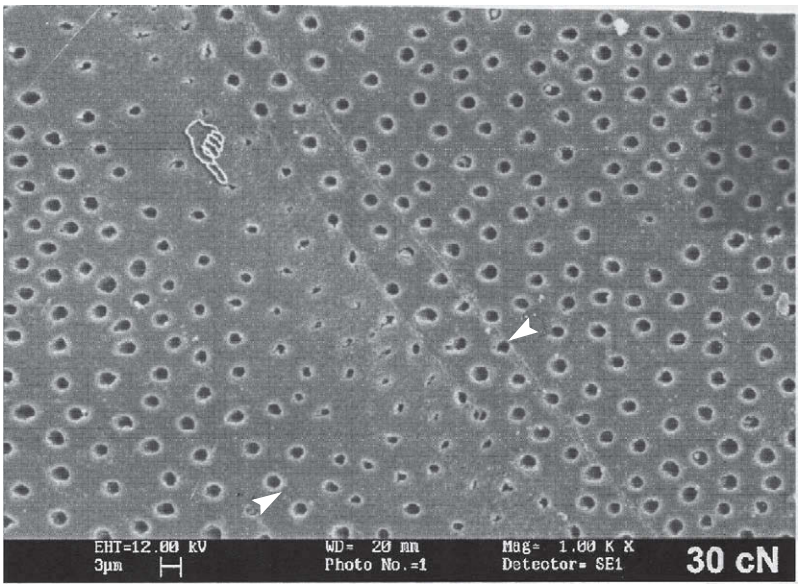

FIG. 12-38 Scanning electron micrograph of a shallow groove *(between white arrowheads)* created in polished dentin by a dental explorer tine under a force of 30 g (30 cN). Note the partial occlusion of the tubules by smeared matrix. *(From Camps J, Salomon JP, Meerbeek BV, et al: Dentin deformation after scratching with clinically relevant forces.* Arch Oral Biol *48:527, 2003.)*

the underlying pulp (Fig. 12-38).[55,56] Considering the density of the tubules in which hydrodynamic forces would be generated by probing, thousands of nerve endings would be simultaneously stimulated when a dental explorer is scratched across dentin.

Another example of the effect of strong hydraulic forces that are created within the dentinal tubules is the phenomenon of odontoblast displacement. In this reaction, the nuclei and cell bodies of odontoblasts are displaced upward in the dentinal tubules, presumably by a rapid movement of fluid in the tubules produced when exposed dentin is desiccated, as with the use of an air syringe or cavity-drying agents (Fig. 12-39).[76,192] Such cellular displacement results in the destruction of odontoblasts, because cells thus affected soon undergo autolysis and disappear from the tubules. Displaced odontoblasts may eventually be replaced by stem cells that migrate from the cell-rich zone of the pulp, as discussed later in the chapter.

The hydrodynamic theory can also be applied to an understanding of the mechanism responsible for hypersensitive dentin.[37,39] There is controversy regarding whether exposed dentin is simply sensitive or becomes truly hypersensitive.[253,254,256] Growing evidence indicates that new sodium channels responsible for activating nerves are expressed in nerve tissue exposed to inflammation.[114,129,293] An increase in the density of sodium channels or their sensitivity may contribute to dentinal hypersensitivity. Hypersensitive dentin is also associated with the exposure of dentin normally covered by cementum or enamel. The thin layer of cementum is frequently lost as gingival recession exposes cementum to the oral environment. Cementum is subsequently worn away by brushing, flossing, or using toothpicks. Once exposed, the dentin may respond to the same stimuli to which any exposed dentin surface responds (e.g., mechanical pressure, dehydrating agents). Although the dentin may at first be very sensitive, within a few weeks the sensitivity usually subsides. This desensitization is thought to occur as a result of gradual occlusion of the tubules by mineral deposits, thus reducing hydrodynamic forces. In addition, deposition of reparative dentin over the pulpal ends of the exposed tubules probably also reduces sensitivity, because reparative dentin is less innervated by sensory nerve fibers.[49] However, some hypersensitive dentin does not spontaneously desensitize, so hypersensitivity may be caused by either inflammatory changes in the pulp or mechanical changes in the patency of dentinal tubules.

Currently the treatment of hypersensitive teeth is directed toward reducing the functional diameter of the dentinal tubules to limit fluid movement. Four possible treatment modalities[271,348,365] can accomplish this objective:

1. Formation of a smear layer on the sensitive dentin by burnishing the exposed root surface[148,253,254]
2. Application of agents, such as oxalate compounds, that form insoluble precipitates within the tubules[148,278]
3. Application of agents such as hydroxyethyl methacrylate (HEMA) with or without glutaraldehyde that are thought to occlude tubules with precipitated plasma proteins in dentinal fluid[309]
4. Application of dentin bonding agents to seal off the tubules[287]

Dentin sensitivity can be modified by laser irradiation, but clinicians must be concerned about its effect on the pulp.[326,336]

Neuropeptides

Of immense importance in pulp biology is the presence of neuropeptides in pulpal nerves.[45,48,52,327] Pulpal nerve fibers contain neuropeptides such as calcitonin gene–related peptide (CGRP) (see Figs. 12-31, 12-33, 12-34),[44] substance P (SP),[253,268] neuropeptide Y (see Fig. 12-29), neurokinin A (NKA),[14] and VIP.[213,365] In rat molars, the largest group of intradental sensory fibers contains CGRP. Some of these fibers also contain other peptides, such as SP and NKA.[45,47] Release of these peptides can be triggered by numerous stimuli, including tissue injury,[14] complement activation, antigen-antibody reactions,[264] or antidromic stimulation of the inferior alveolar nerve.[268,269] Once released, vasoactive peptides produce vascular changes that are similar to those evoked by histamine and bradykinin (i.e., vasodilation).[269] In addition to their neurovascular properties, SP and CGRP contribute to inflammation and promote wound healing.[32,344] The release of CGRP can be mod-

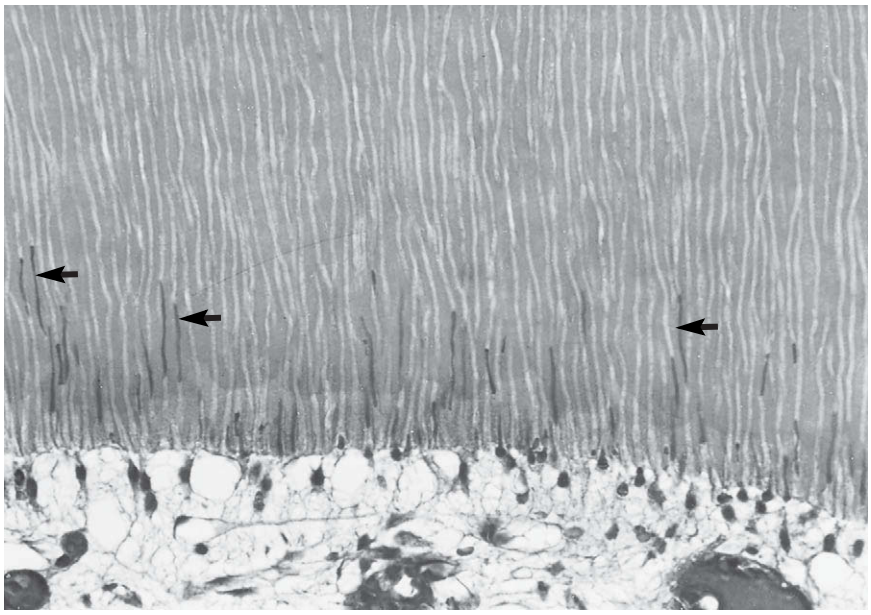

FIG. 12-39 Odontoblasts (*arrows*) displaced upward into the dentinal tubules.

ified by sympathetic agonists and antagonists,[111,130] offering the promise of using such agonists to treat dental pain. This latter point is important because sympathetic agonists are used by clinicians every day—the vasoconstrictors present in local anesthetic solutions may have direct effects on inhibiting dental nerve activity. Local anesthetic reduction in pain may be due to the actions of both the local anesthetic and the vasoconstrictor on the nerves.[129,130] In cats, capsaicin acutely activates and chronically blocks the TRPV1-expressing classes of C and A-delta nociceptors in the pulp.[154] In addition, the chronic application of capsaicin ointment to skin has been shown to relieve pain in patients, suggesting that clinical trials evaluating chronic application of capsaicin for treating pulpal or periradicular pain may be of value.

Antidromic stimulation of nerves (i.e., towards the peripheral terminals) simply means that the afferent barrage goes in the opposite direction of the orthograde stimulation (towards the CNS). Normally, sensory nerves are stimulated at their peripheral terminations, and their action potentials then travel toward the brain. In antidromic nerve stimulation, the sensory nerve is usually cut, then the peripheral end of the nerve is electrically stimulated. This causes an action potential to travel backward toward the periphery, which causes release of neuropeptides in the pulp.[268] All branches of the nerve also depolarize and release neuropeptides (the so-called axon reflex).[306]

It has been reported[230,268] that mechanical stimulation of dentin produces vasodilation within the pulp, presumably by causing the release of neuropeptides from intradental sensory fibers.[268] Electric stimulation of the tooth has a similar effect.[142] The pulpal concentrations of CGRP, SP, and NKA are elevated in painful human teeth over healthy control teeth extracted for orthodontic treatment.[14] These peptides are also elevated in pulps beneath advancing carious lesions.[295,296]

Plasticity of Intradental Nerve Fibers

It has become apparent that the innervation of the tooth is a dynamic situation in which the number, size, and cytochemistry of nerve fibers can change because of aging,[99,207,327] tooth injury,[45,47,48,52] and dental caries.[296] For example, in rats, nerve fibers sprout into inflamed tissue surrounding sites of pulpal injury, and the content of CGRP and SP increases in these sprouting fibers.[45,47,48,52,54] When inflammation subsides, the number of sprouts decreases. Fig. 12-40 compares the normal distribution of CGRP-immunoreactive sensory fibers in an adult rat molar with those beneath a shallow cavity preparation. The innervational pattern in normal and inflamed teeth is governed by neuronal growth factors. Neurotrophic and target-derived factors regulate neuronal structure, survival, and function and are important for the maintenance of neuronal phenotype characteristics. During development, all dental fibers appear to require nerve growth factor (NGF) and express its receptor, TrkA, at some stages,[227] whereas in adult teeth the large trigeminal neurons are potentially dependent only on dental pulp–derived, glial cell line–derived neurotrophic factor (GDNF); the smaller trigeminal neurons remain dependent on NGF.[190,289] This suggests that GDNF may function as a neurotrophic factor for the subset of larger nerves in the tooth, which apparently mediate mechanosensitive stimuli, whereas NGF is suggested to support neurons responsible for nociception.[243] NGF is the most extensively investigated among the trophic factors.[198] Binding of target-derived NGF is dependent on specific TrkA receptors located on the axonal surface, with subsequent internalization and transport to the cell body, where the effects are mediated.

Regulation of neural changes during inflammation seems to be a function of NGF expression.[50,54] NGF receptors are found on intradental sensory fibers and Schwann cells.[47] Evidence indicates that NGF is synthesized by fibroblasts in the coronal subodontoblastic zone (i.e., cell-rich zone), particularly in the tip of the pulp horn.[47] Maximal sprouting of CGRP- and SP-containing nerve fibers corresponds to areas of the pulp where there is increased production of NGF.[54] Fig. 12-41 shows the expression of NGF-mRNA in a pulp horn subjacent to cavity preparation.

It has been suggested that neuroimmune interactions take place in the dental pulp, since a coordinated increase of pulpal

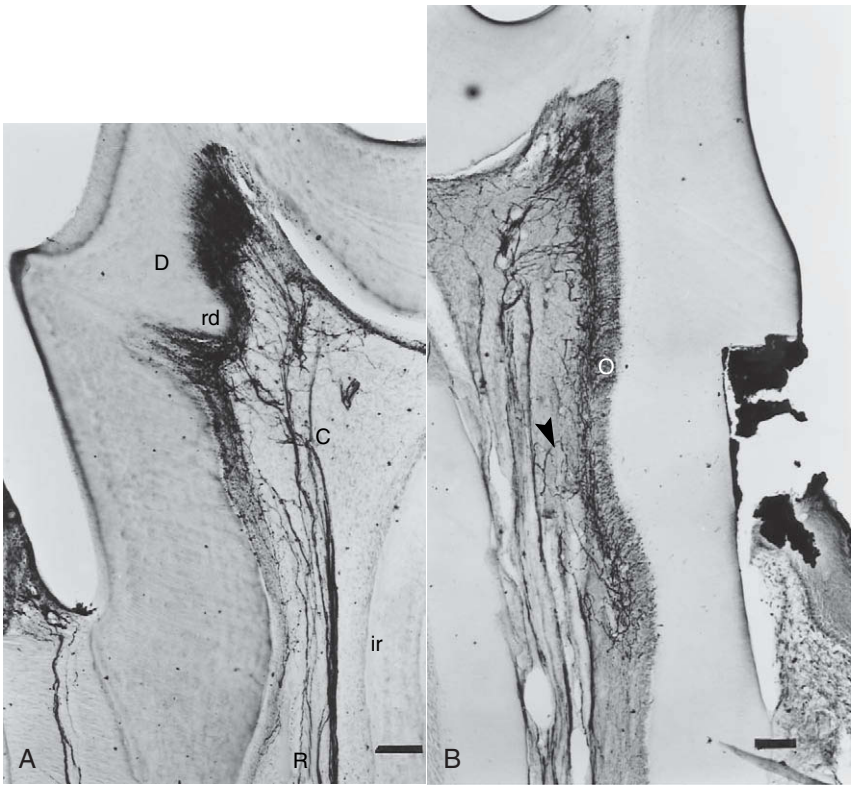

FIG. 12-40 A, Normal distribution of calcitonin gene–related peptide (CGRP)-immunoreactive sensory fibers in adult rat molar. Nerve fibers typically are unbranched in the root (R), avoid interradicular dentin (ir), and form many branches in coronal pulp (C) and dentin (D). Nerve distribution is often asymmetric, with endings concentrated near the most columnar odontoblasts (in this case on the left side of the crown). When reparative dentin (rd) forms, it alters conditions so that dentinal innervation is reduced. **B,** Shallow class I cavity preparation on the cervical root of a rat molar was made 4 days earlier. Primary odontoblast (O) layer survived, and many new CGRP-immunoreactive terminal branches spread beneath and into the injured pulp and dentin. Terminal arbor can be seen branching *(arrowhead)* from a larger axon and growing into the injury site. Scale bar: 0.1 mm. **A,** ×75. **B,** ×45. *(From Byers MR: Dynamic plasticity of dental sensory nerve structure and cytochemistry.* Arch Oral Biol *39[suppl]:13S, 1994.)*

nerves and immune cells has been demonstrated.[164,303] In addition, recruitment of immunocompetent cells has been demonstrated in the dental pulp after electrical tooth stimulation.[66,103] Similar responses have been seen in periapical bone in rats with radicular pulpitis.[182] Neurogenic inflammation is generally thought to enhance healing, because denervated teeth show poorer healing following pulp exposures than innervated teeth.[45,53]

Hyperalgesia

Three characteristics of hyperalgesia are (1) spontaneous pain, (2) a decreased pain threshold, and (3) an increased response to a painful stimulus.[129] It is recognized that hyperalgesia can be produced by sustained inflammation, as in the case of sunburned skin. Clinical observation has shown that the sensitivity of dentin is often increased when the underlying pulp becomes acutely inflamed, and the tooth may be more difficult to anesthetize. This is due in part to the upregulation of tetrodotoxin-resistant (TTX-resistant) sodium channels in inflamed neural tissue.[114,129] NGF seems to play an important role in hyperalgesia. NGF regulates chronic inflammatory hyperalgesia by controlling gene expression in sensory neurons,[257] including genes involved in inflammatory hyperalgesia in the dental pulp.[74] Although a precise explanation for hyperalgesia is lacking, apparently localized elevations in tissue pressure and inflammatory mediators that accompany acute inflammation play an important role (see Chapter 19 for additional detail).[141,143,324,339,356] Clinically, we know that when the pulp chamber of a painful tooth with an abscessed pulp is opened, drainage of exudate soon produces a reduction in the level of pain. This suggests that mechanical stimuli may contribute substantially to pain during inflammatory hyperalgesia.

In addition, certain mediators of inflammation (e.g., bradykinin, 5-hydroxytryptamine [5-HT], prostaglandin E2) are capable of producing hyperalgesia.[253,256] For example, 5-HT and CGRP are able to sensitize intradental fibers to hydrodynamic stimuli such as cold, air blasts, and osmotic stimulation.[256] Unmyelinated fibers are activated by a number of inflammatory mediators. Bradykinin produces a dull, aching pain when placed in a deep cavity in a human tooth.[187]

Leukotriene B_4 (LTB_4) was shown to have a long-lasting sensitizing effect on intradental nerves, suggesting that it may potentiate nociceptor activity during pulpal inflammation.[217]

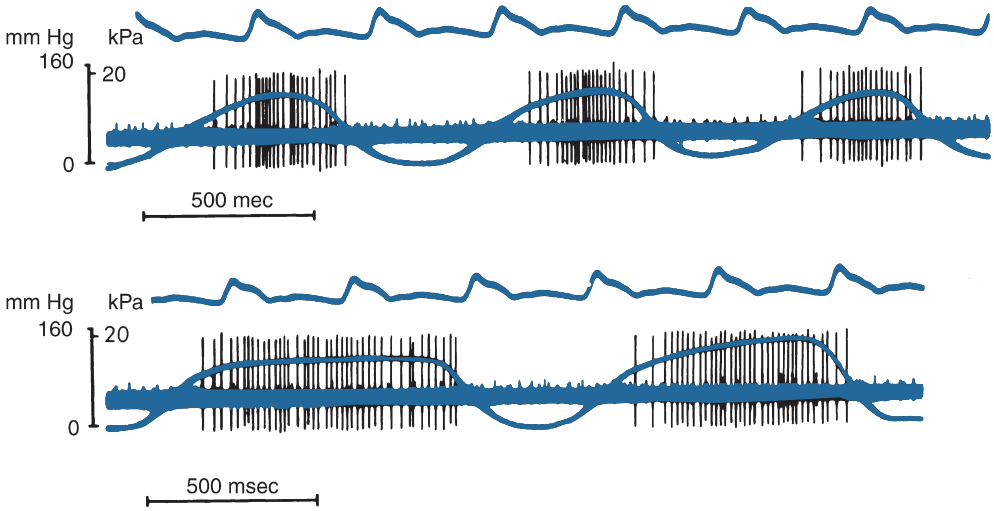

FIG. 12-42 Response of a single dog pulp nerve fiber to repeated hydrostatic pressure stimulation pulses. Lower solid wavy line of each recording indicates the stimulation pressure applied to the pulp. Upper line (kPa) is the femoral artery blood pressure curve recorded to indicate the relative changes in the pulse pressure and the heart cycle. *(Modified from Närhi M: Activation of dental pulp nerves of the cat and the dog with hydrostatic pressure.* Proc Finn Dent Soc *74[suppl 5]:1, 1978.)*

Both LTB_4 and the complement component, C5a, stimulate neutrophils to secrete additional pain-producing cytokines.

Many silent nerve fibers are present in the normal pulp[253,254] and are termed *silent* because they are not excited by ordinary external stimuli. Once they are sensitized through pulpal inflammation, they begin to respond to hydrodynamic stimuli.[48,253,254,256] This phenomenon may provide an additional mechanism for dentin hypersensitivity. The molecular mechanisms of this activation are not known in detail but involve upregulation of numerous genes and their products.[14,47,114]

Painful Pulpitis

From the foregoing, it is apparent that pain associated with the stimulation of the A fibers does not necessarily signify that the pulp is inflamed or that tissue injury has occurred. Clinically, pain produced by A fibers in response to the hydrodynamic mechanism has a sharp or bright quality as contrasted with the dull, boring, or throbbing pain associated with C fibers. A fibers have a relatively low threshold of excitability to external stimuli,[230,252] and painful pulpitis is more likely to be associated with nociceptive C fiber activity indicative of pulpal tissue injury.[252-254,256] The clinician should carefully examine symptomatic teeth to rule out the possibility of hypersensitive dentin, cracked or leaky fillings, or tooth fracture—each of which may initiate hydrodynamic forces—before establishing a diagnosis of reversible or irreversible pulpitis (see also Chapters 1 and 2).

Pain associated with an inflamed or degenerating pulp may be either provoked or spontaneous. The hyperalgesic pulp may demonstrate a lowered threshold of pain by responding to stimuli that usually do not evoke pain (allodynia), or the pain may be exaggerated and persist longer than normal (hyperalgesia).[8] On the other hand, the tooth may commence to ache spontaneously in the absence of any external stimulus.[129] Spontaneous, unprovoked pain generally indicates a pulp that is seriously damaged and generally will not respond to noninvasive therapy. For a more complete discussion of pain mechanisms of the dentin-pulp complex, the reader is referred to Chapter 19.

Several studies have elucidated the role of hydrostatic pressure changes in the activation of pulpal nerve fibers.[249] In experiments involving cats and dogs, both positive and negative pressure changes were introduced into the pulp by means of a cannula inserted into the dentin. Using single-fiber recording techniques, a positive correlation was found between the degree of pressure change and the number of nerve impulses leaving the pulp (Figs. 12-42 and 12-43).[230,250,362]

VASCULAR SUPPLY

Blood from the dental artery enters the tooth by way of arterioles having diameters of 100 µm or less. These vessels pass through the apical foramen or foramina with nerve bundles. Smaller vessels may enter the pulp by way of lateral or accessory canals. They are richly innervated by autonomic and sensory nerves, and the regulation of blood flow seems to be dominated by neuronal control[1,23,181,267,340] (Fig. 12-44).

The arterioles course up through the central portion of the radicular pulp and give off branches that spread laterally toward the odontoblast layer, beneath which they ramify to form a capillary plexus[188] (Fig. 12-45). As the arterioles pass into the coronal pulp, they fan out toward the dentin, diminish in size, and give rise to a capillary network in the subodontoblastic region[329] (Fig. 12-46). This network provides the odontoblasts with a rich source of metabolites.

Capillary blood flow in the coronal portion of the pulp is nearly twice that in the root portion.[176] Moreover, blood flow in the region of the pulp horns is greater than in all other areas of the pulp.[232] In young teeth, capillaries commonly extend into the odontoblast layer, thus ensuring an adequate supply of nutrients for the metabolically active odontoblasts (Fig. 12-47). In the subodontoblastic capillaries, fenestrations are observed in the vessel wall.[291] These fenestrations are thought to promote rapid transport of fluid and metabolites from the

capillaries to the adjacent odontoblasts. The average capillary density is about 1400/mm^2, which is greater than in most other tissues of the body.[364]

Blood passes from the capillary plexus, first into postcapillary venules (see Fig. 12-46; Fig. 12-48) and then into larger venules.[188] Venules in the pulp have unusually thin walls, and the muscular layer is discontinous,[69] which may facilitate the movement of fluid in or out of the vessel. The collecting venules become progressively larger as they course to the central region of the pulp. The largest venules have a diameter that may reach a maximum of 200 µm, considerably larger than the arterioles of the pulp.

The resting pulpal blood flow is relatively high, averaging 0.15 to 0.60 ml/min/g tissue,[228,337] and blood volume represents about 3% of pulpal wet weight,[31] approximately the same as in mammary tumour tissue.[377] As would be anticipated, pulpal blood flow is greater in the peripheral layer of the pulp (i.e., the subodontoblastic capillary plexus)[188] where the oxygen consumption has been shown to be higher than in the central pulp.[27]

Changes in pulpal blood flow can be measured through dentin using laser Doppler flowmeters. Sensitivity to movement requires that they are stabilized in an occlusal stent or a modified rubber dam clamp.[91,305] Because up to 80% of the Doppler signal originates from periodontal tissue, it is helpful to cover periodontal tissues with a black rubber dam.[132] Laser Doppler flowmetry can be used to detect revascularization of traumatized teeth.[76,86] Although measurement of pulpal blood flow would be an ideal tool for determining pulp vitality, the use of laser Dopplers and other techniques is limited due to sensitivity, specificity, reproducibility, and costs.

Regulation of Pulpal Blood Flow

Under normal physiologic conditions, pulpal vascular tone is controlled by neuronal, paracrine, and endocrine mechanisms

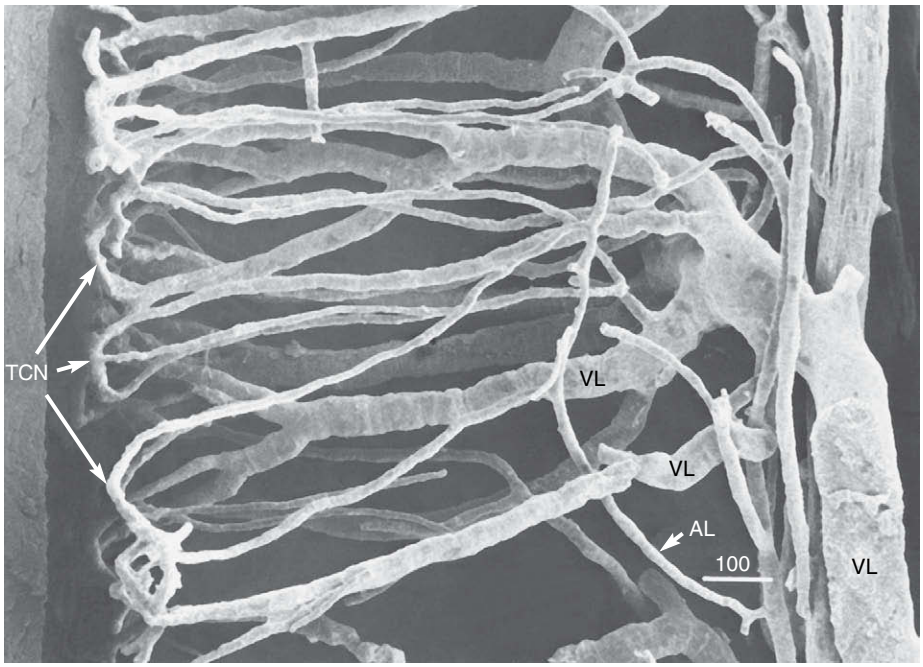

FIG. 12-46 Subodontoblastic terminal capillary network (TCN), arterioles (AL), and venules (VL) of young canine pulp. Dentin would be to the far left and the central pulp to the right. that keep the blood vessels in a state of partial constriction. The pulpal blood flow is also influenced by vascular tone in neighboring tissues. Vasodilatation in these tissues has been shown to cause a drop in pulpal blood flow due to reduction in local arterial pressure of the teeth and thereby reduced pulpal perfusion pressure.[338] The "stealing" of dental perfusion pressure makes the dental pulp vulnerable in clinical situations with inflammatory processes in the adjacent tissues, as in gingivitis and periodontitis.

Neuronal regulation of blood flow is extensive in the pulp. There is little or no vasoconstrictor tone of sympathetic origin in the dental pulp during resting conditions,[158,340] but a neuronal vasodilator tone caused by release of sensory neuropeptides has been demonstrated (Fig. 12-49).[21,23]

There are α-adrenergic receptors in the pulp,[153] and stimulation of the cervical sympathetic trunk causes vasoconstriction and fall in pulpal blood flow that can be partially reversed by α-receptor blockade.[181,340] NPY, colocalized with norepinephrine in pulpal sympathetic nerve fibers, contributes also to vasoconstriction in the pulp.[79,178]

Increase in pulpal blood flow is observed after electrical tooth stimulation and is caused by release of sensory neuropeptides followed by vasodilatation.[23,144,169] CGRP released from sensory nerve fibers is mainly responsible for the observed vasodilatation.[21,23]

There is evidence for sympathetic modulation of sensory neuropeptide release in the dental pulp[130]; presynaptic adrenoceptors are found on the sensory nerve terminals and attenuate the release of vasodilators from the sensory nerves.[36,171]

Muscarinic receptors have been identified in the pulp,[34] and the parasympathetic neurotransmitter acetylcholine (ACh) causes vasodilatation and increases blood flow in the tissue.[385] The vasodilation evoked by acetylcholine has been demonstrated to be partly dependent on nitric oxide (NO) production.

VIP, which coexists with ACh in postganglionic neurons, is found in the dental pulp[102,352] and has been demonstrated to cause vasodilatation and increase in pulpal blood flow in cats.[267]

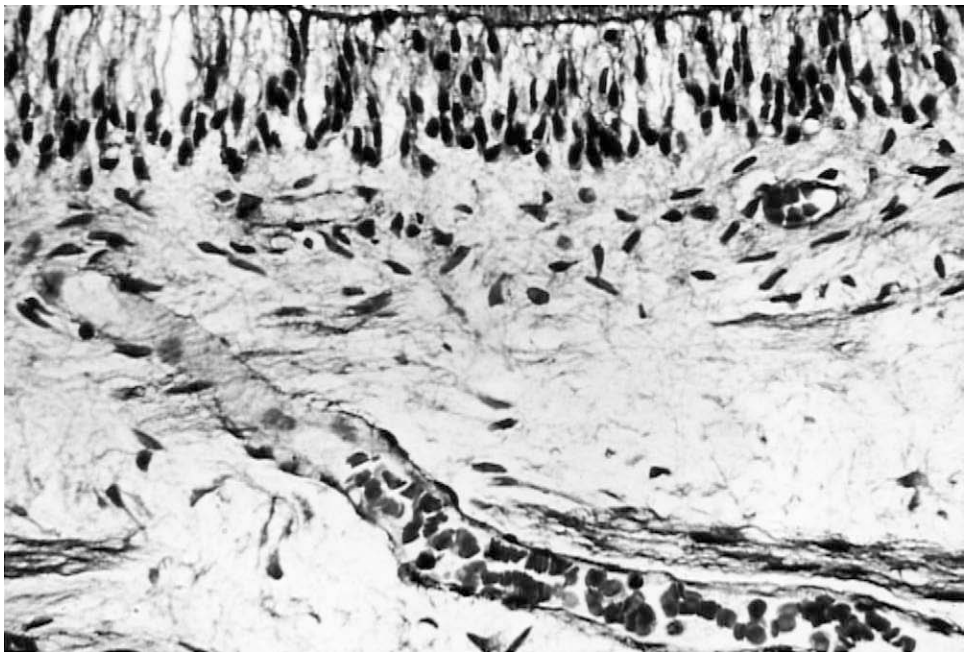

FIG. 12-48 Postcapillary venule draining blood from subodontoblastic capillary plexus.

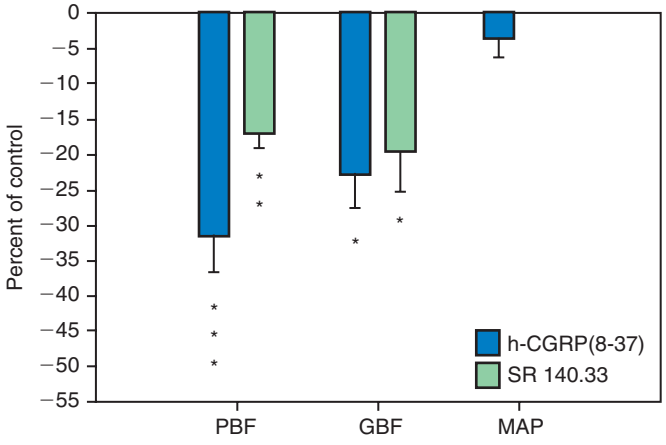

FIG. 12-49 Effect of antagonist infusion of h-CGRP(8-37) (calcitonin gene–related peptide inhibitor) and SR 140.33 (substance P inhibitor) on basal pulpal blood flow (PBF) and gingival blood flow (GBF). *(From Berggreen E, Heyeraas KJ: Effect of the sensory neuropeptide antagonists h-CGRP[8-37] and SR 140.33 on pulpal and gingival blood flow in ferrets.* Arch Oral Biol *45:537–542, 2000.)*

On the other hand, Sasano and co-workers[307] failed to demonstrate parasympathetic nerve-evoked vasodilatation in the cat dental pulp, leaving pulpal vascular responses to parasympathetic neurotransmitters with some uncertainty.

Local Control of Blood Flow

The microvascular bed in the dental pulp has the ability to regulate hemodynamics in response to local tissue demands. Endothelin-1 is located in the endothelium of pulpal vasculature,[58] and close intraarterial infusions of endothelin-1 reduce pulpal blood flow.[22,112,385] However, endothelin-1 does not seem to influence blood vessel vascular tone under basal, resting conditions.[22]

The endothelium in pulpal blood vessels modulates vascular tone by release of vasodilators such as prostacyclin and NO. A basal synthesis of NO provides a vasodilator tone on pulpal vessels.[23,208] The shear forces that blood flow exert on endothelial cells seem to regulate the release of NO.[73]

Adenosine is released from ischemic and hypoxic tissue and is probably important in the metabolic regulation of blood flow in periods of low pulpal oxygen tension. When applied from the extraluminal side of the vessel wall, adenosine mediates vasodilatation in pulpal vessels.[385]

Humoral Control of Blood Flow

Evidence for humoral control of pulpal blood flow exists and takes place when vasoactive substances transported by the bloodstream reach the receptors in the pulp tissue. Angiotensin II is produced by activation of the renin/angiotensin system and exerts a vasoconstrictive basal tone on pulpal blood vessels.[22] The angiotensin II receptors, AT1 and AT2, were recently identified in the rat pulp.[322]

Similarly to the effect of norepinephrine released from sympathetic nerve fibers in the pulp, epinephrine released from the adrenal medulla will cause vasoconstriction due to activation of α-adrenergic receptors in the pulp. Another catecholamine, dihydroxyphenylalanine (DOPA), also induces vasoconstriction in pulpal arterioles when applied intraarterially.[385]

Lymphatics

The lymphatic vasculature forms a vessel network in the interstitium which drains filtered fluid and proteins and returns it to the blood through the larger lymphatics.[147,301] In addition, it serves an important role in the body's immune defense, since dendritic cells enter the blind-ended lymphatic capillaries in the dental pulp and transport captured antigen to regional

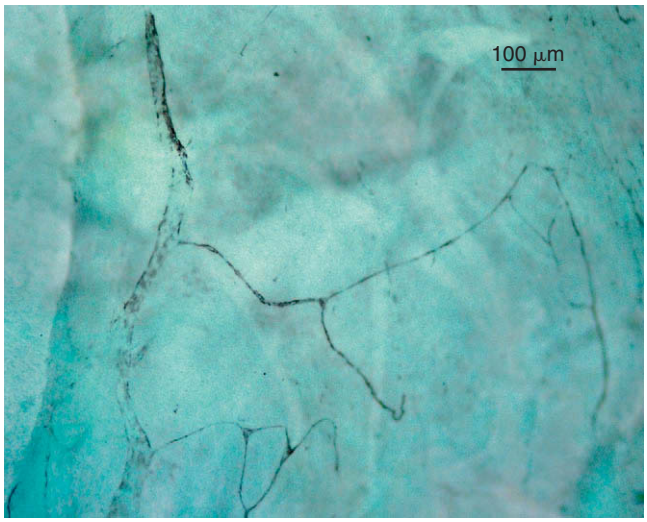

FIG. 12-50 Lymphatic capillaries joining into larger lymphatic vessels in a rodent incisor. The lymphatic endothelium is visualized by whole mount immunohistochemistry utilizing an antibody against vascular endothelial growth factor receptor 3. *(From Berggreen E, Haug SR, Mkonyi LE, Bletsa A: Characterization of the dental lymphatic system and identification of cells immunopositive to specific lymphatic markers.* Eur J Oral Sci *117(1):34–42, 2009.)*

lymph nodes where they present the antigen to lymphocytes. The lymphatic fluid removes foreign invaders such as bacteria and their byproducts from the peripheral tissue and represents a transport system for infectious agents. During inflammation, new lymphatic vessels are formed to meet the demand of increased fluid transport and antigen presentation.[5]

Historically, the existence of lymphatics in the pulp has been a matter of debate because it is difficult to distinguish between blood and lymphatic vessels by ordinary microscopic techniques without specific lymphatic markers.

Recently, specific lymphatic markers have been applied (Fig. 12-50), and an extensive system of lymphatic vessels in the pulp is now recognized to exist (Fig. 12-51).[20,283] These new data indicate that true lymphatics travel from the coronal pulp throughout the roots.[28,262] Lymphatic capillaries are found in the pulp horn but not in the odontoblast layer.[20] Moreover, bundles of lymphatics leave the pulp via the apical foramen and through lateral canals in the root. In the rodent incisor pulp, lymphatic capillaries are found only in the apical third. In the middle and coronal third of the periodontal ligament, lymphatic vessels seem to drain mainly into the alveolar bone, whereas in the apical third, vessels drain toward the apex, where they join into bundles of lymphatic vessels.

Lymphatic capillaries are filled when pulpal interstitial pressure increases after bulk swelling of the interstitium and by strain on the extracellular matrix. When lymph is formed, deformation of interstitial tissue leads to propulsion of lymph by compression of the lymphatics,[308] and inside the rigid pulp chamber, the only force that can cause tissue deformation and strain on the extracellular matrix is the arteriolar pulse pressure converted to a relatively high interstitial pulsatile pressure. It was demonstrated more than 70 years ago in the rabbit ear that the removal rate of an intravital stain injected subcutaneously was higher with than without arterial pressure pulsations in the tissue.[273]

FIG. 12-51 The lymphatic system in a mouse molar immunoreacted with antibody to vascular endothelial growth factor receptor 3. Note that the lymphatic vessels travel from the coronal pulp through the root toward apex. *(From Berggreen E, Haug SR, Mkonyi LE, Bletsa A: Characterization of the dental lymphatic system and identification of cells immunopositive to specific lymphatic markers.* Eur J Oral Sci *117(1):34–42, 2009.)*

As lymphatics from the pulp drain through the periodontal ligament, it is logical to assume that normal tooth movement during chewing will act as an additional extrinsic propulsion mechanism for the lymph.

Transcapillary Fluid Exchange

As in all other tissues in the body, the fluid transport between the pulpal blood vessels and the interstitial space is regulated by differences in colloid osmotic and hydrostatic pressures in the plasma and interstitium in addition to lymph flow (Fig. 12-52).

During normal conditions, a steady state is achieved as the fluid filtered into the interstitial space equals the amount of

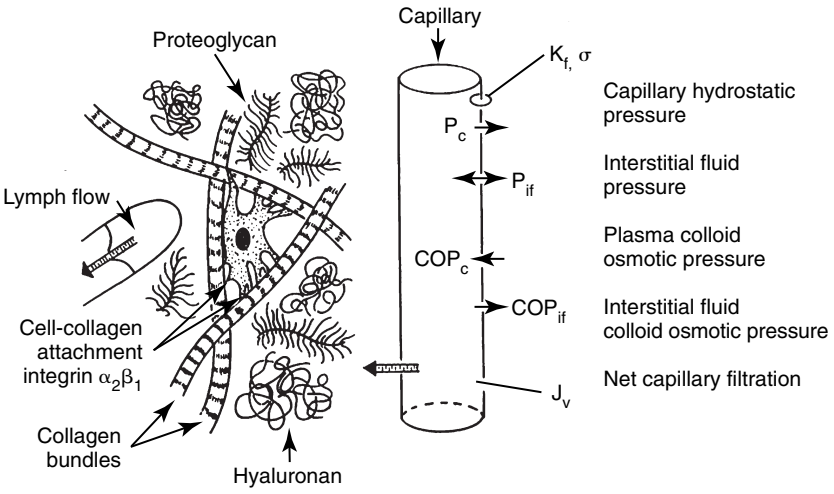

FIG. 12-52 Interstitial structure and pressures that govern transcapillary fluid transport. K_f, Capillary filtration coefficient; σ, capillary reflection coefficient for plasma proteins. *(From Wiig H, Rubin K, Reed RK: New and active role of the interstitium in control of interstitial fluid pressure: potential therapeutic consequences.* Acta Anaesthesiol Scand *47:111–121, 2003.)*

fluid transported out of the same compartment. Using radioisotopes, the interstitial fluid volume in the pulp was measured and averaged 0.6 ± 0.03 ml/g wet weight,[31] demonstrating that as much as 60% of the extracellular fluid in dental pulp is located outside the vascular system. Measurements of interstitial fluid pressure in the pulp with the micropuncture method have given values in the range from 6 to 10 mm Hg,[23,140] but higher values measured with different methods have also been reported.[41,357,361]

Colloid osmotic pressure (COP) measurements in interstitial fluid isolated from rat incisors has shown a relatively high pulpal COP, reaching 83% of plasma COP.[31] The high value may imply that the normal permeability of pulpal vessels to plasma proteins is relatively high and/or the drainage of plasma proteins is ineffective. The fact that lymphatic vessels are only found in the apical part of the rodent incisor may support the latter possibility. Filtered plasma proteins must be removed from the interstitial fluid to maintain homeostasis, and the only possibility for transport is by lymphatics, since proteins cannot be reabsorbed into blood vessels.

Circulation in the Inflamed Pulp

Inflammation in the pulp takes place in a low-compliance environment composed of rigid dentinal walls. *Compliance* is defined as the relationship between volume (V) and interstitial pressure (P) changes: C = Δ V/ Δ P. Consequently, in the low-compliant pulp, an increase in blood or interstitial volume will lead to a relatively large increase in the hydrostatic pressure in the pulp. The acute vascular reactions to an inflammatory stimulus are vasodilatation and increased vascular permeability, both of which will increase pulp interstitial fluid pressure[141,143,340,356] and may tend to compress blood vessels and counteract a beneficial blood flow increase (Fig. 12-53).

Classical studies have demonstrated that an increase in intrapulpal tissue pressure promoted absorption of tissue fluid back into the blood and lymphatic vessels, thereby reducing the pressure.[141,143] This observation can explain why pulpal tissue pressure in inflamed pulps may persist in local regions for long observation periods,[339] contradicting the old concept of a wide, generalized collapse of pulpal venules and cessation of blood flow (pulpal strangulation theory).

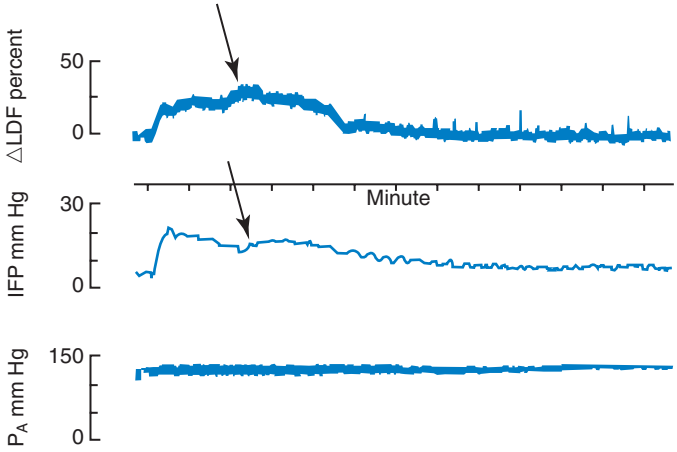

FIG. 12-53 Original simultaneous recordings of percent change in pulpal blood flow (ΔLDF%), interstitial fluid pressure (IFP), and systemic blood pressure (P_A mm Hg) in cat during electrical tooth stimulation. Note that when IFP is first decreasing after an initial rise, the pulpal blood flow reaches its maximal level *(arrows)*, demonstrating compression of vessels in the first phase. *(Courtesy Dr. K.J. Heyeraas.)*

The delivery of dental restorative procedures may lead to substantial increases or decreases in pulpal blood flow, depending upon the precise procedure and time point sampled.[180] Vasoactive mediators are locally released upon an inflammatory insult, and in the pulp, prostaglandin E2, bradykinin, SP, and histamine have all been demonstrated to increase pulpal blood flow after application.[179,266] In contrast, serotonin (5-HT) is released primarily from the platelets, and given intraarterially, it has been shown to reduce pulpal blood flow.[177,385]

Acute inflammation in the dental pulp induce an immediate rise in blood flow and can reach a magnitude of up to nearly 200% of control flow followed by increased vascular permeability.[142,143]

A common outcome of pulpal inflammation is development of tissue necrosis. One study found circulatory dysfunction developed in the pulp after exposure to lipopolysaccharide (LPS) from gram-negative bacteria.[31]

In addition, the inflammatory cytokines IL-1 and TNF-α are elevated in the inflamed pulp. When the endothelium is exposed to endotoxin, it expresses cytokines, chemokines, and thromboxane A2. The latter has been demonstrated to be produced in the pulp exposed to LPS[265] and induces vasoconstriction. The set of changes in endothelial function have been called *endothelial perturbation* and were first described in endothelial cells exposed to endotoxin or to cytokines such as IL-1, TNF-α, and IL-6.[25,255] The activated endothelium also participates in procoagulant reactions that promote fibrin clot formation.[325] A reduced pulpal perfusion due to endothelial perturbation might be the consequence of bacterial infection impairing pulpal defense mechanisms and promoting necrosis. Downregulation of vascular endothelial growth factor (VEGF) expression in stromal cells and reduced microvessel density have been observed in human dental pulps with irreversible pulpitis.[12] VEGF is an essential proangiogenic factor, and the reduced microvessel density might also lead to reduced pulpal perfusion and contribute to development of pulpal necrosis.

The role of lymphatic vessels in dental inflammation is unknown, but Pimenta et al., found an increased number of lymphatic vessels in inflamed pulps from teeth with caries compared to noninflamed pulps, indicating that lymphangiogenesis takes place in the pulp.[283]

Vascular Permeability

Increased vascular permeability takes place as a result of acute inflammation, and vascular leakage has been demonstrated in the pulp after release of inflammatory mediators such as prostaglandin, histamine, bradykinin, and the sensory neuropeptide, SP.[170,179,220]

LPS and lipoteichoic acid (LTA) from gram-negative and gram-positive bacteria, respectively, cause upregulation of VEGF in activated pulpal cells.[35,331] VEGF increases vascular permeability,[88,312] and it is likely that it also causes leakage in pulpal vessels. It is a very potent agent, since its ability to enhance microvascular permeability is estimated to be 50,000 times higher than that of histamine.[316] Cytokines such as IL-1 and TNF-α are released into the pulp interstitial fluid during inflammation[31] and upregulate VEGF mRNA gene expression in pulpal fibroblasts.[60]

The resulting increased vascular permeability allows increased transport of proteins through the capillary vessel wall and results in increased COP in the tissue. In acute pulpitis induced by LPS, it has been shown that COP in the pulp can reach the level of plasma COP, meaning that a barrier between plasma and interstitium can be eleminated.[31]

Clinical Aspects

The influence of posture on pulpal blood flow has been observed in humans.[60] Significantly greater pulpal blood flow was measured when subjects changed from an upright to a supine position. The supine position increases venous return from all tissues below the level of the heart, thereby increasing cardiac output and producing a transient increase in systemic blood pressure. The increase in blood pressure stimulates baroreceptors that reflexively decrease sympathetic vasoconstriction to all vascular beds and thereby increases peripheral blood flow.

Patients with pulpitis often report an inability to sleep at night because they are disturbed by throbbing tooth pain. In addition to the lack of distractions normally present during the day, the following mechanism may be operative in patients with inflamed pulps. When these patients lie down at the end of the day, their pulpal blood flow probably increases due to the cardiovascular postural responses described earlier. This may increase their already elevated pulpal tissue pressure,[141,143,324,339,356] which is then sufficient to activate sensitized pulpal nociceptors and initiate spontaneous pulpal pain. Thus the "throbbing" sensation of a toothache is due to the pulsation in the pulp that follows heart contractions (systole), causing intermittent increases in pulpal tissue pressure.

PULPAL REPAIR

The inherent healing potential of the dental pulp is well recognized. As in all other connective tissues, repair of tissue injury commences with débridement by macrophages, followed by proliferation of fibroblasts, capillary buds, and the formation of collagen. Local circulation is of critical importance in wound healing and repair. An adequate supply of blood is essential to transport immune cells into the area of pulpal injury and to dilute and remove deleterious agents from the area. It is also important to provide fibroblasts with nutrients from which to synthesize collagen. Unlike most tissues, the pulp has essentially no collateral circulation; for this reason, it is theoretically more vulnerable than most other tissues. In the case of severe injury, healing would be impaired in teeth with a limited blood supply. It seems reasonable to assume that the highly cellular pulp of a young tooth, with a wide-open apical foramen and rich blood supply, has a much better healing potential than an older tooth with a narrow foramen and a restricted blood supply.

Dentin can be classified as primary, secondary, or tertiary, depending on when it was formed. *Primary dentin* is the regular tubular dentin formed before eruption, including mantle dentin. *Secondary dentin* is the regular circumferential dentin formed after tooth eruption, whose tubules remain continuous with that of primary dentin. *Tertiary dentin* is the irregular dentin that is formed in response to abnormal stimuli, such as excess tooth wear, cavity preparation, restorative materials, and caries.[64,65] In the past, tertiary dentin has been called *irregular dentin, irritation dentin, reparative dentin,* and *replacement dentin*. Much of the confusion was caused by a lack of understanding of how tertiary dentin is formed.

If the original odontoblasts that made *secondary dentin* are responsible for focal tertiary dentin formation, that particular type of tertiary dentin is termed *reactionary dentin*.[320] Generally, the rate of formation of dentin is increased, but the tubules remain continuous with the secondary dentin.[323] However, if the provoking stimulus caused the destruction of the original odontoblasts, the new, less tubular, more irregular dentin formed by newly differentiated odontoblast-like cells is called *reparative dentin*. In such dentin the tubules are usually not continuous with those of secondary dentin. Initially, the newly formed cells tend to be cuboidal in shape, without the odontoblast process that is necessary to form dentinal tubules. They seem to form in response to the release of a host of growth factors that were bound to collagen during the formation of secondary dentin.[90,294,320] The loss of the continuous layer of odontoblasts exposes unmineralized predentin that is thought to contain both soluble and insoluble forms of TGF-β, insulin-

like growth factor (IGF)-1 and IGF-2, BMPs, VEGF, and other growth factors that attract and cause proliferation and differentiation of mesenchymal stem cells to form reparative dentin and new blood vessels. During caries progression, bacterial acids may solubilize these growth factors from mineralized dentin, liberating them to diffuse to the pulp, where they could stimulate reactionary dentin formation. This is also thought to be the mechanism of action of calcium hydroxide during apexification treatment. Despite its high pH, calcium hydroxide has a slight demineralizing effect on dentin and has been shown to cause the release of TGF-β.[319] TGF-β and other growth factors stimulate and accelerate reparative dentinogenesis. Other researchers have attempted to apply growth factors to dentin to allow it to diffuse through the tubules to the pulp.[299,300,321] Although this has been successful, the remaining dentin thickness must be so thin that this approach may not be practical from a therapeutic perspective. Others have inserted deoxyribonucleic acid (DNA)-sequenced BMP-7 into retroviruses to transfect ferret pulpal fibroblasts to stimulate increased BMP-7 production. Although this was successful in normal pulps,[299] it was unsuccessful in inflamed pulps.[298] Specific amelogenin gene splice products, A+4 and A–4, adsorbed onto agarose beads and applied to pulp exposures, induced complete closure and mineralization of the root canal in rat molars.[116] The regulation of peritubular dentin formation is not well understood. Some have claimed that this is a passive process resulting in occlusion of the tubules over time, but it has also been claimed that this is a mechanism under odontoblast control. If odontoblasts could be stimulated to form excessive peritubular dentin by the application of an appropriate biologic signaling molecule to the floor of cavity preparations, then the tubules of the remaining dentin could be occluded, rendering such dentin impermeable and protecting the pulp from the inward diffusion of noxious substances that might leak around restorations.[277] These are examples of how molecular biology may be used in future restorative dentistry.

The term most commonly applied to irregularly formed dentin is *reparative dentin,* presumably because it frequently forms in response to injury and appears to be a component of the reparative process. It must be recognized, however, that this type of dentin has also been observed in the pulps of normal, unerupted teeth without any obvious injury.[259]

It will be recalled that secondary dentin is deposited circumpulpally at a very slow rate throughout the life of the vital tooth.[323] In contrast, when a carious lesion has invaded dentin, the pulp usually responds by depositing a layer of tertiary dentin over the dentinal tubules of the primary or secondary dentin that communicate with the carious lesion (Fig. 12-54). Similarly, when occlusal wear removes the overlying enamel and exposes the dentin to the oral environment, tertiary dentin is deposited on the pulpal surface of the exposed dentin. Thus the formation of tertiary dentin allows the pulp to retreat behind a barrier of mineralized tissue.[345]

Compared with primary or secondary dentin, tertiary dentin tends to be less tubular, and the tubules tend to be more irregular with larger lumina. In some cases, particularly when the original odontoblasts are destroyed, no tubules are formed. The cells that form reparative dentin are often cuboidal and not as columnar as the primary odontoblasts of the coronal pulp (Fig. 12-55). The quality of tertiary dentin (i.e., the extent to which it resembles primary or secondary dentin) is quite

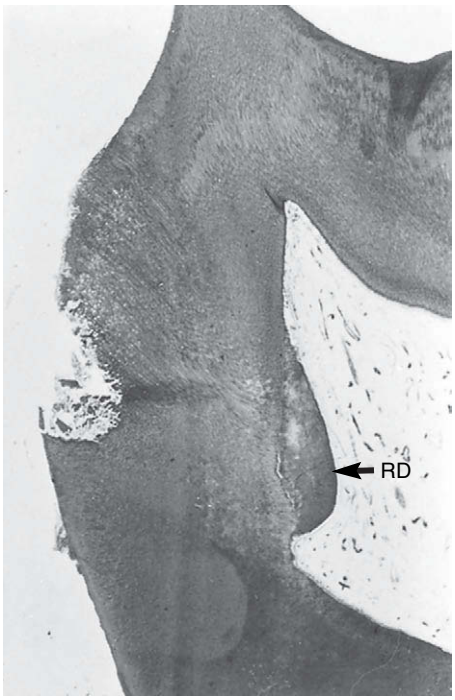

FIG. 12-54 Reparative dentin (RD) deposited in response to a carious lesion in the dentin. *(From Trowbridge HO: Pathogenesis of pulpitis resulting from dental caries.* J Endod *7:52–60, 1981.)*

variable. If irritation to the pulp is relatively mild, as in the case of a superficial carious lesion, then the tertiary dentin formed may resemble primary dentin in terms of tubularity and degree of mineralization. On the other hand, dentin deposited in response to a deep carious lesion may be relatively atubular and poorly mineralized, with many areas of interglobular dentin. The degree of irregularity of this dentin is probably determined by numerous factors, such as the amount of inflammation present, the extent of cellular injury, and the state of differentiation of the replacement odontoblasts.

The poorest quality of reparative dentin is usually observed in association with marked pulpal inflammation.[64,345] In fact, the dentin may be so poorly organized that areas of soft tissue are entrapped within the dentinal matrix. In histologic sections, these areas of soft-tissue entrapment impart a Swiss-cheese appearance to the dentin (Fig. 12-56). As the entrapped soft tissue degenerates, products of tissue degeneration are released that further contribute to the inflammatory stimuli assailing the pulp.[345]

It has been reported that trauma caused by cavity preparation that is too mild to result in the loss of primary odontoblasts does not lead to reparative dentin formation, even if the cavity preparation is relatively deep.[73] This has been confirmed both in rat teeth[242] and human teeth.[240] However, chronic pulpal inflammation associated with deep caries produces reparative dentin. This reparative dentin is formed by new odontoblast-like cells. For many years, it has been recognized that destruction of primary odontoblasts is soon followed by increased mitotic activity within fibroblasts of the subjacent cell-rich zone. It has been shown that the progeny of these dividing cells differentiate into functioning odontoblasts.[96]

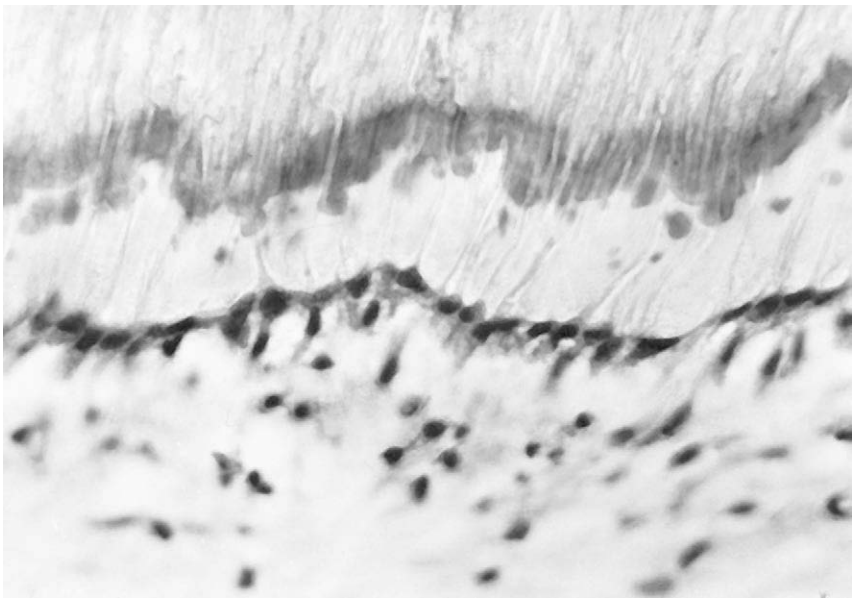

FIG. 12-55 Layer of cells forming reparative dentin. Note the decreased tubularity of reparative dentin compared to the developmental dentin above it.

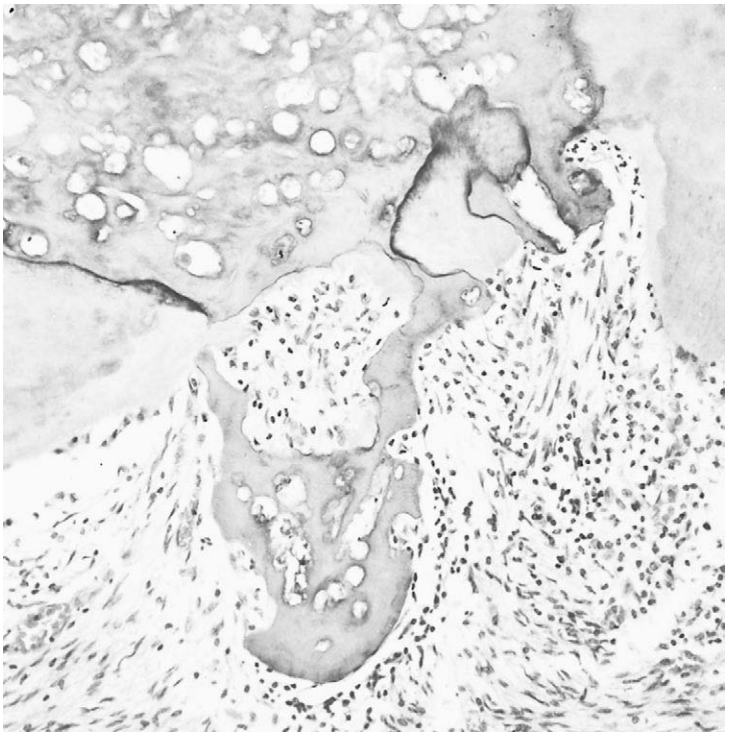

FIG. 12-56 Swiss-cheese type of reparative dentin. Note the numerous areas of soft-tissue inclusion and infiltration of inflammatory cells in the pulp.

Investigators[383] have studied dentin bridge formation in healthy teeth of dogs and found that pulpal fibroblasts appeared to undergo dedifferentiation and revert to undifferentiated mesenchymal stem cells (Fig. 12-57). The similarity of primary odontoblasts to replacement odontoblasts was established by D'Souza et al.[75] They were able to show that cells forming reparative dentin synthesize type I (but not type III) collagen, and they are immunopositive for dentin sialoprotein.

Destruction of primary odontoblasts can occur from cutting cavity preparations dry,[77,192] from bacterial products such as endotoxins shed from deep carious lesions,[19,370] or from mechanical exposure of pulps.[241] Such pulpal wounds do not heal if the tissue is inflamed.[64] Local fibroblast-like cells divide, and the new cells then redifferentiate in a new direction to become odontoblasts. Recalling the migratory potential of ectomesenchymal cells from which the pulpal fibroblasts are derived, it is not difficult to envision the differentiating odontoblasts moving from the subodontoblastic zone to the area of injury to constitute a new odontoblast layer. Activation of antigen-presenting dendritic cells by mild inflammatory processes may also promote osteoblast/odontoblast-like differentiation and expression of molecules implicated in mineralization. Recognition of bacteria by specific odontoblast and fibroblast membrane receptors triggers an inflammatory and

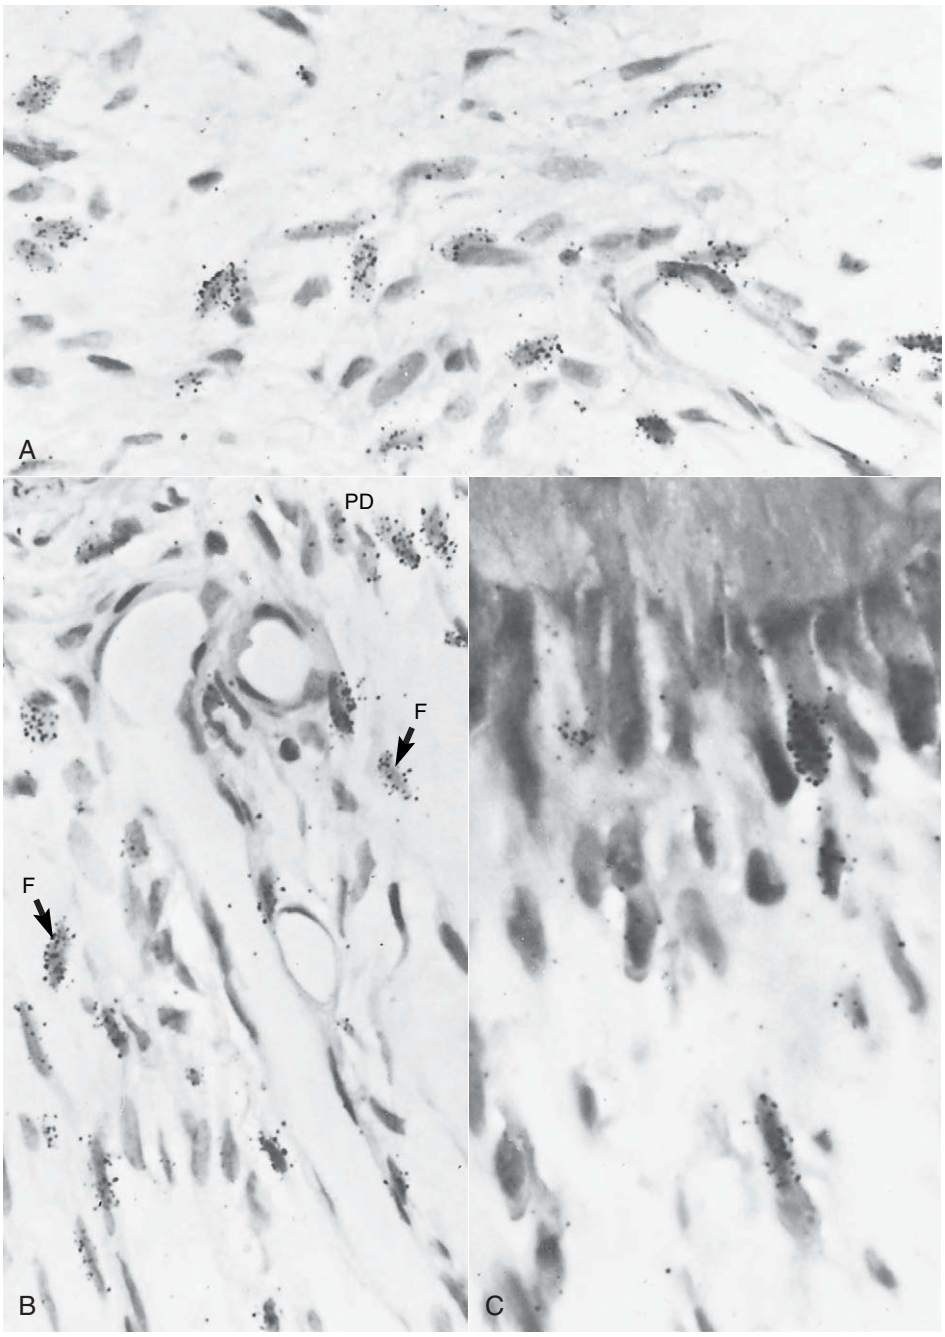

FIG. 12-57 Autoradiographs from dog molars illustrating uptake of ^{3}H-thymidine by pulp cells preparing to undergo cell division after pulpotomy and pulp capping with calcium hydroxide. **A,** Two days after pulp capping. Fibroblasts, endothelial cells, and pericytes beneath the exposure site are labeled. **B,** By the fourth day, fibroblasts (F) and preodontoblasts adjacent to the predentin (PD) are labeled, which suggests that differentiation of preodontoblasts occurred within 2 days. **C,** Six days after pulp capping, new odontoblasts are labeled, and tubular dentin is being formed. (Titrated thymidine was injected 2 days after the pulp capping procedures in **B** and **C.**) *(From Yamamura T, Shimono M, Koike H, et al: Differentiation and induction of undifferentiated mesenchymal cells in tooth and periodontal tissue during wound healing and regeneration.* Bull Tokyo Dent Coll *21:181, 1980.)*

immune response within the pulp tissue that would also modulate the repair process.[118]

Although many animal studies have shown dentin bridge formation in healthy pulps following pulp capping with adhesive resins,[64] such procedures fail in normal human teeth.[62] When small mechanical pulp exposures are inadvertently made in healthy teeth, the current recommendation is to place a small, calcium hydroxide–containing dressing on the wound. After setting, the surrounding dentin can be bonded using a no-rinse, self-etching primer adhesive.[165] Like calcium hydroxide, mineral trioxide aggregate (MTA) has also been recognized to promote hard-tissue formation.[3,7,245]

The formation of atubular "fibrodentin" is another potential product of newly differentiated odontoblasts, provided that

a capillary plexus develops beneath the fibrodentin.[17] This is consistent with the observation made by other researchers[64,96] that the newly formed dentin bridge is composed first of a thin layer of atubular dentin on which a relatively thick layer of tubular dentin is deposited. The fibrodentin was lined by cells resembling mesenchymal cells, whereas the tubular dentin was associated with cells closely resembling odontoblasts.

Other researchers[323] studied reparative dentin formed in response to relatively traumatic experimental class V cavity preparations in human teeth. They found that seldom was reparative dentin formed until about the 30th postoperative day. The rate of dentin formation was 3.5 µm/day for the first 3 weeks after the onset of dentinogenesis, after which it decreased markedly. By postoperative day 132, dentin formation had nearly ceased. Assuming that most of the odontoblasts were destroyed during traumatic cavity preparation, as was likely in this experiment, the 30-day delay between cavity preparation and the onset of reparative dentin formation is thought to reflect the time required for the proliferation, migration, and differentiation of new replacement odontoblasts.

Does reparative dentin protect the pulp, or is it simply a form of scar tissue? To serve a protective function, it would have to provide a relatively impermeable barrier that would exclude irritants from the pulp and compensate for the loss of developmental dentin. The junction between developmental and reparative dentin has been studied using a dye diffusion technique, which demonstrated the presence of an atubular zone situated between secondary dentin and reparative dentin (Fig. 12-58).[92] In addition to a dramatic reduction in the number of tubules, the walls of the tubules along the junction were often thickened and occluded with material similar to peritubular matrix.[310] Taken together, these observations would indicate that the junctional zone between developmental and reparative dentin is an atubular zone of low permeability. Moreover, the accumulation of pulpal dendritic cells was reduced after reparative dentin formation, which may indicate the reduction of incoming bacterial antigens.[303]

One group[335] studied the effect of gold foil placement on human pulp and found that this was better tolerated in teeth in which reparative dentin had previously been deposited beneath the cavity than in teeth that were lacking such a deposit. It would thus appear that reparative dentin can protect the pulp,[19] but it must be emphasized that this is not always the case. It is well known that reparative dentin can be deposited in a pulp that is irreversibly injured and that its presence does not necessarily signify a favorable prognosis (see Fig. 12-55). The quality of the dentin formed, and hence its ability to protect the pulp, to a large extent reflects the environment of the cells producing the matrix. The presence of a single tunnel defect[64] through reparative dentin would circumvent the protective effect of atubular reparative dentin. Therefore any clinical attempt at pulp therapy must include sealing dentin with bonding agent.

Periodontally diseased teeth have smaller root canal diameters than teeth that are periodontally healthy.[193] The root canals of such teeth are narrowed by the deposition of large quantities of reactionary dentin along the dentinal walls.[311] The decrease in root canal diameter with increasing age, in the absence of periodontal disease, is more likely to be the result of secondary dentin formation.

FIG. 12-58 Diffusion of dye from the pulp into reparative dentin. Note atubular zone between reparative dentin (RD) and primary dentin on the left. *(From Fish EW: Experimental investigation of the enamel, dentin, and dental pulp, London, 1932, John Bale Sons & Danielson, Ltd.)*

One study showed that in a rat model, frequent scaling and root planing resulted in reparative dentin formation along the pulpal wall subjacent to the instrumented root surface.[134] However, given that normal rat root dentin is only 100 µm thick, such procedures are probably more traumatic to the pulp in the rat model than in humans, where normal root dentin is more than 2000 µm thick.

Not uncommonly, the cellular elements of the pulp are largely replaced by fibrous connective tissue over a span of 5 decades. It appears that in some cases, the pulp responds to noxious stimuli by accumulating large fiber bundles of collagen, rather than by elaborating reparative dentin (Fig. 12-59). However, fibrosis and reparative dentin formation often go hand in hand, indicating that both are expressions of a reparative potential.

With the expanding knowledge of tooth regeneration and biologic mechanisms of functional dental tissue repair, current treatment strategies are beginning to give way to evolving fields such as tissue engineering and biomimetics. Pulpal stem cells in scaffolds have been shown to produce pulp-like tissues with tubular-like dentin,[85] and in animal models, root perforations have been treated with scaffolds of collagen, pulpal stem cells, and dentin matrix protein 1, resulting in organized matrix similar to that of pulpal tissue.[288]

A case report indicates that it might be possible to revascularize the pulp in infected necrotic immature roots (Fig. 12-60; see also Chapter 16).[16] A young patient presented with an immature second lower right premolar with radiographic and clinical signs of apical periodontitis with the presence of a sinus tract. The canal was disinfected without mechanical

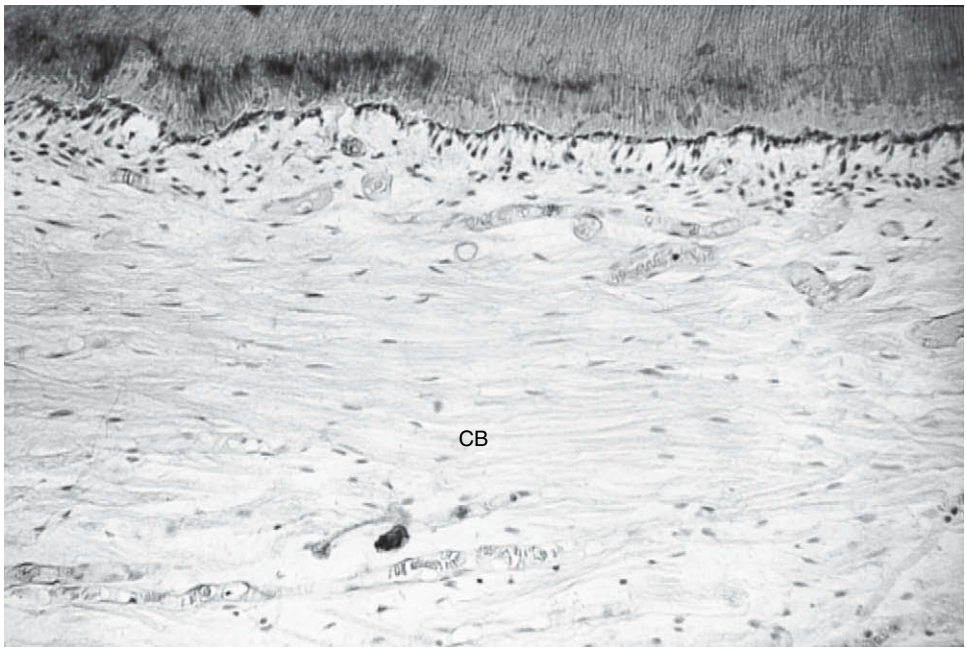

FIG. 12-59 Fibrosis of dental pulp showing replacement of pulp tissue by large collagen bundles (CB).

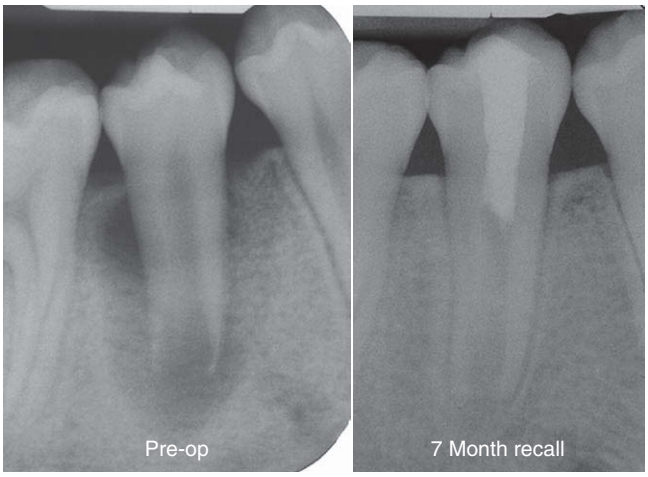

FIG. 12-60 Immature tooth with a necrotic infected canal with apical periodontitis. The canal is disinfected with copious irrigation with sodium hypochlorite and an antibiotic paste. Seven months after treatment, the patient is asymptomatic, and the apex shows healing of the apical periodontitis and some closure of the apex. *(From Banchs F, Trope M: Revascularization of immature permanent teeth with apical periodontitis: new treatment protocol?* J Endod *30:196–200, 2004.)*

instrumentation, with copious irrigation and the use of a mixture of antibiotic agents. Later, a blood clot is created in the canal space and the access is filled with an MTA base. The treatment allows revascularization of the immature tooth and regain of a vital state of the pulp chamber, as well as normal root development below the restoration similar to the adjacent and contralateral teeth.

In the future, the field of pulpal repair will probably develop rapidly, and new treatment strategies will appear.

PULPAL CALCIFICATIONS

Calcification of pulp tissue is a very common occurrence. Although estimates of the incidence of this phenomenon vary widely, it is safe to say that one or more pulp calcifications are present in at least 50% of all teeth. In the coronal pulp, calcification usually takes the form of discrete, concentric pulp stones (Fig. 12-61), whereas in the radicular pulp, calcification tends to be diffuse (Fig. 12-62).[349] There is no clear evidence whether pulp calcification is a pathologic process related to various forms of injury or a natural phenomenon. The clinical significance of pulp calcification is that it may hinder root canal treatment.

Pulp stones (denticles) range in size from small, microscopic particles often seen in association with the wall of arterioles to accretions that occupy almost the entire pulp chamber (Fig. 12-63). The mineral phase of pulp calcifications has been shown to consist of typical carbonated hydroxyapatite.[349] Histologically, two types of stones are recognized: (1) those that are round or ovoid, with smooth surfaces and concentric laminations (see Fig. 12-61) and (2) those that assume no particular shape, lack laminations, and have rough surfaces (Fig. 12-64). Laminated stones appear to grow by the addition of collagen fibrils to their surface, whereas unlaminated stones develop by way of the mineralization of preformed collagen fiber bundles. In the latter type, the mineralization front seems to extend out along the coarse fibers, making the surface of the stones appear fuzzy (Fig. 12-65). Often these coarse fiber bundles appear to have undergone hyalinization, thus resembling old scar tissue.

Pulp stones may also form around epithelial cells (i.e., remnants of Hertwig's epithelial root sheath). Presumably the epithelial remnants induce adjacent mesenchymal stem cells to differentiate into odontoblasts. Characteristically these pulp stones are found near the root apex and contain dentinal tubules.

FIG. 12-62 Diffuse calcification near the apical foramen.

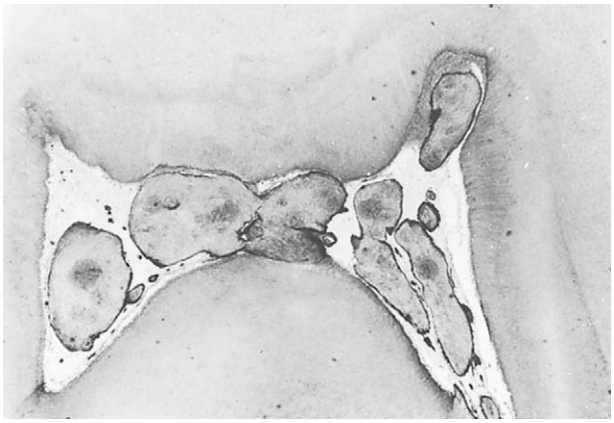

FIG. 12-63 Pulp stones occupying much of the pulp chamber.

The cause of pulpal calcification is largely unknown. Calcification may occur around a nidus of degenerating cells, blood thrombi, or collagen fibers. Many authors believe that this represents a form of dystrophic calcification. In this type of calcification, calcium is deposited in tissues that are degenerating. Calcium phosphate crystals may be deposited within the cells themselves. Initially this takes place within the mitochondria because of the increased membrane permeability to calcium resulting from a failure to maintain active transport systems within the cell membranes. Thus degenerating cells serving as a nidus may initiate calcification of a tissue. In the absence of obvious tissue degeneration, the cause of pulpal calcification is enigmatic. It is often difficult to assign the term *dystrophic calcification* to pulp stones because they so often occur in apparently healthy pulps, suggesting that functional stress need not be present for calcification to occur. Calcification in the mature pulp is often assumed to be related to the aging process, but in a study involving 52 impacted canines from patients between 11 and 76 years of age, there was a constant incidence of concentric denticles for all age groups, indicating no relation to aging.[259] Diffuse calcifications, on the other hand, increased in incidence to age 25 years; thereafter they remained constant in successive age groups.

At times, numerous concentric pulp stones with no apparent cause are seen in all the teeth of young individuals. In such cases, the appearance of pulp stones may be ascribed to individual biologic characteristics (e.g., tori, cutaneous nevi).[259]

Although soft-tissue collagen does not usually calcify, it is common to find calcification occurring in old hyalinized scar tissue in the skin. This may be due to the increase in the extent of cross linking between collagen molecules (because increased cross linkage is thought to enhance the tendency for collagen fibers to calcify). A relationship may exist between pathologic alterations in collagen molecules within the pulp and pulpal calcification.

Calcification replaces the cellular components of the pulp and may possibly hinder the blood supply, although concrete evidence for this strangulation theory is lacking. Idiopathic

FIG. 12-65 High-power view of a pulp stone from Fig. 12-57, showing the relationship of mineralization fronts to collagen fibers.

pulpal pain was classically attributed to the presence of pulp stones. Modern knowledge of mechanisms of nociceptor activation, coupled with the observation that pulp stones are so frequently observed in teeth lacking a history of pain, have largely discounted this hypothesis. Therefore, from a clinical perspective, it would be very unlikely that a patient's unexplained pain symptoms are due to pulpal calcifications, no matter how dramatic they may appear on a radiograph.

Luxation of teeth as a result of trauma may result in calcific metamorphosis, a condition that can, in a matter of months or years, lead to partial or complete radiographic obliteration of the pulp chamber. The cause of radiographic obliteration is excessive deposition of mineralized tissue resembling cementum or, occasionally, bone on the dentin walls, also referred to as *internal ankylosis* (Fig. 12-66). Histologic examination invariably reveals the presence of some soft tissue, and cells

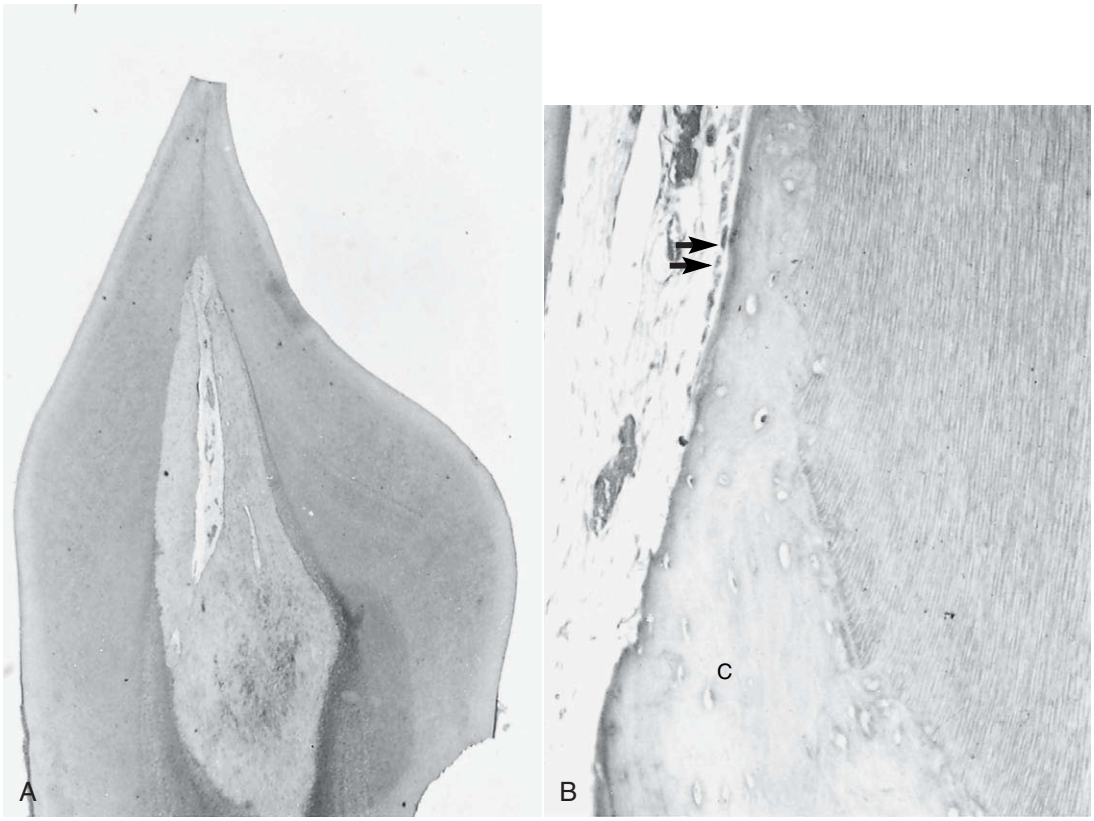

FIG. 12-66 A, Calcific metamorphosis of pulp tissue after luxation of tooth as a result of trauma. Note presence of soft-tissue inclusion. **B,** High-power view showing cementoblasts *(arrows)* lining cementum (C), which has been deposited on the dentin walls.

resembling cementoblasts can be observed lining the mineralized tissue. Such calcific metamorphosis of the pulp has also been reported in replanted teeth of the rat.[258]

Clinically, the crowns of teeth affected by calcific metamorphosis may show a yellowish hue compared with adjacent normal teeth. This condition usually occurs in teeth with incomplete root formation. Trauma results in disruption of blood vessels entering the tooth, thus producing pulpal infarction. The wide periapical foramen allows connective tissue from the periodontal ligament to proliferate and replace the infarcted tissue, bringing with it cementoprogenitor and osteoprogenitor cells capable of differentiating into either cementoblasts or osteoblasts or both.

When calcific metamorphosis is noted on a patient's radiograph, it is sometimes suggested that the tooth be treated endodontically because the pulp is expected to be secondarily infected, and endodontic therapy should be performed while the pulp canal is still large enough to instrument. In a classic study of luxated teeth, Andreasen[9] found only 7% of the pulps that underwent calcific metamorphosis exhibited secondary infection. Since the success rate for nonsurgical endodontic therapy, not only in general[373] but also for obliterated teeth,[68] is considered high, prophylactic intervention does not seem to be warranted.

AGE CHANGES

Continued formation of secondary dentin throughout life gradually reduces the size of the pulp chamber and root canals, although the width of the cementodentinal junction appears to stay relatively the same.[105,323] In addition, certain regressive changes in the pulp appear to be related to the aging process. There is a gradual decrease in the cellularity and a concomitant increase in the number and thickness of collagen fibers, particularly in the radicular pulp. The thick collagen fibers may serve as foci for pulpal calcification (see Fig. 12-64). The odontoblasts decrease in size and number, and they may disappear altogether in certain areas of the pulp, particularly on the pulpal floor over the bifurcation or trifurcation areas of multirooted teeth.

With age there is a progressive reduction in the number of nerves[99] and blood vessels.[24,26] Evidence also suggests that aging results in an increase in the resistance of pulp tissue to the action of proteolytic enzymes,[387] hyaluronidase, and sialidase,[26] suggesting an alteration of both collagen and proteoglycans in the pulps of older teeth. The main changes in dentin associated with aging are an increase in peritubular dentin, dentinal sclerosis, and the number of dead tracts.*[323] Dentinal sclerosis produces a gradual decrease in dentinal permeability as the dentinal tubules become progressively reduced in diameter.[328]

*The term *dead tract* refers to a group of dentinal tubules in which odontoblast processes are absent. Dead tracts are easily recognized in ground sections because the empty tubules refract transmitted light, and the tract appears black in contrast to the light color of normal dentin.

CHAPTER
13

Pulpal Reactions to Caries and Dental Procedures

ASHRAF F. FOUAD and LINDA LEVIN

CHAPTER OUTLINE

PULPAL REACTION TO CARIES
NEUROGENIC MEDIATORS
CORRELATION BETWEEN CLINICAL SYMPTOMS AND ACTUAL PULPAL INFLAMMATION
DENTIN HYPERSENSITIVITY AND ITS MANAGEMENT
PULPAL REACTIONS TO LOCAL ANESTHETICS
PULPAL REACTIONS TO RESTORATIVE PROCEDURES
- Degree of Pretreatment Pulp Inflammation
- Degree of Physical Irritation Caused by Procedure
- Proximity of Restorative Procedures to Dental Pulp and Surface Area of Dentin Exposed
- Permeability of Dentin and Odontoblastic Layer Between Area Being Restored and Pulp
- Patient Age

PULPAL REACTIONS TO RESTORATIVE MATERIALS
DIRECT PULP CAPPING WITH MINERAL TRIOXIDE AGGREGATE
USE OF HEMOSTATIC AGENTS AND DISINFECTANTS ON DIRECT PULP EXPOSURES
PULPAL REACTIONS TO LASER PROCEDURES
- Lasers in the Prevention, Diagnosis, and Treatment of Caries
- Lasers in the Treatment of Dentin Hypersensitivity
- Use of Lasers as a Protective Measure for Dentin

PULPAL REACTIONS TO CAVITY PREPARATION USING AIR ABRASION TECHNIQUES
PULPAL REACTIONS TO VITAL BLEACHING TECHNIQUES
PULPAL REACTIONS TO PERIODONTAL PROCEDURES
MECHANICAL IRRITANTS: ORTHODONTIC MOVEMENT
PULPAL REACTIONS TO ORTHODONTIC SURGERY
BIOMECHANICAL IRRITATION: PARAFUNCTIONAL HABITS
PULPAL REACTIONS TO IMPLANT PLACEMENT AND FUNCTION
REGENERATIVE POTENTIAL OF THE DENTAL PULP

The dental pulp is a very dynamic tissue that responds to external stimuli in a variety of different ways. However, there are certain unique features about the dental pulp response that distinguish it from other connective tissues in the body. The pulp's exposure to dental caries, a very prevalent chronic infectious disease, its encasement in an unyielding environment after complete tooth maturation, and the scarcity of collateral circulation render it susceptible to injury and complicate its regeneration. Moreover, the pulp is endowed with a rich neurovascular supply that promotes the effects of inflammation and may lead to rapid degeneration and necrosis, a condition considered very serious in any tissue in the body. The treatment of dental caries and other tooth abnormalities involves the cleaning and shaping of the enamel and dentin, the hardest tissues in the body, thus adding to the irritation of the pulp. In this chapter, the response of the pulp to all these variables will be discussed, and recent advances in our understanding of dental procedures and their effects on the pulp will be presented.

PULPAL REACTION TO CARIES

Dental caries is a localized, destructive, and progressive infection of dentin; if left unchecked, caries can result in pulpal necrosis and potential tooth loss. Both bacterial byproducts and products from the dissolution of the organic and inorganic constituents of dentin mediate the effects of dental caries on the pulp. Three basic reactions tend to protect the pulp against caries: (1) a decrease in dentin permeability, (2) tertiary dentin formation, and (3) inflammatory and immune reactions. These responses occur concomitantly, and their robustness is highly dependent on the aggressive nature of the advancing lesion.

In the advancing infection front of the carious lesion, multiple intrinsic and extrinsic factors are released that are stimulatory to subjacent pulpal parenchyma. Bacterial metabolites such as acids have been thought to be initiators of pulpal reactions, yet the buffering capacity of dentin fluid likely attenuates the pH before it can directly effect a deleterious response, except when the remaining dentin thickness is minimal.[214]

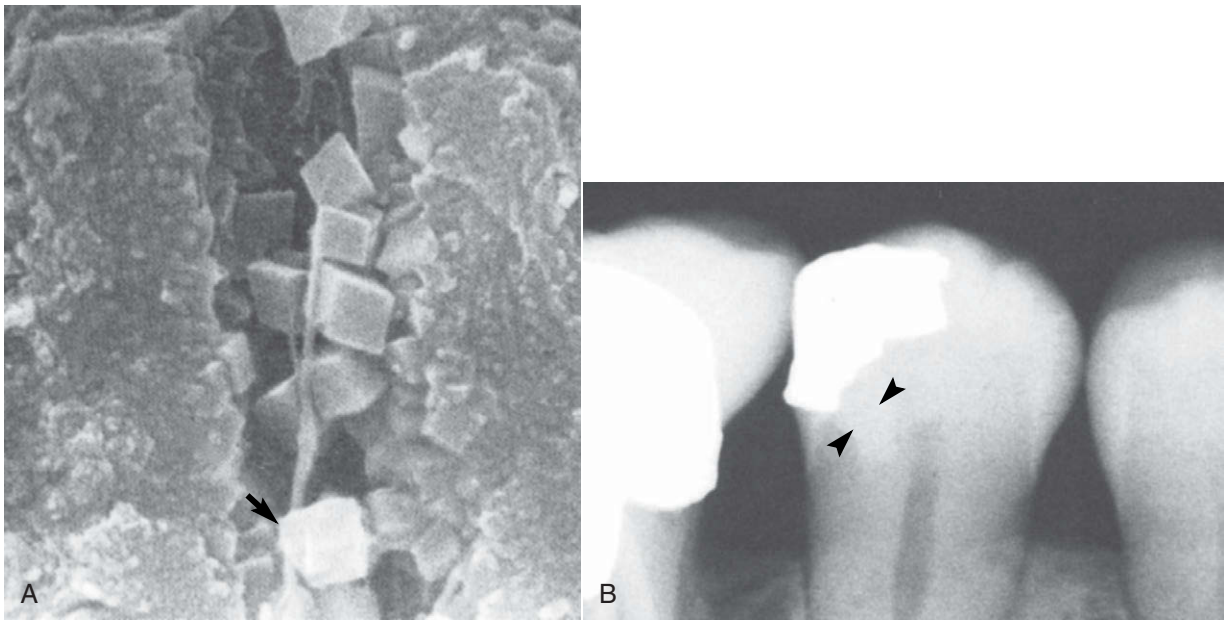

FIG. 13-1 A, Whitlockite crystals occlude the dentinal tubules in sclerotic dentin. **B,** Dentinal sclerosis is radiographically apparent beneath a deep class II lesion. (***A*** *from Yoshiyama M, Masada J, Uchida A, Ishida H: Scanning electron microscopic characterization of sensitive vs. insensitive human radicular dentin.* J Dent Res *68:1498–1502, 1989.)*

When relatively unhindered access to pulpal tissue is present, both bacterial metabolites and cell wall components induce inflammation. In initial to moderate lesions, current evidence suggests that acidic byproducts of the carious process act indirectly by degrading the dentin matrix, thereby liberating bioactive molecules previously sequestered during dentinogenesis. Once liberated, these molecules once again assume their role in dentin formation, this time stimulatory for *tertiary* dentinogenesis.[216] This theory is supported by the findings that demineralized dentin matrix implanted at the site of pulpal exposure can induce dentinogenesis.[243] Furthermore, placement of purified dentin matrix proteins on exposed dentin or exposed pulp stimulates tertiary dentin formation, indicating that these molecules can act directly or across intact dentin.[217,242]

Recent evidence offers several candidate molecules that are stimulatory for reparative dentinogenesis. Heparin-binding growth factor, transforming growth factor (TGF)-β1, TGF-β3, insulin-like growth factors (IGF)-1 and -2, platelet-derived growth factor, and angiogenic growth factors have been shown to be stimulatory for dentinogenesis in vitro. The TGF-β superfamily in particular seems to be important in the signaling process for odontoblast differentiation as well as primary and tertiary dentinogenesis. As the predominant isoform, TGF-β1 is equally distributed in the soluble and insoluble fractions of dentin matrix.[39] During the carious dissolution of dentin, it is believed that the soluble pool of TGF-β1 can diffuse across intact dentin while the insoluble pool is immobilized on insoluble dentin matrix and serves to stimulate odontoblasts, much like membrane-bound TGF-βs during odontogenesis.[214]

Despite the research interest in tertiary dentinogenesis, it is neither the first nor necessarily the most effective pulpally mediated defense against invading pathogens. A combination of an increased deposition of intratubular dentin and the direct deposition of mineral crystals into the narrowed dentin tubules to decrease dentin permeability is the first defense to caries and is called *dentin sclerosis*. It occurs by a combination of increased deposition of intratubular dentin and tubule occlusion by precipitated crystals. This results in an effective decrease in dentin permeability that occurs in a relatively short period of time. Classic studies have noted that while sclerosis is observed in the dentin of disease-free and attrition-free teeth, there is a 95% increase in the incidence in carious teeth.[222] In vitro studies with cultured tooth slices implicate TGF-β1 as a central player in the increased deposition of intratubular dentin.[213] The deposition of whitlockite crystals in the tubular lumen most likely results from a similar stimulation of vital associated odontoblasts, possibly in combination with precipitation of mineral released during the demineralization process[140,239] (Fig. 13-1).

The formation of tertiary dentin occurs over a longer period than does that of sclerotic dentin, and its resultant character is highly dependent on the stimulus. Mild stimuli activate resident quiescent odontoblasts, whereupon they elaborate the organic matrix of dentin. This type of tertiary dentin is referred to as *reactionary dentin* and can be observed when initial dentin demineralization occurs beneath the noncavitated enamel lesion.[135] Mediators present during the carious process induce a focal upregulation of matrix production by resident odontoblasts. The resultant dentin is similar in morphology to physiologic dentin and may only be apparent due to a change in the direction of the new dentinal tubules (Fig. 13-2). In the aggressive lesion, the carious process may prove cytocidal to subjacent odontoblasts and require repopulation of the disrupted odontoblast layer with differentiating progenitors. The appearance of the resultant matrix is a direct reflection of the differentiation state of the secretory cells. This accounts for the heterogeneity of *reparative dentin*, where the morphology can range from organized tubular dentin to more disorganized irregular *fibrodentin*. Fibrodentin, owing to its irregular con-

FIG. 13-2 Reactionary dentinogenesis (TD); note the tubular morphology and the discontinuity of the tubules at the interface of secondary and reactionary dentin. Resident odontoblasts are still present.

FIG. 13-3 Reparative dentin; the strong stimulus of the impinging infection is cytocidal for odontoblasts. The resultant dentin is irregular with soft-tissue inclusions.

figuration and tissue inclusions, is more permeable than physiologic dentin[252] (Fig. 13-3).

Although dentin can provide a physical barrier against noxious stimuli, the pulpal immune response provides humoral and cellular challenges to invading pathogens. In the progressing carious lesion, the host immune response increases in intensity as the infection advances. It has been shown that titers of T helper cells, B-lineage cells, neutrophils, and macrophages are directly proportional to lesion depth in human teeth.[107] The disintegration of large amounts of dentin, however, is not necessary to elicit a pulpal immune response. This is supported by the observation that a pulpal inflammatory response can be seen beneath noncavitated lesions and noncoalesced pits and fissures.[33]

The early inflammatory response to caries is characterized by the focal accumulation of chronic inflammatory cells (Fig. 13-4). This is mediated initially by odontoblasts and later by dendritic cells. As the most peripheral cell in the pulp, the odontoblast is positioned to encounter foreign antigens first and initiate the innate immune response. Pathogen detection in general is accomplished via specific receptors called *pattern recognition receptors* (PRRs).[109] These receptors recognize pathogen-associated molecular patterns (PAMPs) on invading organisms and initiate a host defense through the activation of the nuclear factor (NF)-κB pathway.[91] One class of the PAMP recognition molecules is the toll-like receptor family (TLRs). Odontoblasts have been shown to have increased expression of certain TLRs in response to bacterial products. Under experimental conditions, odontoblast expression of TLR3, 5, and 9

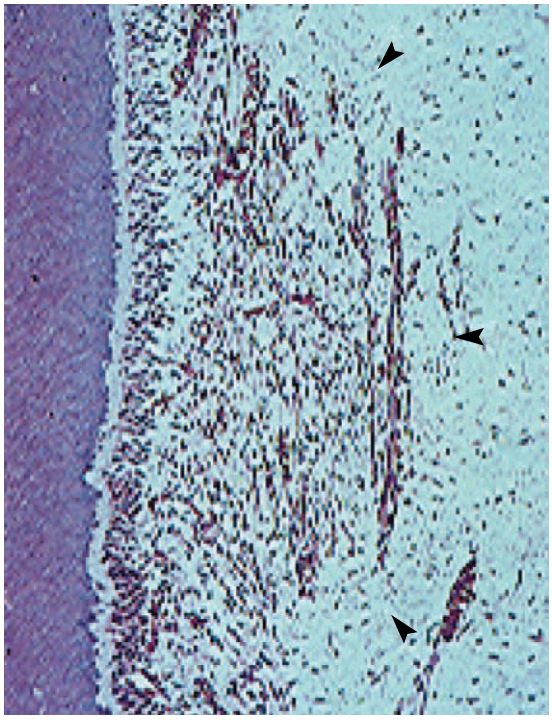

FIG. 13-4 The early pulpal response to caries is represented by a focal accumulation of chronic inflammatory cells. Note that peripheral to the inflammation, the pulpal parenchyma is relatively unaffected.

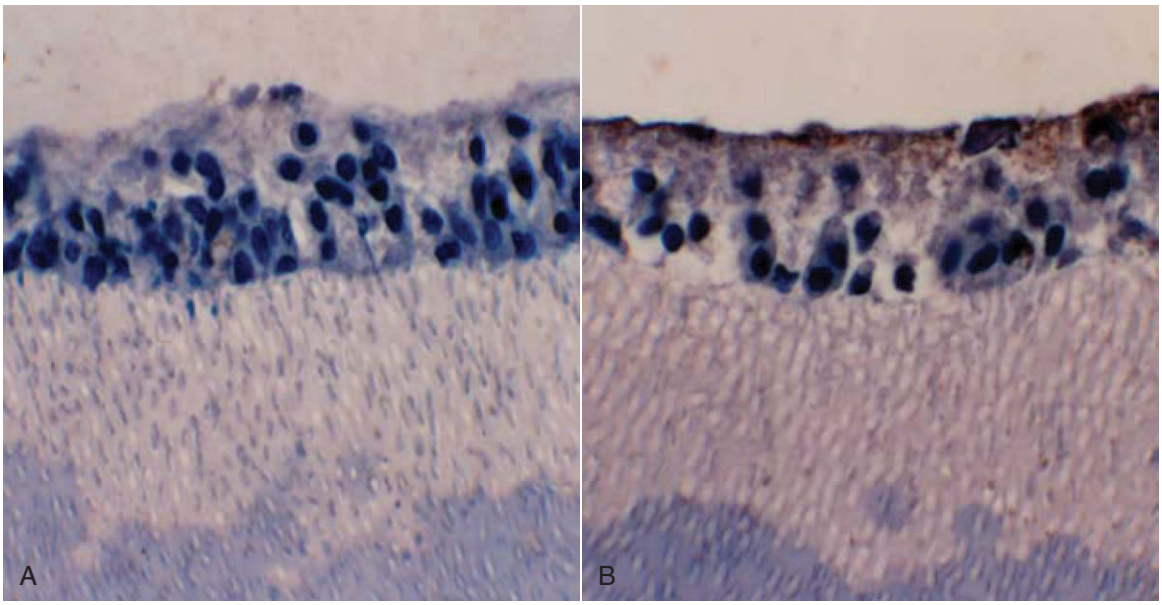

FIG. 13-5 Odontoblasts exposed to lipopolysaccharide (LPS) in an in vitro culture model express interleukin 8 (IL-8), evidenced by immunostaining with anti-IL-8 antibodies.

was increased in response to lipoteichoic acid, whereas lipopolysaccharide increased TLR2 expression.[59,166] Once the odontoblast TLR is stimulated by a pathogen, proinflammatory cytokines, chemokines, and antimicrobial peptides are elaborated by the odontoblast, resulting in recruitment and stimulation of immune effector cells as well as direct bacterial killing.[67]

Many cells constitutively produce chemokines at low levels. Unstimulated odontoblasts express genes coding for CCl2, CXCL12, and CXCL14, three genes known to code for factors chemotactic for immature dendritic cells.[40] They also produce CCL26, a natural antagonist for CCR1, CCR2, and CCR5, which are chemokines normally produced by monocytes and dendritic cells.[264] Stimulation with bacterial cell wall constituents has been shown to upregulate the production of several chemokines, suggesting that odontoblasts sense pathogens and express factors that recruit immune effector cells[40,136] (Fig. 13-5). These data suggest a scenario whereby stimulated odontoblasts express high levels of chemokines such as interleukin (IL)-8 (CXCL8) that act in concert with the release of formerly sequestered TGF-β1 from carious dentin, the result of which is a focal increase in dendritic cell numbers, with additional release of chemotactic mediators.[68] The subsequent influx of immune effector cells is composed of lymphocytes, macrophages, and plasma cells. This cellular infiltrate is accompanied by localized capillary sprouting in response to angiogenic factors, as well as coaggregation of nerve fibers and HLA-DR-positive dendritic cells.[257,258]

As the carious lesion progresses, the density of the chronic inflammatory infiltrate, as well as that of dendritic cells in the odontoblast region, increases. Pulpal dendritic cells are responsible for antigen presentation and stimulation of T lymphocytes. In the uninflamed pulp, they are scattered throughout the pulp. With caries progression, they aggregate initially in the pulp and subodontoblastic regions, then extend into the odontoblast layer, and eventually migrate into the entrance to tubules beside the odontoblast process[259] (Fig. 13-6). There are

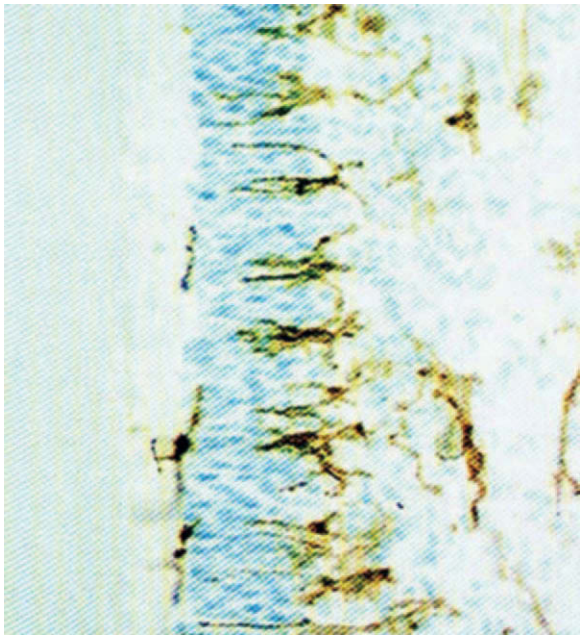

FIG. 13-6 Dental caries stimulates the accumulation of pulpal dendritic cells in and around the odontoblastic layer. *(Courtesy Mats Jontell.)*

two distinct populations of dendritic cells that have been identified in the dental pulp. CD11c+ are found in the pulp/dentin border and subjacent to pits and fissures. F4/80+ dendritic cells are concentrated in the perivascular spaces in the subodontoblastic zone and inner pulp.[264] CD11c+ dendritic cells express toll-like receptors 2 and 4 and are CD205 positive. F4/80+ dendritic cells have migratory ability. As they migrate from the central pulp, they increase in size and become CD86 positive. The close spatial relationship between odontoblasts and den-

dritic cells under the carious lesion have led to speculation that dendritic cells may play a role in odontoblast differentiation and/or secretory activity in the immune defense and dentinogenesis. Pulpal Schwann cells have also been shown to produce molecules in response to caries, which is indicative of the acquisition of the ability for antigen presentation.

Evidence suggests that odontoblasts also play a role in the humoral immune response to caries. Immunoglobulin (Ig)G, IgM, and IgA have been localized in the cytoplasm and cell processes of odontoblasts in human carious dentin, suggesting that these cells actively transport antibodies to the infection front.[171] In the incipient lesion, antibodies accumulate in the odontoblast layer and with lesion progression can be seen in the dentinal tubules. Eventually this leads to a focal concentration of antibodies beneath the advancing lesion.[170]

In the most advanced phase of carious destruction, the humoral immune response is accompanied by immunopathologic destruction of pulpal tissue. In animal studies where monkeys were hyperimmunized to bovine serum albumin (BSA), there was an observed increase in pulpal tissue destruction subsequent to antigenic challenge across freshly cut dentin.[20] These findings support the contention that antigen-antibody complex formation, in addition to various products of the inflammatory cascade, gives rise to a nonspecific response that, while designed to rid the body of pathogens, effects destruction of parenchymal tissues as well.

NEUROGENIC MEDIATORS

Neurogenic mediators are involved in the pulpal response to irritants and like immune components; they can mediate pathology as well as the healing response (for a review see Ref. 43). External stimulation of dentin causes the release of pro-inflammatory neuropeptides from pulpal afferent nerves.[35] Substance P, calcitonin gene-related peptide (CGRP), neurokinin A (NKA), NKY, and vasoactive intestinal peptide are released and affect vascular events such as vasodilatation and increased vascular permeability. This results in a net increase in tissue pressure that can progress to necrosis in extreme and persistent circumstances. Stimulation of sympathetic nerves in response to the local release of mediators such as norepinephrine, neuropeptide Y, and adenosine triphosphate (ATP) has been shown to alter pulpal blood flow. Both receptor field studies and anatomic studies have shown sprouting of afferent fibers in response to inflammation.[35]

Neuropeptides can act to modulate the pulpal immune response. It has been demonstrated that substance P acts as a chemotactic and stimulatory agent for macrophages and T lymphocytes. The result of this stimulation is increased production of arachidonic acid metabolites, stimulation of lymphocytic mitosis, and production of cytokines. CGRP demonstrates immunosuppressive activity, which is evidenced by a decrease in H_2O_2 production by macrophages and a diminution of class II antigen presentation and lymphocyte proliferation.

Substance P and CGRP are mitogenic for pulpal and odontoblast-like cells and thereby initiate and propagate the pulpal healing response.[237] CGRP has been shown to stimulate the production of bone morphogenic protein by human pulpal cells. The result of such stimulation has been postulated to induce tertiary dentinogenesis.[37]

As the carious lesion approximates the pulp, there is an acute exacerbation of the precedent chronic inflammation. This is characterized by an influx of neutrophils. The accumulation of inflammatory cells becomes marked when the infection front reaches tertiary dentin.[128,129,200] In the presence of severe pulpal inflammation, focal microabscesses form and eventually coalesce, leading to progressive pulpal necrosis (Fig. 13-7).

Pulpal exposure in primary and immature permanent teeth can lead to a proliferative response, or *hyperplastic pulpitis*. Exuberant inflammatory tissue proliferates through the exposure and forms a "pulp polyp" (Fig. 13-8). It is presumed that

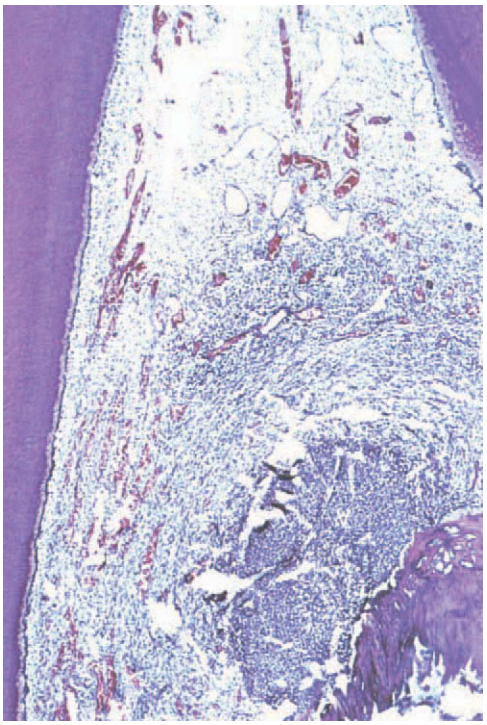

FIG. 13-7 Hematoxylin- and eosin-stained section of a dental pulp, displaying pulpal necrosis.

FIG. 13-8 A proliferative response to caries in a young tooth, typically referred to as *proliferative pulpitis, hyperplastic pulpitis,* or *pulp polyp. (Courtesy Dr. Howard Strassler, University of Maryland.)*

a rich blood supply coupled with ample lymphatic and oral drainage allows this proliferative response. Conventional root canal therapy or progressive vital pulp therapy is indicated.

CORRELATION BETWEEN CLINICAL SYMPTOMS AND ACTUAL PULPAL INFLAMMATION

From a clinical perspective, it would be most helpful to the clinician to be able to diagnose pulpal conditions from a profile of the patient's presenting symptoms. If symptoms are not conclusive, a number of objective tests should aid the clinician in reaching a definitive diagnosis of the pulpal pathologic status. In actuality, such combinations of subjective and objective findings are frequently insufficient in reaching definitive diagnosis of the status of the dental pulp. This is particularly true in cases of vital inflamed pulp, where it is difficult for the clinician to determine clinically whether the inflammation is reversible or irreversible.

Many clinicians rely on painful symptoms to determine the status of the pulp. Several studies have examined this question in some detail. A number of classic studies were performed in which the subjective and objective clinical findings related to carious teeth were recorded prior to extracting the teeth and examining them histologically. The underlying hypothesis in these studies was that the more severe the clinical symptoms, the more intense pulpal inflammation and destruction was evident histologically. The findings of these studies revealed that in the vital pulp, clinical symptoms generally did not correlate with gross histomorphologic findings.[90,150,209] Furthermore, carious pulp exposure was associated with severe inflammatory response or liquefactive necrosis, regardless of symptoms (Fig. 13-9). These histologic changes ranged in extent from being present only at the site of the exposure to deep into the root canals.[209] In a few studies, prolonged or spontaneous severe symptoms were associated with chronic partial or total pulpitis or pulp necrosis.[57,209] However, in these as well as other studies, it was common to find cases with histologic evidence of severe inflammatory responses, including partial necrosis, but little or no clinical symptoms—the so-called painless pulpitis.[57,90,150,209] Based on these studies and more recent data, it was reported that the incidence of painless pulpitis that leads to pulp necrosis and chronic periradicular periodontitis is about 40% to 60% of pulpitis cases.[149]

FIG. 13-9 Histologic photomicrograph of a molar with carious pulp exposure. The exposure had been capped but had failed, and the patient presented with symptoms. The photomicrograph shows an area of necrosis and extensive inflammation throughout the coronal pulp. *(Courtesy Dr. Larz Spangberg, University of Connecticut.)*

Objective clinical findings are essential for determining the vitality of the pulp and whether the inflammation has extended into the periapical tissues. Lack of response to electric pulp testing is generally indicative that the pulp has become necrotic.[202,209] Thermal pulp testing is valuable in reproducing a symptom of thermal sensitivity and allowing the clinician to assess the reaction of the patient to a stimulus and the duration of the response. However, pulp testing cannot determine the degree of pulpal inflammation.[57,209] These studies show that irreversible pulpal inflammation can be diagnosed with some certainty only in cases where, in addition to being responsive to pulp testing, the pulp develops severe spontaneous symptoms. Pulp necrosis could be predictably diagnosed by a consistent negative response to pulp tests, preferably to both cold and electrical tests to avoid false responses.[190,191] Pulp necrosis could be verified by a test cavity and/or lack of hemorrhagic pulp tissue upon access preparation. It should be noted, however, that the latter sign should be assessed cautiously. Occasionally, the pulp space is very small, such as in older individuals with calcified canals, and hemorrhage upon access to the pulp may not be clinically appreciable. Conversely, cases with pulp necrosis and acute periapical infections may have hemorrhagic purulent drainage through the large pulp space upon access preparation, particularly after initial instrumentation.

The lack of correlation between the histologic status of the pulp and clinical symptoms may be explained by recent advances in the science of pulp biology. In the last few decades, studies have shown that numerous molecular mediators may act in synchrony to initiate, promote, and/or modulate the inflammatory response in the dental pulp. Without the use of very specialized staining techniques, the nature and quantity of these inflammatory mediators cannot be determined from histologic analysis. Many of these molecular mediators tend to reduce the pain threshold, either directly by acting on peripheral nerve cells or through promoting the inflammatory process. Thus a number of these mediators were shown to be elevated in human pulp diagnosed with painful pulpitis. These mediators include prostaglandins[47,204]; the vasoactive amine, bradykinin[134]; tumor necrosis factor alpha (TNF-α)[123]; neuropeptides such as substance P,[29] CGRP, and NKA[11]; and catecholamines.[167] In fact, it was even shown that when patients have painful pulpitis, the crevicular fluid related to the affected teeth has significantly increased neuropeptides compared to the levels in contralateral teeth.[11] In another study, trained volunteers had an incisor stimulated with a constant current threefold the threshold value for 90 seconds.[10] This resulted in a significant increase in crevicular matrix metalloproteinase 8 (MMP8), one of the collagenases involved in tissue destruction.

It has also been determined that peripheral opioid receptors are present in the dental pulp,[108] and these could play a role in why many cases with irreversible pulpitis are asymptomatic. As noted before, carious teeth are frequently not associated

with significant symptoms. However, they still have a significant amount of inflammation. The pulp in teeth with mild to moderate caries has increased neuropeptide Y[61] and its Y1 receptor,[62] compared to normal teeth. Neuropeptide Y is a sympathetic nervous system neurotransmitter and is thought to act as a modulator of neurogenic inflammation. Likewise, the levels of vasoactive intestinal peptide (VIP), although not its receptor VPAC1, seemed to increase in the pulp of moderately carious teeth.[60]

With recent advances in molecular biology, efficient simultaneous detection of hundreds of molecular mediators by their gene expression has become a reality. Current research seeks to examine which genes are specifically expressed or upregulated in the pulp in response to the carious lesion. In this regard, preliminary studies have shown that various cytokines and other inflammatory mediators are upregulated underneath a carious lesion in a manner that correlates with the depth of caries.[147] Gene microarrays have been used in several studies to obtain an accurate mapping of candidate genes that show elevated expression in inflamed pulp, the odontoblastic cell layer.[148,176,177] Development of more accurate chairside diagnostic methods is potentially feasible, particularly sampling from crevicular fluid, dentinal fluid, or the pulp directly. For this reason, more research is needed to determine the key mediators that would predict survival or degeneration of the dental pulp in difficult diagnostic cases.

DENTIN HYPERSENSITIVITY AND ITS MANAGEMENT

Dentin hypersensitivity represents a special situation in which a significant, usually chronic, pulpal problem arises that does not seem to be associated with irreversible pulpal pathosis in the majority of cases. Dentin hypersensitivity is characterized by short, sharp pain arising from exposed dentin in response to stimuli—typically thermal, evaporative, tactile, osmotic, or chemical—that cannot be ascribed to any other form of dental defect or pathology.[94] Facial root surfaces in canines, premolars, and molars are particularly affected, especially in areas of periodontal attachment loss. Dentin hypersensitivity may be related to excessive abrasion during tooth brushing, periodontal disease, or erosion from dietary or gastric acids[2,3,44] and may be increased following scaling and root planning.[44,251] The dentin is hypersensitive most likely due to the lack of protection by cementum, loss of smear layer, and the hydrodynamic movement of fluid in dentinal tubules.[4,31] The degree of inflammation in the pulp in cases of dentin hypersensitivity is not well characterized because the condition is usually not severe enough to warrant tooth extraction or endodontic therapy. However, patent dentinal tubules are present in areas of hypersensitivity[261] (Fig. 13-10) and may result in increased irritation and localized reversible inflammation of the pulp at the sites involved.

The application of neural modulating agents such as potassium nitrate[146] or tubule blocking agents such as strontium chloride, oxalates, or dentin bonding agents (Fig. 13-11)[4,184] usually alleviates the condition, at least temporarily. However, the placement of passive molecules or crystals may provide only temporary relief, so there has been a need to provide biocompatible materials that bond to the root surface to provide a more lasting solution. One such material was a calcium sodium phosphosilicate bioactive glass,[141] which was developed into a commercial product (SootheRx, NovaMin Technology Inc, Alachua, FL). Another product uses a combination of a calcium oxalate and an acid-etched bonding material to seal the dentinal tubules (BisBlock, Bisco Inc, Schaumberg, IL). A concern has been raised that the acidic pH during etching may cause dissolution of the oxalate crystals, thus interfering with the effectiveness of the material.[256] However, a recent study found that BisBlock and two other products (Seal&Protect, DENTSPLY DeTrey GmbH, Konstanz, Germany, and Vivasens, Ivoclar Vivadent AG, Schaan, Liechtenstein) were effective several weeks after treatment, compared to placebo.[180] In the long term, the development of smear layer, such as from tooth brushing, dentin sclerosis, reactionary dentin, and the blockage of tubules with large endogenous macromolecules are all thought to reduce the problem[183] (illustrated by Mechanism of Dentin Hypersensitivity animation on the Expert Consult Site).

PULPAL REACTIONS TO LOCAL ANESTHETICS

An intact pulpal blood flow is critical for maintaining the health of the dental pulp. Because the dental pulp is enclosed in a rigid chamber and supplied by few arterioles through the apical foramina, it cannot benefit from collateral circulation or volumetric changes that compensate for changes in blood flow in other soft tissues. Furthermore, reduction in blood flow has the compounding effect of reducing the clearance of large molecular-weight toxins or waste products,[185] thus causing irreversible pulpal pathosis. Vasoconstrictors are added to local anesthetics to enhance the duration of anesthesia. However, vasoconstrictors in local anesthetics could negatively impact the health of the pulp if they reduce blood flow, particularly if the pulp is inflamed preoperatively. Earlier studies have documented that vasoconstrictors in local anesthetics do reduce pulpal blood flow in experimental animals when administered by infiltration and nerve block[118] (Fig. 13-12), and that this effect was more severe with periodontal ligament injections[117] (Fig. 13-13). More recently, clinical trials were conducted in which subjects were given infiltration of different local anesthetics with or without epinephrine at a concentration of 1:100,000, and the pulpal blood flow was measured by laser Doppler flowmetry. In groups that received the epinephrine, there were consistently significant reductions in pulpal blood flow,[5,46,160] even if the infiltration was palatal to maxillary premolars.[193] Interestingly in one study, the reduction in pulpal blood flow with epinephrine infiltration was more than the reduction in gingival blood flow and did not return to baseline values after 1 hour of injection.[5] Similar reductions in pulpal blood flow were reported when inferior alveolar nerve block injections of lidocaine and 1:100,000 or 1:80,000 epinephrine were administered.[169] It is important to note a limitation of studies using laser Doppler flowmetry: a large proportion of the signal measured may be from sources other than the dental pulp.[192,219] Thus the monitoring of minor changes in pulpal blood flow must be interpreted with caution, particularly if the rubber dam or a similar barrier was not used.[89] Human studies on the effects of periodontal ligament or intraosseous injections on pulpal blood flow are unavailable, but from animal studies, it is probable that these supplemental anesthetic techniques cause more severe reduction or even transient cessation

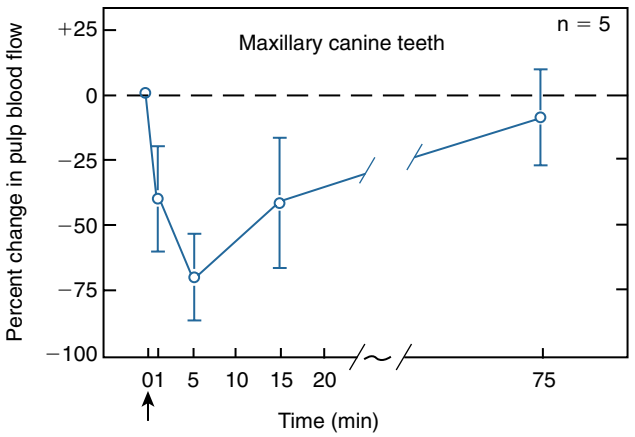

FIG. 13-12 Effects of infiltration anesthesia (i.e., 2% lidocaine with 1:100,000 epinephrine) on pulpal blood flow in the maxillary canine teeth of dogs. There is a drastic decrease in pulpal blood flow soon after the injection. *Arrow* indicates the time of injection. *Bars* depict standard deviation. *(From Kim S, Edwall L, Trowbridge H, Chien S: Effects of local anesthetics on pulpal blood flow in dogs.* J Dent Res *63:650, 1984.)*

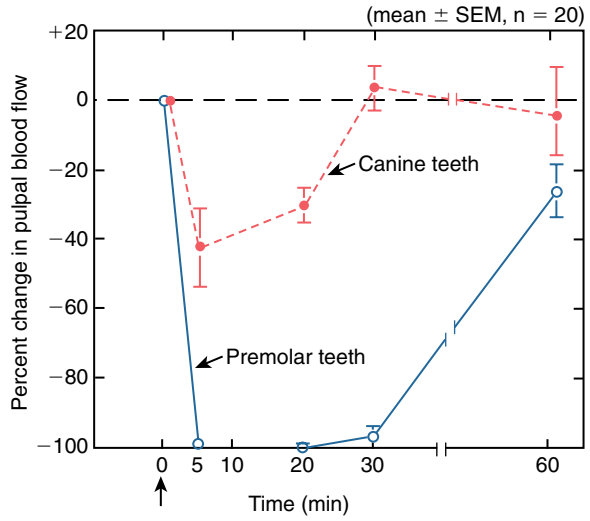

FIG. 13-13 Effects of ligamental injection (i.e., 2% lidocaine with 1:100,000 epinephrine) on pulpal blood flow in the mandibular canine and premolar teeth of dogs. Injection was given in the mesial and distal sulcus of premolar teeth. Injection caused total cessation of pulpal blood flow that lasted about 30 minutes in the premolar teeth. *Arrow* indicates time of injection. *(From Kim S: Ligamental injection: a physiological explanation of its efficacy.* J Endod *12:486, 1986.)*

of pulpal blood flow. It was also shown that intraosseous injection of Depo-Medrol (a corticosteroid) in patients with symptomatic irreversible pulpitis causes significant reduction of prostaglandin E2 in the pulp 1 day after administration, indicating that this route of injection results in significant permeation into the pulpal tissues.[104] Taken together, these findings suggest that local anesthesia may compromise the inflamed pulp's ability to recover from inflammation, particularly if it is severely inflamed, if the tooth is subjected to extensive restorative procedures, or if the anesthetic is delivered via a periodontal ligament or an intraosseous route. However, it is important to realize that this hypothesis should be supported or refuted by prospective randomized clinical trials.

Intrapulpal anesthesia is often used as a last resort when pulpal anesthesia is insufficient during root canal therapy. The effect of intrapulpal anesthesia on the pulp in these cases is not considered, since the pulp will be removed. However, occasionally a pulpotomy is performed to maintain pulpal vitality, such as in children, where the tooth has an immature apex. One study has shown that intrapulpal anesthesia can be used in these cases, with no clinical differences on follow-up of over 24 weeks between the groups that did or did not receive intrapulpal anesthesia, and when given, in the groups where the anesthetic contained or did not contain epinephrine.[233]

PULPAL REACTIONS TO RESTORATIVE PROCEDURES

A voluminous body of literature exists on the effects of restorative procedures on the dental pulp. This topic understandably has been important for practicing dentists for many years. Restorative procedures are performed primarily to treat an infectious disease—dental caries—which itself causes significant irritation of the pulp. They may also be performed to help restore missing teeth, correct developmental anomalies, address fractures, cracks, or failures of previous restorations, or a myriad of other abnormalities. One key requirement of a successful restorative procedure is to cause minimal additional irritation of the pulp so as not to interfere with normal pulpal healing. When pulp vitality is to be maintained during a restorative procedure, a provisional diagnosis of reversible pulpitis (rather than irreversible pulpitis) must preexist. Therefore, it would be most desirable to perform a minimally traumatic restorative procedure that would not potentially convert the diagnosis to irreversible pulpitis. As was discussed previously, irreversible pulpitis may present clinically with severe spontaneous postoperative pain, but it may also be asymptomatic, leading to the quiet demise of the pulp. The additive effects of restorative procedures are particularly critical in borderline cases, such as those of mildly symptomatic teeth with deep caries but no pulp exposure. There are still many factors whose influence on the response of the dental pulp to cumulative effects of caries, microleakage, restorative procedures, and materials is not well understood. It is generally accepted that the effects of pulpal insults, be they from caries, restorative procedures, or trauma, are cumulative. That is, with each succeeding irritation, the pulp has a diminished capacity to remain vital.

As a part of informed consent, the clinician is often faced with the task of outlining possible risks of restorative treatment. The question of the fate of pulps beneath single unit metal-ceramic (MC) crowns or MC bridge abutments was addressed.[45] Patients who had received either treatment from 1981 to 1989 at the Prince Philip Dental Hospital in Hong Kong were randomly selected and invited to attend a recall appointment that involved both clinical and radiographic examinations. One hundred twenty-two teeth with preoperatively vital pulps treated with single unit MC crowns and 77 treated as bridge abutments were examined. The mean observation period was 169 months for the former and 187 months for the latter. Pulpal necrosis had occurred in 15.6% of the teeth treated with single unit crowns after 10 years, while 32.5% of the pulps in the bridge retainer groups had become necrotic. There was a significantly higher percentage of pulpal necrosis in anterior teeth that served as bridge abutments (54.5% of anterior abutment teeth examined). In general, however, the available evidence indicates that the effects of dental procedures on the pulp depend on several key factors discussed in the following sections.

Degree of Pretreatment Pulp Inflammation

As stated previously, the dental pulp is compromised in its ability to respond to external irritants because (1) it is enclosed in a noncompliant environment, and (2) it lacks sufficient collateral circulation. Thus the more severely the pulp is inflamed, the less will be its ability to respond to further irritation, such as in the form of restorative procedures.[130]

Most research studies designed to evaluate the effects of restorative procedures (or materials) on the pulp are conducted on human or experimental animal teeth with normal pulp. Furthermore, many of the animal research projects have been performed on anesthetized animals without the use of local anesthesia, which as stated previously, reduces pulpal blood flow. Therefore, the results of these studies may not reveal the true effects of these procedures when the pulp is

already inflamed by the carious lesion and pulpal blood flow is reduced by local anesthetic injection. Classic experiments have documented that different levels of irritation induce different degrees of inflammation in the pulp,[154] and more severe inflammation may take longer to heal.[155] In a study that evaluated the response of the pulp to capping procedures as a function of duration of exposure, it was shown that the pulp responds favorably to exposures of up to 24 hours after exposure, but not as favorably after longer periods of exposure to oral environment.[52] It may be that the longer exposure periods lead to the formation of a bacterial biofilm that is difficult for the pulpal immune responses to eliminate. This is relevant in cases of aseptic mechanical exposures or teeth where the pulp is exposed by traumatic injuries for a brief duration. In these cases, the pulp usually responds favorably to vital pulp therapy procedures. Models of standardized pulpal inflammation with chronic caries are not commonly used in determining the effects of dental procedures. Older clinical studies show an unfavorable long-term outcome of capping cases with carious pulp exposures,[17,95] but newer studies in which MTA was used show more favorable results in these cases.[16,26]

In the absence of severe spontaneous symptoms or pulp exposure, the clinician currently cannot accurately determine the degree of preoperative pulpal inflammation. Thus, every effort should be made to minimize added irritation during restorative procedures, because it is possible that excessive irritation could convert the inflammatory status of the pulp from a reversible to an irreversible condition.

Degree of Physical Irritation Caused by Procedure

The physical irritation of the pulp during restorative procedures, such as from heat, desiccation or vibration, may adversely affect the dental pulp.

Heat

Restorative procedures such as cavity preparation, crown preparation, or curing of resins during direct fabrication of provisional restorations[234] may cause significant increases in pulpal temperatures. It has been shown using primate models that an intrapulpal temperature rise of 10° C causes irreversible pulp pathosis in 15%, and a 20° C rise caused pulp abscess formation in 60% of teeth evaluated.[262] A number of other older studies documented burns or severe inflammation in the pulp when cavity or crown preparations were performed without coolants (Figs. 13-14, 13-15, 13-16). However, a study, in which gradual controlled heat application over a large area of the intact occlusal surface of human unanesthetized teeth was employed, failed to corroborate these earlier findings.[12] In this study, an increase of intrapulpal temperature of about 11° C, followed for 2 to 3 months of evaluation, did not induce any clinical or histologic changes in the pulp of any of the teeth evaluated. Heat increase in rat pulp tissue to 42° C in vitro raised heat shock protein-70, which is known to be tissue protective, and caused changes in alkaline phosphatase and gap junction proteins that were reversed to normalcy a few hours later.[7] By contrast, in another study, heat applied in deep cavity preparations (prepared atraumatically in human teeth) caused histologic changes that were dependent on the proximity of the heat source to the pulp.[168] It was common in that study to see loss of odontoblasts or their aspiration into the dentinal tubules. In cases where the cavity floor was less than 0.5 mm from the pulp, areas of coagulation necrosis could be seen, although the patients remained asymptomatic for the 1-month duration of the study. The measurement of heat in the tooth being prepared, in areas other than the site of tooth preparation, occasionally shows reduction in temperature,[80] presumably because of the poor conductive properties of dentin and the cooling effect of compressed air from the high-speed handpiece. Furthermore, cavity and crown preparations include a number of other irritating stimuli, such as desiccation, severance of odontoblastic processes, vibration, and smearing of bacterial irritants onto the surface of dentin. Taken together, these findings suggest that the transient increase in temperature to levels relevant to modern dental procedures on its own may not be the culprit in inducing pulpal changes. Rather, the synergistic application of excessive heat with other irritation factors and its proximity to the pulp may induce pathologic changes.

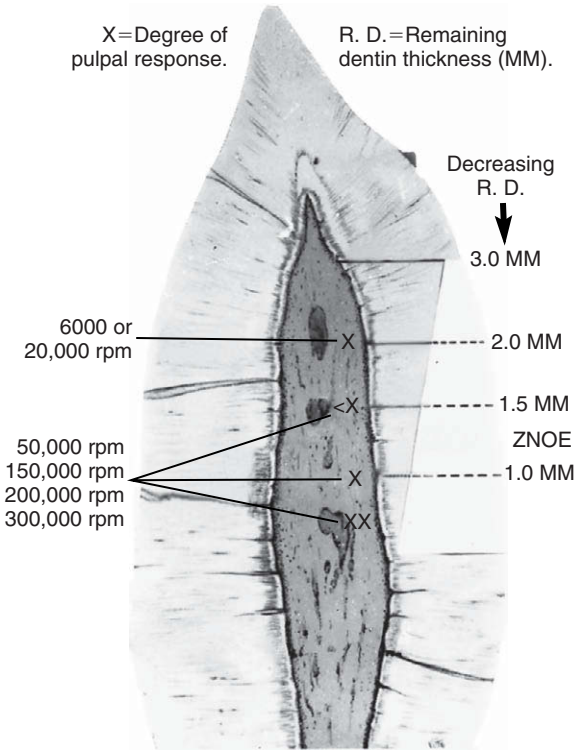

FIG. 13-14 With adequate water and air spray coolant, the same cutting tools, and a comparable remaining dentin thickness, the intensity of the pulpal response with high-speed techniques (i.e., decreasing force) is considerably less traumatic than with lower-speed techniques (i.e., increasing force). *(From Stanley HR, Swerdlow H: An approach to biologic variation in human pulpal studies.* J Prosthet Dent *14:365, 1964.)*

Desiccation

Desiccation during cavity and crown preparation has long been known to cause aspiration of odontoblastic nuclei into dentinal tubules and pulpal inflammation.[30] One study showed that as little as 30 seconds of continuous air drying of class V cavities in human molars with uninflamed pulp caused significant displacement of odontoblastic nuclei, pulp inflammation, and even areas of necrosis related to the areas that were dried.[51]

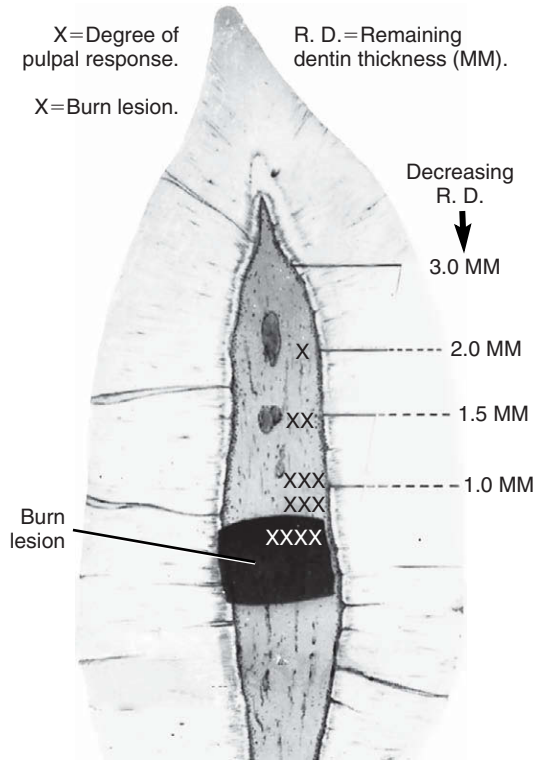

FIG. 13-15 Without adequate water coolant, larger cutting tools (e.g., No. 37 diamond point) create typical burn lesions within the pulp when the remaining dentin thickness becomes less than 1.5 mm. *(From Stanley HR, Swerdlow H: An approach to biologic variation in human pulpal studies.* J Prosthet Dent *14:365, 1964.)*

However, another study showed that the effects of desiccation are transient, in that within 7 to 30 days there is autolysis of the aspirated cells and formation of reactionary dentin.[32] The pulp in cases with aspirated odontoblasts, following desiccation for 1 minute, was not sensitive to clinical scraping with an explorer. The sensitivity was restored with rehydration of the cavities and was increased in other cases where pulp inflammation was induced by microbial contamination.[138] In this study, despite the lack of sensitivity in desiccated cavities, neural elements were seen histologically to be pushed into the tubules like the odontoblastic nuclei. The disruption of the odontoblastic layer and peripheral neural elements in the pulp with desiccation was also observed in a rat model using axonal transport of radioactive protein.[36]

Biologic and Chemical Irritation

Dental caries is clearly an infectious disease in which microorganisms and their virulence determinants constantly irritate the pulp, even at the early stages long before pulp exposure.[33] However, despite the elimination of visible caries during cavity preparation, the cavity floor is undoubtedly left with some contamination by caries bacteria. Whereas the rubber dam should be used with any cavity preparation to prevent cavity contamination with salivary microorganisms, the use of water coolants allows the cavity to be contaminated with bacteria from water lines. Concerns about residual cavity contamination prompted some to use cavity disinfection with caustic chemicals. Chemicals such as hydrogen peroxide, sodium hypochlorite, or calcium hydroxide solutions have been proposed for this purpose, although they may exert a toxic effect.[50] An earlier study showed that the amounts of residual bacteria following adequate restoration are not significant.[151] Once dentin is exposed, there is constant outward flow of dentinal fluid that minimizes the inward flow of any noxious agents.[252] This may aid in the reduction of irritation from residual microbial factors in dentinal tubules.

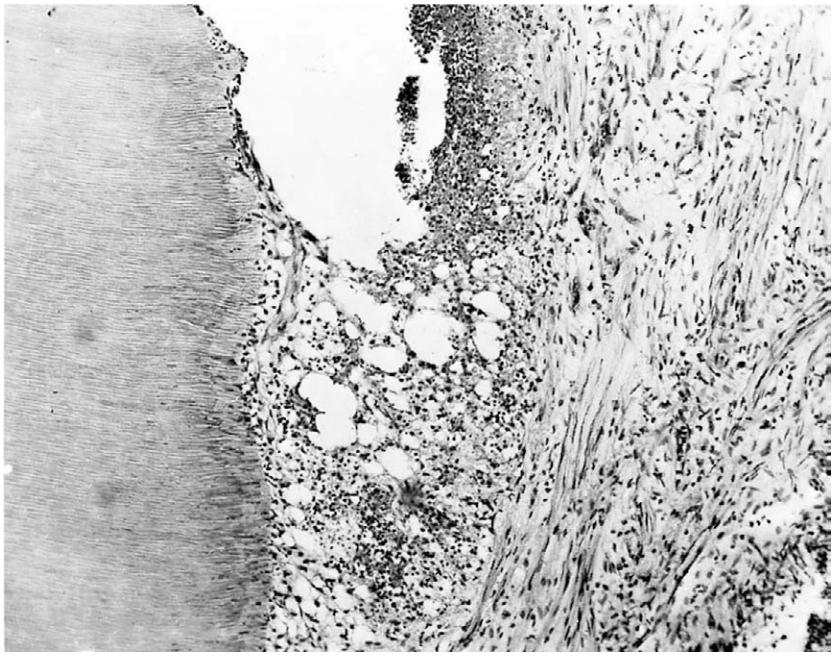

FIG. 13-16 Burn lesion with necrosis and expanding abscess formation in a 10-day specimen. Cavity preparation dry at 20,000 rpm, with remaining dentin thickness 0.23 mm. *(From Swerdlow H, Stanley HR Jr: Reaction of the human dental pulp to cavity preparation. I. Effect of water spray at 20,000 rpm.* J Am Dent Assoc *56:317, 1958.)*

In contemporary practice, most chemical irritation during restorative procedures results from the application of etching agents, especially strong acids in the form of total dentin etch, particularly if capping of exposed pulp is performed.[81,179] Etching is performed to remove the smear layer, promote physical adhesion of bonding agents to dentin by forming resin tags in the dentinal tubules, and promote permeation of the newer unfilled resin primers into the unmineralized surface layer of collagen to form the so-called hybrid layer.

If the cavity is relatively superficial and is adequately sealed with a restorative resin, then etching of dentin is probably not detrimental to the pulp, because of the narrow diameter of dentinal tubules and their low density in peripheral dentin.[28] In fact, one study documented that histologic evidence of bacteria in human cavities restored with composite was significantly less if the cavity had been etched with phosphoric acid than if it were etched with 17% ethylenediamine tetra-acetic acid (EDTA) or not etched.[159] Pulpal inflammation in this study was not correlated with the etching treatments but with bacterial presence; in cases of etching with phosphoric acid, if bacteria were also present, severe pulpal inflammation and necrosis could be seen.

In recent years, self-etching formulations have become popular because they eliminate the separate etching step involved in total-etch procedures. Some have speculated that the bonding of self-etching systems may be poorer than total-etch systems because of the weaker acidity of the acidic primers of self-etching systems compared to total-etch systems.[28] However, studies have shown no significant differences between the two adhesive systems in long-term in vitro bond strength, postoperative sensitivity,[188] long-term in vivo degradation,[125] or long-term in vitro bond strength.[9] One clinical study showed no differences between the two systems with respect to bacterial leakage and the inflammatory response in the pulp.[164] The most important variable that affected the pulp in this study was the amount of bacterial leakage with either system.

Other factors that may contribute to pulpal irritation during resin placement from chemical/biologic irritants include unpolymerized monomer and polymerization shrinkage. Higher concentrations of monomeric resin components were shown to exert an inhibitory effect on T-lymphocytes and spleen cells[113] and monocytes/macrophages[133,196,197,208] in vitro. These components may leach directly into the pulp in deep cavities and cause chemical irritation.[98] Shrinkage during polymerization of composites may induce internal stresses on dentin and create voids that allow microleakage. Shrinkage of resins is estimated to range from 0.6% to 1.4% and should be minimized during placement by incremental curing and possibly starting the restoration with flowable resins.[28]

In summary, the available evidence indicates that chemicals involved in modern restorative procedures may irritate the pulp if placed directly on an exposure or if there is microbial leakage along the tooth/restoration interface.

Proximity of Restorative Procedures to Dental Pulp and Surface Area of Dentin Exposed

It has been known for several decades that as the carious lesion progresses towards the pulp, particularly when the remaining dentin thickness (RDT) is less than 0.5 mm, there is an increasingly severe pulpal reaction, with a greater likelihood of the pulp undergoing irreversible pathosis.[201] The diameter and density of dentinal tubules increase closer to the pulp (Fig. 13-17). Based on the dentinal tubule density at the dentin-enamel junction (DEJ) (about 65,000/mm^2) and the pulp (about 15,000/mm^2),[74,78] it was estimated that the area occupied by tubule lumina at the DEJ was 1% of the total surface area at the DEJ and 22% at the pulp.[183] Thus it is not surprising that several studies have shown that pulpal inflammation in response to restorative procedures increases with the reduction in RDT.[1,53,158] A recent study examined the differential effects on the rat pulp of the preparation method, remaining dentin thickness, coolant, drill speed, conditioning with EDTA, and filling materials.[157] Subsequent to the cavity preparations, a tooth slice was obtained and maintained ex vivo as an organ culture for up to 2 weeks. The results showed that the remaining dentin thickness was the most important factor on pulpal injury.

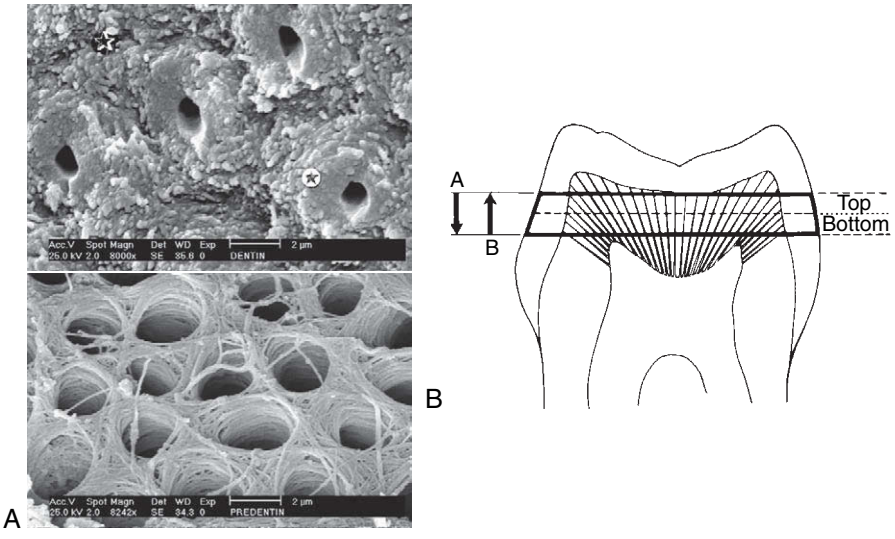

FIG. 13-17 Convergence of tubules toward the pulp. **A,** Periphery of the dentin. Most surface area is occupied by intertubular dentin (☆), with a few tubules surrounded by hypermineralized peritubular dentin (✪). **B,** Near the pulp, the increase in tubule diameter has occurred largely at the expense of the peritubular dentin. This substrate has a high protein content. As the remaining dentin is made thinner (from **A-B**), the permeability of the dentin increases because both diameter and density of dentinal tubules are increased. *(Bouillaguet S: Biological risks of resin-based materials to the dentin-pulp complex.* Crit Rev Oral Biol Med *15:47–60, 2004.)*

With the passage of time following cavity preparation, there is reduction in the permeability of RDT.[186] This may be due to rapid deposition of reactionary dentin, the migration of large proteins into the tubules, and/or the diminution of tubule diameter as dentin becomes more sclerotic. Using a primate model, one study showed that the basic rate of secondary dentin deposition is about 0.8 µm/day, and this rate increases to an average of 2.9 µm/day following restorative procedures. Interestingly, dentin deposition was more rapid next to shallow cavities than deep cavities in one study,[254] but another study showed that total reactionary dentin deposited was thicker in deeper and wider cavities.[156]

Clinically it has been observed that postoperative sensitivity is common with many restorative procedures. In one study, it was shown that following resin composite restorations on patients, postoperative sensitivity was related to the depth of the cavity but not to the presence or absence of liners or bases.[244]

In addition to the depth and/or width of a large cavity preparation, a crown preparation exposes more dentinal tubules to microbial or chemical irritation. During crown fabrication, there are added irritation factors, such as length of time of the preparation, impression techniques, and imperfect adaptation of temporary restorations, leading to microleakage during the temporization period. Because of the precise engineering requirements of some restorations, some providers may be inclined to reduce the coolant during crown preparation steps such as finalizing the finishing lines. However, crown preparations without coolants have been shown to dramatically reduce pulpal blood flow in an animal model (Fig. 13-18). There are few studies available on the effects of modern crown and bridge techniques on the pulp. However, some long-term outcome studies have documented that the incidence of pulp necrosis following crown placement ranges from 10% to 18%.[70,245] As noted earlier, a more recent paper of work done in the 1980s in Hong Kong showed these figures to be much larger in bridge retainers compared to single crowns, reaching a value of up to 54% in anterior teeth.[45]

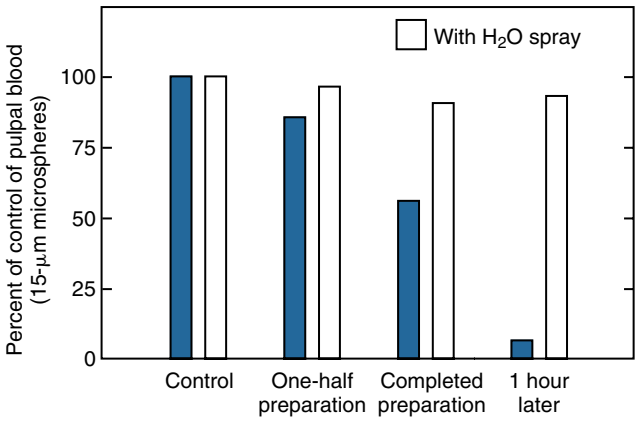

FIG. 13-18 Effects of crown preparation in dogs, with and without water and air spray (at 350,000 rpm) on pulpal blood flow. Tooth preparation without water and air spray caused substantial decrease in pulpal blood flow, whereas that with water and air spray caused insignificant changes in the flow.

Permeability of Dentin and Odontoblastic Layer Between Area Being Restored and Pulp

The permeability of dentin plays an important role in the ingress of potential irritants to the pulp. It is clear from research done in the last 3 decades that dentin is not uniformly permeable, and that permeability depends on factors such as the location within the same tooth, the age of the patient, and the presence of pathologic conditions such as dental caries. Fundamentally, the permeability of dentin depends on the collective sum of permeability of individual tubules at a particular site in the tooth. The tubular diameter increases from about 0.6 to 0.8 µm close to the DEJ to about 3 µm at the pulp.[86] Given that bacterial cells are about 0.5 to 1 µm in diameter, it is evident that in deep cavity preparations, particularly when total-etch procedures are employed, bacteria can migrate through the remaining dentin into the pulp.

With age, the width of peritubular dentin increases, causing reduction in tubular lumen or sclerosis. Caries causes demineralization in superficial dentin, which is associated with remineralization and the formation of caries crystals within the tubules of inner undemineralized dentin (Fig. 13-19). This causes a decrease in permeability in dentin subjacent to the carious lesion[184] and could be considered a protective mechanism, since it may delay the progress of the carious lesion.

It has been reported that the odontoblastic cell layer itself may contribute to the reduction of permeability to large molecules such as bacterial proteins or toxins. Experiments were conducted in which large protein markers were allowed to permeate the odontoblastic layer in experimental animals before and after cavity preparation. It was shown that irritation from cavity preparation increased the odontoblastic permeability only at the site of the cavity preparation.[106,240] In addition to the physical barrier to permeability and the production of reactionary or reparative dentin, the odontoblastic layer may in fact contribute to the host response of the dental pulp by expressing important inflammatory mediators[136,178] or recognize bacteria through toll-like receptors.[27,59,67,112]

Patient Age

It was reported that resting pulpal blood flow (PBF), as well as the changes in PBF in response to cold application, decrease with age.[100] Age may also be associated with reduction in pulpal neuropeptides.[75] However, a recent animal study failed to show any differences between young and old pulp in the regenerative capacity of odontoblast-like cells and in the presence of cells positive for class II major histocompatibility complex, heat shock protein 25, or nestin, when subjected to cavity preparation.[116] Thus in humans with advancing age, the net result of the ability of the pulp to cope with external stimulation or irritation is not clear.

PULPAL REACTIONS TO RESTORATIVE MATERIALS

The effects of restorative materials on the dental pulp have been investigated and seem to relate directly to the permeability of the associated dentin. The degree of dentin permeability, however, is often variable and is governed by several factors including age and caries status.[230] As noted before with respect to restorative procedures and bacterial ingress, perhaps the

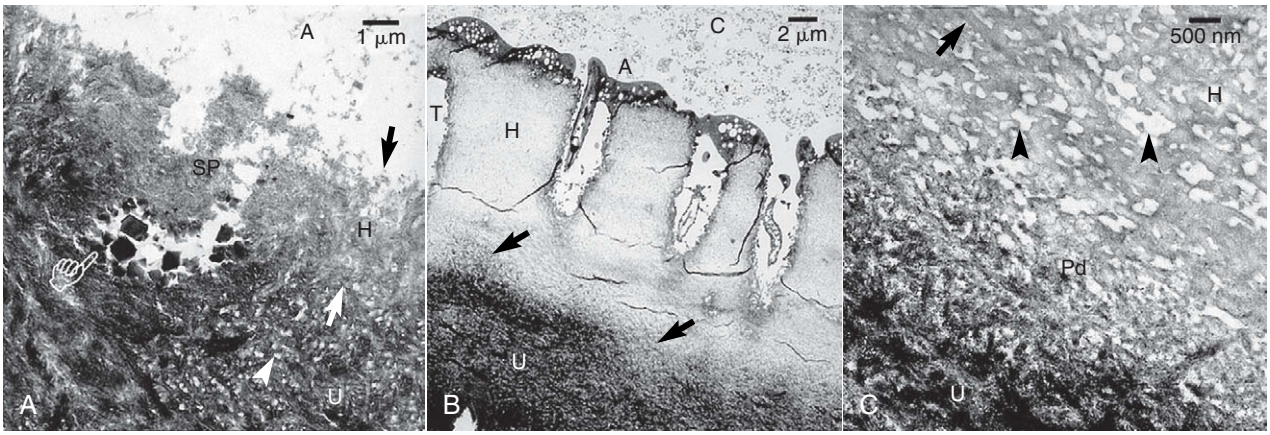

FIG. 13-19 Transmission electron micrographs (TEM) of undemineralized specimens of resin-bonded caries-affected dentin. **A,** Stained TEM of undemineralized specimens following the application of the self-etch ABF system to caries-affected dentin. most important variable in dentin permeability to restorative materials is the thickness of dentin between the floor of the cavity preparation and the pulp.[1]

Unbound components of resin materials and preparative agents such as acid etchants can affect the subjacent pulp by inducing an inflammatory response.[77,195] The indirect effects of desiccation and/or demineralization of dentin, as well as direct effects of the material itself when in contact with pulpal tissue, mediate this inflammatory response. Studies have shown that certain cytotoxic components of resin monomers (e.g., triethylene glycol dimethacrylate and 2-hydroxyethyl methacrylate) readily penetrate dentin.[72] Similarly, eugenol and components of Ledermix (triamcinolone and demeclocycline) have been shown to pass through dentin into the subjacent pulp.[97,99] In vivo data show that these chemicals have an effect on the pulp, but the effect seems to be short lived and, in the absence of bacteria, reversible.[21]

The mechanisms whereby restorative materials exert an injurious effect on the dental pulp are varied. Evidence exists that supports direct and, in some instances, prolonged cytotoxicity, stimulation of hypersensitivity reactions, or impairment of the host immune response to bacteria. Some of the components of resin restorations are released at cytotoxic levels after polymerization is completed, leading to chronic stimulation and a resultant prolonged inflammatory response.[71] Furthermore, even subtoxic concentrations of certain agents are capable of eliciting allergic reactions in humans.[98] Primates hyperimmunized with BSA showed significant pulpal damage with repeated antigenic challenge in class V cavity preparations, suggesting a role for antigen-antibody complex–mediated hypersensitivity in tissue destruction.[24] In a separate study, exposure to dentin primers elicited a delayed-type hypersensitivity reaction in guinea pigs.[115] These studies taken together present a compelling argument for immune-mediated pulpal tissue damage subsequent to exposure to restorative materials. Foreign body reactions have also been described in pulps containing extruded globules of resin material.[102,103] Histologic examination of such pulps shows macrophages and giant cells surrounding the resin particles. Lastly, resin monomers have been shown to decrease the activity of immunocompetent cells in a dose-dependent manner in in vitro functional assays.[113] Although all of these effects are documented, their extent and therefore morbidity on the dental pulp is speculative and doubtless does not act solely to effect pulpal demise. As previously noted, most restorative materials are placed adjacent to pulps that are previously compromised by bacterial insult; disease, débridement, and restoration of the tooth have cumulative effects on the dental pulp.

Although pulpal irritation is largely considered to be a negative sequela, the irritant potential of certain restorative materials is central to their usefulness in restorative dentistry. Calcium hydroxide is one of the oldest and most widely used medicaments for stimulation of dentinal bridge formation subsequent to microscopic or gross pulpal exposure. The low-grade pulpal irritation that it induces is important for dentinal bridge formation in exposures.[55,207] The degree of inflammation is dependent on the preparation of calcium hydroxide used. Aqueous suspensions of calcium hydroxide applied to exposed pulps causes superficial necrosis of pulpal tissue followed by tissue displaying low-grade inflammation. Within 30 days, the tissue subjacent to the necrotic zone has reorganized and resumed normal architecture. Hard-setting calcium hydroxide preparations are effective in eliciting dentinal bridge formation with a much smaller to nonexistent necrotic zone.[92] This is preferable in vital pulp therapies such as the Cvek pulpotomy, where maintenance of the maximum amount of vital pulp tissue is desirable, and the extent of pulpal inflammation is minimal[54] (Fig. 13-20). The irritation potential of calcium hydroxide across intact dentin is dependent on factors such as the remaining dentin thickness and permeability. Application

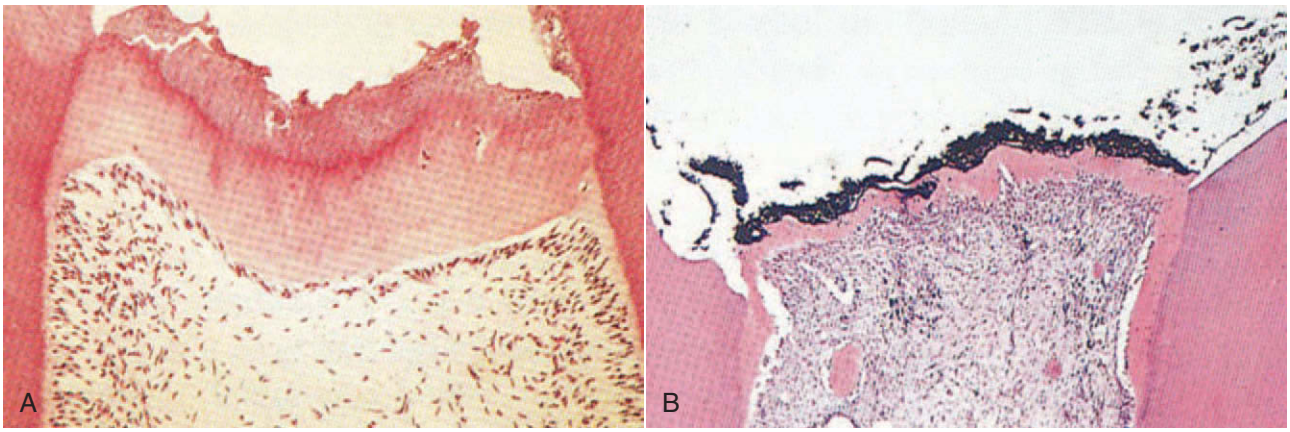

FIG. 13-20 Calcium hydroxide produces an inflammatory response that stimulates dentinal bridge formation. The dentin bridge forms lower in the tooth with calcium hydroxide paste **(A)** versus hard-setting calcium hydroxide **(B)**.

of calcium hydroxide to intact dentin appears to induce sclerosis by promoting crystal precipitation within the tubules, accompanied by reductions in permeability.[153]

In addition to the direct chemical effects of restorative materials, there are indirect factors that contribute to pulpal irritation. The technique sensitivity of certain materials predisposes them to faulty bonds to tooth structure that can translate to dentin hypersensitivity, recurrent disease, and pulpal inflammation or necrosis. Much attention has been given to the interface created between resin-bonded materials and dentin. During the etching process, the more highly mineralized peritubular dentin is preferentially dissolved, leaving free collagen fibrils and opening lateral tubular branches.[82,152] Applied resin infiltrates the exposed collagen mesh, creating a layer 5 to 10 µm thick referred to as the *hybrid layer*.[161] This layer, along with the resin permeating exposed tubules, forms the bond between the resin and dentin. If the preparation is too dry, the collagen fibrils collapse, and the resin cannot effectively permeate the mesh, which results in a defective bond. The optimal degree of hydration of the preparation surface can vary from material to material, so resin restoration placement is technique sensitive. This same principle is applicable to the practice of bonding fractured tooth fragments where the segment has become dehydrated while outside of the mouth. Current protocols recommend rehydration of the segment prior to bonding, thus increasing the mechanical and presumably the microbial seal.[69] This is particularly important with a complicated crown fracture where the pulpal protection by intact dentin is absent.

Some restorative materials rely on their medicinal properties as well as their ability to seal a cavity preparation. Materials containing zinc oxide and eugenol (ZOE) fall into this category. ZOE is used for a variety of purposes in dentistry, largely because of its anesthetic and antiseptic properties. It has been shown to block transmission of action potentials in nerve fibers and to suppress nerve excitability in the pulp when applied to deep excavations.[238] In addition, ZOE has good adaptation to dentin and inhibits bacterial growth on cavity walls. These properties have made this a favored material for temporary fillings but not long-term restorations; ZOE temporaries have been shown to leak after only a few weeks in situ.[263]

DIRECT PULP CAPPING WITH MINERAL TRIOXIDE AGGREGATE

Direct capping of pulp exposures is indicated in pulps that were previously healthy and exposed by trauma or dental restorative procedures.[229] Although calcium hydroxide has historically been the preferred dressing agent on mechanically exposed pulps, the use of mineral trioxide aggregate (MTA) has recently been proposed, even on carious pulp exposures.[16,26] Prospective animal studies and human case reports have evaluated the ability of MTA to allow for the formation of a reparative dentin bridge and maintain continued pulp vitality.[66,73,121] Although the results are generally favorable, one concern is of tooth discoloration if the gray MTA formulation is used on anterior teeth.

In a recent investigation, white MTA was compared to gray MTA in the capping of direct mechanical pulp exposures created in dogs' teeth.[182] No significant differences were found in the healing response to either material. At 1 week, none of the capped pulps showed necrosis close to the exposure site, and odontoblast-like cells were observed at the periphery and under the calcified bridge. At 2 weeks, almost all of the specimens from both types of MTA showed complete calcified bridge formation just below the exposure site. In a recent clinical study, MTA was used as a pulp capping material for carious pulp exposures.[26] Forty patients aged 7 to 45 were diagnosed with reversible pulpitis and had caries removed using a caries-detection dye and sodium hypochlorite for hemostasis. The treatment was performed in two visits to allow the MTA to set up and to confirm pulp sensibility to pulp tests in the second visit. Success was determined radiographically, with subjective symptoms, pulp testing with cold, and continued root formation on immature teeth. Outcomes were measured over a period of up to 9 years postoperatively and showed an overall success of 97%, with all the teeth in the immature root group showing success. Within the parameters of these studies, it seems that white MTA is a suitable capping agent for pulp exposures of healthy or reversibly inflamed pulps. It must be emphasized, however, that not only must the pulp capping agent be biocompatible and hopefully stimulate the formation of reparative dentin, but the prevention of bacterial ingress by the placement of a well-sealed restoration must also be provided.

USE OF HEMOSTATIC AGENTS AND DISINFECTANTS ON DIRECT PULP EXPOSURES

As noted before, the use of direct capping procedures in an attempt to maintain the vitality of an exposed dental pulp has been a controversial area of pulp biology. In particular, the impact of preoperative diagnosis and the effects of various dental medicaments and materials on the long-term prognosis of exposed pulps have been questioned.[53,95,179,215,221] With regard to the former, it has generally been accepted that carious pulp exposures offer poor therapeutic opportunities for continued pulp vitality with direct capping techniques.[17,95] In the case of the latter, there is still debate as to whether the toxicity of medicaments and materials placed on vital pulp tissues determines outcome, or if their ability to seal the cavity from further bacterial ingress is of prime importance. It is likely a combination of the two, as was shown in the recent clinical trial with MTA mentioned before.[26] Another factor in the prognosis of direct pulp caps is the ability to control hemorrhage at the exposure site.[221] Given the difficulty in creating a bacteria-free operating environment during tooth preparation, the ideal hemostatic agent also would have the ability to kill bacteria.

A recent study compared the effects of two hemostatic/disinfectant agents on the healing of experimental pulp exposures created in human third molar teeth and capped with calcium hydroxide.[211] Pulp exposures were made in 45 maxillary wisdom teeth scheduled for extraction for orthodontic reasons. Teeth were randomly assigned to receive hard-setting calcium hydroxide pulp caps after a 30-second surface treatment with one of three agents: 0.9% saline, 2% chlorhexidine, or 5.25% sodium hypochlorite. The teeth were restored with class I bonded resin restorations, extracted after 7, 30, or 90 days, and processed for routine histologic evaluation. Although the 7-day saline specimens showed slightly less inflammatory response, there were no statistically significant differences between the groups with respect to all dependent measures over the course of the study. Complete healing was seen in 88% of all specimens at 90 days.

The pulps in these teeth were previously uninjured, and the exposures were made in a clean environment. Therefore, it seems that a *mechanical* exposure of a healthy pulp created during cavity preparation could be disinfected with either 2% chlorhexidine or 5.25% sodium hypochlorite (full concentration is now 6.0%), capped with a hard-setting calcium hydroxide formulation, and expected to have a favorable prognosis for healing.

PULPAL REACTIONS TO LASER PROCEDURES

Numerous studies have been published on the effect of using lasers on enamel, dentin, and pulp (see also Chapter 8). Laser use on hard tissue has been a popular area of research because of the potential benefits of efficiency, reduced sensitivity, disinfection, and precision. There are several different types of laser technologies available that depend on the wavelength, active medium, emission mode, delivery system, power output, and duration of application. The main types available in dentistry today are shown in Fig. 13-21. The *CO_2 laser* is historically the oldest type used on soft tissues and thus has been the most studied. It has the longest wavelength

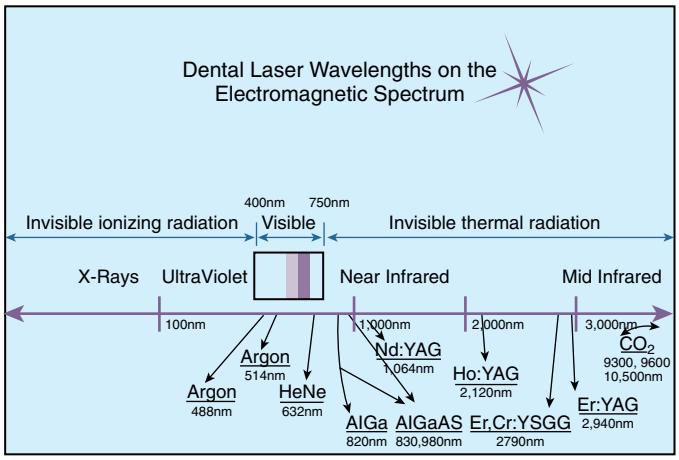

FIG. 13-21 Currently available dental wavelengths on the electromagnetic spectrum. Note all of the wavelengths are nonionizing. *(From Coluzzi DJ: An overview of laser wavelengths used in dentistry.* Dent Clin North Am *44:753, 2000.)*

(10,600 nm). It cannot be delivered in an optic fiber, thus must be used in a hollow-tubelike wave guide in continuous gated-pulse mode. This means that the operator does not feel a solid resistance when using this laser. *Er:YAG, Nd:YAG, or Ho:YAG lasers* all have an active medium of a solid crystal of yttrium-aluminum-garnet, which is impregnated in erbium, neodymium, or holmium, respectively. Er:YAG has a wavelength of 2940 nm, delivered using a solid optic fiber. It has a high affinity for water and hydroxyapatite, thus can be used for removal of caries and cutting dentin with coolant. It can also be used on soft tissue. Ho:YAG laser has a wavelength of 2120 nm and has high affinity to water but not to tooth structure, thus is used primarily for soft-tissue surgery. Nd:YAG laser is also delivered fiberoptically, has a wavelength of 1064 nm, and has been used extensively in dentistry because it has high affinity for water and pigmented tissues and offers good hemostasis, thus is used extensively in surgery.[48] In addition, there are lasers with low power output, such as *HeNe,* or helium neon (632 nm), and *GaAlAs,* or gallium-aluminum-arsenide (diode; semiconductor) (720-904 nm) lasers, which have been used in laser Doppler flowmetry and in treating dentin hypersensitivity.[119]

Lasers in the Prevention, Diagnosis, and Treatment of Caries

Laser irradiation of deep susceptible pits and fissures may reduce the incidence of dental caries. Once caries develops, some lasers may be effective in removing the carious lesion and sparing undemineralized dentin because of their differential absorption by water and hydroxyapatite. Furthermore, if caries exposes the pulp in young teeth, particularly those with immature apex, lasers may be able to effectively excise coronal infected pulp in pulpotomy because of their hemostatic and antibacterial properties. All these potential uses prompted a large number of investigations on the effectiveness of lasers in these applications.

Some clinicians have proposed using lasers to enhance adhesion of pit and fissure sealants, but this was shown to not add any advantage following acid etching—a necessity for

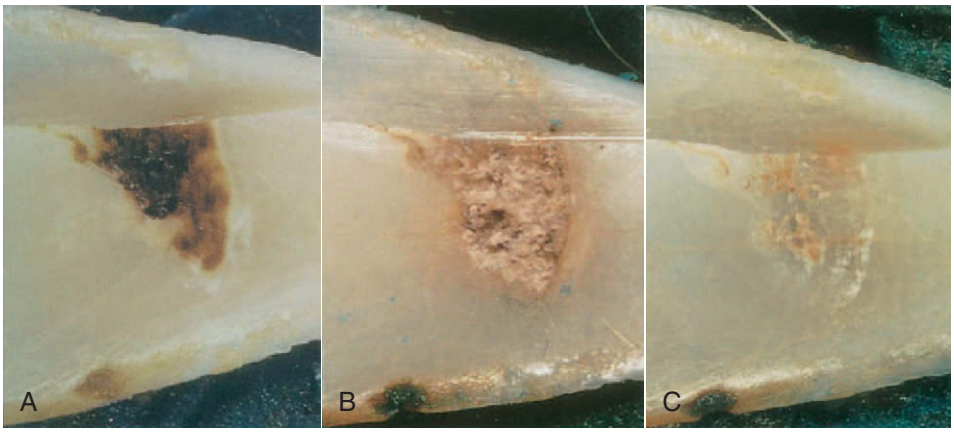

FIG. 13-22 A, Dental caries. **B,** Pulsed Nd:YAG ablation byproducts (160 mJ, 10 Hz). **C,** Debris removed with acid etch and polishing. Enamel surface was faceted for reflection spectroscopy. *(From Harris DM, White JM, Goodis H, et al: Selective ablation of surface enamel caries with a pulsed Nd:YAG dental laser.* Lasers Surg Med *30:342, 2002.)*

adhesion.[143] Laser fluorescence is used by the DIAGNOdent and DIAGNOdent pen, which are laser devices that have been introduced for the diagnosis of noncavitated caries. Although these devices initially showed some promising results,[144] more recent work suggests that they are best used as adjunctive devices to radiography and visual examination.[6,49,126]

Laser ablation of superficial carious lesions may be more conservative than bur preparation. A controlled clinical trial supported this tenet when free-running pulsed Nd:YAG laser was used to ablate superficial pit and fissure caries in third molars scheduled for extraction[88] (Fig. 13-22). In this study, there were no histologic differences in the pulp response between the two groups.

From the perspective of effects on the pulp, most laser applications employed in cutting or modifying cavities in dentin or acting directly on the pulp tissue are important. Earlier studies showed reduced permeability of dentin in vitro with a XeCl excimer laser (a laser with a relatively short wavelength of 308 nm in the ultraviolet range).[220] The apparent fusion of tubules in superficial layers of dentin was shown to occur with CO_2, Nd:YAG, and Er:YAG lasers in vitro.[255] The pulpal responses to Nd:YAG and CO_2 lasers were not favorable. It was shown that Nd:YAG and, to a lesser degree, CO_2 lasers may be associated with charring and significant inflammation in the pulp compared with Er:YAG laser[235,255] (Fig. 13-23). More recently it was reported that water cooling was as necessary for laser ablation as it is for high-speed bur preparations.[41] Studies have shown that Er:YAG laser appears to induce similar responses in the pulp to those seen with high-speed bur preparations at the level of light microscopy analysis.[65,231,232,255] However, the findings with electron microscopy were different. It was reported that whereas shallow cavities ablated in rat molars using Er:YAG lasers did not show changes from baseline using light microscopy, transmission electron microscopy (TEM) showed disruption and degeneration of pulpal peripheral nerve endings and of myelin sheath in the immediate postoperative period (Fig. 13-24).[101] This may explain the reduced sensitivity that accompanies laser cavity preparations. Thus in summary, it does not appear that the use of lasers provides predictable advantages in cavity preparation compared with traditional methods at this time.

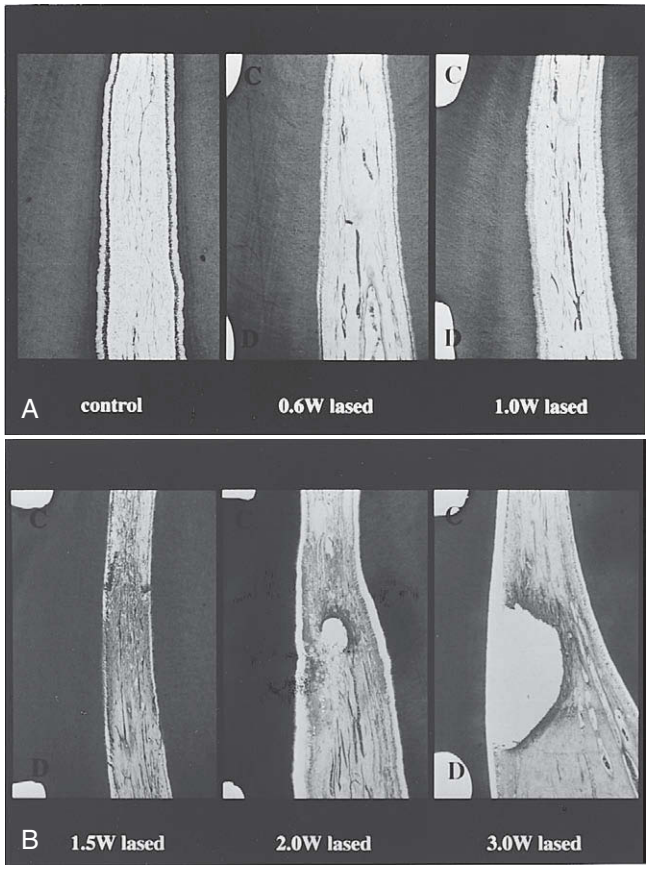

FIG. 13-23 A-B, Histopathologic picture of Nd:YAG laser specimen with an increasing power. There is a direct relationship between the degree of pathologic changes and the increasing power of the laser. In fact, 1.5 W and the greater power cause permanent damage to the pulp.

For pulpotomy procedures, such as in primary teeth, permanent teeth with immature apex, or pulps that are exposed due to fracture and treated promptly, the lasers (particularly CO_2 lasers) may be useful in achieving precise surgical excision of coronal pulp and immediate hemostasis. A controlled

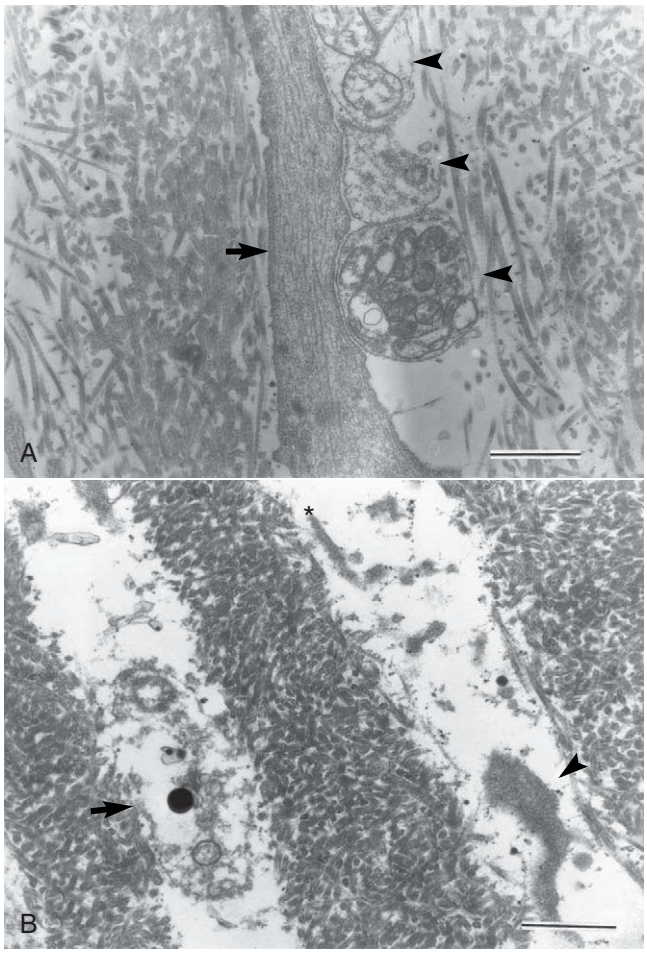

FIG. 13-24 A, Control; normal odontoblastic process *(arrow)* and a few nerve terminals *(arrowheads)* are seen in a dental tubule of rat upper first molar. **B,** Six hours after Er:YAG laser irradiation; disrupted cell membrane of a nerve terminal that contains some granular vesicles *(arrow)* and shrinkage of an odontoblastic process *(arrowhead)* are noted in dentinal tubules just under the ablated area. *Asterisk* indicates the irradiated side (transmission electron micrograph, ×13,700; bar = 1 μm). *(From Inoue H, Izumi T, Ishikawa H, Watanabe K: Short-term histomorphological effects of Er:YAG laser irradiation to rat coronal dentin-pulp complex.* Oral Surg Oral Med Oral Pathol Oral Radiol Endod *97:246, 2004.)*

clinical study showed that CO_2 laser pulpotomy was comparable to traditional methods in experimental pulpotomies of primary teeth scheduled for extraction for orthodontic reasons.[63] However, an animal study in which CO_2 and Nd:YAG lasers were compared revealed poor response with both lasers compared with calcium hydroxide.[114] A more recent animal study using Er:YAG laser showed that the results are dependent on the power settings, in that lower energy delivered with this laser produced favorable results.[120]

Lasers in the Treatment of Dentin Hypersensitivity

Earlier studies have shown effectiveness ranging from 5% to 100% of low-output lasers on dentin hypersensitivity.[119] One author reported a reduction of hypersensitivity in 73% of mild cases, 19% of moderate cases, and 14% of severe cases after 4 months, using a GaAlAs laser.[119] Low-output lasers do not have any effects on the morphology of enamel or dentin, but they are thought to cause transient reduction in action potential mediated by pulpal C-fibers, but not Aδ-fibers,[253] although this finding was not consistent.[174] Nd:YAG lasers have also been used in dentin hypersensitivity. Because of the higher power output, these lasers cause superficial occlusion of dentinal tubules of up to 4 μm,[142] in addition to action potential blockage within the pulp in vitro or in experimental animals.[173,174] However, a placebo-controlled clinical trial has shown that both Nd:YAG and placebo caused significant reduction in dentin hypersensitivity for up to 4 months postoperatively but were not different from each other.[137] Therefore, the collective available evidence does not support the use of lasers for treating dentin hypersensitivity. Other more conservative and economical therapies are recommended.

Use of Lasers as a Protective Measure for Dentin

A recent clinical study has proposed that if lasers are used to prepare cavities or used on prepared dentin after traditional cavity preparation with burs, this would protect the dentin because its permeability and bacterial content may decrease. In this study, two patients were scheduled to have six teeth extracted during orthodontic treatment.[79] In the teeth that had laser irradiation (GaA1As laser, lambda = 660 nm, power of 30 mW and energy dose of 2 J/cm^2) and were examined with TEM after 28 days, the odontoblastic process had increased contact with the extracellular matrix, and the collagen fibrils appeared more organized than those of the control group (traditional bur preparation only). The study concluded that laser irradiation accelerates the recovery of the dental tissues in the predentin region.

PULPAL REACTIONS TO CAVITY PREPARATION USING AIR ABRASION TECHNIQUES

Air abrasion is another modality that has been adopted for conservative, nonpainful cavity preparations. Aluminum oxide particles are forced in a rapid stream onto the tooth structure and simultaneously evacuated from the field. An earlier study evaluated the effects of air abrasion in class V preparations using two different particle sizes (25 and 50 μm) and two different forces (80 and 160 psi) on the dental pulp of dogs. The findings showed that histologically, higher pressures and smaller particles yielded significantly fewer pulpal effects than the high-speed treated teeth, whereas lower pressures and larger particles were not significantly different.[132] Air abrasion cavity preparations were more recently shown to be equivalent to high-speed bur preparations in microleakage studies if both techniques are followed by acid etching.[250] Because of the lack of tactile control, the use of air abrasion is limited to specific situations such as shallow caries or pediatric applications.

PULPAL REACTIONS TO VITAL BLEACHING TECHNIQUES

Vital bleaching techniques employ the use of strong oxidizing agents, namely 10% carbamide peroxide and hydrogen peroxide, to bleach enamel of teeth with vital pulp. There have been concerns about the potential for pulpal irritation during these

procedures because of the long duration that the chemicals are in contact with the teeth, particularly if dentin with open tubules or cracks are present. An earlier study identified the toxicity of these chemicals on cell cultures in vitro.[84] Histologic or histochemical analysis of the pulp following bleaching for up to 2 weeks showed minor inflammatory changes in the pulp of the bleached teeth that were reversible.[8,76] One clinical report documented that if 16% carbamide peroxide was used, gingival irritation was evident; however, no changes in pulp vitality or in symptoms were noted. Even in patients who develop post-treatment symptoms, these tend to be reversible and could be prevented by treating the teeth with fluorides and by correcting restorative pretreatment deficiencies.[163] Clinical symptoms are likely to be due to increases in neuropeptides in the pulp. A recent report showed that light- and laser-activated bleaching systems increase substance P expression in the pulp to significant levels.[42] An earlier clinical trial showed that vital bleaching using 10% carbamide peroxide in a custom tray for 6 weeks was safe for the pulp health for up to 10 years post treatment, although the bleaching effectiveness may decline with time.[203]

PULPAL REACTIONS TO PERIODONTAL PROCEDURES

In an intact nontraumatized tooth, the dental pulp maintains its healthy existence throughout life because it is insulated from microbial irritation in the oral cavity (see also Chapter 15). Periodontal disease causes attachment loss, which exposes the root surface to the oral cavity. Occasionally, pulpal inflammation secondary to severe periodontitis is observed.[131] Some reports have described bacterial infiltration through dentinal tubules of exposed root surface, causing mild inflammatory changes in the pulp (Fig. 13-25).[129] However, in a case report of 25 teeth that were extracted in a patient with extensive periodontal disease, none of the pulp tissue had significant inflammatory changes.[236] It is much more common for pulp necrosis or failed healing of periradicular lesions to present clinically with signs of periodontal disease than for periodontal disease to cause pulpal pathosis. Primary endodontic, secondary periodontal pathosis is particularly evident if a perforation occurs in the pulp chamber or coronal third of the root during endodontic treatment and is not promptly treated, as happens in cases of vertical root fractures or congenital tooth defects such as palatal groove defect. Thus it is more likely for microbial irritants to move outward from a necrotic pulp to cause periodontal breakdown than for them to move inward from a periodontal pocket to cause irreversible pathosis in the pulp. The reasons for this observation are not fully understood. However, if the assumption is that bacteria may migrate through patent dentinal tubules in these situations, as is shown in Fig. 13-25, then it may be that the outward dentinal fluid flow in teeth with vital pulp contributes to the resistance to

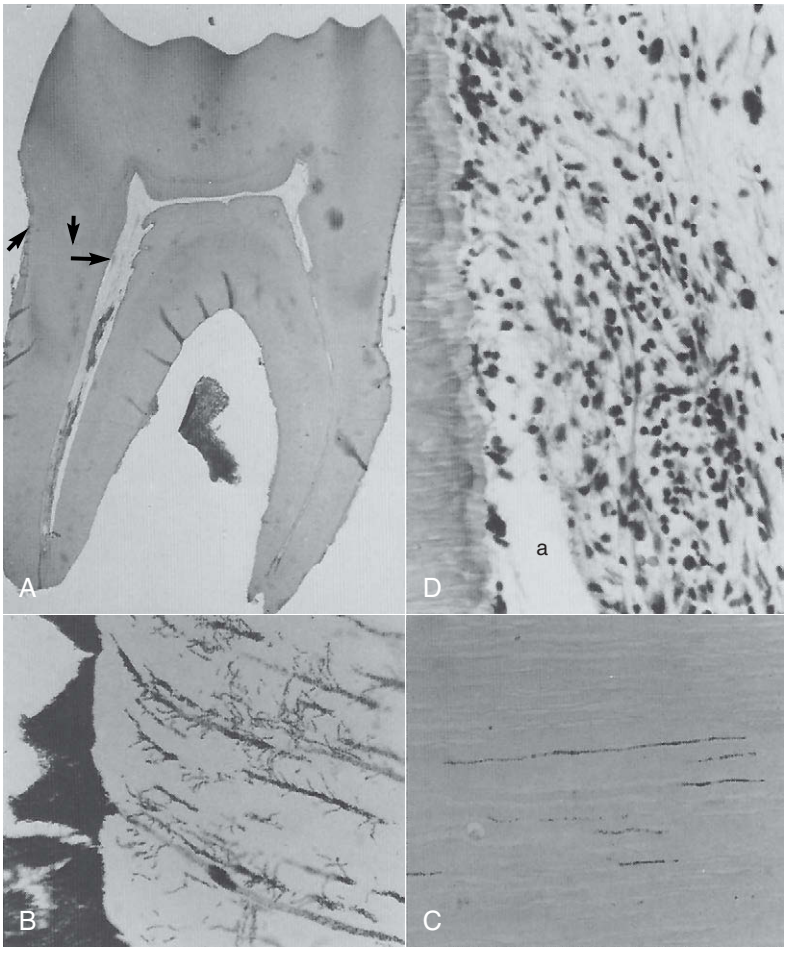

FIG. 13-25 Mandibular first molar of 49-year-old female, no pain. Clinically caries free. Calculus, periodontal disease, and bone loss from two thirds to three fourths of root. **A,** Note narrowness of pulp chamber seen throughout all serial sections (×8.5). **B,** Bacterial plaque and adjacent dentinal tubules with bacteria *(oblique arrows in A)* (×400). **C,** Farthest penetration of bacteria in dentinal tubules *(vertical arrow in A)* (×400). **D,** Where dentinal tubules invaded by bacteria terminate in the pulp *(horizontal arrow in A)*, a small but dense accumulation of lymphocytes and macrophages can be seen. *a,* Artifact, pulp tissue torn away from dentin during processing (×400). *(From Langeland K: Tissue response to dental caries.* Endod Dent Traumatol *3:149–171, 1987.)*

ingress of bacteria in sufficient amounts to cause a clinically significant disease process. Once the pulp degenerates, dentinal fluid flow no longer exists. Thus microbial irritants from the pulp may promote pocket formation and periodontal bone loss,[110] and the prognosis of endodontic and periodontal treatment may be related,[111] since the microbial factors may pass across dentin more readily.

Periodontal scaling and root planing may result in removal of cementum and exposure of dentin to the oral cavity. Frequently this treatment results in dentin hypersensitivity, as discussed previously. In theory, periodontal disease and its treatment should be associated with increased incidence of pulpal pathosis. In an older study, investigators induced periodontal disease in a primate model (using ligatures) and compared the effects on the pulp of periodontal disease with or without scaling.[22] In teeth with periodontal disease, mild chronic inflammatory changes were observed in 29% of the teeth and could be seen in areas of the pulp related to bone loss. One of 40 teeth developed pulp necrosis. In teeth that received scaling, a similar percentage of 32% developed the same mild inflammation, but none developed pulp necrosis. In a later clinical study,[23] 52 periodontitis patients who had 672 teeth with vital pulp were followed up and maintained every 3 to 6 months for 4 to 13 years (mean 8.7 years). Of those teeth, 255 were bridge abutments. The results showed a significantly higher chance of pulpal complications in teeth that were bridge abutments than teeth that were not abutments (15% versus 3%; $P < 0.01$). Considering that both types of teeth had similar degrees of periodontal disease, the authors concluded that prosthodontic treatment is associated with pulpal involvement more frequently than periodontal disease and its treatment. Another histologic analysis of 46 teeth with varying degrees of periodontal disease and coronal restorations reached a similar conclusion.[56] Furthermore, two comprehensive reviews of the topic concluded that although the potential exists for periodontal disease and its treatment to cause pulpal pathosis, particularly if large lateral or accessory canals are exposed, this occurrence is rare.[87,205]

MECHANICAL IRRITANTS: ORTHODONTIC MOVEMENT

The most conspicuous pulpal change observed in response to orthodontic forces is hemodynamic. Both human and animal studies have confirmed that both lateral and intrusive forces result in an increase in pulpal blood flow.[127,165,172] Furthermore, blood flow alterations are not confined to the tooth in active movement. Observed increases in blood flow are seen in teeth adjacent to the focus of movement forces, implying that directed forces on one tooth could shunt blood to proximal vessels supplying other oral structures including teeth. If orthodontic forces are extreme, circulatory interruptions can occur and result in pulpal necrosis.[34]

Biochemical, biologic, and histologic studies of the effects of orthodontic movement have confirmed that metabolic as well as inflammatory changes can result. The dental pulp tissue respiration rate is depressed after short-term application of orthodontic force.[83] Biochemical and molecular markers confirm that apoptosis and necrosis of pulpal cells is also increased subsequent to movement.[189] However, it was shown that the inflammatory mediators IL-1α and TNF-α show minor increase in the pulp during orthodontic movement, compared to the increase in periodontal tissues.[25] Histologic examination of pulps in teeth subjected to intrusive forces showed vascular congestion and dilatation as well as vacuolization of the odontoblastic layer.[224-226] Most if not all of these effects are due to circulatory changes, and the consensus is that they are transient, provided the movement forces are not excessive.[124] It was recently shown, however, that pulp necrosis of teeth that had suffered trauma prior to undergoing orthodontic treatment was significantly increased, compared to teeth that had either of these conditions alone—particularly in lateral incisors and when the traumatized tooth had pulp canal obliteration.[18,19]

PULPAL REACTIONS TO ORTHODONTIC SURGERY

It has been known for decades that osteotomies in the maxilla or mandible may cause disruption in the blood supply to teeth in the area of the surgery, with resultant inflammation and/or necrosis.[15,122,162,187] Occasionally the teeth affected show postoperative manifestations common with traumatic injuries, such as pulp canal obliteration.[247] Animal studies have shown that if a safe distance of 5 to 10 mm is maintained between the site of the surgery and the teeth, minimal disruption occurs.[58,260] Using laser Doppler flowmetry, a number of studies have documented actual reduction in PBF immediately following maxillary Le Fort I osteotomy,[175,198,206] particularly if segmental osteotomy is performed.[64] In most cases, the blood flow is regained within months of the surgery. Recently a modification of the Le Fort I osteotomy technique was described in which the Le Fort I sectioning was combined with a horseshoe palatal osteotomy to spare any disruption to the descending palatine artery.[85] An examination of PBF of maxillary teeth using laser Doppler flowmetry, as well as the responsiveness to electric pulp testing, showed significant differences between the two surgical techniques in the postoperative recovery values (Fig. 13-26). In cases where the surgery did not disrupt the palatine artery, the PBF in the anterior teeth consistently increased without disruption in the postoperative period.

It should also be noted that occasionally teeth are traumatized during endotracheal intubation for surgery that requires general anesthesia, when the surgery itself is not related to the jaws or teeth.[212]

BIOMECHANICAL IRRITATION: PARAFUNCTIONAL HABITS

Occlusal loading of teeth affects deformation to varying degrees.[86] Enamel is largely resistant to flexure, but the underlying dentin demonstrates considerable elastic and viscoelastic characteristics. As a result, defects in enamel secondary to cracks, decay, and/or restorative preparation allow cuspal flexure, with subsequent pulpal responses presumably due to dentinal fluid flow secondary to compression and microleakage.[93] The magnitude of the pulpal response is dictated by the degree and chronicity of dentinal deformation.

Multiple factors influence the degree of tooth deformation during occlusal loading. Investigators have noted that preparation geometry has a direct impact on cuspal flexure. The width

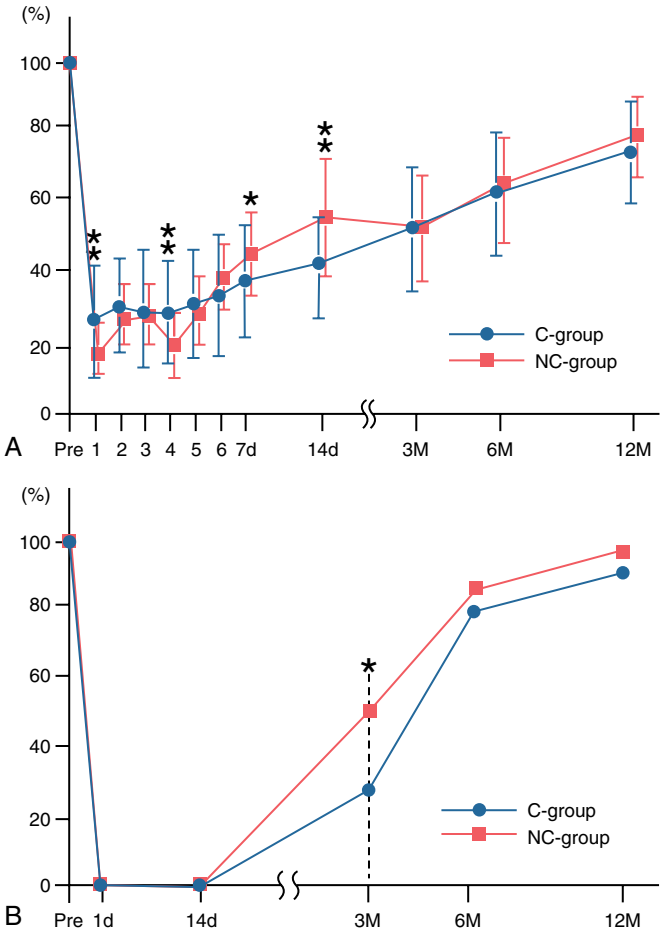

FIG. 13-26 A, Postoperative change of the mean pulpal blood flow in the upper incisors of the two groups. *Pre,* Before the operation; *d,* day(s) after the operation; *M,* months after the operation; *bars,* SD; *, $P < 0.05$; **, $P < 0.01$. **B,** The postoperative change in the percentages of teeth (upper incisors) with positive pulpal sensibility in the two groups. *Pre,* Before the operation; *d,* day(s) after the operation; *M,* months after the operation; *, $P < 0.05$. *(From Harada K, Sato M, Omura K: Blood-flow and neurosensory changes in the maxillary dental pulp after differing Le Fort I osteotomies.* Oral Surg Oral Med Oral Pathol Oral Radiol Endod *97:12–17, 2004.)*

of the occlusal isthmus relative to the faciolingual dimension of the tooth, as well as the ablation of marginal ridges, directly impact on the degree of cuspal flexure.[246,199,181] MOD preparations have been shown to effect a 50% reduction in cuspal stiffness and resistance to fracture. Physical properties of the restorative material can also play a part in cuspal flexure. Studies have shown that polymerization shrinkage of certain resin composites can induce an inward deflection of cusps, with resultant stresses on tooth structure.[248,249]

Symptomology from cuspal flexure can result from two primary sources. It has been theorized that cuspal flexure results in dentin deformation, thus promoting dentinal fluid flow that activates nerve endings in the odontoblastic layer of the tooth. This is supported in part by an in vitro study that found that dentinal fluid flow could be induced by occlusal loading of restored teeth.[93] A second source of pulpal pain is bacterial microleakage created by a gap at the restoration/dentin interface that is repeatedly opened during cycles of occlusal loading. If repeated cuspal flexure gives rise to a crack, dentinal exposure to bacteria and their byproducts is even greater. It is likely that in vivo, both dentinal fluid flow and bacterial access to dentinal surfaces work together to produce inflammation that is often manifested by thermal and biting sensitivity for the patient. In the instance of parafunctional habits, this is often combined with concussive periodontal forces to the periodontium that induce acute periradicular periodontitis, mobility, and radiographic changes.

Dentinal cracks expose tubules unoccluded by a smear layer and therefore offer a direct portal to the subjacent pulp. When dentinal tubules are freely exposed, there is an outward flow of dentinal fluid driven by relatively high pulpal tissue pressures. Dentinal fluid is composed of proteins such as fibrinogen and serum albumin, which can coagulate and effectively block the tubule lumen, thereby limiting fluid egress and resultant dentin hypersensitivity. This phenomenon can occur within 2 days. As this serves as a short-term protective mechanism for the pulp, dentinal sclerosis and tertiary dentin formation ultimately can provide greater protection for the pulp and ablation of symptoms. Clinical interventions include the application of materials that occlude the tubules and extracoronal restorations to prevent the propagation of cracks.

PULPAL REACTIONS TO IMPLANT PLACEMENT AND FUNCTION

Osseointegrated implants are now a common option for the replacement of missing teeth. The placement of implants requires multifaceted preoperative radiographic techniques, including intraoral, tomographic, cephalometric, and panoramic imaging.[241] This assures that implant placement fully rests in bone and does not compromise neighboring structures, including teeth. The lack of attention to (1) the three-dimensional anatomy of the site of implant placement and (2) the orientation of neighboring teeth may lead to the implant perforating the root and devitalizing the pulp.[145,228]

It is usually recommended that implants not be placed directly at a site where a periradicular lesion, particularly one with signs of purulence, exists; microbial irritants may interfere with osseointegration.[194] However, recent data suggest that immediate implant placement in sites that have been adequately débrided is successful.[38]

Case reports have also claimed that teeth with periradicular lesions may reduce the success of neighboring implants, even if adequate endodontic treatment is performed.[227] To address this issue, a study was reported in which implants were placed to replace premolars in dogs, and periradicular lesions were then induced. Some were treated nonsurgically or with combined surgical and nonsurgical treatment.[210] The results showed that the presence of treated or untreated periradicular lesions did not affect the long-term osseointegration of implants that were already osseointegrated. Following adequate endodontic treatment, complete resolution of periapical lesions that also involve neighboring implants has been reported.[139,223] Furthermore, implants that are not mobile but have apical periimplant lesions have been successfully treated with local débridement and "implant-apex resection" procedures.[13]

REGENERATIVE POTENTIAL OF THE DENTAL PULP

Recent studies and case reports suggest that the dental pulp has great regenerative potential, particularly in the immature permanent tooth (see also Chapter 16).[14,105] This has been attributed to the store of stem cells resident in the dental papillae of developing teeth.[218] Mesenchymal stem cells (MSCs) have been found in a variety of tissues and have proven to be pluripotential. Stem cells from the apical papilla (SCAP) of immature teeth have likewise been identified and have been shown to develop into dentinogenic cells, given the proper stimulation.[96,218] The results of these studies, coupled with case reports of continued root development subsequent to apical periodontitis in young teeth, suggest the potential for bioroot engineering in the future.[96]

- Periapical Wound Healing After Surgical Endodontic Therapy
- Can Radicular Cysts in Apical Periodontitis Lesions Regress After Nonsurgical Endodontic Therapy?

FACTORS INFLUENCING PERIAPICAL WOUND HEALING

Periradicular tissues consist of cementum, periodontal ligament, and alveolar bone. *Cementum* is a mineralized, avascular connective tissue and consists of three different types. Acellular afibrillar cementum covers the teeth at and along the cemento-enamel junction. Acellular extrinsic fiber cementum is confined to the coronal half of the root. Cellular intrinsic fiber cementum is present on the apical half of the root where no acellular extrinsic fiber cementum has been laid down.[171] Many growth factors, such as insulin-like growth factor-1 (IGF-1), fibroblast growth factors (FGFs), epidermal growth factor (EGF), bone morphogenetic proteins (BMPs), transforming growth factor-β (TGF-β), and platelet-derived growth factor (PDGF) are contained in the cementum matrix.[41,81,147] These growth factors may be released under certain conditions, since they have been shown to be associated with cementoblast proliferation, migration, and differentiation during cementum wound healing.[81]

The *periodontal ligament* is a soft, specialized connective tissue that connects the cementum to the alveolar bone. Periodontal ligament contains heterogeneous cell populations[128] and extracellular matrix (ECM). The cells of the periodontal ligament include osteoblasts, osteoclasts, fibroblasts, epithelial cell rests of Malassez, macrophages, cementoblasts, and undifferentiated mesenchymal cells (stem cells).[171] Fibroblasts, osteoblasts, and epithelial cells are differentiated cells that have retained the ability to undergo cell division and proliferation upon stimulation by appropriate signals. Multipotent stem cells of the periodontal ligament are capable of differentiating into cementoblast-like cells and periodontal ligament cells as well as osteoblasts.[102,161,209] The ECM of the periodontal liga-

ment consists of collagen fibers, fibronectin, elastin, other noncollagenous proteins, and proteoglycans. The ECM serves as stratum for cell adhesion and promotes cell spreading and cytoskeletal organization. The collagen fibers (Sharpey's fiber) of the periodontal ligament connect the tooth with the alveolar bone. The periodontal ligament is highly vascularized and innervated. The tissue apical to the dentinocemental junction should be considered part of the periodontal ligament because cementum is not a normal component of the pulp tissue.

Epithelial cell rests of Malassez (ERM), the remnants of Hertwig's epithelial root sheath that disintegrates after tooth development, are present in the periodontal ligament near the root surface in all teeth after root formation.[187] They are nests of epithelial cells connected as a network and surrounded by a basal lamina.[171] ERM are quiescent in normal periodontal ligament[171] but can be stimulated to proliferate in apical periodontitis.[139] They are believed to be the cellular source that when properly stimulated can form radicular cysts in certain apical periodontitis lesions.[139,171,178]

Alveolar bone or *alveolar process* is that part of bone of the jaws housing the sockets for the teeth. It consists of outer cortical plate, a central spongy or cancellous bone, and bone lining the sockets.[171] Bone matrix contains IGFs, TGF-β, BMPs, FGF, and PDGF.[36,222] These growth factors are essential for osteoblast proliferation, migration, and differentiation during bone wound healing.[145]

The response of the periradicular tissues to various injuries is similar to that of other connective tissues elsewhere in the body. The response is manifested as an immunoinflammatory reaction. Although microbial infection of the pulp in the root canals is the primary cause of apical periodontitis,[108,158] the pathologic changes of the periapical tissues in apical periodontitis are usually not directly caused by microbes themselves, but rather by their toxins, noxious metabolic byproducts, and disintegrated pulp tissue in the root canal system. These irritants are capable of inducing both innate and adaptive immune responses; they can activate either nonantigenic pathways or serve as antigens to activate adaptive responses. The host's immunoinflammatory responses are quite diverse and can involve changes in microvasculature, transmigration of blood-borne cells and plasma proteins out of the blood circulation into the tissue space, and activation of sensory nerves. In addition, endothelial cells, mast cells, platelets, fibroblasts, neutrophils, macrophages, dendritic cells, innate and adaptive immune cells, immunoglobulins, inflammatory mediators, proinflammatory cytokines, chemokines, and neuropeptides are also involved in the immunoinflammatory response. Apical periodontitis can be protective or destructive, depending on the dynamic interaction between microbial insult and the host's defenses in the periapical tissues. Unfortunately, the bacterial biofilm formed in the root canal system with necrotic pulp is protected from host's defenses and antibiotic therapy because of a lack of blood circulation in the root canal system. Consequently, any attempt of wounded periradicular tissues to repair/regenerate is futile, since bacterial toxins and noxious metabolic byproducts in the root canal system continuously egress into the periapical area and irritate the periapical tissues. Emerging lines of evidence suggest that under most conditions, bacterial biofilms in the complex root canal system can be greatly reduced, but not eliminated, by conventional endodontic procedures such as mechanical instrumentation, antiseptic irrigation, and intracanal medication. If microbes in the root canal system are effectively eliminated or entombed within the root canal filling material, and the root canal system is adequately sealed and protected from coronal microleakage, then periradicular tissues have the ability to restore their original structures by means of a repair/regeneration process. Nevertheless, the presence of posttreatment apical periodontitis may be due to persistent microbial biofilms,[70] and this recognition has spurred considerable research into treating biofilms (see Chapters 9 and 15).

APICAL PERIODONTITIS

Prevalence

Epidemiologic study of apical periodontitis documents that the prevalence of apical periodontitis varies among patients aged 20 to 30 (33% prevalence of apical periodontitis), 30 to 40 (40%), 40 to 50 (48%), 50 to 60 (57%), and older than 60 years of age (62%).[181] Most studies on the prevalence of apical periodontitis are from European and Scandinavian countries.[64,106,212] According to a survey by the American Dental Association in 1990, an estimated 14 million root canal treatments were performed in the United States alone.[8] Apical periodontitis is a very prevalent problem.[65]

ETIOLOGY

The etiology, pathogenesis, and histopathology of apical periodontitis are very similar to that of marginal periodontitis (see also Chapter 15). Both diseases are caused by bacterial infection and involve pathologic changes of alveolar bone, periodontal ligament, and cementum. Marginal periodontitis affects coronal periodontal tissues, whereas apical periodontitis affects apical periodontal tissues. Bone loss is one of characteristic features in both diseases: crestal bone is lost in marginal periodontitis, and apical bone undergoes resorption in apical periodontitis.

Apical periodontitis can be caused by both exogenous and endogenous factors. Exogenous factors include microbes and their toxins and noxious metabolic byproducts, chemical agents, mechanical irritation, foreign bodies, and trauma. Endogenous factors include the host's metabolic products, such as urate and cholesterol crystals, as well as cytokines or other inflammatory mediators that activate osteoclasts. These irritants can activate nonantigenic pathways or antigenic pathways to induce innate and adaptive immunoinflammatory responses, respectively.

In the root canal system, infection of the pulp tissue caused by caries or other pathways is the primary cause of apical periodontitis.[108,158,232] The classic study of Kakehashi et al.[108] demonstrated that pulp necrosis and periradicular inflammation developed in conventional rats when the pulps of teeth were exposed to oral microorganisms. However, in germ-free laboratory rats, no pulp necrosis and periradicular inflammation occurred even when the pulps of teeth were exposed to the oral environment and packed with sterile food debris. A similar response occurs in humans. Using bacterial culturing, it has been demonstrated that traumatized human teeth with intact crowns and necrotic pulps *without bacterial contamination* did not show radiographic evidence of periapical bone destruction. In contrast, if bacteria were isolated from trauma-

tized teeth with intact crowns and necrotic pulps, radiographic evidence of periradicular bone destruction was observed.[232] These important findings have been replicated in nonhuman primate experiments. When the pulps of intact vital teeth were intentionally devitalized under aseptic conditions and left in the root canals with bacteria-tight, sealed coronal restoration for 6 months to 1 year, no periradicular inflammatory reaction was observed.[137,158] Taken together, there is considerable evidence that bacteria constitute a major etiologic factor in the development of apical periodontitis.

Bacterial toxins (e.g., lipopolysaccharide [LPS], lipoteichoic acid [LTA]) and noxious metabolic byproducts that egress from the root canal system into the periapical tissues are capable of inducing a periapical immunoinflammatory reaction.[47,58,203,280] These substances can activate the innate immune system via receptors that recognize the stereotypic pathogen-associated molecular patterns (PAMPs) that are found in the structure of these toxins. Different classes of microbes express different molecular patterns that are recognized by different pattern recognition receptors (PRRs) or toll-like receptors (TLRs) on host cells, such as phagocytes, dendritic cells, and B lymphocytes.[1,154] PRRs or TLRs are encoded in the germline. In mammalian species, there are at least 10 TLRs, and each appears to have a distinct function in innate immune recognition.[154] For example, LPS can stimulate sensory nerve fibers to release calcitonin gene–related peptide (CGRP) and substance P (SP)[55,96] to cause vasodilation and increased vascular permeability. LPS and lipoproteins can also activate TLRs on dendritic cells to stimulate T lymphocyte differentiation.[4] The common shared structural features of various toxins (i.e., PAMPS) are recognized by certain subtypes of TLRs. Since the TLRs are synthesized before an infection, they are classified as part of the innate immune system.

Apical periodontitis can be caused either by entry into the periapical tissues of bacterial toxins, enzymes, and noxious metabolic byproducts or by direct invasion of the periapical tissues by microbes originating from the root canal system. It is important to differentiate between apical inflammation and apical infection. *Apical inflammation* is the periapical tissue reaction to irritants emerging from the root canal system that manifests as vasodilation, increased vascular permeability and exudation. In contrast, *apical infection* is due to the physical presence of pathogenic microorganisms in the periapical tissues that subsequently produce tissue damage. There can be infection without inflammation, for instance, in a severely immunocompromised patient. There can also be inflammation without infection, such as in a myocardial infarct, cerebral infarct, physical, or chemical injury.[148] In diseases caused by infection, bacteria are usually present in the involved tissues or organs,[265] such as acute necrotizing gingivitis, marginal periodontitis, actinomycosis, tuberculosis, and bacterial bronchitis. Although apical periodontitis is primarily an infectious disease, bacteria are usually not present in the periapical tissues but in the root canal system,[123,162,267] except in certain cases of apical periodontitis associated with abscess formation,[179,262,274] a draining sinus tract,[83,181,272] or extraradicular endodontic infection.[231,255] One major current hypothesis is that apical periodontitis is triggered by entry into the periapical tissues of bacterial toxins, enzymes, and noxious metabolic byproducts.[240] The mere presence of bacteria (colonization) in some apical periodontitis lesions does not necessarily denote a periradicular infection. Periapical infection is related to both virulence and the number and perhaps combinations of microorganisms in the periapical tissues.[235] Bacteria may be temporarily present in the inflamed periradicular tissues only to be killed by the host's defense mechanisms when the focus of infection in the root canal system is effectively eliminated by mechanical instrumentation, antiseptic irrigation, and intracanal medication. For instance, the majority of apical periodontitis lesions with abscess formation or draining sinus tracts heal satisfactorily after nonsurgical root canal treatment without the need for systemic antimicrobial therapy.[181]

Primary root canal infection in untreated root canals is a polymicrobial mix with approximately equal proportions of gram-positive and gram-negative species, dominated by obligate anaerobes (see Chapter 15).[233,235] In root-filled teeth with apical periodontitis, gram-positive microorganisms, with a relatively equal distribution of facultative and anaerobic species, appear to dominate other microorganisms.[156,236] A high prevalence of *E. faecalis* is frequently observed in filled root canals associated with persistent apical periodontitis.* These issues are described in greater detail in Chapter 15.

Physical (overinstrumentation, overfilling) and chemical (irrigants, intracanal medication, root canal filling materials) insults,[205] as well as traumatic injury[10] to the periapical tissues, can also cause apical periodontitis, depending on the severity of injury and cytotoxicity of the chemicals. Foreign bodies, such as root canal filling materials, have been shown to cause persistent periapical inflammation.[91,118,166,183,282] However, the possibility of bacterial contamination in foreign body–induced apical periodontitis lesions was not carefully ruled out in many studies, so it is possible that the foreign bodies served as carriers for the microorganisms. In addition, foreign bodies have the odd property of favoring infection because they cause granulocytes to develop phagocytic defect, loss of ammunition.[283] Although most root canal filling materials are not inert and are capable of inducing certain degrees of inflammation, in general they are biocompatible and well tolerated by periapical tissues.[91]

INFECTION: A CONFLICT BETWEEN HOST AND PARASITES

Every infection is a race between the capabilities of the microorganism to multiply, spread, and cause disease and the ability of the host to control and finally eliminate the microorganisms and resulting infection.[265] The host has physical barriers—surface epithelium, enamel, and dentin—as well as innate and adaptive immune defenses to prevent pulpal and periapical infection. Nevertheless, parasites also possess weapons, leading to inhibition of phagocytosis, inhibited lysosomal function, reduced killing by phagocytes, inactivation of complement system and immunoglobulins, and specific mechanisms that permit invasion of the host's physical barriers.[265] Infection of a tissue can manifest different histopathologic features as a result of specific host-parasite interactions that occur. Many infections are asymptomatic in more than 90% of individuals.[265] For instance, pulp necrosis and chronic apical periodontitis caused by root canal infection are usually asymptomatic, and patients are often surprised to find out that this infection

*References 87, 112, 156, 184, 218, and 236.

has been present for a sufficient time to lead to destruction of periapical bone. Therefore, there is no simple correlation between infection and clinical symptoms of apical periodontitis, except in cases of symptomatic apical periodontitis and acute apical abscess.

PATHOGENESIS

When pulps are infected/inflamed, many innate and adaptive immune cells release elevated amounts of various inflammatory mediators, including cytokines, chemokines, and neuropeptides. As the pulpal inflammation spreads, the inflammatory mediators begin to alter the physiology of the periapical tissues. Clinically, the observable changes on radiographic examination are widening of the periodontal ligament space or development of apical osteolytic lesions due to bone resorption. The loss of bone is mainly caused by activated osteoclasts. Many cytokines, such as interleukin (IL)-1, IL-11, IL-17, and tumor necrosis factor α (TNF-α), are found to have the ability to induce osteoclast differentiation and activation.[21] The inflammation-induced bone resorption in the periapical tissues is accompanied by recruitment of immune cells that essentially build a defensive line against the spread of microbial invasion from the root canal.[152] The pathogenesis of apical periodontitis involves innate and adaptive immune responses as well as sensory nerve response in the periapical tissues. Immune cells present in human periradicular lesions consist of lymphocytes, macrophages, plasma cells, neutrophils, and natural killer (NK) cells with the former two types as the majority.[135,151] The characteristic features of innate and adaptive immunity are summarized in Table 14-1.

TABLE 14-1

Features of Innate and Adaptive Immunity

Property	Innate	Adaptive
Recognition	Structures shared by groups of related microbes (conserved molecular patterns)	Antigens of microbes and of nonmicrobial antigens (details of molecular structure)
Diversity	Limited	Very large
Memory	None	Yes
Receptors	Encoded in the genome	Encoded in gene segments (somatic recombination)
Blood proteins	Complement	Antibodies
Cells	Macrophages	Lymphocytes Neutrophils NK cells
Action time	Immediate activation of effectors	Delayed activation of effectors
Response	Costimulatory molecules, Cytokines	
(IL-1, IL-6)		
IL-2	Clonal expansion	
Chemokines (IL-8)	Effector cytokines (IL-4, IFN*r*)	

IFN, Interferon; *IL,* interleukin; *NK,* natural killer.

Data from Janeway CA, Medzhitov R: Innate immune recognition. *Annu Rev Immunol* 20:197, 2002; and Abbas AK, Lichtman AH, Pober JS: *Cellular and molecular immunology,* ed 5, Philadelphia, Saunders, 2003.

Innate Immune Response

Specificity of Innate Immune Response

In recent years, the concept of the nonspecific nature of innate immunity has changed since identification of a network of germline-encoded receptors, the pattern-recognition receptors (PRRs) mentioned earlier, that recognize specific molecular motifs of microorganisms.[5,153] PRRs can be expressed on the cell surface (macrophages, dendritic cells, neutrophils, NK cells, B cells), in intracellular compartments, or secreted into the blood and tissue fluids.[104] There are numerous microbial constitutive and conserved products, the pathogen-associated molecular patterns (PAMPs), also noted earlier. Importantly, the PRRs of the innate immune system recognize PAMPs.[5,153]

The specificity of innate immunity is due to the recognition of PAMPs of microorganisms by PRRs, also called *toll-like receptors* (TLRs), of the host's cells. Activation of PRRs triggers numerous host responses, including opsonization, activation of complement and coagulation cascades, phagocytosis, activation of proinflammatory signaling pathways, and induction of apoptosis.[104] For example, TLR4/CD14 is the receptor for the gram-negative bacterial LPS. TLR4-mutated C3H/HeJ mice (LPS hyporesponsive) have reduced response to gram-negative bacteria and are highly susceptible to infection by *Salmonella typhimurium* or *Neisseria meningitidis*.[42] Importantly, there is a reduced expression of IL-1 and IL-12 and decreased periradicular bone destruction in TLR-4 deficient mice when teeth are subjected to pulpal exposures and infection with a mixture of four anaerobic pathogens: *Prevotella intermedia, Fusobacterium nucleatum, Streptococcus intermedius* (G+), and *Peptostreptococcus micros* (G+).[94] In addition, LPS is shown to be capable of inducing pain via direct activation of TLR4/CD14 expressed on nociceptive sensory neurons.[264] Thus, the TLR4 PRR receptor is importantly involved in odontogenic infections.

Components such as lipoteichoic acid (LTA) of gram-positive bacterial cell walls can also stimulate innate immunity in a way similar to LPS. TLR2 plays a major role in detecting gram-positive bacteria and is involved in the recognition of a variety of microbial components, including LTA, lipoproteins, and peptidoglycan. The importance of TLR2 in the host defense against gram-positive bacteria has been demonstrated using TLR2-deficient ($TLR2^{-/-}$) mice, which were found to be highly susceptible to challenge with *Staphylococcus aureus* or *Streptococcus pneumoniae*.[60,241] LTA also stimulates leukocytes to release inflammatory mediators, including TNF-a, IL-1b, IL-6, IL-8, and prostaglandin (PG) E2, which are known to play a role in various phases of the inflammatory response. All these inflammatory mediators have been detected in periapical samples, and each has a well-known tissue-damaging effect by activating various host responses.

The innate immune response to bacterial infection induces expression of proinflammatory cytokines, chemokines, and costimulators, which are essential for activation and influence of the nature of adaptive immune response.[4,154] The innate

immune system is capable of recognizing nonself and self-antigens, while the adaptive immune system does not; thus, many autoimmune diseases are disorders of adaptive immunity.[154]

Nonspecific Innate Immune Response

The primary nonspecific innate immune defense mechanism in apical periodontitis is phagocytosis of microbes by specialized phagocytes such as polymorphonuclear leukocytes (PMNs) and macrophages. Tissue inflammation leads to the recruitment of PMNs from the blood circulation into the periradicular tissue. Activated PMNs exhibit an abrupt increase in oxygen consumption, the well-known respiratory burst, resulting in the release of oxygen radicals, a family of extremely destructive, short-lived substances that destroy nearby microorganisms and host cells.[12] Phagocytosed microbes or foreign particles are exposed to a very toxic environment containing specific and azurophil granules and oxygen-derived free radicals and are eventually degraded.[173] PMNs also possess an extracellular killing mechanism via neutrophil extracellular traps (NETs), which are extracellular structures composed of chromatin with specific proteins from the neutrophilic granules. Upon activation (e.g., by IL-8, LPS, bacteria, fungi, activated platelets), neutrophils start a cellular program called *apoptosis* that leads to their death and the formation of NETs, which have antimicrobial activities.[27,71] Besides their role in the innate immunity as professional phagocytes, macrophages also serve as antigen-presenting cells by expressing MHC class II molecules that interact with antigen-specific clones of T-helper lymphocytes. Circulating monocytes are the precursors of both tissue macrophages and many dendritic cell subsets.[1,208] The details of the immunologic activities of neutrophils and macrophages in periapical pathosis are described in Chapters 12 and 13.

Adaptive/Specific Immune Response

The specificity of adaptive immunity is regulated at genetic levels in B and T lymphocytes through a complex process leading to the generation of molecules that recognize and bind to foreign or self-antigens. These molecules are specific receptors on T cells (T-cell antigen receptors or TCRs) and on B cells (B-cell antigen receptor or BCRs; also termed *immunoglobulins*). TCRs on T cells interact with antigens that are presented by MHC molecules along with other accessory molecules, whereas BCRs on B cells interact with antigens directly. BCRs may be secreted in the blood circulation or in the tissues as antibodies. The variable region of both TCR and BCR proteins are rearranged at the genomic level via genetic recombination of the V(D)J segments. The estimated total diversity after this recombination for TCR is approximately 10^{18} and for BCR is approximately 10^{14} that generates the repertoire of different individual T and B cell clones.[1,105] Each T or B cell clone generated in the bone marrow carries a specific TCR and BCR. They undergo a positive and negative selection process through which most clones are deleted via apoptosis because they bind to self-antigens. This initial "negative screening" process serves to reduce the potential for autoimmune disorders. Only those that do not interact with self-antigens are released into the lymphatic system and blood circulation. The naïve T cells circulate back and forth between the lymphatic system and blood circulation until they encounter foreign antigens presented by antigen-presenting cells. About 97% of T cells undergo apoptosis, and only a small percentage of these cells are exported to the periphery as mature T cells.[1]

The interaction between TCR and the antigen peptide/MHC complex and costimulators activate T cells, leading to the synthesis of T-cell growth factor, IL-2, and its receptor that causes T-cell clonal expansion/proliferation. Some of these T cells differentiate into armed, effector T cells and other become memory cells. There are a number of T-cell subpopulations, categorized by their functions: (1) T helper cells (T_H), (2) T regulatory cells (T_{reg}), (3) T suppressor cells (T_S), and (4) T cytotoxic (cytolytic) (T_C) cells.[1,50,261] Some of them can be distinguished by their cell surface markers, cytokine profiles, or transcriptional factors. See also Chapter 13 for additional details.

Upon antigen stimulation, naïve CD4 T cells proliferate and differentiate into T_H0, which are subsequently committed to develop into T_H1 or T_H2 cells. Monocytoid DC (DC1) induces T_H1-type responses; plasmacytoid DC (DC2) selectively induces T_H2 responses. Each subset of T_H cells has distinct functions and cytokine profiles. T_H1 cells mainly produce IL-2 and interferon (IFN)-γ, which activate macrophages and induce B cells to produce opsonizing antibody. T_H2 cells produce IL-4, -5, -10, and -13, which activate B cells to make neutralizing antibody. Overall, T_H1 and T_H2 have mutually inhibitory effects.[1] The development of CD4 T_H cells involves the encounter of antigen presented by antigen-presenting cells (APCs) in association with class II MHC. All cells express MHC class I, but only certain cells express class II MHC. These class II MHC–expressing cells comprise the body's population of APCs and consist of (1) dendritic cells, (2) macrophages, (3) B cells, (4) vascular endothelial cells, and (5) epithelial cells. The former three are considered "professional" APCs, since they are dedicated to this function. The latter two APCs are quiescent under normal conditions but can be induced to express class II MHC when exposed to elevated concentrations of IFN-γ.[1,105]

Dendritic cells and macrophages phagocytose foreign antigens, while B cells utilize the membrane-bound immunoglobulin to bind and internalize antigens. Other APCs endocytose foreign antigens into the cytoplasm for antigen processing. The processed antigens are partially degraded into small peptides. Many of them are 10 to 30 amino acids long and capable of binding onto the newly synthesized class II MHC molecules before the antigen/class II MHC complex is transported to the surface of cells and presented to TCRs of $CD4^+$ T cells.

While controversial, evidence has suggested that $CD8^+$ T_S and $CD8^+$ CTLs represent distinct subpopulations of $CD8^+$ T cells. T_S are MHC class I–restricted $CD8^+/CD28^-$ T_S cells, which act on antigen-presenting cells (APC) by a contact-dependent manner, rendering them tolerogenic to T_H cells. They inhibit the proliferation of T_H cells.[44,285] T cytotoxic cells ($CD8^+T_C$), also known as *cytolytic T lymphocytes* (CTLs), are a subset of T cells that kill target cells expressing MHC-associated peptide antigens. The majority of T_C express CD8 and recognize antigens degraded in the cytosol and expressed on the cell surface in association with class I MHC molecules of the target cells. Functional T_C acquire specific membrane-bound cytoplasmic granules, including a membrane pore-forming protein called *perforin* or *cytolysin* and enzymes called *granzymes*.[1]

The role of B cells in adaptive immunity is mainly the production of antibodies that constitute the host humoral

immune response. The V(D)J gene recombination occurs in both heavy and light (κ and λ) chains. A recombinase system, which is an enzymatic complex consisting of several enzymes—including recombination activating gene 1 and 2 (RAG-1, RAG-2), terminal deoxynucleotidyl transferase (TdT), DNA ligase IV, Ku proteins, and XRCC4—is essential for successful recombination. This recombinase system is also used for TCR recombination. Mature IgM/IgD coexpressing B cells undergo isotype switching via a process called *switch recombination* after encountering antigen. The rearranged V(D)J gene segment recombines with a downstream C region gene (γ, ε, or α), and the intervening DNA sequence is deleted. This gives rise to other classes of immunoglobulins (IgG, IgE, IgA) besides IgM. In addition to isotype switching, activated B cells also undergo somatic mutation in the V region gene, leading to affinity maturation of antibodies and alternative splicing of VDJ RNA to membrane or secreted immunoglobulin mRNA. A large quantity of antibody is secreted when B cells terminally differentiate into plasma cells.[1,105] The ability of antigens to selectively stimulate the differentiation of plasma cells supports the clinical finding that plasma cells isolated from periapical lesions secrete antibodies specific for the particular bacteria found in the adjacent root canal system.

The immune response and the role of lymphocyte subpopulations in apical periodontitis lesions were investigated by employing lymphocyte-deficient rodents as study models. T-cell deficiency appears to accelerate bone loss at the early phase of apical periodontitis lesions (2 weeks) but does not affect the overall course of lesion development.[242,266] Using RAG-2 SCID mice (both T- and B-cell-deficient), it was found that approximately a third of the RAG-2 mice developed endodontic abscesses, while no immunocompetent controls had abscesses.[244] In another study, specific RAG 2 knockout (k/o) mice were used to determine which immune element was important for the defense mechanism in endodontic infection. The results demonstrated that B cells, but not T cells, played a pivotal role in preventing dissemination of endodontic infection.[95] Therefore, both T and B cells mediate the observed immune responses in apical periodontitis lesions.[152]

Neurogenic Inflammation

Certain primary afferent nerve fibers, upon stimulation by various irritants, release neuropeptides, which cause vasodilation, protein extravasation, and recruitment/regulation of immune cells such as macrophages, neutrophils, mast cells, and lymphocytes. This phenomenon is termed *neurogenic inflammation*. Pivotal neuropeptides in the induction of neurogenic inflammation are CGRP, for vasodilation, and SP, for the induction of protein extravasation. Neuropeptides and their receptors are widely distributed throughout the body. During inflammation, there is a sprouting of afferent fibers[89] and local increases in inflammatory mediators that trigger neuropeptide release, leading to neurogenic inflammation.[23,38] Besides the cardinal functions of the key neuropeptides that cause the first sign of inflammation—vasodilation and increased vascular permeability—the role of these neuropeptides in the process of inflammation is now known to be far more complex. In the development of chronic apical periodontitis lesions, neuropeptides are also involved in immune regulation, bone resorption, and wound healing. At sufficient concentrations, SP increases the secretion of IL-1, TNF-α, and IL-6 from macrophages and stimulates T-lymphocyte proliferation and enhances antigen-induced IFN-γ production by T cells.[225] Certain neuropeptides, such as SP, upregulate immune and inflammatory responses, whereas other neuropeptides, such as vasoactive intestinal peptide (VIP) and neuropeptide Y (NPY), inhibit inflammatory responses. Synergistic interactions among neuropeptides, such as CGRP and other inflammatory mediators, eicosanoids, and bradykinin, suggests a complex interplay between these molecules in the immune response.[77,189,225]

In chronic apical periodontitis lesions, specific receptors for SP and CGRP are expressed in certain immune cells, including macrophages and lymphocytes. Both CGRP and VIP may play a role in inhibiting bone resorption by suppressing osteoclastic functions. The level of VIP in apical periodontitis lesions is inversely related to lesion size. Osteoclast cell culture studies have demonstrated that the presence of greater concentrations of VIP leads to a decrease in their ability to form lacunae of osseous resorption, causing rapid cytoplasmatic contraction and reduced cell mobility. VIP exerts an effect on macrophages to block the production of TNF-α, IL-6 and IL-12, suggesting that VIP could have a role in controlling growth of apical periodontitis lesions.[38]

The major innate and adaptive immune responses and neurogenic inflammation in the pathogenesis of apical periodontitis caused by root canal infection is illustrated in Fig. 14-1.

DIAGNOSIS

Correlation Between Clinical and Histologic Findings

Clinical diagnosis of inflammatory periapical disease is mainly based on clinical signs and/or symptoms, duration of disease, pulp tests, percussion, palpation, and radiographic findings. In contrast, a histologic diagnosis is a morphologic and biologic description of cells and extracellular matrix of diseased tissues. The clinical diagnosis represents a provisional diagnosis based upon signs, symptoms, and testing results, whereas the histologic diagnosis is a definitive diagnosis of tissue disease.

Similar to pulpitis,[206] apical periodontitis is not always symptomatic or painful. Although many inflammatory mediators (histamine, bradykinin, prostaglandins) and proinflammatory cytokines (IL-1, IL-6, TNF, nerve growth factor [NGF]), as well as neuropeptides (SP, CGRP), are capable of sensitizing and activating nociceptive sensory nerve fibers,[89,90] other mediators such as endogenous opioids and somatostatin released by inflammatory cells during inflammation are able to inhibit firing of sensory nerve fibers.[93,211] Activation of nociceptive sensory nerve fibers may also be related to concentrations of inflammatory mediators. The complexity of these findings supports the clinical observation that there is no good correlation between clinical symptoms and histopathologic findings of apical periodontitis.[24,143,213] For example, many teeth with apical periodontitis are free of symptoms.

Correlation Between Radiographic and Histologic Findings

Radiography is designed to detect pathologic changes at tissue not cellular levels. Even using very sensitive imaging systems such as ultrasound, cone-beam computed tomography, and other technologies, it is impossible to detect the presence of inflammatory cells or other subtle changes in the periapical

tissues. Using conventional radiographic and histologic methods in the same cadavers, evidence of inflammation was often observed in the periapical tissues of endodontically treated teeth with normal radiographic features.[15,32,78] This finding is supported by the fact that lesions localized in the cancellous bone may not be visible radiographically unless they involve cortical bone.[17,19,98] In addition, radiographic findings are unable to predict asymptomatic apical periodontitis (granuloma) from asymptomatic apical periodontitis with cyst formation (radicular cyst).[125,238] Accordingly, radiographic findings and histopathologic features of apical periodontitis have a poor correlation based on available case series studies.

The absence of clinical symptoms and negative periapical radiographic findings of endodontically involved teeth does not necessarily indicate absence of apical periodontitis. By the same token, clinical success of endodontically involved teeth (i.e., absence of signs and symptoms and negative periapical radiographic findings) after nonsurgical root canal therapy does not necessarily imply complete histologic healing of periapical lesions. Thus, currently available diagnostic methods used in endodontics, such as percussion, palpation, and pulp tests (cold, heat, electric), are not sensitive enough to provide histologic diagnosis of an inflammatory periapical disease. In fact, all endodontic tests are basically used to examine the functions of nociceptive sensory nerves and not the pathologic changes of the pulp and/or periapical tissues. Until we have more advanced and sophisticated clinical diagnostic technologies, we will continue to face the problem of clinical diagnosis of inflammatory periapical disease. Nevertheless, the treatment of various types of apical periodontitis lesions is basically the same: nonsurgical root canal therapy. Interestingly, this treatment does provide a consistently good clinical outcome, as measured by either clinical signs of success or survival of the treated tooth. Future research should focus on developing testing methods that provide greater insight into the status of the periapical tissue.

HISTOPATHOLOGY

The study of the histopathology of diseased tissues and organs has gone through an interesting evolution. It began at macroscopic, light microscopic, and then electron microscopic observations of diseased tissues and organs. Nowadays, histopathology is focused on cellular and molecular biology of diseased tissues and organs. Biochemical disorders occur inside the cells before light and electron microscopic observable morphologic changes of cell injury. Cell death (protein denaturation) occurs before observable morphologic changes of cell necrosis. Gene transformation or mutation occurs before observable morphologic changes of neoplastic cells.[148]

Based on etiology, clinical signs and symptoms, and duration of the disease process, the World Health Organization (WHO) classifies disease of periapical tissues into many categories.[278] There are also many classifications of inflammatory periradicular disease in several endodontic textbooks[99,181,253] and by the American Board of Endodontists, depending on clinical manifestations and histologic appearances. In addition, the American Association of Endodontists held a consensus conference on diagnostic terms in the fall of 2008. Traditionally, there has been a lack of consensus on clinical diagnostic

terminology of pulpal and periapical disease in the endodontic community because of the paucity of studies with high levels of evidence. Since the focus of this chapter is on pathobiology of the periapex, inflammatory periapical disease will be classified based on histologic appearances and cell biology of the injured periapical tissues. To avoid confusion between histologic and clinical diagnosis, readers are encouraged to read the chapters related to clinical examination, radiographic interpretation, and clinical diagnosis of inflammatory periapical disease (see Chapters 1, 2, and 4).

The histopathologic analysis of a diseased tissue or organ only shows structural changes of cells and extracellular matrix at the time the tissue or organ is removed. Therefore, it does not represent the complete kinetics or spectrum of disease development. Histologic classification of apical periodontitis is based on types of cells participating in immunoinflammatory responses in the periapical tissues. In general, inflammation can be divided into acute and chronic responses, depending on types of cells present at the site of injured tissue.[121,148,220,270] Acute immunoinflammatory response is characterized by participation of neutrophilic leukocytes and chronic immunoinflammatory response by participation of macrophages and lymphocytes. However, many factors, such as severity of tissue injury, specific etiology, host's resistance, and particular tissue involved, can modify the course and morphologic variations as well as cell biology of both acute and chronic immunoinflammatory responses.[121,148] Acute and chronic immunoinflammatory responses are in fact not rigid phases of a single programmed event but two overlapping responses with partially different triggering mechanisms and programs.[148]

SYMPTOMATIC APICAL PERIODONTITIS

It is a general belief that the development of apical periodontitis follows total pulp necrosis. This belief is based on (1) the pulpal strangulation theory due to a generalized increase in pulpal interstitial pressure inside the uncompromised pulp space during pulpal inflammation that causes collapse of venules and cessation of blood flow[89]; and (2) animal and human studies that concluded that uncontaminated necrotic pulps which are intentionally devitalized or accidentally traumatized are generally incapable of inducing periapical inflammation unless they are infected.[137,158,232] However, if the vital pulps become infected due to caries or other pathways, periapical inflammation can develop even when inflamed, but vital tissue is still present in the apical portion of the root canal. Most of our information related to the histopathology of apical periodontitis comes from analysis of longstanding, chronic human lesions caused by caries or from time-course studies of development of apical periodontitis induced by artificial root canal infection in animals. In these instances, the moment of transition from pulpitis to apical periodontitis was not captured. In fact, apical periodontitis has been demonstrated to be a direct extension of apical pulpitis into the periapical tissues before total pulp necrosis caused by root canal infection (Fig. 14-2).* For example, Kovacevic et al.[119] studied the transition from pulpitis to apical periodontitis in dogs' teeth by artificial exposure of pulps to the oral cavity and observed that pulpitis was coupled with an acute apical periodontitis. Similarly,

Kimberly and Byers[115] demonstrated that periapical changes, including sprouting of nerve fibers, appeared 3 to 5 weeks following establishment of irreversible pulpitis subsequent to pulp exposure lesions in animals. Yamasaki et al.[279] and Stashenko et al.[226] also showed that periapical inflammatory infiltrates, increased osteoclast numbers, and bone destruction were apparent well in advance of total pulpal necrosis, with vital pulp tissue still present in the apical portion of the root canal. The biologic basis for these observations appears to hinge on the apical development of pulpal infection/inflammation leading to the diffusion of many inflammatory mediators, proinflammatory cytokines, chemokines, and bacterial toxins into the periapical area[140] prior to total pulpal necrosis.

The development of acute apical periodontitis largely reflects the innate immune system and is the first line of active defense against irritants from the root canal. Acute apical periodontitis is an immediate defense reaction to irritants and does not require exquisite specificity and memory. Characteristic features of acute apical periodontitis are similar to the typical acute inflammatory reaction and consists of vasodilatation, increased vascular permeability, and transmigration of leukocytes from the blood vessels into perivascular tissue space. The beneficial actions of acute inflammation are (1) infiltration of leukocytes to the injured tissue to phagocytose and kill microbial agents; (2) accumulation and activation of humoral factors such as immunoglobulins, complement factors, and plasma proteins in the injured tissue to recruit more neutrophils and macrophages; and (3) neutralization or degradation of bacterial toxins and their harmful metabolic byproducts.[121,148]

Cell Biology

The immunoinflammatory response is a dynamic interaction between host defense mechanisms and microbial insults. The interlacing activation and control pathways of cellular and humoral components involved in the immunoinflammatory response are complex. The cells involved—neutrophils,

monocytes/macrophages, platelets, mast cells, T lymphocytes, B lymphocytes, NK cells, dendritic cells, endothelial cells, fibroblasts, eosinophils, and basophils—each have numerous functions that are activated and modulated by a multiplicity of biochemical messengers.[1,121,148] *Cell activation* means that the cell acquires the ability to perform one or more new functions or to perform normal functions at a higher rate;[1] it often results in transcription of new genes and synthesis of new proteins.[1]

Mast Cells

Histamine stored in the cytoplasmic granules of mast cells is the mediator that first appears in acute inflammation to induce vasodilation and increased vascular permeability; mast cells are the designated triggers of acute inflammation. They are widely distributed in perivascular tissue spaces and originate in the bone marrow from precursor cells. Mature mast cells contain numerous cytoplasmic granules, which are the source of vasoactive mediators. The preformed histamine is released by mast cell degranulation and can be triggered by (1) physical stimuli such as cold, heat, and mechanical trauma; (2) binding of IgE-specific antigen to mast cells, membrane-bound IgE antibodies; (3) binding of complement components (C3a and C5a) to their complementary receptors on mast cells; and (4) stimulation by neuropeptide (SP) and cytokines (IL-1, IL-8).[1,26,121,148] In addition, activated mast cells secret cytokines (TNF-α, IL-1, IL-3, IL-4, IL-5, IL-6, IL-13), prostaglandins, and leukotrienes to enhance inflammatory defense mechanisms.[1,33,114]

Endothelial Cells

Endothelial cells are important players in the immunoinflammatory response. Without participation of endothelial cells, the host is unable to deliver its cellular and humoral defense components from the circulating blood to the site of tissue injury. Inflammatory mediators, complement components, proinflammatory cytokines, nitric oxide, neuropeptides, and bacterial toxins can all affect endothelial cells, resulting in vasodilation and increased vascular permeability.[1,121,148] IL-1 and TNF released by activated macrophages and NK cells can stimulate endothelial cells to express intercellular adhesion molecules (ICAMs), such as ICAM-1, ICAM-2, ICAM-3, vascular cell adhesion molecule (VCAM), and platelet endothelial cell adhesion molecule (PECAM), which enhance leukocyte adhesion to endothelial cells and transmigration through the blood vessels.[1,121,132,148] IL-1, TNF, and LPS also can activate endothelial cells to synthesize chemokine (IL-8), a potent chemotactic mediator for neutrophils.[1]

Polymorphonuclear Neutrophilic Leukocytes

Polymorphonuclear neutrophilic leukocytes (PMNs) are the principal effector cells in acute apical periodontitis.[3,111,180] They are derived from bone marrow stem cells. Neutrophils have a lobulated nucleus and contain primary or azurophil (elastase and myeloperoxidase) and secondary or specific (lysozyme and other protease) granules in their cytoplasm.[114,121,148] Neutrophils are only present in the blood circulation. They are the first leukocytes to transmigrate through the blood vessels into perivascular tissue space and then are directed toward the wound or irritants, peaking at 24 to 48 hours. The transmigration of neutrophilic leukocytes from the blood vessels into perivascular space involves complex cellular and molecular biology. Following vasodilation and increased vascular permeability, leukocyte margination, rolling, capture, and activation in the blood vessel and then transmigration through the blood vessel are mediated by an intricate interaction of cell adhesion molecules expressed on leukocytes (L-selectin, integrins) and on endothelial cells (P- and E-selectins, ICAM, VCAM, PECAM-1). Neutrophil rolling is mediated by interaction between leukocyte selectin ligands and P-selectins on endothelial cells. Leukocyte sticking is mediated by interaction between leukocyte integrins and ICAMs and VCAMs on endothelial cells. Leukocyte transmigration is mediated by interaction between PECAM-1 on both leukocytes and endothelial cells.[148] Chemokines (IL-8) increase the affinity of leukocyte integrins for their ligands on endothelial cells.[1] Once transmigrating through the junction between endothelial cells and basement membrane into the perivascular tissue space, neutrophilic leukocytes are directed toward stimuli by chemotactic factors or chemotaxins, such as bacterial products (fLMP), C3a, C5a, leukotriene B4 (LTB4), platelet-activating factor (PAF), fibrinopeptides, dead cells, and chemokines (IL-8) by receptor-mediated mechanisms.[1,121,148,220]

Neutrophils can be activated by bacteria and pathogen-associated molecular patterns (also known as the TLRs, described earlier). They can also be stimulated by IL-1, TNF, and chemokines produced by activated macrophages and NK cells to enhance their phagocytic activity of infectious agents and synthesis of defensins, which are broad-spectrum antibiotics.[1] Neutrophilic leukocytes are terminally differentiated cells and short lived—within hours to a few days. Most neutrophilic leukocytes in acute inflammatory response die as a result of apoptosis or programmed cell death. The apoptotic neutrophils are phagocytosed by macrophages.[82,121,148] However, some neutrophilic leukocytes die after a furious battle against microbial infection and release intracellular proteolytic lysosomal enzymes, oxygen-derived active metabolites, nitric oxide, proinflammatory cytokines, eicosanoids, and matrix metalloproteinases into tissue to intensify inflammation and tissue damage.[121,148] The release of lysosomal enzymes by neutrophils and macrophages can also occur by lysosomal suicide due to rupture of phagolysosome in the cytosol, regurgitation during phagocytosis of irritants, or frustrated phagocytosis of indigestible foreign bodies.[121,148] The main effector functions of neutrophilic leukocytes are phagocytosis, killing of microbes, and release of inflammatory mediators (including proinflammatory cytokines) to recruit more leukocytes to prevent spread of infection.

Macrophages

Macrophages make their appearance as a second wave in acute apical periodontitis within 48 to 96 hours. Macrophages are blood-borne but have a counterpart in the connective tissue.[148] Blood monocytes transmigrate through the blood vessel into the tissues and become macrophages. Mature macrophages have an irregular-shaped nucleus and contain abundant lysosomes and many phagocytic vesicles (phagosomes). Monocytes use mechanisms similar to neutrophils to adhere to endothelial cells in high endothelial venule–expressing adhe-

sion molecules for mononuclear leukocytes (ICAM for macrophages and VCAM for lymphocytes); they then transmigrate through the blood vessel and are directed toward the site of tissue injury by chemotactic factors.[148]

Macrophages can be activated by bacteria, PAMPs, and interferon-*r* (INF-*r*) and produce numerous products: lysosomal enzymes, coagulation factors, bioactive lipids, reactive oxygen species, chemokines, cytokines/growth factors, and angiogenesis factors.[121,148,220] Macrophages are the most dynamic and versatile leukocytes. The main functions of macrophages are numerous. They include phagocytosis of microbes and foreign bodies, production of inflammatory mediators, initiation of the immune response, cleanup operation of necrotic cells and tissue, induction of systemic effects (fever, acute phase reaction, cachexia), synthesis of molecules or cytokines affecting cell and vascular growth in wound healing, as well as antibacterial and antiviral defenses.[148] Tissue macrophages are not terminally differentiated cells and are able to undergo mitosis. Their lifespan is from several weeks to months.

Activated neutrophilic leukocytes and macrophages are very capable of phagocytosing and killing pathogens. They recognize microbes through TLRs and receptors for the Fc fragment of immunoglobulin IgG as well as complement component C3b on their cell surface. C3b opsonization and antibody coating of microbes enhance recognition and phagocytosis of pathogens by activated neutrophilic leukocytes and macrophages.[1,121,148] Activated neutrophilic leukocytes are effective in phagocytosing and killing extracellular microbes, whereas macrophages activated by IFN-*r* produced by NK cells and T_H1 cells are more effective in phagocytosing and killing intracellular microbes.[1] Killing of phagocytosed microbes by neutrophilic leukocytes and macrophages is mediated through oxygen-dependent and oxygen-independent mechanisms. Oxygen-dependent mechanisms are more effective in killing all kinds of bacteria than oxygen-independent mechanisms.[1,121,220] The effector molecules of an oxygen-dependent system are hydrogen peroxide, superoxide anion, hydroxyl radical, singlet oxygen, and hypochlorite. An oxygen-independent system is also important in killing microbes and is dependent on lysozymes, defensins, and lactoferrin contained in phagocyte granules.[1,121,148,220] Some antimicrobial peptides and other oxygen-independent mechanisms possessed by phagocytes are specialized for killing of certain groups of microbes.[1,220]

Microbes phagocytosed by phagocytes are enclosed in membrane-bound phagosomes in the cytosol. The phagosomes fuse with lysosomes to form phagolysosomes. Irritants such as microbes, foreign protein antigens, and dead cells inside the phagolysosome are destroyed or degraded by proteolytic enzymes stored in lysosomes.[1] There are also granules that are fused with the nascent phagosome and release their contents into the phagosome. Some of these granules have direct antimicrobial action, such as defensins and the bactericidal permeability-increasing protein, azurocidin. Others are proteases, such as elastase and cathepsins, lactoferrin, and peroxidase myeloperoxidase. Lysosomal enzymes, reactive oxygen intermediates, and nitric oxide released by neutrophils and macrophages indiscriminately kill not only bacteria but also tissue cells. Much of periapical tissue damage that occurs during acute inflammation can be attributed to release of proteolytic lysosomal enzymes and matrix metalloproteinases from disintegrated neutrophilic leukocytes and macrophages rather than to bacteria and their toxins.[1,148]

Platelets

Platelets normally circulate in the blood but also play an important role in inflammation. They are small cytoplasmic fragments derived from the megakaryocyte.[114] Platelets are essential for blood clotting, hemostasis, and fibrinolysis. Platelets produce vasoactive amines (PAF, serotonin), chemokines, and growth factors (PGDF, FGF, TGF) during inflammation.[148]

Natural Killer Cells

NK cells may also be players in acute apical periodontitis. They are a subset of lymphocytes found in blood and lymphoid tissues. NK cells are derived from the bone marrow stem cells but lack the specific T-cell receptor for antigen recognition.[1] NK cells also possess TLRs for microbial constitutive and conserved products. The effector functions of NK cells are to lyse virus-infected cells without expressing class 1 MHC molecules and to secret IFN-*r* to activate macrophages. Antibody-coated cells, cells infected by viruses, some intracellular bacteria, and IL-2 released by activated macrophages can activate NK cells. Viruses have been isolated in apical periodontitis lesions.[196,221] NK cells kill target cells by antibody-dependent cell-mediated cytotoxicity because NK cells express receptor for the Fc fragment of IgG.[1] NK cells provide a link between the innate and adaptive immune systems.

Inflammatory Mediators

Numerous biochemical mediators are involved in the acute innate immunoinflammatory response. They are mainly derived from plasma and cells. The main biologic functions of inflammatory mediators are to cause vasodilation and increased vascular permeability and recruit inflammatory cells, mainly neutrophilic leukocytes and macrophages from blood circulation to the site of tissue injury. Some mediators can also cause tissue damage. The major mediators involved in vascular changes, cell recruitment, and tissue damage in the acute immunoinflammatory response are listed in Table 14-2.

All listed inflammatory mediators have been shown to be present in apical periodontitis.[249,250] Bradykinin is the product of kinin-system activation; fibrinopeptides, the products of blood-clotting system activation; and fibrin degradation products, the products of fibrinolytic-system activation. Kinin, fibrinolytic, and clotting systems are initiated by activated Hageman factor. Prostaglandins and leukotrienes are the products of arachidonic acid metabolism. Activated phospholipase A2 splits cell membrane phospholipid molecules into arachidonic acid and platelet activating factor. Arachidonic acid molecules can be processed along two pathways: the cyclooxygenase pathway, which leads to production of prostaglandins and thromboxanes, and the lipoxygenase pathway, which produces leukotrienes.[121,148]

Complement components, such as C3a, C3b, C5a, C5b, and C5-C9, are products of the complement cascade, which can be activated by two pathways. The classic pathway is initiated by activation of C1 by multimolecular aggregates of IgG or IgM antibody complexed with specific antigen. The alternate pathway is activated by microbial cell components (lipopolysaccharide, teichoic acid) and plasmin. C3a and C5a are

TABLE 14-2

Major Mediators in Inflammation

Mediator	Source	Effector Cells and Tissues
VASODILATOR		
Histamine	Mast cells Platelets	Endothelial cells
Prostaglandins	Leukocytes Mast cells	Endothelial cells
Nitric oxide	Endothelial cells Macrophages	Vascular smooth muscle

Data from Kumar V, Abbas AK, Fausto N, et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, Saunders, 2010; Slauson DO, Cooper BJ: *Mechanisms of disease*, ed 3, St Louis, Mosby, 2002; Majno G, Joris I: *Cell, tissues, and disease*, ed 2, Oxford, Oxford University Press, 2004; Abbas AK, Lichtman, Pober JS: *Cellular and molecular immunology*, ed 5, Philadelphia, Saunders, 2003.

anaphylatoxins which stimulate mast cells and basophils to release histamine. They also cause phagocytes to release lysosomal enzymes. C3b is an opsonin and can coat bacteria to enhance phagocytosis by phagocytes. In addition, C3b can also bind to antibody bound to antigen or microbes. C5a is a strong chemotaxin for neutrophils. C5b-C9 is a membrane attack complex and able to cause cell lysis if activated on the host cell and bacterial cell membrane.[121,148]

Besides inflammatory mediators, the immunoinflammatory response is also dependent upon the timing and extent of various cytokine and chemokine secretions. IL-1, TNF, IL-6, IL-12, and IFN-γ are present in the acute inflammatory response.[1,84,148] IL-6 is produced by activated mononuclear phagocytes, endothelial cells, and fibroblasts in response to microbial infection and other cytokines, such as IL-1 and TNF. IL-6 stimulates the synthesis of acute-phase proteins by hepatocytes.[1] The major source of IL-12 is activated mononuclear phagocytes and dendritic cells. IL-12 provides a link between innate and adaptive immune responses.[1] IFN-*r* is produced by activated NK cells, T_H1 cells, and cytotoxic T cells and can activate macrophages and enhance their microbial killing ability. IL-1β and TNF are associated with apical bone resorption during chronic apical periodontitis.[224]

Chemokines are a large family of structurally homologous cytokines that stimulate leukocyte movement and regulate the transmigration of leukocytes from the blood vessel to tissue space.[1] They are produced by leukocytes, endothelial cells, and fibroblasts. The secretion of chemokines is induced by microbial infection, TNF, and IL-1.[1,84,214] Different types of leukocytes express different chemokine receptors.[1]

Neuropeptides are released via axon reflexes of afferent sensory neurons in response to various stimuli. Neuropeptides, as mediators of the immunoinflammatory process, are described in detail in Neurogenic Inflammation in this chapter. Inflammatory mediators such as histamine, kinins, prostaglandins, and proinflammatory cytokines are capable of sensitizing and activating sensory nerves to release neuropeptides.[26,89,90,191,202]

Histopathology

The acute immunoinflammatory response is practically immutable in all vascularized living tissues, largely due to the programmed actions of the innate immune system. Initially, blood vessels are engorged by a local infiltration of inflammatory cells, mainly activated neutrophilic leukocytes and some macrophages in the apical periodontal ligament of the infected/inflamed root canal.[3,180] In addition, sprouting of sensory nerve fibers has been shown early in the inflamed periapical tissues.[35,115] Several studies have also demonstrated the presence of inflamed vital pulp tissue with intact nerve fibers in the apical portion of the root canal in association with apical periodontitis.[140,192,193,226,279] This explains the clinical observation that a patient may experience some pain if an instrument is introduced into the canal short of the apex in some teeth with apical periodontitis lesions.

In primary acute apical periodontitis, apical bone destruction is usually not observed radiographically because the duration of acute response is short, and activated neutrophilic leukocytes and macrophages are not able to resorb bone. Only osteoclasts are capable of resorbing bone, and they have to differentiate from the monocyte/macrophage cell lineage in the blood circulation. However, in a rat model experiment, Stashenko et al.[226] showed histologically that periapical inflammatory cell infiltration increases osteoclast numbers, and that bone destruction was apparent well in advance of total pulpal necrosis.

Bacteria are usually not present in acute apical periodontitis lesions.

Clinical Features

As discussed earlier, there is no correlation between clinical and radiographic findings and histologic appearance of inflammatory periapical disease. Teeth with acute apical periodontitis are usually symptomatic and painful to bite and percussion, which results from mechanical allodynia and hyperalgesia.[113] Pain is induced by sensitization and activation of nociceptive sensory nerve fibers by inflammatory mediators, proinflammatory cytokines, nerve growth factor, and pressure.[113] Sprouting of sensory nerve fibers in inflamed periapical tissues could also increase receptive field size in teeth with apical periodontitis.[34,35] Radiographic examination usually does not show periapical bone destruction of involved tooth in acute apical periodontitis, although occasional slight widening of the apical periodontal ligament space and loss of the apical lamina dura of the involved tooth may be present.

Outcomes

The fundamental purpose of the acute immunoinflammatory response is to restore the structural and functional integrity of damaged tissue by eliminating irritants as soon as possible.[270] Tissue damage can also occur in acute inflammation by release of lysosomal enzymes, toxic oxygen radicals, and nitric acid from disintegrated neutrophilic leukocytes and macrophages into tissue.[148] Depending on the dynamic interaction between host defenses and microbial insults, acute apical periodontitis can result in (1) restitution of normal periapical tissues if irritants are immediately eliminated by root canal therapy; (2) abscess formation if massive invasion of periapical tissues by highly pyogenic bacteria occurs; (3) organization by scarring if extensive destruction of periapical tissues results; or (4) progression to chronic apical inflammation if irritants continue to persist.

Abscess is a focal localized collection of purulent exudate in a tissue or an organ.[121] It is a morphologic variation of acute and chronic inflammation.[121,148,270] The development of an abscess in apical periodontitis lesions is probably caused by invasion of a combination of specific pyogenic bacteria in the inflamed periapical tissues.[29,179,234,262] Neutrophilic leukocytes are the predominant cells in acute apical periodontitis with abscess formation. Abscess begins as a furious battle between highly virulent pathogens and an army of neutrophilic leukocytes. The pathogens produce massive toxins to kill neutrophils. As neutrophils attack the pathogens, they secrete lysosomal enzymes that digest not only the dead cells but also some live ones. Many neutrophils die fighting against pathogens. The resulting purulent fluid is poorly oxygenated and has a low pH. The bactericidal ability of leukocytes appears to be impaired because of deprivation of oxygen and interference of respiratory burst. The purpose of respiratory burst is to generate bactericidal agents.[12,148] However, the phagocytic activity of leukocytes is not impaired in aerobic conditions.[148]

Histologically, apical abscess formation is characterized by local collection of suppurative or purulent exudate composed of dead and live neutrophilic leukocytes, disintegrated tissue cells, degraded extracellular matrix, and lysosomal enzymes released by dead neutrophilic leukocytes. It also contains dead and live bacteria and bacterial toxins released by dead bacteria in the inflamed periapical tissues. Abscess formation also involves destruction of periodontal ligament and sometimes periapical bone—especially in chronic apical periodontitis with abscess formation—and a surrounding layer of viable neutrophilic leukocytes and a band of fibrovascular granulation tissue. Both layers are thought to serve as protective barriers to prevent the spread of infection. Epithelial cell proliferation is scanty in acute apical periodontitis with abscess formation (Fig. 14-3).[39,193,205]

Clinically, teeth with acute apical abscess formation usually have symptoms such as pain to biting and percussion. The periapical area of the involved tooth may be very tender to palpation. Intraoral or extraoral swelling is often present. Because of a sudden outpouring of suppurative exudate in the periapical area, tissue pressure increases such that mechanical stimuli are capable of activating terminals of nociceptive neurons in the inflamed periapical tissues. The severe pain of an acute apical abscess can be due to activation of nociceptors

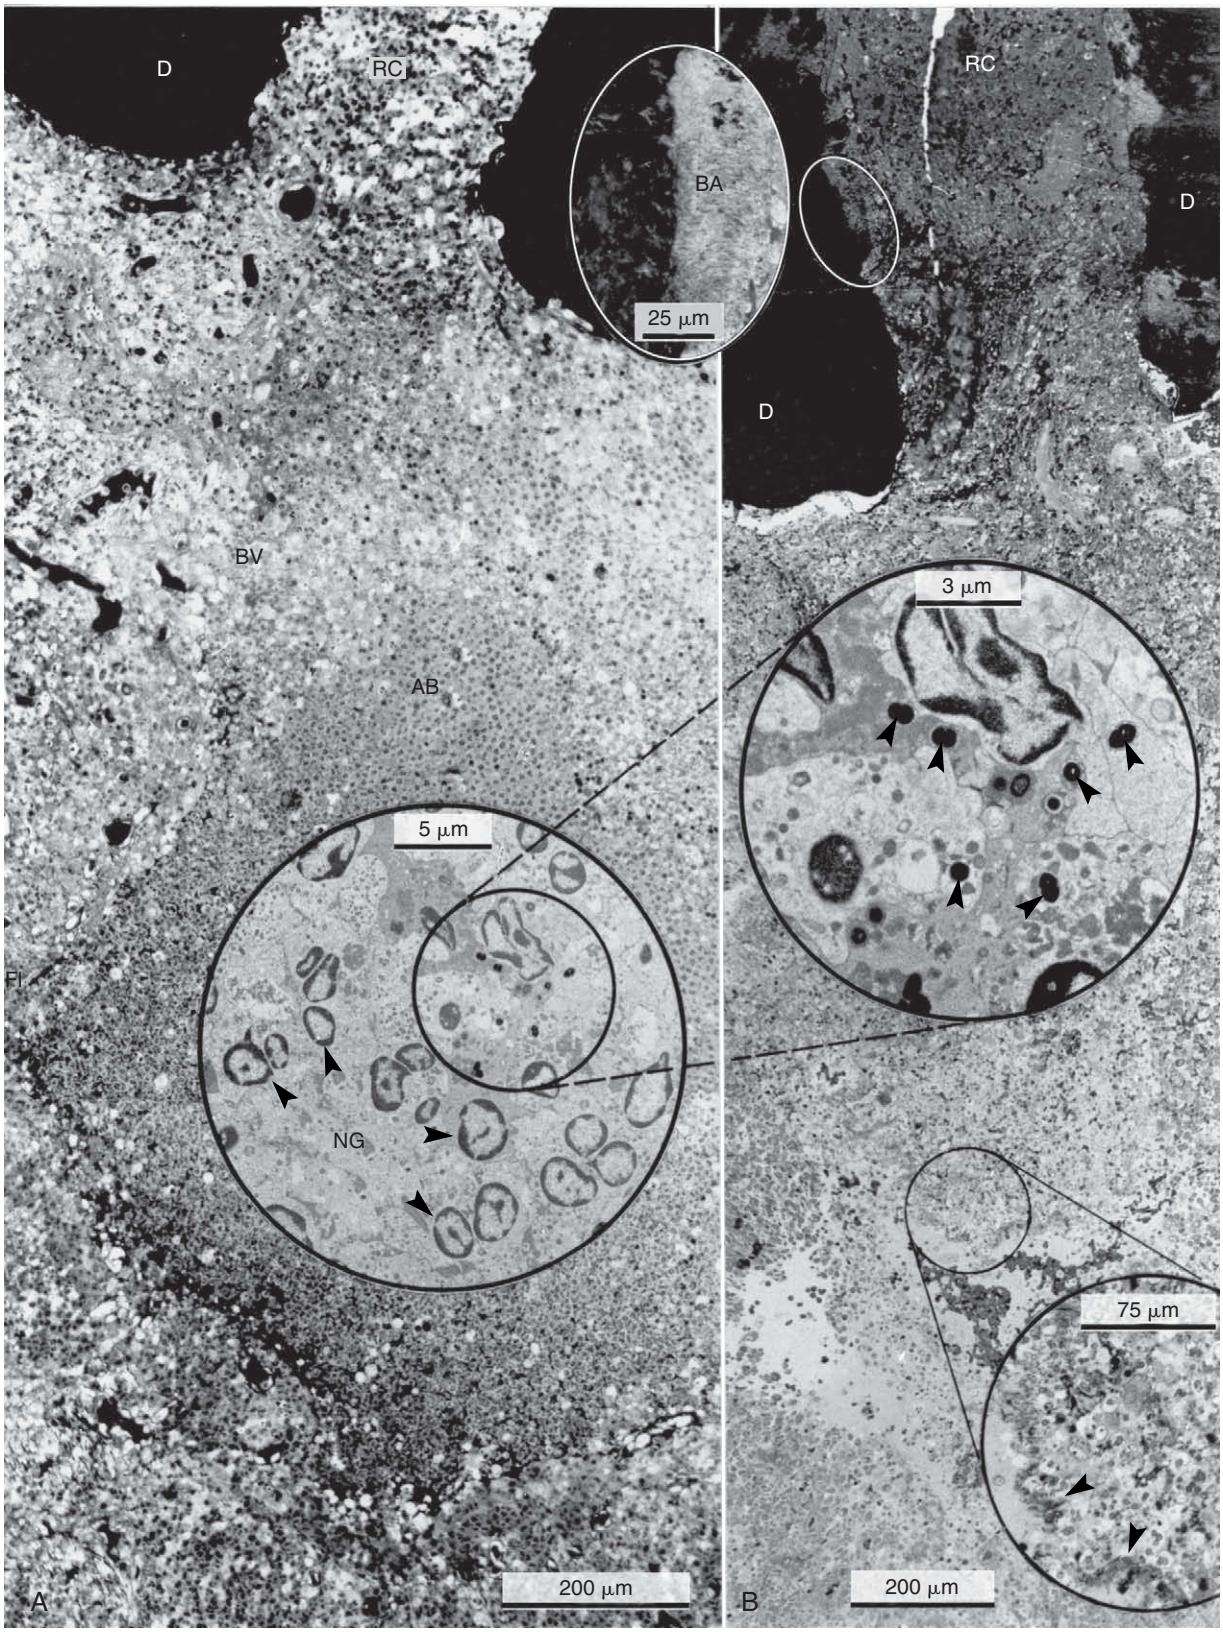

FIG. 14-3 Structure of a secondary periapical abscess. **A,** Axial section of an abscessed apical periodontitis. The microabscess (AB) contains a focus of neutrophils (NG inset in **A**). Note the phagocytosed bacteria in one of the neutrophils (further magnified in large inset in **B**). A secondary abscess forms when bacteria (BA in oval inset) from the apical root canal (RC) advance into the chronic apical periodontitis lesion **(B).** Note the tissue necrosis immediately in front of the apical foramen and the bacterial front in the body of the lesion *(arrowhead in lower inset). BV,* Blood vessels; *D,* dentin. (**A** ×130; **B** ×100; oval inset, ×400; inset in **A,** ×2680; upper inset in **B,** ×4900; lower inset in **B,** ×250.) *(From Nair PNR:* Periodontol *2000 13:121, 1997.)*

by inflammatory mediators and sensitization to mechanical stimuli due to increased interstitial pressures.[207] If the periapical purulent exudate can be evacuated through the root canal (or through incision and drainage when indicated) during root canal therapy, the patient usually experiences an immediate relief of acute pain. Radiographically, the involved teeth may show slight widening of the apical periodontal ligament space to loss of apical lamina dura. In chronic apical abscess, the involved teeth may be symptomatic or asymptomatic. If an intraoral or extraoral draining sinus tract is present, swelling is usually absent. Radiographic bone destruction is obvious in teeth with chronic apical abscess formation.

In most cases, if the source of infection in the root canal is eliminated by root canal therapy, the abscess will heal by reabsorption of the pus in teeth with an acute apical abscess. Phagocytes will kill all bacteria in the abscess. The continued influx of leukocytes stops because the chemotactic stimuli have been removed, and the existing neutrophilic leukocytes die of apoptosis. Finally, macrophages move in to clean up necrotic neutrophilic leukocytes and disintegrated tissue cells. In chronic apical abscess formations, wound healing will take place mainly by means of regeneration and to some degree by tissue repair. However, if bacterial virulence and numbers of pathogens overwhelm the host's defenses, the abscess may break through the cortical bone, periosteum, and oral mucosa or facial skin to develop an intraoral or extraoral draining sinus tract. Sometimes, the uncontrolled abscess may spread along the fascial planes of the head and neck to develop serious cellulitis (see also Chapter 15).[126,205]

ASYMPTOMATIC APICAL PERIODONTITIS: APICAL GRANULOMA, CHRONIC APICAL PERIODONTITIS

If pathogens in the root canal are not eliminated, the symptomatic apical periodontitis may progress to become an asymptomatic apical periodontitis. Asymptomatic apical periodontitis is characterized by the persistence of inflammatory stimuli, adaptation of the host's response to stimuli, presence of adaptive immune responses, and initiation of the repair process.[121,148,220,270] Chronic inflammation is good news and bad news. The good news is that the host's defenses are able to maintain an active defense against the invading microorganisms and toxins; the bad news is that the host response is inadequate to eliminate these factors.[148]

Asymptomatic apical periodontitis is a form of adaptive immune response that requires exquisite specificity and memory. The adaptive immune response enhances bacterial killing compared with the innate immune response. Traditionally, *asymptomatic chronic apical periodontitis* and *periapical granuloma* are terms used interchangeably. A granuloma is a focal area of *granulomatous inflammation,* which is a histologic term for a chronic inflammatory reaction.[121,148,258] Granulomatous inflammation is characterized by the presence of activated macrophages with modified epithelioid cells in diseases such as tuberculosis, leprosy, syphilis, cryptococcosis, sarcoidosis, rheumatic fever, and foreign body granuloma.[92,121,148,275] The presence of poorly digestible irritants (nonantigenic or antigenic), T cell–mediated immunity to irritants, or both appears to be necessary for granuloma formation.[1,121,148] A granuloma is relatively avascular,[121,148] whereas a chronic apical periodontitis is very vascular. Histologically, some but not all chronic apical periodontitis lesions may show some features of granulomatous inflammation,[121,148] so the terms *apical granuloma* and *asymptomatic chronic apical periodontitis* should not be used interchangeably. A *granuloma* is best considered a histologic term used to describe a specific form of chronic inflammation such as foreign body granuloma or immune granuloma.[121,148]

The foreign body reaction is a specific subtype of chronic inflammation.[121,148,270] Foreign materials such as root canal filling materials, paper points, cotton fibers, and surgical sutures can trigger a foreign body giant cell granuloma.[118,166,282] If activated macrophages are unable to engulf large indigestible foreign particles, they can fuse to form giant cells on the surface of the particles and continuously release lysosomal enzymes, inflammatory mediators, and proinflammatory cytokines as a result of frustrated phagocytosis. Giant cells appear to be at least as active metabolically as a regular macrophage.[148] In addition, foreign bodies can favor infection in several ways, since they can be a source of bacterial biofilm[45,176] and they lower the infectious dose of bacteria to induce infection. For example, if a small, sterile plastic cage is implanted under the skin of a guinea pig, as few as 100 *Staphylococcus aureus* are sufficient to infect the tissue, whereas even 10^8 bacteria (i.e., a million-fold increase in dose) fails to produce an abscess in normal guinea pig skin.[284] Finally, foreign bodies can make the infection hard to treat because bacteria in biofilms can switch on appropriate genes and cover themselves with a thick layer of biopolymer that is resistant to both host defense mechanisms and antimicrobial agents.[107,148]

Cell Biology

Macrophages and Lymphocytes

Macrophages and lymphocytes are the primary players in asymptomatic apical periodontitis.* Lymphocytes are bloodborne and have counterparts in the connective tissue.[148] Macrophages play a dual role in host defenses. In the innate immune response, activated macrophages phagocytose microbes, dead cells, and foreign bodies and produce inflammatory mediators and proinflammatory cytokines to enhance the host defense against stimuli. In the adaptive immune response, activated macrophages function as APCs. They phagocytose and present the processed foreign antigens in association with MHC to T cells. Thus, activated macrophages are effector cells of adaptive immune response.

Lymphocytes are the only cells in the body capable of specifically recognizing and distinguishing different antigenic determinants; they are responsible for the two defining characteristics of the adaptive immune response, specificity and memory. The functions of lymphocytes were described earlier in the section on the adaptive immune response.

Dendritic Cell

Dendritic cells play a vital role in asymptomatic apical periodontitis. They have been shown to be present in apical periodontitis lesions in rats.[109,180] Dendritic cells are accessory immune cells derived from bone marrow stem cells and may

*References 46, 73, 117, 229, 230, 252, and 281.

be related to the mononuclear phagocyte lineage.[1] They function as antigen-presenting cells for naïve T lymphocytes and are important for the initiation of adaptive immune responses to protein antigen.[1] Activated dendritic cells produce IL-12, which is a key inducer of cell-mediated immunity.

Osteoclasts

Periapical bone destruction is a hallmark of asymptomatic apical periodontitis. During the chronic stage of apical periodontitis, both osteoclast and osteoblast activity are decreased,[268] so the periapical osteolytic lesion remains stationary. Based on magnified radiographic and automated image analysis, periapical bone destruction was observed at 7 days after the pulps of experimental teeth were exposed to oral microorganisms in animal studies. A period of rapid bone destruction took place between 10 and 20 days, with slower bone resorption thereafter.[268] The stationary phase of bone resorbing activity was correlated to asymptomatic apical periodontitis.[268] Increased expression of bone resorptive cytokines such as IL-1, IL-6, and TNF was related to the period of active bone resorption.[269] T_H cells appear to outnumber T_S cells during the active stage of periapical bone destruction in induced rat periapical lesions, but T_S cells dominate T_H cells during the stationary stage of bone destruction.[227]

Bone resorption is caused by osteoclasts. The formation of osteoclasts involves differentiation of the osteoclast precursor from the monocyte-macrophage cell lineage in bone marrow. Several cytokines and growth factors, such as granulocyte/macrophage colony-stimulating factor (GM-CSF), RANKL (receptor activator of nuclear factor κB ligand), osteoprotegerin (OPG), IL-1, IL-6, TNF, as well as prostaglandins, bradykinin, kallidin, and thrombin, have been shown to mediate osteoclast differentiation.[59,131,159,186,243] Parathyroid hormone is capable of stimulating osteoblasts to synthesize GM-CSF and RANKL. Bone stromal cells and T cells also produce RANKL. Osteoclast progenitor cells express receptor activator of nuclear factor κB (RANK). OPG, a decoy receptor for RANKL secreted by osteoblasts, negatively regulates the differentiation of osteoclasts by absorbing RANKL and reducing its ability to activate the RANK pathway.[114]

RANKL activates the RANK pathway on osteoclast progenitor cells, resulting in differentiation of these cells along the osteoclast lineage. Proinflammatory cytokines, IL-1, TNF, and IL-6 also mediate the differentiation of osteoclast progenitor cells to osteoclasts. The differentiation of the mononuclear osteoclast progenitor cells terminates with fusion to latent multinucleated osteoclasts, which are finally activated to become bone-resorbing osteoclasts. The mature osteoclasts then attach to mineralized bone surface after osteoblasts have primed the unmineralized bone surface and released chemotactic factor to attract osteoclasts.[169] Osteoclasts attach to bone by the vitronectin receptor (integrin superfamily), expressed preferentially in the sealing zone. Vitronectin has binding sites for the arginine-glycine-aspartic amino acid (RDG) sequences present in many extracellular matrix proteins, including osteopontin, bone sialoprotein, and fibronectin, on the surface of the exposed mineralized bone.[75] When bound to bone extracellular matrix, osteoclasts develop a ruffled border. Inside the ruffled border, osteoclasts use ATP to drive H^+ pumps, leading to the acidification of the extracellular compartment. They subsequently secrete proteolytic lysosomal enzymes and carbonic anhydrase to degrade both the mineralized and unmineralized components of bone.[13,14,25,243] (See Fig. 14-5 for the mechanism of bone resorption by osteoclasts in apical periodontitis.)

The resorption of root cementum and/or dentin in apical periodontitis lesions is less well understood than resorption of bone. Bone is constantly remolding (resorption and deposition) through physiologic and functional processes and thus is much easier to study. In contrast, cementum and dentin are more stable. The cells responsible for dental hard-tissue resorption are called *odontoclasts*.[197] It has been shown in ultrastructure and gene expression studies that odontoclasts and osteoclasts are similar.[198,199] Therefore, it is believed that the cellular mechanisms of bone, cementum, and dentin resorption are similar.[198] Nevertheless, little is known about how the precursors of the odontoclasts appear and what causes odontoclast differentiation and activation to resorb dentin and cementum. Bone resorption by osteoclasts in apical periodontitis is illustrated in Fig. 14-4.

Epithelial Cell Rests of Malassez

Proliferation of epithelial cell rests of Malassez (ERM) is evident in approximately 52% of inflammatory periapical lesions collected from extracted teeth.[164] It is a form of pathologic (inflammatory) hyperplasia. This type of hyperplasia is caused by stimulation of growth factors and cytokines produced during the immunoinflammatory response. Hyperplasia is a self-limiting process and is reversible when the causative stimulus is eliminated.[121,148,220] During periapical inflammation, innate and adaptive immune cells and stromal cells (e.g., activated macrophages, neutrophilic leukocytes, NK cells, T cells, fibroblasts) in the periapical tissues produce many inflammatory mediators (e.g., prostaglandin, histamine), proinflammatory cytokines (e.g., IL-1, IL-6, TNF), and growth factors (e.g., PDGF, epidermal growth factor [EGF], keratinocyte growth factor [KGF], FGF). These inflammatory mediators,[31] proinflammatory cytokines,[80,155,201] and growth factors* are capable of stimulating epithelial cell rests to proliferate (Fig. 14-5). The extent of cellular proliferation appears to be related to the degree of inflammatory cell infiltration.[192,193]

Fibroblasts

Fibroblasts are important cells in chronic inflammation and wound healing. They are derived from undifferentiated mesenchymal cells and exist in all connective tissues. They synthesize and secret proteoglycans, glycoproteins, and precursor molecules of various types of collagens and elastin.[114] In chronic inflammation, fibroblast migration and proliferation are triggered by multiple growth factors (TGF-β, PDGF, EGF, FGF) and the fibrogenic cytokines, IL-1 and TGF-α, produced by activated platelets, macrophages, endothelial cells, and inflammatory cells.[121,148] In turn, activated fibroblasts produce an array of cytokines such as IL-1, IL-6, and granulocyte/macrophage colony-stimulating factor, which influence leukocyte development. Fibroblasts stimulated by inflammation also produce matrix metalloproteinase to degrade the proteins that comprise the extracellular matrix.[148,258]

Fibrovascular granulation tissue is also a prominent feature of chronic apical periodontitis as a repair process. Migration

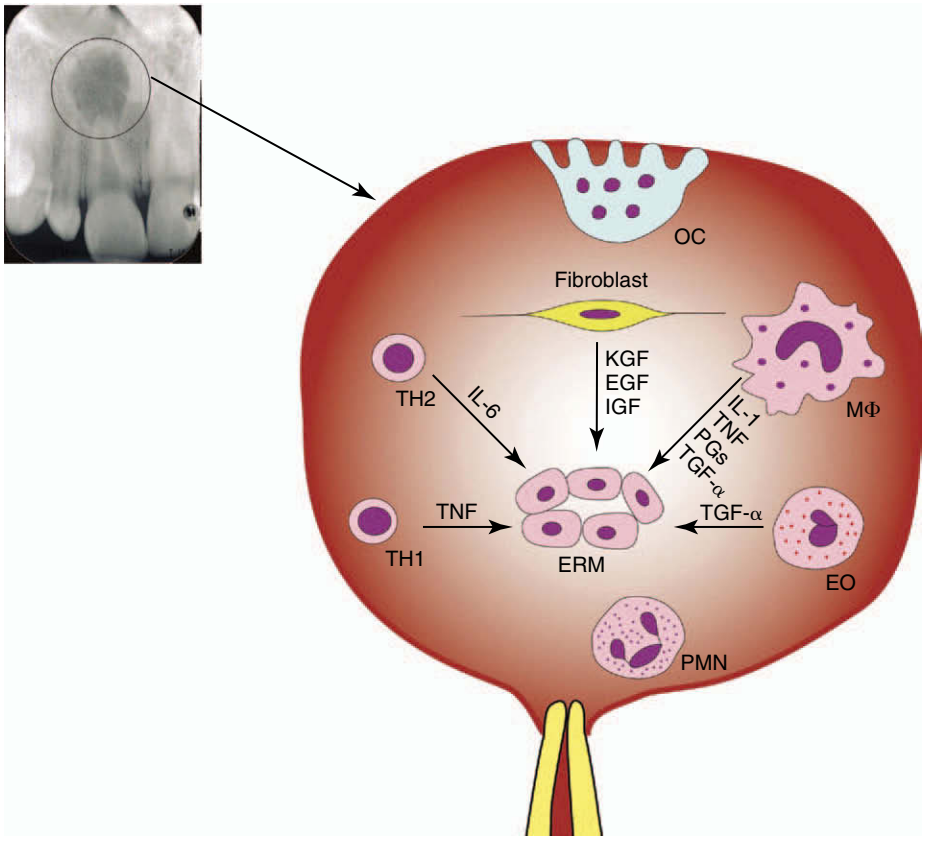

FIG. 14-5 Schematic illustration of the major mechanisms that activate proliferation of epithelial cell rests in apical periodontitis. *(From Lin LM, Huang GT-J, Rosenberg P: Proliferation of epithelial cell rests, formation of apical cysts, and regression of apical cysts after periapical wound healing.* J Endod *33:908, 2007.)*

and proliferation of endothelial cells from preexisting capillaries and venules into the site of chronic inflammation is called *neovascularization*. It is mediated by angiogenesis factors, such as vascular endothelial growth factor (VEGF) and TGF-β, produced by activated macrophages, platelets, and endothelium.[148,220] Neovascularization supplies oxygen and nutrients for the support of metabolically active macrophages and fibroblasts during wound healing.

Inflammatory Mediators

Many inflammatory mediators present in symptomatic apical periodontitis are also expressed in asymptomatic apical periodontitis. In addition, several different cytokines and growth factors are secreted by cells such as activated macrophages, lymphocytes, dendritic cells, and fibroblasts, in the chronic/adaptive immunoinflammatory response described earlier.

Histopathology

Macrophages and lymphocytes are predominant cells in asymptomatic apical periodontitis lesions (Fig. 14-6). Occasionally, foamy macrophages and giant cells are seen, especially associated with cholesterol crystal deposits, which are products of disintegrated cell membranes. Cholesterol crystals are present in approximately 18% to 44% of all apical periodontitis lesions.[30,210,257] Bone resorption is a hallmark of asymptomatic apical periodontitis. Multinucleated osteoclasts may sometimes be seen in resorptive Howship's lacunae. Proliferation of epithelial cell rests is often present in asymptomatic apical periodontitis lesions. ERM proliferate in three dimensions and form irregular strands or islands of epithelium, which are often infiltrated by varying degrees of inflammatory cells (see Fig. 14-6, *B*). A key feature of asymptomatic apical periodontitis is a proliferation of fibrovascular granulation tissue that is an attempt to prevent further spread of infection/inflammation and to repair wounded periapical tissues.

Little information is available concerning cemental changes in apical periodontitis. Using a scanning electron microscope, Simon et al.[216] observed that projections, depressions, and fibers of cementum were haphazardly arranged in root canal infection under scanning electron microscopy. There was an increase of mineralized projections, cementum lacunae, and surface resorptions and a decrease in fibers. All these changes may provide a more favorable condition for attachment of bacterial biofilm on the apical external root surface in extraradicular infection.

It is a general belief that asymptomatic apical periodontitis lesions are usually devoid of innervation, so local anesthesia may not be necessary if teeth with asymptomatic apical periodontitis require root canal therapy. However, light and transmission electron microscopic studies have demonstrated that teeth with chronic apical periodontitis were well innervated (Fig. 14-7).[141,150] This explains why instruments accidentally introduced into inflamed periapical tissues without local anesthesia can cause the patient pain.

External root resorption that involves cementum or both cementum and dentin usually occurs in asymptomatic apical periodontitis lesions.[127,263] Fortunately, cementum and dentin appear to be less readily resorbed than bone by inflammatory processes.[85] However, the radiographic presence of root "blunting" should be interpreted by the astute clinician as evidence for resorption of dentin and cementum, and the working length of the instrumentation and obturation phases of nonsurgical endodontic treatment should be adjusted by a corresponding amount.

Using light and transmission electron microscopy and microbiologic culturing, bacteria have been shown to be present in many asymptomatic apical periodontitis lesions.[2,101,162,255,271] Inadvertent contamination is a major concern when culturing bacteria from these lesions. Under meticulous transmission electron microscopic examination, Nair[162] was unable to observe bacteria in most asymptomatic apical periodontitis lesions. If bacteria are present in the inflamed periapical tissues, they are usually found inside the phagocytes (Fig. 14-8).[140] Importantly, the mere presence of bacteria in the inflamed periapical tissues (colonization) does not necessarily imply periapical infection. Bacteria have to be able to establish an infectious process, such as survival and tissue destruction, in the inflamed periapical tissues to be considered etiologic factors for the resulting infection. Most apical periodontitis lesions are not infected; nonsurgical root canal therapy of teeth with apical periodontitis can achieve a high success rate, provided root canal infection is controlled.

Clinical Features

Involved teeth are usually asymptomatic and show an ill-defined or well-defined periapical radiolucent lesion. The chronic apical abscess and associated sinus tract are usually asymptomatic. Occasionally, the sinus tract from an apical abscess may drain along the root surface and opens into the gingival sulcus. This leads to the development of a deep, narrow pseudopocket that often mimics a periodontal pocket or a vertical root fracture (see Chapter 18 for details).

Outcomes

Asymptomatic apical periodontitis may result in (1) regeneration or repair of the periapical tissues after root canal therapy; (2) severe periapical tissue destruction; (3) acute exacerbation; (4) development of an abscess with an intraoral or extraoral draining sinus tract; or (5) development of a serious cellulitis.

ASYMPTOMATIC APICAL PERIODONTITIS WITH CYST FORMATION: RADICULAR CYST, CHRONIC APICAL PERIODONTITIS WITH CYST FORMATION

The radicular cyst is unique because no cysts in the body have similar pathogenesis. It is believed that the radicular cyst is likely formed by inflammatory proliferation of epithelial cell rests in the inflamed periodontal ligament.[139,168,178,245] The radicular cyst is a pathologic cavity completely lined by nonkeratinized stratified squamous epithelium of variable thickness in a three-dimensional structure in an apical periodontitis lesion. A radicular cyst can be a "pocket cyst" (i.e., attached to the apical foramen) or a "true cyst" (no attachment to the root structure), but it cannot form by itself. Therefore, a radicular cyst should not be considered a separate disease entity from asymptomatic apical periodontitis. A radicular cyst (pocket or true) is classified as an inflammatory and not a neoplastic lesion in the WHO Histological Typing of Odontogenic Tumors, Jaw Cysts and Allied Lesions.[120] The prevalence of radicular cysts in apical periodontitis lesions from extracted teeth ranges from 15% to 20%.[164]

Cell Biology

In addition to the presence of all chronic inflammatory cells, the epithelial cells are the most prominent cell type found in asymptomatic apical periodontitis with cyst formation. ERM can be considered unipotent or restricted-potential stem cells.

FIG. 14-7 Presence of intact myelinated and nonmyelinated nerve fibers in chronic apical periodontitis lesion. *ly,* Lymphocyte; *M,* myelinated nerve fiber; *N,* nucleus of Schwann cell; *nl,* neutrophilic leukocyte; *NM,* nonmyelinated nerve fiber; *p,* plasma cell (EM, ×1600). *(From Lin L, Langeland K: Innervation of inflammatory periapical lesions.* Oral Surg Oral Med Oral Pathol Oral Radiol Endod *51:535, 1981.)*

They can be stimulated to divide symmetrically and asymmetrically into basal cells and suprabasal squamous cells of lining epithelium of radicular cysts.[139] Many theories about apical cyst formation have been proposed. The nutritional deficiency theory assumes that when islands of epithelium keep growing, the central cells of the epithelial island will move farther away from their source of nutritional supply and undergo necrosis and liquefaction degeneration. The products accumulated attract neutrophils and granulocytes into the necrotic area. Microcavities then coalesce to form a cyst cavity lined by stratified squamous epithelium.[245] The abscess theory postulates that when an abscess is formed in connective tissue, epithelial cells proliferate and line the abscess cavity because of their inherent tendency to cover exposed connective-tissue surface.[168,178] The theory of merging of epithelial strands proposes that proliferating epithelial strands merge in all directions to form a three-dimensional spherelike structure composed of fibrovascular connective tissue, with varying degrees of inflammatory cells trapped, that gradually degenerates due to lack of blood supply. This leads to formation of a cyst cavity.[139] Regardless of how a radicular cyst (pocket or true) is formed, it is likely caused by inflammatory proliferation (hyperplasia) of epithelial cell rests in these lesions.

It has been speculated that radicular cyst expansion is caused by increased osmotic pressure in the cyst cavity,[248] but this hypothesis overlooks the cellular aspects of cyst growth and the biochemistry of bone destruction.[66,155] Radicular cyst expansion is likely caused by degradation of fibrous connective tissue capsule by matrix metalloproteinases, which are produced by activated neutrophils, fibroblasts, and macrophages[246] and bone resorption. The ERM have also been shown to be capable of secreting a bone resorbing factor.[22] Most inflammatory mediators and proinflammatory cytokines that stimulate proliferation of epithelial cell rests also mediate bone resorption in apical periodontitis lesions.

Inflammatory Mediators

Mediators are basically similar to those present in chronic apical periodontitis.

Histopathology

Two types of cysts have been described in chronic apical periodontitis lesions. The pocket cyst's lumen opens into the root canal of the involved tooth (Fig. 14-9).[164,215] The true cyst is completely enclosed by a lining epithelium, and its lumen has no communication with the root canal of the involved tooth (Fig. 14-10).[164,215] Apical cysts are lined by hyperplastic, nonkeratinized stratified squamous epithelium of variable thickness, which is separated from the fibrovascular connective tissue capsule by a basement membrane. Both the lining epithelium and the connective tissue capsule are usually infiltrated with inflammatory cells, indicating that inflammatory cells are attracted to these tissues by chemotactic irritants, either in the root canal system and/or in the periapical tissues. In nonproliferating epithelium, there is less inflammatory cell infiltration.[39,205] Occasionally, mucous cell metaplasia or ciliated respiratory-type cells are present in cystic epithelial lining.[174] The epithelial cells of lining epithelium do not show any characteristic features of neoplastic changes, such as pleomorphism, lack of polarity, nuclear enlargement, large nucleoli, abnormal nuclear/cytoplasmic ratio, hyperchromatism, or abnormal mitosis. Unlike odontogenic keratocysts and calcifying odontogenic cysts, the basal cells of radicular cystic lining epithelium are incapable of proliferation by themselves without stimulation of growth factors or cytokines released by innate and adaptive immune cells during periapical inflammation. The lumen of cysts may contain inflammatory exudates, cholesterol crystals, clear fluid, or bacterial colonies (Fig. 14-11; Fig. 14-12).[164,193]

Clinical Features

The involved tooth is usually asymptomatic. Periapical osteolytic lesions of endodontically involved teeth may sometimes show a well-demarcated radiolucency surrounded by a rim of radiopaque border.

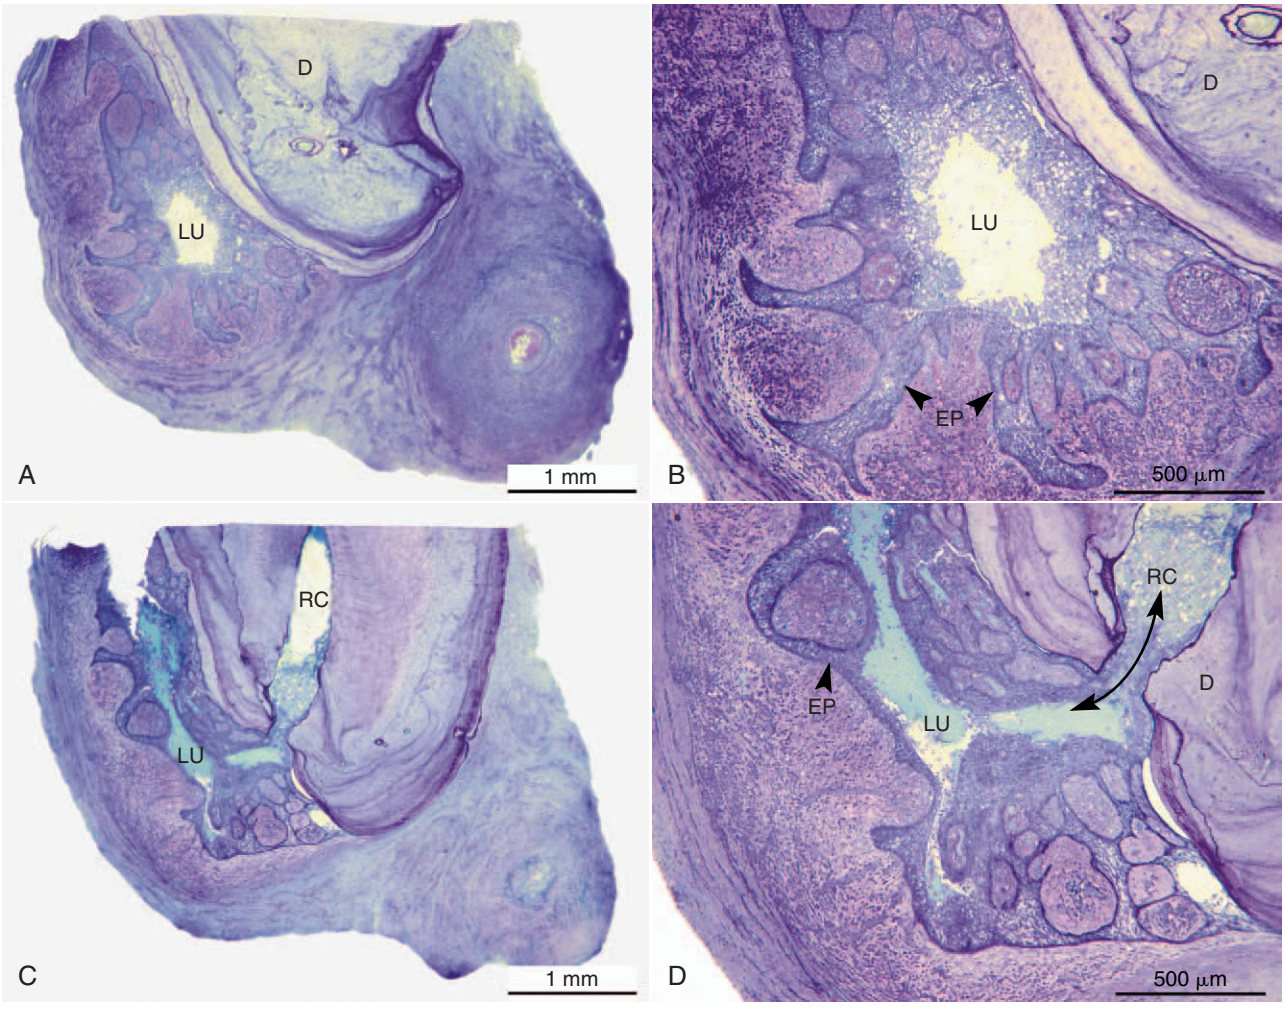

FIG. 14-9 A, A well-developed pocket cyst in apical periodontitis lesion. **B,** Note the saclike epithelial lumen. **C-D,** Sequential axial serial section passing through the apical foramen in the root canal plane (RC) shows the continuity of the lumen with the root canal. *D,* Dentin (**A, C,** ×16; **B, D,** ×40). *(From Nair PNR:* Endod Topics *6:96, 2003.)*

Outcomes

There is no direct evidence demonstrating whether asymptomatic apical periodontitis with cyst formation (pocket and true) can or cannot regress after nonsurgical root canal therapy. Unfortunately, apical cysts cannot be diagnosed clinically and can only be diagnosed after surgical biopsy or extraction of teeth with apical periodontitis. Clinical outcome studies have shown that after proper nonsurgical root canal therapy, teeth with apical periodontitis heal in 78% of cases, regardless of whether preobturation bacterial cultures are negative or positive.[219] Therefore, it is speculated that some cysts, especially pocket cysts, may heal after nonsurgical root canal therapy.[163] Apical true cysts are less likely to heal after nonsurgical root canal therapy because of their self-sustaining nature; surgical intervention is necessary.[163] Nonetheless, similar to the periapical pocket cyst, a periapical true cyst is also formed within an apical periodontitis lesion and is not a neoplastic lesion. Any disease caused by inflammation/infection should be able to heal if the causative irritant/irritants are removed, unless the irritant/irritants are neoplasm-inducing agents or a carcinogen.

ASYMPTOMATIC APICAL PERIODONTITIS WITH REACTIVE BONE FORMATION: CONDENSING OSTEITIS OR CHRONIC FOCAL SCLEROSING OSTEOMYELITIS

Asymptomatic apical periodontitis with reactive bone formation is analogous to chronic osteomyelitis with proliferative periostitis. The etiology and pathogenesis of these two diseases are not well understood. It is generally believed that both lesions are caused by a long-term, low-grade inflammation/infection or a high resistance of local tissue to inflammation/infection.[174,188] Instead of bone resorption, the inflammation induces reactive bone formation of alveolar trabecular or spongy bone around the periapex of endodontically involved teeth.

Cell Biology

As described previously, during the chronic stage of apical periodontitis, both osteoclast and osteoblast activity is decreased.[268] However, in asymptomatic apical periodontitis with reactive bone formation, osteoblasts appear to be stimulated to produce more bone. It is not clear what factor/factors stimulate osteoblasts to produce more bone mass. It could be due to increased expression of growth factors/cytokines, such as TGF-β, BMP, PDGF, and transcription factor Cbfa1 (core-binding factor family).[114]

Histopathology

There is an excessive apposition of bone mass without bone resorption in the apical area. As the bone marrow spaces become smaller and obliterated, the bone resembles compact bone which is infiltrated by a small number of lymphocytes. The compact bone has few lacunae, and many of them are empty of osteocytes. It has many prominent resting and reversal lines, similar to an idiopathic osteosclerosis or a Pagetoid appearance.[39,174,188]

Clinical Features

The lesion is usually observed in young patients, and the mandibular first molar is most commonly involved. The teeth often have gross carious lesions and can be vital or nonvital. They are usually asymptomatic. Radiographically, the lesion may have a well-defined or ill-defined radiopaque mass associated with the apex of an endodontically involved tooth. The lamina dura around the root apex is usually intact.

Outcomes

Most apical periodontitis lesions with reactive bone formation demonstrate healing after nonsurgical root canal therapy. The excessive compact bone in most cases will be remodeled to normal appearance.[63]

PERIAPICAL LESIONS OF NONENDODONTIC ORIGIN

There are many periapical lesions that are not of endodontic origin and should be considered in the differential diagnosis of apical periodontitis. These lesions include (but are not limited to) trauma,[9] foreign bodies,[118,166,282] host metabolic byproducts,[167] advanced periodontal disease,[124] fibro-osseous lesions, and benign and malignant tumors.[174] A complete description of these lesions is beyond the scope of this chapter; the interested reader is encouraged to seek the cited references.

EXTRARADICULAR ENDODONTIC INFECTION

Extraradicular endodontic infection implies that bacteria have established an infectious process outside the root canal system in the periapical area.[162,217,231,255] Extraradicular endodontic infection can only be diagnosed after surgical biopsy or microbiologic sampling or molecular detection of therapy-resistant periapical lesions during apical surgery. The method of sample collection should be carefully reviewed, since contamination is a problem in bacteriologic study of apical periodontitis lesions during apical surgery.

Extraradicular endodontic infection can be a part of intraradicular infection or an independent entity without an intraradicular component. To be considered an independent extraradicular infection, the presence of pathogens in the root canal system must be completely ruled out, because intraradicular bacteria pose more potential problems than extraradicular bacteria in periapical inflammation. Bacteria in the complex root canal system are well protected from root canal procedures (i.e., mechanical instrumentation, antiseptic irrigation, intracanal medication), host defenses, and antimicrobial therapy because of lack of blood circulation and areas resistant to access (e.g., isthmi; see Chapter 7). In our opinion, the independent extraradicular infection probably does not occur often and is usually associated with apical actinomycosis.[88,165,237] Bacteria have been observed as biofilm on the apical external root surface.[217,254] In addition, viruses have also been isolated from apical periodontitis lesions.[133,196,221] If microbiologic root canal cultures are not completely reliable (because bacteria may remain in the complex root canal system),[200] then interpretation of independent extraradicular infections as endodontic treatment failures should be carefully evaluated.

Although virulence and number of pathogens, as well as the host's defenses, determine whether extraradicular infection will develop or not, the development of extraradicular infection is still not fully understood. What are the predisposing factors to extraradicular infection? How are bacteria able to evade the host's powerful defenses in order to colonize and establish an infectious process in the periapical tissues? Are all extraradicular infections resistant to nonsurgical root canal therapy? For instance, are bacteria present in apical periodontitis with abscess formation?[29,83,179,234,262] Importantly, most periapical abscesses heal after proper nonsurgical root canal therapy. Similarly, most apical periodontitis lesions with draining sinus tracts also heal after proper nonsurgical root canal therapy, because the primary source of infection in the root canal system is removed. The preponderance of evidence does not support the consistent presence of an independent periapical infection in endodontic infections.

APICAL PERIODONTITIS AND SYSTEMIC DISEASES

Information concerning apical periodontitis and systemic diseases is limited. Systemic conditions affecting the severity of inflammatory periapical lesions have been documented and include diabetes, smoking, hypertension, cytokine gene polymorphisms, and nonspecific disorders of the immune system. In general, diabetic patients are prone to infections due to generalized vascular disorders caused by accumulation of atheromatous plaques in the vascular walls, particularly of capillaries. Atherosclerotic vessels cause impaired leukotactic response and failure in delivering humoral and cellular components of the immune system.[18] Clinical and radiographic studies have shown that there is a greater prevalence of periapical lesions in diabetics than in nondiabetics.[18] Type 2 diabetes mellitus is significantly associated with an increased prevalence of apical periodontitis.[204] Other findings demonstrated that type 2 diabetes is associated with increased risk of a poor response by the periradicular tissues to odontogenic pathogens.[28] In rodent models, diabetic conditions enhance the development of periradicular lesions and increase mortality.[67,103,116] Mice deficient in P/E-selectin are shown to be more prone to infection-mediated early-onset periodontal disease.[175]

Genetic polymorphisms may also play a role in the individual's response to various diseases. Haplotype analyses indicated that a variant of the IL-1β gene was likely to be most important for early-onset periodontitis risk.[56] In a Chinese male population, it was reported that the polymorphisms of *IL1A*+4845 and *IL1B*–511 might play an important role in determining generalized aggressive periodontitis susceptibility. A possible combined effect of the polymorphism of *IL1B*–511 and smoking on this type of periodontitis susceptibility was suggested.[134] In a study on patients from Chile, the heterozygous inheritance of the *IL1B*+3954 gene was found significantly higher in periodontitis cases than in control patients. The prevalence of a positive genotype (at least one allele of the two variants present at each locus) is significantly higher in cases (26%) than in controls (10%) and significantly associated with periodontitis, irrespective of smoking status and periodontitis severity.[146] Those displaying high-producer *IL6* genotype, intermediate and high-producer *IL1B* genotypes, and low-producer *TNFA* genotype tend to exhibit symptomatic dental abscesses.[54]

Apical periodontitis was once considered a focus of infection, and the microorganisms from the focus could disseminate through blood circulation to remote parts of the body, where secondary disease occurred.[97] Even though bacteremias do occur during root canal treatment of teeth with apical periodontitis when instrumentation is carried through the apical foramen into the periapical tissues, the incidence and magnitude of bacteremias is not clinically significant for a healthy person and in fact appears to be lower than that observed by flossing.[16,51,52] Microorganisms in the blood circulation are rapidly eliminated by the host's humoral and cellular defense components within minutes.[16,52] However, bacteremia may pose a potential danger to immunocompromised patients or patients with congenital heart valve disease.[51] No correlation between apical periodontitis and coronal heart disease and rheumatoid arthritis has been observed.[37,160] There is insufficient evidence to support that apical periodontitis could serve as a focus of infection and cause significant systemic diseases.[62,182]

WOUND HEALING OF APICAL PERIODONTITIS

Periapical Wound Healing After Nonsurgical Root Canal Therapy

Understanding of wound healing is as important as knowing the pathogenesis of disease, because satisfactory wound healing is the ultimate goal of treatment. If we are able to understand the mechanisms of periapical wound healing, we can design treatment approaches that maximize favorable conditions for wound healing to occur, such as effective disinfection of the root canal system in nonsurgical root canal therapy, control of periapical inflammation by medication, or incorporation of growth factors in bone grafts in surgical endodontic therapy (see also Chapters 9 and 21).

Interestingly, healing begins as soon as inflammation starts. When irritants (microbial and nonmicrobial) in the canal systems or in the periapical tissues are eliminated by nonsurgical or surgical endodontic therapy, inflammatory mediators are no longer produced in the periapical tissues because of reduction of immunoinflammatory cells. Inflammatory mediators already present are inactivated by the body's control mechanisms to prevent an inflammatory reaction from going unchecked. This process precedes wound healing. Although a great deal of information is known about what turns on the inflammation, relatively little is known about what turns off the inflammatory system after elimination of irritants. Examples of host antiinflammatory control mechanisms are (1) enzyme destruction of inflammatory activators; (2) natural inhibitors of inflammatory mediators (e.g., opioids, somatostatin, glucocorticoids, etc.); (3) relative balance between intracellular levels of cyclic AMP and cyclic GMP; (4) the antiphlogistic role of histamine; (5) inhibitors of the complement system[258]; and (6) antiinflammatory cytokines, such as IL-4, IL-10, IL-13 and TGF-β.[86,172] In addition, the major cellular inducer of inflammation, neutrophilic leukocytes, undergo apoptosis,[82] and the major cellular player of wound healing, macrophages, secrete antiinflammatory molecules.[172]

The process of wound healing is tightly regulated by cell-to-cell and cell-to–extracellular matrix interactions, as well as

TABLE 14-3

Important Growth Factors/Cytokines in Wound Healing

Cytokines	Major Source	Target Cells and Major Effects
EGF	Macrophages, platelets, fibroblasts	Epithelial cells, fibroblasts, endothelial cells
FGF	Macrophages, endothelial cells	Endothelial cells (angiogenesis), mesenchymal cells
TGF-α	Macrophages, platelets, keratinocytes	Angiogenesis Fibroblasts
TGF-β	Macrophages, platelets	Similar to EGF
PDGF	Macrophages, platelets, endothelial cells	Chemoattractant for macrophages, fibroblasts
VEGF	Macrophages, epithelial cells	Angiogenesis
IGF	Fibroblasts, epithelial cells	Granulation tissue formation, reepithelialization
CSF	Multiple cells	Macrophages, granulation tissue formation
SP, CGRP	Sensory nerve	Endothelial cells, fibroblasts, keratinocytes

CGRP, Calcitonin gene–related peptide; *CSF,* colony-stimulating factor; *EGF,* epidermal growth factor; *FGF,* fibroblast growth factor; *IGF,* insulin-like growth factor; *PDGF,* platelet-derived growth factor; *TGF,* transforming growth factor; *VEGF,* vascular endothelial growth factor.

the temporal and spatial expression of a variety of cytokines, growth factors, and neuropeptides and apoptosis (Table 14-3).[26,79,82,228,273] All these cellular and humoral factors operate together in either an antagonistic or synergistic manner and are precisely orchestrated during wound healing. This results in a highly organized response permitting regeneration of the original tissue architecture. Wound healing appears to be a programmed event. Much information concerning the pathogenesis of apical periodontitis has been gained from animal studies.[69,108,251] Although studies of wound healing of teeth with apical periodontitis after nonsurgical root canal therapy and endodontic surgery are available in a few animal experiments and a human study,[11,129,130] no studies of wound healing of apical periodontitis lesions with cyst formation after nonsurgical root canal therapy exist in the literature.

Wound healing of apical periodontitis lesions after proper nonsurgical root canal therapy follows the general principle of wound healing of connective tissues elsewhere in the body, with the formation of fibrovascular granulation tissue, removal of necrotic tissue and dead bacteria by activated macrophages, and finally repair and/or regeneration of the wounded tissue. Healing of apical periodontitis lesions is largely accomplished by regeneration and to some degree by fibrosis. Local tissue resident cells involved in periapical wound healing are osteoblasts and bone marrow stromal cells in alveolar bone and multipotent stem cells in periodontal ligament.[209] During periapical wound healing, many unwanted hyperplastic cells (e.g., endothelial cells, fibroblasts, epithelial cells) are deleted by apoptosis,[53,79,82] and the extracellular matrix is remodeled by metalloproteinases. Pathologic processes such as extensive fibrosis do not occur, and the damaged periapical tissues can be ideally restored to their original structure by the process of regeneration.

The temporal and spatial relationship between alveolar bone, cementum, and periodontal ligament during periapical wound healing after nonsurgical root canal therapy cannot be clearly delineated. Nevertheless, wound healing appears to recapitulate the initial histogenesis of damaged tissues or organs in many instances. The process of periapical wound healing after nonsurgical root canal therapy may be similar to wound healing following guided tissue regeneration in periodontal therapy: regeneration of new periodontal ligament, new cementum, and new alveolar bone.[61,256] Both nonsurgical root canal therapy and guided tissue regeneration therapy are able to remove irritants and provide a favorable environment conducive to regeneration of periodontal tissues damaged by apical periodontitis and marginal periodontitis, respectively.

During periapical wound healing, the cells of viable periodontal ligament from adjacent root surfaces proliferate to cover the root surfaces in which the periodontal ligament was damaged by apical periodontitis and removed by macrophages. Proteins derived from Hertwig's epithelial root sheath (i.e., enamel matrix proteins) are required for cementoblast differentiation from ectomesenchymal stem cells in the dental follicle during tooth development.[171] The cells of Hertwig's epithelial root sheath are absent in mature teeth.[147,223]

Nevertheless, the extracellular matrix and growth factors of cementum (i.e., IGF-1, FGFs, EGF, BMP, TGF-β, PDGF) sequestered after cemental resorption in mature teeth are capable of inducing proliferation, migration, attachment, and differentiation of multipotent stem cells in the periodontal ligament into cementoblast-like cells and produce cementoid tissue on the root surface denuded of periodontal ligament.[81,209] This is similar to reparative dentin formation by pulp stem cells in direct pulp capping procedures where growth factors such as TGF-β are released from dentin matrix binding sites.[170,195,260] Root resorption that involves cementum or both cementum and dentin can only be repaired by cementoid tissue, because multipotent stem cells of the periodontal ligament are incapable of differentiating into odontoblasts that produce dentin.[209]

Bone has a remarkable capacity for regeneration in response to injury. During periapical wound healing, the osteoblasts or mesenchymal cells lining the surfaces of endosteum—stimulated by TGF-β, BMPs, IGFs, PDGF, VEGF, and cytokines released by stromal cells, osteoblasts, platelets, and bone matrix after bone resorption—can undergo proliferation and differentiation into osteoblasts and produce bone matrix.[6,145] When one of the cortical bone plates (buccal or lingual/palatal) is destroyed, mesenchymal cells in the inner layer of perios-

teum beneath the oral mucosa—stimulated by TGF-β, BMPs, IGFs, PDGF, and VEGF—are also capable of proliferation and differentiation into osteoblasts and can produce bone matrix.[114,145] If both buccal and lingual/palatal cortical bone plates are destroyed by large apical periodontitis lesions, it is possible that the lesion may be repaired with fibrous scar tissue because of extensive destruction of the periosteum beneath the oral mucosa.[11] Accordingly, a guided tissue regeneration procedure using membrane barriers and bone grafts is recommended to prevent ingrowth of fibroblasts from periosteum or submucosa into the bony defect and to enhance periapical wound healing if periapical surgery is necessary.[48,49] The cellular and molecular mechanisms of excess scar tissue formation in periapical wound healing is not completely understood. Growth factors/cytokines may play an important role in regulating fibroblast gene expression and excess scar tissue formation.[259]

The newly regenerated periodontal ligament will finally undergo remodeling into mature periodontal ligament, with one group of collagen fibers (Sharpey's fibers) inserted into the newly formed cementum and another group of collagen fibers inserted into the newly formed alveolar bone. Thereby, regeneration of damaged periapical tissues, cementum, periodontal ligament, and alveolar bone is completed.

Periapical Wound Healing After Surgical Endodontic Therapy

The mechanism of periapical wound healing after nonsurgical and surgical endodontic therapy is quite similar, but the kinetics of healing of the periapical wound after endodontic surgery is much faster than nonsurgical endodontic therapy.[122] In surgical endodontic therapy, a surgeon performs removal of irritants, such as necrotic cells, tissue debris, and bacteria in the periapical lesions, which is called *surgical débridement*. In contrast, in nonsurgical endodontic therapy, activated macrophages perform bacterial killing and cleanup of periapical lesions, which is called *biologic débridement*.[138] Surgical débridement is very effective and of course quite rapid, whereas biologic débridement takes time. However, endodontic surgery is more invasive. In addition, proper case selection is more important in endodontic surgery than in nonsurgical endodontic therapy. The distinctive difference between nonsurgical and surgical endodontic therapy is that the goal of nonsurgical endodontic therapy is to remove primary microbial etiology from the root canal system, and the goal of surgical endodontic therapy is often to seal microbial etiology within the root canal system by root-end filling in most cases (see also Chapter 21).

Can Radicular Cysts in Apical Periodontitis Lesions Regress After Nonsurgical Endodontic Therapy?

Based on histology and cell biology, no studies have ever shown that apical true cysts are different from apical pocket cysts. It was suggested that pocket cysts in apical periodontitis lesions might regress after nonsurgical root canal therapy by the mechanism of apoptosis or programmed cell death, based on molecular cell biology.[139] In contrast, apical true cysts may be less likely to heal after nonsurgical root canal therapy because of their self-sustaining nature.[163] Histologically, inflammatory cell infiltration is always present in the lining epithelium and/or fibrous connective tissue capsule of apical true cysts.[164,192,193] This indicates there is continued presentation of irritants (such as bacteria)—present in the root canal system, the periapical tissues, or the lumen of cysts—to attract inflammatory cells to the cystic lining epithelium and/or fibrous connective tissue capsule.[164,192,193] It is not known if epithelial cells of apical true cysts alone are capable of acting as autocrine cells and secreting growth factors to sustain their own survival. It is important to realize that the apical true cyst is completely different from the odontogenic keratocyst, which is self-sustaining because it is a neoplastic lesion. Biologically, it is very unlikely that the hyperplastic epithelial cells of inflammatory apical true cysts would suddenly transform into cells that behave like self-sustaining neoplasms. Any disease caused by infection should be able to regress after removal of its causative irritant(s), unless the irritants themselves are neoplasm-inducing agents or carcinogens, such as some viruses and human malignant tumors.[148,265] From pathogenesis, histology, and molecular cell biology, apical true cysts are similar to pocket cysts. Accordingly, apical true cysts, similar to pocket cysts, may be able to regress after nonsurgical root canal therapy by the mechanism of apoptosis if root canal infection is effectively under control.[139] This prediction is consistent with the high level of healing observed after nonsurgical root canal treatment.

In apical periodontitis lesions with cyst formation, the cysts have to regress before the periapical tissues can be restored to their original architecture. It is not known what matrix serves as a scaffold for endothelial cells, fibroblasts, and osteoblasts to migrate into the lumen of regressing cysts after nonsurgical root canal therapy. Complete regression of radicular cysts after nonsurgical root canal therapy could be due to any of several possible scenarios. Regression of radicular cysts and regeneration of bone may occur concurrently; or during regression of radicular cysts, part of the cystic lining epithelium could disintegrate due to apoptosis of local epithelial cells. Together with degradation of the basal lamina by matrix metalloproteinases, this could allow a fibrous connective tissue capsule to grow into the lumen of radicular cysts. Eventually, the cystic lining epithelium will completely regress or become remnants of epithelial cell rests remaining in the periodontal ligament.

Taken together, our knowledge of cyst mechanisms and healing offer tantalizing clinical implications and clearly support the conclusion that more studies are required to understand the complex mechanisms of regression of inflammatory apical cysts, both pocket and true.

FACTORS INFLUENCING PERIAPICAL WOUND HEALING

Local and systemic factors may affect periapical wound healing. Infection will complicate and prevent wound healing, foreign bodies can impair wound healing,[166,282] and nutrition can also affect wound healing.[276] Diabetes was reported to reduce the likelihood of healing of apical periodontitis lesions after nonsurgical root canal therapy.[68] Impaired nonspecific immune response and disorders of the vascular system appeared to have a significant influence on the success rate of nonsurgical root canal therapy on teeth with apical periodontitis.[149] However, immunocompromised patients, such as HIV patients, responded as well as counterpart patients after nonsurgical endodontic

therapy.[43,76,185] Although smoking has not been shown to be associated with increased incidence of apical periodontitis and prognosis of nonsurgical root canal therapy,[20,57] smoking may increase complications of periapical surgery, such as pain and swelling.[74]

Patients receiving radiotherapy of jaws and bisphosphonate therapy have a risk of developing osteonecrosis of jawbones,[190,194,277] so nonsurgical root canal therapy is recommended for these patients.[110,136] However, for endodontic surgery, the guidelines of the American Association of Oral and Maxillofacial Surgeons position paper on bisphosphonate-related osteonecrosis of the jaws are highly recommended.[7] For asymptomatic patients who have taken an oral bisphosphonate for less then 3 years and have no clinical risk factors, endodontic surgery is not contraindicated.[7] Nevertheless, the patient's physician should be consulted. Any kind of surgical procedures should be avoided for patients receiving intravenous bisphosphonate.[7] To prevent the complication of osteonecrosis, if patients are going to receive radiation of jaws or bisphosphonate therapy, nonsurgical or surgical endodontic therapy should be completed before initiation of radiation or bisphosphonate therapy.[7]

MANAGEMENT OF ABSCESSES AND CELLULITIS
SYSTEMIC ANTIBIOTICS FOR ENDODONTIC INFECTIONS

Apical periodontitis is essentially an inflammatory disease of microbial etiology primarily caused by infection of the root canal system.[233] Although chemical and physical factors can induce periradicular inflammation, a large body of scientific evidence indicates that endodontic infection is essential to the progression and perpetuation of the different forms of apical periodontitis.[23,110,160,287] Endodontic infection develops in root canals devoid of host defenses, either as a consequence of pulp necrosis (as a sequel to caries, trauma, periodontal disease, or iatrogenic operative procedures) or pulp removal for treatment.

Although fungi and most recently archaea and viruses have been found in association with endodontic infections,[217,264,273,305] bacteria are the major microorganisms implicated in the pathogenesis of apical periodontitis. In advanced stages of the endodontic infectious process, bacterial organizations resembling biofilms can be observed adhered to the canal walls.[161,167,257] Therefore, there is a current trend to include apical periodontitis in the roll of biofilm-induced oral diseases. Bacteria colonizing the root canal system enter in contact with the periradicular tissues via apical/lateral foramens or root perforations. As a consequence of the encounter between bacteria and host defenses, inflammatory changes take place in the periradicular tissues and give rise to the development of apical periodontitis. Depending on several bacterial and host-related factors, endodontic infections can lead to acute or chronic apical periodontitis.

The ultimate goal of the endodontic treatment is either to prevent the development of apical periodontitis or, in cases where the disease is already present, to create adequate conditions for periradicular tissue healing. Because apical periodontitis is an infectious disease, the rationale for endodontic treatment is unarguably to eradicate the occurring infection and/or prevent microorganisms from infecting or reinfecting the root canal or the periradicular tissues. The cardinal principle of any healthcare profession is the thorough understanding of disease etiology and pathogenesis, which provides a framework for effective treatment. In this context, understanding the microbiologic aspects of apical periodontitis is the basis for endodontic practice of high quality and founded on solid scientific insight. This chapter focuses on diverse aspects of endodontic microbiology, including pathogenetic, taxonomic,

morphologic, and ecological issues. Special emphasis is also placed on the underlying principles for sound antimicrobial treatment of endodontic infections.

APICAL PERIODONTITIS AS AN INFECTIOUS DISEASE

The first recorded observation of bacteria in the root canal dates back to the 17th century and the Dutch amateur microscope builder Antony van Leeuwenhoek (1632-1723). He reported that the root canals of a decayed tooth "were stuffed with a soft matter" and that "the whole stuff" seemed to him to be alive,[54] but the role of Leeuwenhoek's "animalcules" in disease causation was unsuspected at that time. It took almost 200 years before his observation was confirmed and a cause-and-effect relationship between bacteria and apical periodontitis was suggested.

This occurred specifically in 1894, when Willoughby Dayton Miller, an American dentist working at the laboratory of Robert Koch in Berlin, Germany, published a milestone study reporting on the association between bacteria and apical periodontitis after the analysis of samples collected from root canals.[155] By means of bacterioscopy of the canal samples, he found bacterial cells in the three basic morphologies known at the time: cocci, bacilli, and spirilla (or spirochetes) (Fig. 15-1). Morphologically, the endodontic microbiota was clearly different in the coronal, middle, and apical parts of the root canal. Spirochetes were found in high frequencies in abscessed cases, and an etiologic role was suspected for these bacteria. Most of the bacteria Miller had seen under light microscopy could not be cultivated using the technology available at his time. Those bacteria were conceivably anaerobic bacteria, which were only successfully cultivated about 50 to 100 years later with the advent of anaerobic culture techniques. However, it is now widely recognized that a large number of bacterial species living in diverse environments still remain to be cultivated by current technology,[6,200] and the root canal is no exception (discussed later in this chapter). Based on his findings, Miller raised the hypothesis that bacteria were the causative agents of apical periodontitis.

Approximately 70 years after Miller's classic study, his assumptions were confirmed by an elegant study from Kakehashi et al.[110] These authors investigated the response of the dental pulps of conventional and germ-free rats after exposure to the oral cavities. Histologic evaluation was performed and revealed that whereas pulp necrosis and apical periodontitis lesions developed in all conventional rats, the pulps of germ-free rats not only remained vital but also repaired themselves by hard-tissue formation. Dentinlike tissue sealed the exposure area and isolated the pulps again from the oral cavity.

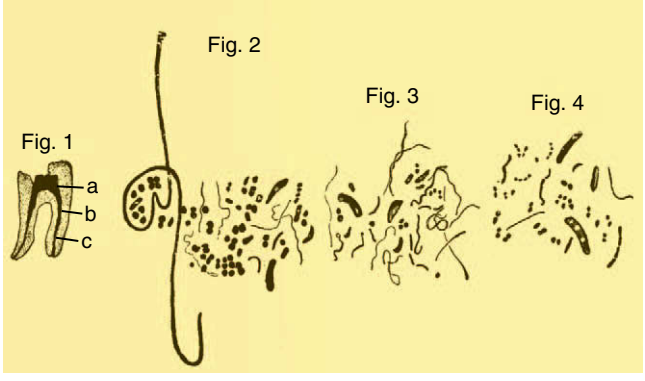

FIG. 15-1 Drawings from Miller's classic paper showing different bacterial forms in a root canal sample observed by microscopy.

The important role of bacteria in the etiology of apical periodontitis was further confirmed by Sundqvist's classic study.[287] This author applied advanced anaerobic culturing techniques to the evaluation of bacteria occurring in the root canals of teeth whose pulps became necrotic after trauma. Bacteria were found only in the root canals of teeth exhibiting radiographic evidence of apical periodontitis, confirming the infectious etiology of this disease. Anaerobic bacteria accounted for more than 90% of the isolates. Findings from Sundqvist's study also served to demonstrate that in the absence of infection, the necrotic pulp tissue itself and stagnant tissue fluid in the root canal cannot induce and perpetuate apical periodontitis lesions.

Möller et al.[160] also provided strong evidence about the microbial causation of apical periodontitis. Their study using monkeys' teeth demonstrated that only devitalized pulps that were infected induced apical periodontitis lesions, whereas devitalized and noninfected pulps showed an absence of significant pathologic changes in the periradicular tissues. In addition to corroborating the importance of microorganisms for the development of apical periodontitis, this study also confirmed that necrotic pulp tissue per se is unable to induce and maintain an apical periodontitis lesion.

ROUTES OF ROOT CANAL INFECTION

Under normal conditions, the pulpodentin complex is sterile and isolated from oral microbiota by overlying enamel and cementum. In the event that the integrity of these natural layers is breached (e.g., as a result of caries, trauma-induced fractures and cracks, restorative procedures, scaling and root planning, attrition, abrasion) or naturally absent (e.g., because of gaps in the cemental coating at the cervical root surface), the pulpodentin complex is exposed to the oral environment and then challenged by microorganisms present in caries lesions, in saliva bathing the exposed area, or in dental plaque formed onto the exposed area. Microorganisms from subgingival biofilms associated with periodontal disease may also have access to the pulp via dentinal tubules at the cervical region of the tooth and lateral and apical foramens. Microorganisms may also have access to the root canal any time during or after professional endodontic intervention.

Whenever dentin is exposed, the pulp is put at risk of infection as a consequence of the permeability of normal dentin dictated by its tubular structure (Fig. 15-2). Dentinal tubules traverse the entire width of the dentin and have a conical conformation, with the largest diameter located near the pulp (mean, 2.5 µm) and the smallest diameter in the periphery, near the enamel or cementum (mean, 0.9 µm).[75] The smallest tubule diameter is entirely compatible with the cell diameter of most oral bacterial species, which usually ranges from 0.2 to 0.7 µm. One might well assume that once exposed, dentin offers an unimpeded access pathway for bacteria to reach the pulp via tubules. This is not necessarily the

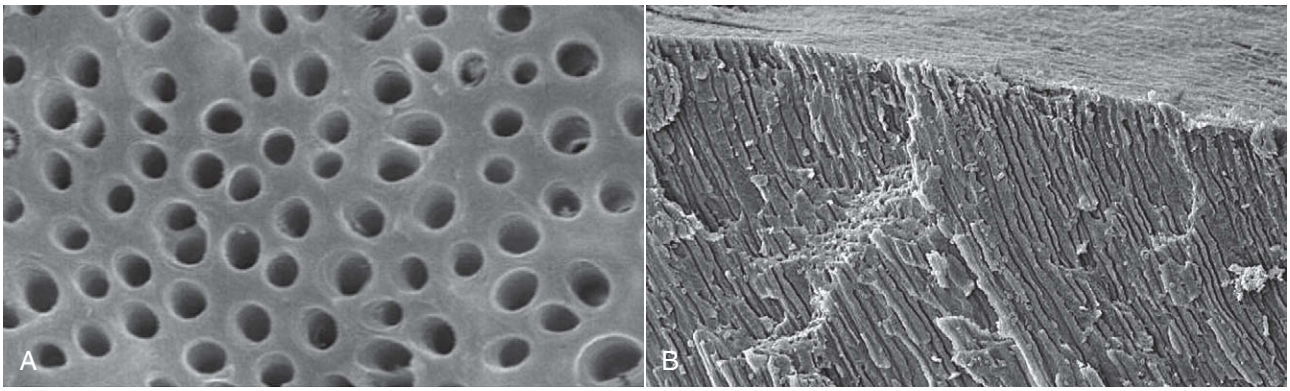

FIG. 15-2 Scanning electron micrographs of dentin showing tubules in cross-sectional **(A),** and longitudinal **(B),** views (**A-B,** ×850 and ×130, respectively).

case. It has been demonstrated that bacterial invasion of dentinal tubules occurs more rapidly in nonvital teeth than in vital ones.[164] In vital teeth, outward movement of dentinal fluid and the tubular contents (including odontoblast processes, collagen fibrils, and the sheathlike lamina limitans that lines the tubules) influence dentinal permeability and can conceivably delay intratubular invasion by bacteria. Because of the presence of tubular contents, the functional or physiologic diameter of the tubules is only 5% to 10% of the anatomic diameter seen by microscopy.[152] Other factors such as dentinal sclerosis beneath a carious lesion, tertiary dentin, smear layer, and intratubular deposition of fibrinogen also reduce dentin permeability and thereby limit or even impede bacterial progression to the pulp via dentinal tubules.[183] Host defense molecules, such as antibodies and components of the complement system, may also be present in the dentinal fluid of vital teeth and can assist in the protection against deep bacterial invasion of dentin.[3,172,173] So long as the pulp is vital, dentinal exposure does not represent a significant route of pulpal infection, except when dentin thickness is considerably reduced and dentin permeability is significantly increased.

Most of the bacteria in the carious process are nonmotile; they invade dentin by repeated cell division which pushes cells into tubules. Bacterial cells may also be forced into tubules by hydrostatic pressures developed on dentin during mastication.[153] Bacteria inside tubules under a deep carious lesion can reach the pulp even before frank pulpal exposure.[101] As mentioned, it has been assumed that the pulp will not be infected if it is still vital, and the few bacteria that reach the pulp can be of no importance, since the vital pulp can eliminate such a transient infection and rapidly clear or remove bacterial products. This efficient clearance mechanism tends to prevent injurious agents from reaching a high enough concentration to induce significant inflammatory reactions.[182] On the other hand, if the vitality of the pulp is compromised and the defense mechanisms are impaired, even very few bacteria may initiate infection.

Bacteria have been isolated from traumatized teeth with necrotic pulps and apparently intact crowns.[287,318] It has been suggested that bacteria from the gingival crevice or periodontal pockets might reach the root canals of teeth whose pulps became necrotic after trauma through severed blood vessels of the periodontium—a phenomenon called *anachoresis*.[86] However, this theory has never been supported by scientific evidence. In fact, trauma can induce exposure of dentin by fracturing the crown or inducing the formation of enamel cracks. Macro- and microcracks in enamel can be present in most teeth (not only traumatized ones) and do not necessarily end at the enamel-dentin junction but extend deep into the dentin.[142] A large number of dentinal tubules can be exposed to the oral environment by a single crack. These cracks can be clogged with dental plaque and provide portals of entry for bacteria. If the pulp remains vital after trauma, bacterial penetration into tubules is counteracted by the dentinal fluid and tubular contents, as discussed earlier, and pulpal health is not usually jeopardized. But if the pulp becomes necrotic as a consequence of trauma, it loses the ability to protect itself against bacterial invasion, and regardless of dentin thickness, dentinal tubules then will become true avenues through which bacteria can reach and colonize the necrotic pulp.

Direct exposure of the dental pulp to the oral cavity is the most obvious route of endodontic infection. Caries is the most common cause of pulp exposure, but bacteria may also reach the pulp via direct pulp exposure as a result of iatrogenic restorative procedures or trauma. The exposed pulp tissue enters in direct contact with oral bacteria from caries lesions, saliva, and/or plaque accumulated onto the exposed surface. Almost invariably, exposed pulps will undergo inflammation and necrosis and become infected. The time elapsed between pulp exposure and infection of the entire canal is unpredictable, but it is usually a slow process.[45]

The egress of microorganisms and their products from infected root canals through apical, lateral, or furcation foramina, dentinal tubules, and iatrogenic root perforations can directly affect the surrounding periodontal tissues and give rise to pathologic changes in these tissues. However, there is no consensus as to whether the opposite is true, that is, whether subgingival biofilms associated with periodontal disease can directly cause pulpal disease. Conceptually, microorganisms in subgingival plaque biofilms associated with periodontal disease could reach the pulp by the same pathways intracanal microorganisms reach the periodontium and could thereby exert harmful effects on the pulp. However, it has been demonstrated that although degenerative and inflammatory changes of different degrees may occur in the pulp of teeth with associated marginal periodontitis, pulpal necrosis as a consequence

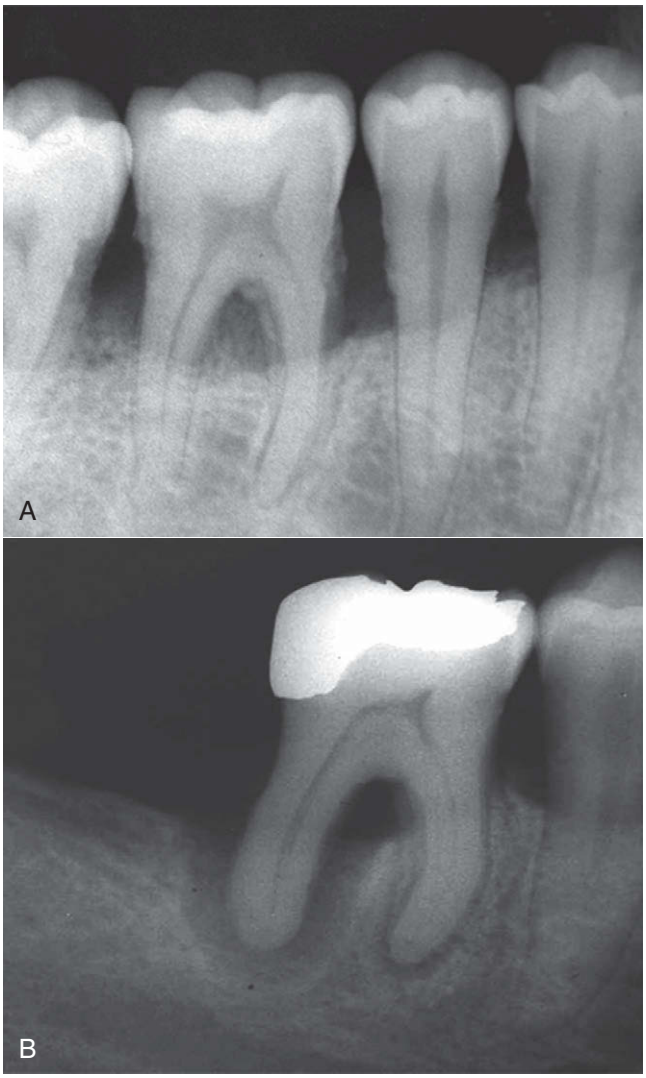

FIG. 15-3 Periodontal disease **(A)** mostly affects the pulp vitality when the subgingival biofilm reaches the apical foramen **(B).**

of periodontal disease only develops if the periodontal pocket reaches the apical foramen, leading to irreversible damage to the main blood vessels that penetrate through this foramen to irrigate the pulp[127] (Fig. 15-3). After the pulp becomes necrotic, periodontal bacteria can reach the root canal system via exposed dentinal tubules at the cervical area of the root or via lateral and apical foramina to establish an endodontic infectious process.

It has been claimed that microorganisms can reach the pulp by anachoresis. Theoretically, microorganisms are transported in the blood or lymph to an area of tissue damage, where they leave the vessel, enter the damaged tissue, and establish an infection[77,203]; there is no clear evidence showing that this process can represent a route for root canal infection. It has been revealed that bacteria could not be recovered from unfilled root canals when the bloodstream was experimentally infected, unless the root canals were overinstrumented during the period of bacteremia, with resulting injury to periodontal blood vessels and blood seepage into the canal.[51] Another argument against anachoresis as a route of pulpal infection comes from the study by Möller et al.,[160] who induced pulpal necrosis in monkeys' teeth and reported that all cases of aseptic necrosis remained bacteria-free after 6 to 7 months of observation. Although anachoresis has been suggested to be the mechanism through which traumatized teeth with seemingly intact crowns become infected,[86] current evidence indicates the main pathway of pulpal infection in these cases is dentinal exposure due to enamel cracks.[141,142]

Whatever the route of bacterial access to the root canal, necrosis of pulp tissue is a prerequisite for the establishment of primary endodontic infections. To reiterate: if the pulp is vital, it can protect itself against bacterial invasion and colonization. If the pulp becomes necrotic due to caries, trauma, operative procedures, or periodontal disease, it can be very easily infected. This is because host defenses do not function in the necrotic pulp tissue, and those in the periradicular tissues do not reach deep into the root canal space.

Another situation in which the root canal system is devoid of host defenses relates to cases where the pulp was removed for treatment. Microbial penetration in the canal can occur during treatment, between appointments, or even after root canal filling. The main causes of microbial introduction into the canal *during treatment* include remnants of dental biofilm, calculus or caries on the tooth crown; leaking rubber dam; contamination of endodontic instruments (e.g., after touch with the fingers); and contamination of irrigant solutions or other solutions of intracanal use (e.g., saline solution, distilled water, citric acid). Microorganisms can also enter the root canal system *between appointments* by leakage through the temporary restorative material; breakdown, fracture, or loss of the temporary restoration; fracture of the tooth structure; and in teeth left open for drainage. Microorganisms can penetrate the root canal system even *after completion of the root canal filling* by leakage through the temporary or permanent restorative material; breakdown, fracture, or loss of the temporary/permanent restoration; fracture of the tooth structure; recurrent decay, exposing the root canal filling material; or delay in placement of permanent restorations.[242]

MECHANISMS OF MICROBIAL PATHOGENICITY AND VIRULENCE FACTORS

The ability of a microorganism to cause disease is regarded as *pathogenicity*. *Virulence* denotes the degree of pathogenicity of a microorganism, and *virulence factors* are the microbial products, structural components, or strategies that contribute to pathogenicity. Bacterial virulence factors comprise structural cellular components and released products. Bacterial strategies that contribute to pathogenicity include the ability to coaggregate and form biofilms, which confers protection against host defenses and antimicrobial agents. Some microorganisms routinely cause disease in a given host and are called *primary pathogens*. Other microorganisms cause disease only when host defenses are impaired and are called *opportunistic pathogens*. Bacteria that make up the normal microbiota are present as harmless commensals and live in balance with the host. One of the greatest beneficial effects of human microbiota is probably the tendency to protect the host from exogenous infections by excluding other microorganisms. Nevertheless, in certain situations, the balance may be disturbed by a decrease in the normal level of resistance, and then the commensal bacteria are usually the first to take advantage. Most bacteria

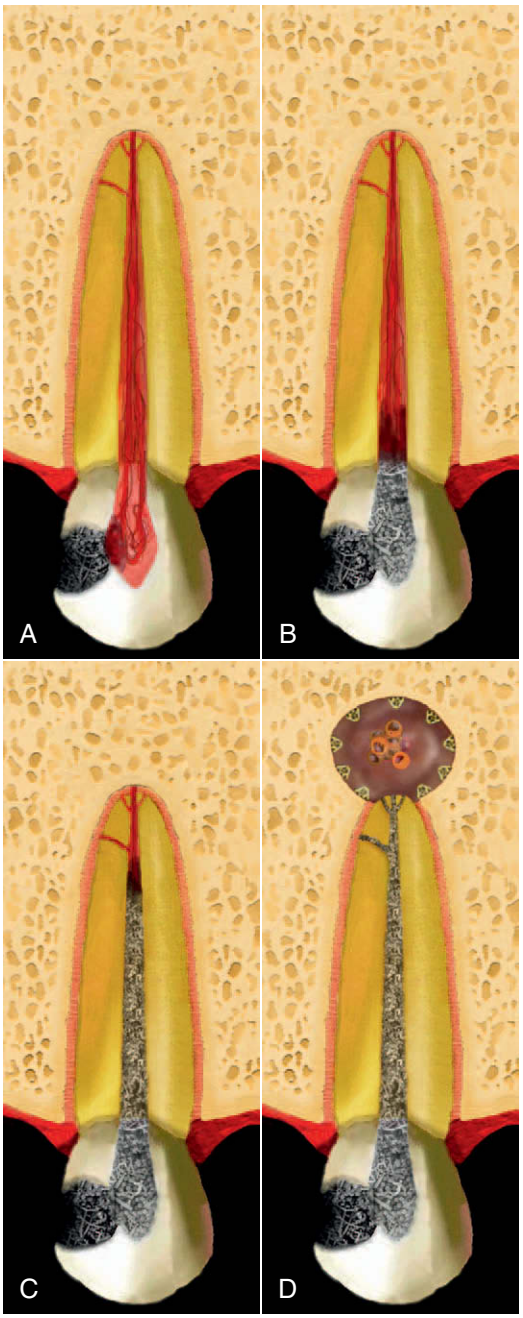

FIG. 15-5 Dynamics of pulp inflammation, necrosis, and infection from caries exposure **(A)** to apical periodontitis formation **(D).**

involved with endodontic infections are normal inhabitants of the oral microbiota that exploit changes in the balance of the host/bacteria relationship, becoming opportunistic pathogens and causing endogenous infections.

Bacteria involved with the pathogenesis of primary apical periodontitis may have participated in the early stages of pulp inflammation and necrosis, or they may have gained entry into the root canal space any time after pulpal necrosis. In the former situation, involved bacteria are usually those present in the advanced front of caries lesions and from saliva bathing the affected area. Bacteria in caries lesions form authentic biofilms adhered to dentin (Fig. 15-4). Diffusion of bacterial products through dentinal tubules induces pulpal inflammation long before the tissue is exposed. After pulp exposure, the surface of the tissue can also be colonized and covered by bacteria present in the caries biofilm. The exposed pulp tissue is in direct contact with bacteria and their products and responds with severe inflammation. Some tissue invasion by bacteria may also occur. Bacteria in the battlefront have to survive the attack from the host defenses and at the same time acquire nutrients to keep themselves alive. In this bacteria/pulp clash, the latter invariably is "defeated" and becomes necrotic, so bacteria move forward and "occupy the territory," that is, colonize the necrotic tissue. These events advance through tissue compartments, coalesce, and move towards the apical part of the canal until virtually the entire root canal is necrotic and infected (Fig. 15-5). At this stage, involved bacteria can be regarded as the early root canal colonizers or pioneer species.

Bacteria colonizing the necrotic root canal induce damage to the periradicular tissues and give rise to inflammatory changes. In fact, periradicular inflammation can be observed even before the entire root canal is necrotic.[7,161,279,320] Therefore, the early colonizers play an important role in the initiation of the apical periodontitis disease process. The environmental conditions in the root canal are modified by pioneer species and the disease process and may then be conducive to the establishment of bacterial groups different from the early colonizers. Once the pulp is necrotic, species other than those that participated in the initial infectious process may also have access to the canal via coronal exposure or exposed dentinal tubules, and a shift in the microbiota is observed. Rearrangement in the proportions of the pioneer species and latecomers occurs, and as the environment changes, some early colonizers are expected to no longer participate in the consortium in advanced disease. With the passage of time, the endodontic microbiota becomes more and more structurally and spatially organized.

Some virulence attributes required for pathogens to thrive in other sites may be of no value for bacteria that reach the

root canal after necrosis—for instance, the ability to evade host defenses. This is because latecomers face no significant opposition from host defenses, which are no longer active in the canal after necrosis. Although colonization may appear an easy task for late colonizers, other environmental factors (e.g., interaction with pioneer species, oxygen tension, nutrient availability) will determine whether new species entering the canal will succeed in establishing themselves and join the early colonizers to make up a dynamic mixed community in the root canal. Ultimately, the root canals of teeth evincing radiographically detectable apical periodontitis lesions harbor both early colonizers that managed to stay in the canals and late colonizers that managed to adapt to the new but propitious environmental conditions.[248]

Bacteria exert their pathogenicity by wreaking havoc on the host tissues through direct and/or indirect mechanisms. Bacterial virulence factors that cause direct tissue harm include those that damage host cells and/or the intercellular matrix of the connective tissue. These factors usually involve secreted products, including enzymes, exotoxins, heat-shock proteins and metabolic end products.[231] Furthermore, bacterial structural components, including lipopolysaccharide (LPS), peptidoglycan, lipoteichoic acid, fimbriae, flagella, outer membrane proteins and vesicles, lipoproteins, DNA, and exopolysaccharides can act as modulins by stimulating the development of host immune reactions capable not only of defending the host against infection but also of causing severe tissue destruction[98,248,301] (Fig. 15-6). For instance, inflammatory and noninflammatory host cells can be stimulated by bacterial components to release chemical mediators such as cytokines and prostaglandins, which are involved in the induction of bone resorption characteristically observed in chronic apical periodontitis lesions.[278] Another example of indirect damage caused by bacteria is the formation of purulent exudate in acute apical abscesses. Host defense mechanisms against bacteria emanating from the root canal appear to be the most important factor involved in formation of purulent exudate associated with abscesses. Formation of oxygen-derived free radicals, such as superoxide and hydrogen peroxide, alongside the release of lysosomal enzymes by polymorphonuclear leukocytes, gives rise to destruction of the connective extracellular matrix, leading to pus formation.[300] Although bacterial products may certainly be involved in the pathogenesis of diseases related to endodontic infections, bacterial indirect destructive effects seem to be more significant in the tissue damage associated with acute and chronic apical periodontitis lesions.

Depending on several factors, apical periodontitis can be chronic or acute. A chronic disease is usually associated with low virulence of the bacterial consortium involved, but this represents a persistent source of aggression to the tissues. Persistence in chronic infections is usually related to community organization in biofilms and the inaccessibility to host defenses because of the anatomic location of the infection. In chronic infections, the juxtaposition of bacterial biofilms to susceptible tissues that are not adapted to their presence triggers harmful inflammatory responses.[42] Thus, bacteria in the necrotic root canal cause chronic infection by forming biofilms on the canal walls and maintaining a close contact with the apical periodontal ligament, which reacts in a damaging way because periodontal ligament and bone cells are never adapted

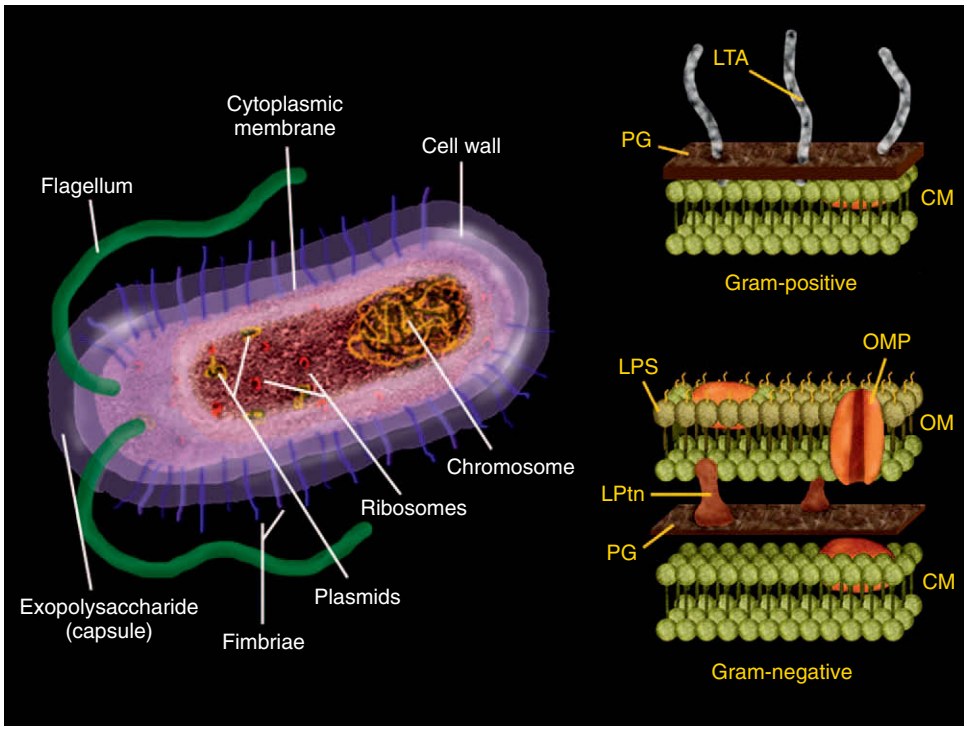

FIG. 15-6 Bacterial cell and its structural components that can act as virulence factors. *Right,* a detailed scheme of the bacterial cell walls from gram-positive and gram-negative bacteria. *CM,* Cytoplasmic membrane; *LPS,* lipopolysaccharide (endotoxin); *LPtns,* lipoproteins; *LTA,* lipoteichoic acid; *OM,* outer membrane; *OMP,* outer membrane protein; *PG,* peptidoglycan.

to the presence of bacteria. An acute infection in turn is usually caused by a high virulent bacterial consortium. High virulence may be a result of synergism between species. Acute infections are usually related to bacterial cells in a planktonic state, at high numbers, with tissue invasion ability, counteracted by a diminished host resistance. It has been demonstrated for some pathogens that genes coding for many virulence factors are much more expressed in planktonic cells than in sessile (biofilm) cells, suggesting that planktonic cells are more likely to participate in acute infections.[73]

Apical periodontitis is a multifactorial disease that is resultant of the interplay of many host and bacterial factors. Few if any of the putative endodontic pathogens are individually capable of inducing all of the events involved in the pathogenesis of the different forms of apical periodontitis. Probably, the process requires an integrated and orchestrated interaction of the selected members of the mixed endodontic microbiota and their respective virulence attributes. Although LPS is undoubtedly the most studied and quoted virulence factor, it sounds simplistic to ascribe to this molecule all responsibility for apical periodontitis causation. This statement is further reinforced by the fact that some cases of primary infections and many cases of secondary/persistent infections harbor exclusively gram-positive bacteria. Therefore, the involvement of other factors must not be overlooked. In fact, the pathogenesis of different forms of apical periodontitis and even the same form in different individuals is unlikely to follow a stereotyped course with regard to the bacterial mediators involved.[248]

BIOFILM AND COMMUNITY-BASED MICROBIAL PATHOGENESIS

Individual microorganisms proliferating in a habitat give rise to *populations*. Such populations often occur as microcolonies in the environment. Populations interact with one another to form a community. Thus, *community* refers to a unified assemblage of populations that coexist and interact at a given habitat. The community and habitat are part of a larger system called an *ecosystem,* which can be defined as a functional self-supporting system that includes the microbial community and its environment. To sum up, the following hierarchy becomes apparent: ecosystem, community, population, and the single individual (cell).

Populations perform functions that contribute to the overall community and maintain the ecological balance of the ecosystem. Each population occupies a functional role *(niche)* within the community. There are a limited number of niches within the community for which populations must compete. More competent populations occupy the niches and displace those less competent. As discussed later, highly structured and spatially organized microbial communities may exhibit properties that are greater than the sum of the component populations. In reality, complex microbial communities have been shown to be endowed with the ability to confront and withstand the challenges imposed by the environment by creating a mosaic of microenvironments that enable the survival and growth of the community members.[146]

Historically, microbiologists have faced periods of "reductionism" and "holism."[121] *Reductionism* is based on the idea that the whole can be understood by examining smaller and smaller pieces of it, that is, all complex systems can be completely understood in terms of their individual components. Through reductionist approaches, individual species are isolated from complex mixed communities and metabolically and genetically studied so as to allow understanding of the community by examining every single constituent. However, it has become quite apparent for the microbiota associated with many human infectious diseases that the whole is very often greater than the simple sum of its parts. This concept has prompted microbiologists to adopt a holistic approach to understand the community behavior associated with pathogenesis of many infectious diseases known to have a polymicrobial etiology. *Holism* holds that any component cannot be thoroughly understood except in their relation to the whole. The holistic theory has been largely employed in ecology: the interplay of the different parts composing the ecosystem will ultimately determine its properties.

Traditionally, the study of the etiology of the main human diseases (including oral diseases) has been based on reductionism. More recently, it has been recognized that the biofilm (dental plaque) associated with caries and periodontal diseases represents a sophisticated community that exert functions essential for the biofilm architecture and physiology, with consequent pathogenetic implications. Recent evidence indicates that apical periodontitis can also be due to collaborative activities of a biofilm community.

Community profiling studies[143,209,261] revealed that bacterial composition of the endodontic microbiota differs consistently between individuals. This indicates that apical periodontitis has a heterogeneous etiology, where multiple bacterial combinations can play a role in disease causation. Moreover, community structure differs significantly between different disease forms (e.g., chronic apical periodontitis versus acute apical abscess),[219,261] suggesting existence of a pattern associated with each form. Differences are still observed between individuals suffering from the same disease, disclosing an interindividual variability even more pronounced when different geographic locations are studied. There is seemingly a geography-related pattern, where individuals from a given location tend to cluster together based on similarities of the microbial community profiles.

The high interindividual variability observed for samples from the same clinical disease indicates that different compositions of bacterial communities can result in similar disease outcomes. Identification of community members can reveal the presence of some species or groups of species that may be important for the causation of some forms of disease. It is reasonable to realize that different magnitudes of disease, based on intensity of signs and symptoms, may be related to the species composition of the community. Indeed, it has been demonstrated that, despite individual uniqueness, bacterial communities associated with acute abscesses (severe pain and swelling) are more similar among them in comparison to bacterial communities associated with chronic apical periodontitis (no pain).[219,261] Although there may be no specific species related to some forms of disease, specificity seems to be related to community level, and certain communities (species composition) are specifically associated with some forms of apical periodontitis. From the perspective of the single-pathogen concept, apical periodontitis can be considered as having no specific microbial etiology. However, based on the community-

as-a-pathogen concept, it is possible to infer that some communities are more related to certain forms of the disease.[219,261]

Biofilm and Bacterial Interactions

The community-forming ability can be regarded as essential for microbial survival in virtually all environments. Indeed, the vast majority of microorganisms in nature invariably grow and function as members of metabolically integrated communities, or biofilms.[42,147] *Biofilm* can be defined as a sessile multicellular microbial community characterized by cells that are firmly attached to a surface and enmeshed in a self-produced matrix of extracellular polymeric substance (EPS), usually polysaccharide[42,55] (Fig. 15-7). The ability to form biofilms has been regarded as a virulence factor,[90] and biofilm infections account for an estimated 65% to 80% of bacterial infections that affect humans in the developed world.[41] Given its importance in varied aspects, there has been a high level of interest in the study of biofilm properties, not only in medical microbiology but also in different sectors of industrial and environmental microbiology.

Biofilms are not merely passive assemblages of bacterial cells that are stuck to surfaces; they are structurally and dynamically organized complex biologic systems. Bacterial cells in biofilms form microcolonies (±15% by volume) that are embedded and nonrandomly distributed in the EPS matrix (±85% by volume) and separated by water channels.[44,55,276,281] Microcolonies are usually shaped as "towers" or "mushrooms." Dental biofilms can reach up to 300 or more cell layers in thickness.[276] Individual microcolonies may consist of a single bacterial species but more frequently are composed of several different species in a mixed community.

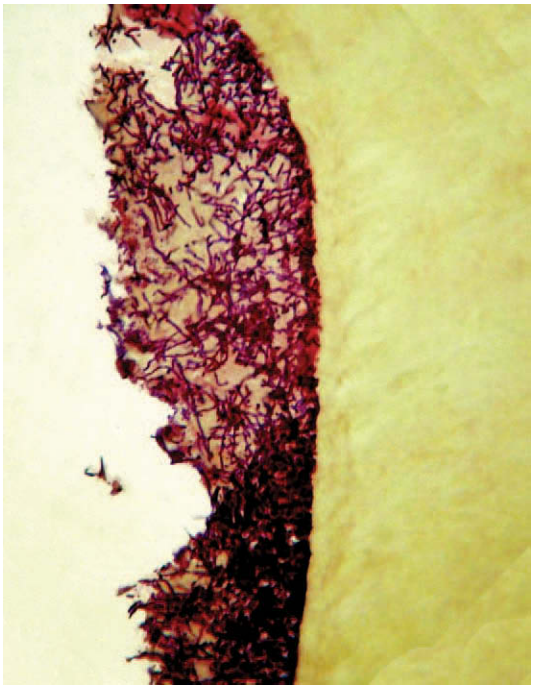

FIG. 15-7 Mixed bacterial biofilm adhered to the tooth surface (Brown and Brenn staining, ×1000).

As the biofilm matures on the surface, extracellular polysaccharides are continually synthesized to form an extracellular matrix that eventually may constitute as much as 85% of the volume of the biofilm.[41] Although the matrix is primarily composed of polysaccharides, it can also contain proteins and nucleic acids.[90] The matrix is not only important physically as part of the scaffold that determines the biofilm structure, but it is also biologically active and can retain nutrients, water, and essential enzymes within the biofilm.[5] The matrix can also protect the biofilm community from exogenous threats and may participate in adherence to the surface.

Community members form distinct populations or microcolonies separated by open water channels that traverse the biofilm matrix and create primitive circulatory systems.[43] Fluid in these channels carries substrate, end products of bacterial metabolism and signal molecules involved in bacterial interactions.[27] Thus, vital nutrients and communication molecules can diffuse, and wastes can be washed out through these channels.

Microcolonies that form in the biofilm arise from surface colonization by planktonic (unattached) bacterial cells. During the early stages of biofilm formation, bacteria bind to many host proteins and coaggregate with other bacteria. These interactions lead to changes in growth rate, gene expression, and protein production. It has been demonstrated by proteomic techniques or DNA arrays that genes expressed by cells in biofilms differed by 20% to 70% from those expressed by the same cells growing in planktonic culture.[20,174,222] Thus, bacteria in biofilms adopt a radically different phenotype compared to their planktonic counterparts. Within biofilms, sophisticated systems of cell-cell communication (quorum sensing) are also used by some bacteria to coordinate gene expression. Phenotypic heterogeneity in biofilms is also observed as a result of exposure of microcolonies to a variety of gradients (e.g., oxygen tension, pH, osmolarity, type and amounts of nutrients, cell density), which contribute to form diverse microenvironments throughout the biofilm structure.

Biofilm Community Lifestyle

As a community of bacteria, biofilms have a collective physiology, responding in concert to environmental challenges. Many naturally occurring biofilms have a highly diverse microbiota. The component species form populations (microcolonies) that are not randomly distributed but are spatially and functionally organized throughout the mixed community.

The properties displayed by a mixed biofilm community are mostly dictated by the interactions between populations, which create novel physiologic functions that cannot be observed with individual components. Populations are strategically positioned for optimal metabolic interaction, and the resultant architecture favors the ecological role of the community in the ecosystem. The biofilm community lifestyle affords a number of advantages to colonizing bacteria, including those discussed in the sections that follow.[148]

A Broader Habitat Range for Growth

The metabolism of early colonizers alters the local environment, setting the stage for attachment and growth of latecomers (including more fastidious species). This may include increased availability of some types of nutrients, removal of harmful metabolic end products, and the development of

appropriate physicochemical conditions (e.g., reduced oxygen tension and redox potential). As a consequence, the diversity of the microbiota increases over time because of bacterial succession.

Increased Metabolic Diversity and Efficiency

Nutrients are limited in most ecosystems, so the communities that can fix and process their resources most efficiently will thrive and be perpetuated. Bacteria living in mixed communities take part in a number of nutritional interrelationships, and food webs develop. For instance, products of the metabolism of one species may become the main source of nutrients for other species. Also in food webs, the concerted action of interacting species is required for the sequential breakdown of complex host-derived substrates to simpler products, which can favor less competent species. Many complex host macromolecules, especially glycoproteins, can only be degraded efficiently by mixed consortia of oral bacteria. Byproducts of the degradation of complex nutrients are trapped in the biofilm matrix and shared with other community members.

Protection From Competing Microorganisms, Host Defenses, Antimicrobial Agents, and Environmental Stress

Neighboring cells of a different species can produce enzymes such as beta-lactamases, catalase, and proteinases that are retained in the biofilm matrix and protect other bacteria against antimicrobials and host defenses. The same is true for metabolites and bacteriocins, which can inhibit competing species. The biofilm matrix also confers physical protection against phagocytosis.

Genetic Exchanges

Cell-cell associations and the biofilm architecture facilitate horizontal gene transfer in the community. Potential mechanisms mediating genetic exchange in biofilms include conjugation, transformation, and transduction. The main consequences of genetic exchanges among community members are related to the acquisition and dissemination of virulence and antibiotic-resistance genes.

Enhanced Pathogenicity

To cause disease, bacteria must adhere to host surfaces, obtain nutrients from the host, and multiply, invade tissues, overcome or evade the host defenses, and induce tissue damage. A diverse range of virulence traits are required for these particular stages of the disease process, and it is highly likely that each will require the concerted action of bacteria in a community. Similarly, it is possible that certain species can have more than one role in disease, and different species can perform similar functions. This helps explain why communities with different bacterial composition can be found in different individuals with similar disease. In mixed communities, a broad spectrum of relationships may arise between the component species, ranging from no effect or reduced pathogenicity to additive or synergistic pathogenic effects. Endodontic abscesses are examples of polymicrobial infections whereby bacterial species that individually have low virulence and are unable to cause disease can do so when in association with others as part of a mixed consortium (pathogenic synergism).[30]

Resistance to Antimicrobial Agents

From a clinical standpoint, biofilm increased resistance to antimicrobial agents is of special concern. Bacteria arranged in biofilms are more resistant to antibiotics than the same cells grown in planktonic state. The antibiotic concentration required to kill bacteria in the biofilm is about 100 to 1000 times higher than that needed to kill the same species in planktonic state.[145] There are several possible mechanisms involved with biofilm resistance to antimicrobials.

Biofilm Structure May Restrict Penetration of Antimicrobial Agents

The agent may adsorb to and inhibit the bacteria at the biofilm surface, leaving cells deeply located in the biofilm relatively unaffected. The matrix in biofilms can also bind and retain neutralizing enzymes at concentrations that could inactivate the antimicrobial agent.[280]

Altered Growth Rate of Biofilm Bacteria

Many antibiotics can freely penetrate the biofilm matrix, but cells are often still protected. The occurrence of starved bacteria entering the stationary phase in biofilms seems to be a significant factor in the resistance of biofilm populations to antimicrobials. Bacteria grow slowly under conditions of low availability of nutrients in an established biofilm and as a consequence are much less susceptible than faster-dividing cells. Most antibiotics require at least some degree of cellular activity to be effective. Therefore, bacterial cells in stationary phase might represent a general mechanism of antibiotic resistance in the biofilm.[90]

Presence of "Persister" Bacteria

Increased tolerance of some biofilms to antibiotics may be largely due to the presence of a subpopulation of specialized survivor cells known as *persisters*.[113] It remains unclear whether these bacteria actually represent a distinct phenotype or are simply the most resistant cells within a population.[90]

Quorum Sensing—Bacterial Intercommunication

Quorum sensing is a term currently used for systems based on cell-cell communication that regulate gene expression in a cell density–dependent manner.[180] Quorum-sensing systems capacitate bacteria to behave collectively as a group. This phenomenon has been described in both gram-positive and gram-negative bacterial species.[10,57,317] Quorum sensing involves the production, release, and subsequent detection of diffusible signaling molecules called *autoinducers*. Two predominant types of autoinducers, *N*-acyl-L-homoserine lactones (AHLs) and posttranslationally modified peptides, are used by gram-negative and gram-positive bacteria, respectively. For example, the human pathogens *Pseudomonas aeruginosa* and *Staphylococcus aureus* employ AHLs and peptides, respectively, to control the expression of multiple virulence genes in concert with cell population density. Several other small-molecule quorum-sensing autoinducers have recently been discovered, including *Pseudomonas* quinolone signal (PQS) and AI-2.[35]

As members of a bacterial population producing and releasing autoinducers multiply, the extracellular concentration of these signaling molecules also increases. When autoinducers

reach a crucial threshold level, the group responds with a population-wide alteration in gene expression, activating or repressing target genes.[181] Since alterations in gene expression are linked to the presence of autoinducers, bacteria can perform specific functions only when living in groups. Such behavior provides some advantages to a bacterial population, affording adaptability to and protection against threatening environments.

Quorum-sensing systems are known to regulate virulence, competence for DNA uptake, entry into stationary phase, and biofilm formation.[35,46,184] With regard to virulence, quorum sensing allows the community to regulate expression of virulence genes in accordance with cell density. Thus, some opportunistic pathogens express virulence factors in response to sensing their own cell density. Using quorum sensing, bacteria can amass a high cell density before virulence factors are expressed, and in so doing, the bacteria are able to make a consolidated attack to overcome the host defenses and establish infection.[116] Teleologically, it appears bacteria were able to strategically wait for a critical number of cells to be reached and then start inducing damage, not giving the host sufficient time to mount an effective defense response. In reality, with regard to energy yield, it would be difficult for bacteria to produce some virulence factors before a critical community density is reached. For instance, production of proteinases by a few cells are not expected to have significant impact on the host environment, representing "wasted energy" for the growing population.[180]

The process of biofilm formation, including surface attachment, proliferation, matrix production, and detachment, is also partially controlled by quorum sensing.[74] Moreover, bacteria can monitor crowding as a measure of competition for nutrients. At high cell density, there may be too much competition to utilize available nutrients for growth, and starvation is anticipated. If bacteria are already starved and crowded, as they often are when growing as a biofilm, it may be advantageous to enter stationary phase. Entry into stationary phase dramatically alters patterns of gene expression to allow extended cell survival in the absence of nutrients.[128] Control of cell density in biofilms is also important to prevent water circulatory channels, essential for biofilm physiology, from being clogged and then inactivated by cells under excessive growth.

Several oral bacteria have been demonstrated to produce quorum-sensing signaling molecules,[71,194,321] indicating that bacteria in endodontic biofilms may also communicate with one another through this system.

METHODS FOR MICROBIAL IDENTIFICATION

The endodontic microbiota has been traditionally investigated by microbiologic culture methods. Culture is the process of propagating microorganisms in the laboratory by providing them with the required nutrients and proper physicochemical conditions, including temperature, moisture, atmosphere, salt concentration, and pH.[272] Essentially, culture analyses involve the following steps: sample collection and transport, dispersion, dilution, cultivation, isolation, and identification. Endodontic samples are collected and transported to the laboratory in a viability-preserving, nonsupportive, anaerobic medium. They are then dispersed by sonication or vortex mixing, diluted, distributed onto various types of agar media, and cultivated under aerobic or anaerobic conditions. After a suitable period of incubation, individual colonies are subcultivated and identified on the basis of multiple phenotype-based aspects, including colony and cellular morphology, gram-staining pattern, oxygen tolerance, comprehensive biochemical characterization, and metabolic end-product analysis by gas-liquid chromatography. The outer cellular membrane protein profile as examined by gel electrophoresis, fluorescence under ultraviolet light, and susceptibility tests to selected antibiotics can be needed for identification of some species.[61] Marketed packaged kits that test for preformed enzymes have also been used for rapid identification of several species.

Culture analyses of endodontic infections have provided a substantial body of information about the etiology of apical periodontitis, composition of the endodontic microbiota in different clinical conditions, effects of treatment procedures in microbial elimination, susceptibilities of endodontic microorganisms to antibiotics, and so on. Advantages and limitations of culture methods are listed in Box 15-1. As one can tell, however, some important limitations of culture methods make a comprehensive analysis of the endodontic microbiota difficult to achieve.

The difficulties in culturing or identifying many microbial species are of special concern. Unfortunately, not all microorganisms can be cultivated under artificial conditions, and this is simply because the nutritional and physiologic needs of most microorganisms are still unknown. Investigations of many aquatic and terrestrial environments using culture-independent methods have revealed that the cultivable members of these systems represent less than 1% of the total

BOX 15-1

Advantages and Limitations of Culture Methods

Advantages	Limitations
◆ Broad-range nature, identification of unexpected species	◆ Impossibility of culturing a large number of extant bacterial species
◆ Allow quantification of all major viable cultivable microorganisms in samples	◆ Not all viable bacteria can be recovered
◆ Allow determination of antimicrobial susceptibilities of isolates	◆ Once isolated, bacteria require identification using a number of techniques
◆ Physiologic studies are possible	◆ Misidentification of strains with ambiguous or aberrant phenotypic behavior
◆ Pathogenicity studies are possible	◆ Low sensitivity
◆ Widely available	◆ Strict dependence on the mode of sample transport
	◆ Samples require immediate processing
	◆ Costly, time consuming, and laborious, as for cultivation of anaerobes
	◆ Specificity is dependent on experience of microbiologist
	◆ Extensive expertise and specialized equipment needed to isolate anaerobes
	◆ Takes several days to weeks to identify most anaerobes

extant population.[6,314] Furthermore, 50% to 80% of bacterial species composing the microbiota associated with diverse human sites, including the oral cavity, represent unknown and still uncultivated bacteria.[2,58,120,185,282]

That a given species has not been cultivated does not imply that this species will remain indefinitely impossible to cultivate. A myriad of obligate anaerobic bacteria were uncultivable 100 years ago, but further developments in anaerobic culturing techniques have to a large extent helped to solve this problem. It must be assumed that no single method or culture medium is suitable for isolating the vast diversity of microorganisms present in most environments.[83] While we remain relatively unaware of the requirements for many bacteria to grow, identification methods not based on cultivability are required.

In some situations, even the successful cultivation of a given microorganism does not necessarily mean that this microorganism can be successfully identified. Culture-dependent identification is based on phenotypic traits observed in reference strains, with predictable biochemical and physical properties under optimal growth conditions. However, many phenotype-related factors can lead to difficulties in identification and even to misidentification.[19,25,295] As a consequence of all these factors, phenotype-based identification does not always allow an unequivocal identification.

To sidestep the limitations of culture, tools and procedures based on molecular biology have become available and have been substantially improved to achieve a more realistic description of the microbial world without the need for cultivation (Fig. 15-8). Molecular biology techniques have been widely used to directly identify microorganisms in samples without the need for cultivation. In addition, molecular technology has also been applied to reliably identify cultivated bacteria, including strains with ambiguous or aberrant phenotypic behavior, rare isolates, poorly described or uncharacterized bacteria, and newly named species.*

Molecular approaches for microbial identification rely on certain genes that contain revealing information about the microbial identity. Of the several genes that have been chosen as targets for bacterial identification, the 16S rRNA gene (or 16S rDNA) has been the most widely used because it is universally distributed among bacteria, is long enough to be highly informative and short enough to be easily sequenced, possesses conserved and variable regions, and affords reliability for inferring phylogenetic relationships.[319] Similarly, the 18S rRNA gene of fungi and other eukaryotes has also been extensively used for identification of these organisms.

Data from 16S rRNA gene sequences can be used for accurate and rapid identification of known and unknown bacterial species, using techniques that do not require cultivation. The 16S RNA gene of virtually all bacterial species in a given environment, including still uncultivated and uncharacterized bacteria, can be amplified by polymerase chain reaction (PCR) using broad-range (or universal) primers that are complementary to conserved regions of this gene. Sequencing of the variable regions flanked by the broad-range primers will provide information for accurate bacterial identification. Primers or probes that are complementary to variable regions can also be designed to detect specific target species directly in clinical samples (see Fig. 15-4).

*References 26, 56, 195, 249, 277, and 294.

Many molecular methods for the study of microorganisms exist; the choice of a particular approach depends on the questions being addressed (see Fig. 15-5). Broad-range PCR followed by cloning and sequencing can be used to unravel the breadth of microbial diversity in a given environment. Microbial community structures can be analyzed via fingerprinting techniques, such as denaturing gradient gel electrophoresis (DGGE) and terminal restriction fragment length polymorphism (T-RFLP). Fluorescence in situ hybridization (FISH) can measure abundance of target species and provide information on their spatial distribution in tissues. Among other applications, DNA-DNA hybridization arrays (checkerboard techniques, DNA microarrays), species-specific single PCR, nested PCR, multiplex PCR, and quantitative real-time PCR can be used to survey large numbers of clinical samples for the presence of target species. Variations in PCR technology can also be used to type microbial strains.

As with any other method, molecular methods have their own advantages and limitations (Box 15-2).

Impact of Molecular Methods in Endodontic Microbiology

Traditionally, endodontic infections have been studied by means of culture approaches. Such studies identified a set of species thought to play an important role in the pathogenesis of apical periodontitis.[288] More recently, not only have findings from culture-based methods been confirmed, but they have also been significantly supplemented with those from culture-independent molecular biology techniques.[236] Molecular methods have confirmed and strengthened the association of many cultivable bacterial species with apical periodontitis and have also revealed new suspected endodontic pathogens.[250] The list of candidate pathogens has expanded to include culture-difficult species or as-yet-uncultivated bacteria that had never been found in endodontic infections by culturing approaches. The results from molecular studies impact remarkably on the knowledge of bacterial diversity in endodontic infections. More than 400 different bacterial species have already been detected in different types of endodontic infections. Of these, about 45% were exclusively reported by molecular biology studies, compared to 32% detected by culture studies alone. Twenty-three percent of the total bacterial species richness has been detected by application of both culture and molecular studies (Fig. 15-9). As a consequence, it becomes quite apparent that the endodontic microbiota has been refined and redefined by molecular methods.[250]

TYPES OF ENDODONTIC INFECTIONS

Endodontic infections can be classified according to anatomic location (intraradicular or extraradicular infection). *Intraradicular infection* is caused by microorganisms colonizing the root canal system and can be subdivided into three categories according to the time microorganisms entered the root canal system: *primary infection,* caused by microorganisms that initially invade and colonize necrotic pulp tissue (initial or "virgin" infection); *secondary infection,* caused by microorganisms not present in the primary infection but introduced in the root canal at some time after professional intervention (i.e., *secondary* to intervention); and *persistent infection,* caused by microorganisms that were members of a primary or secondary

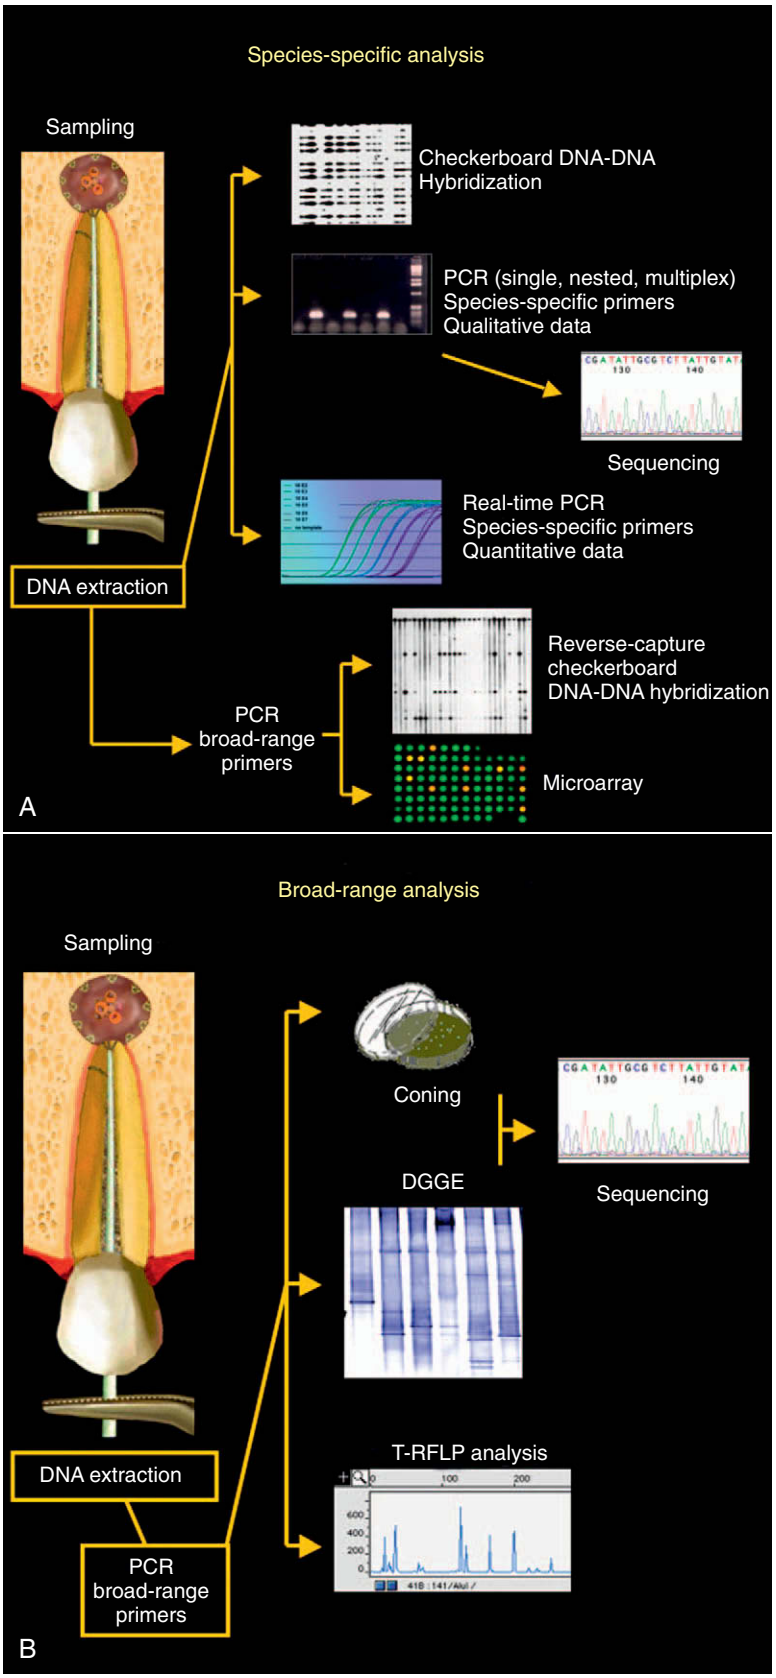

FIG. 15-8 Molecular biology methods used (or with potential to be used) in the study of endodontic infections. The choice for a particular technique will depend on the type of analysis to be performed. Some methods can be used for detection of target microbial species or groups **(A)** and others for a broader analysis of the microbiota **(B).**

Advantages and Limitations of Molecular Biology Methods

Advantages	Limitations
◆ Detect both cultivable and as-yet-uncultivated species or strains	◆ Most assays are qualitative or semiquantitative (exceptions: real-time PCR, microarray)
◆ High specificity and accurate identification of strains with ambiguous or aberrant phenotypic behavior	◆ Most assays only detect one species or a few different species at a time (exceptions: broad-range PCR, checkerboard, microarray)
◆ Detect species directly in clinical samples	◆ Most assays detect only the target species and fail to detect unexpected species (exception: broad-range PCR)
◆ High sensitivity	◆ Some assays can be laborious and costly (e.g., broad-range PCR)
◆ Rapid; most assays take no more than minutes to a few hours to identify a microbial species	◆ Biases in broad-range PCR introduced by homogenization procedures, preferential DNA amplification, and differential DNA extraction
◆ Do not require carefully controlled anaerobic conditions during sampling and transportation	◆ Hybridization assays using whole genome probes detect only cultivable species
◆ Can be used during antimicrobial treatment	◆ Can be very expensive
◆ Anaerobic handling and expertise not required	◆ Detect dead microorganisms
◆ Samples can be stored frozen for later analysis	
◆ DNA can be transported easily between laboratories	
◆ Detect dead microorganisms	

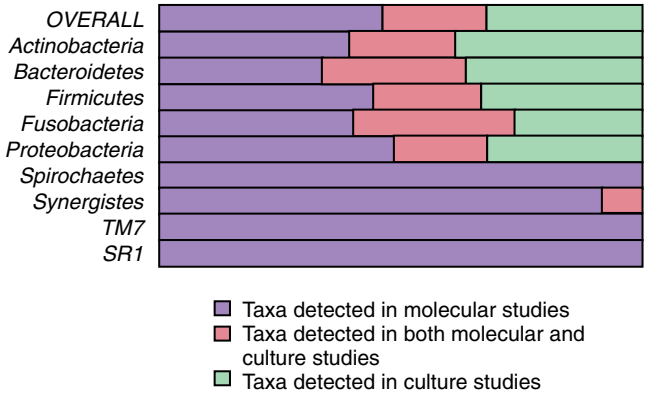

FIG. 15-9 Percent distribution of bacterial species/phylotypes found in endodontic infections according to the detection method. Data refer to the percentage of species or phylotypes overall or in each of the nine phyla that have endodontic representatives.

infection and in some way resisted intracanal antimicrobial procedures and were able to endure periods of nutrient deprivation in treated canals. Both persistent and secondary infections are for the most part clinically indistinguishable, except for cases where signs and/or symptoms of infection arise in a previously noninfected tooth—a typical example of secondary infection. *Extraradicular infection* is characterized by microbial invasion of the inflamed periradicular tissues and is a sequel to the intraradicular infection. Admittedly, extraradicular infections can be dependent on or independent of the intraradicular infection.

DIVERSITY OF THE ENDODONTIC MICROBIOTA

Microbiota is a collective term for microorganisms and should replace terms such as *flora* and *microflora,* which perpetuate an outdated classification of microorganisms as plants.[52] *Diversity* refers to the number of different species present (richness) and their relative abundance (evenness) in a given ecosystem.[105]

The oral cavity harbors one of the highest accumulations of microorganisms in the body. Even though viruses, archaea, fungi, and protozoa can be found as constituents of the oral microbiota, bacteria are by far the most dominant inhabitants of the oral cavity. There are an estimated 10 billion bacterial cells in the oral cavity,[156] and culture-independent studies (microscopy and molecular biology technologies) have shown that over 50% to 60% of the oral microbiota still remains to be cultivated and fully characterized.[2,275] A high diversity of bacterial species has been revealed in the oral cavity by culturing approaches, but application of molecular biology methods to the analysis of the bacterial diversity has revealed a still broader and more diverse spectrum of extant oral bacteria. Over 700 bacterial taxa have been found in the human oral cavity, and phylogenetic studies have revealed that these taxa fall into 13 separate phyla: *Firmicutes, Bacteroidetes, Actinobacteria, Fusobacteria, Proteobacteria, Spirochaetes, Synergistes,* TM7, Sulphur River 1 (SR1), *Chloroflexi, Cyanobacteria, Deinococcus,* and *Acidobacteria.*[1,112,133,185,186]

Modern anaerobic culture and sophisticated molecular biology techniques have disclosed important aspects of the endodontic microbiota in the different types of infection. Of particular interest, they have allowed the assessment of the microbial diversity in endodontic infections, collectively revealing that more than 400 different microbial species/phylotypes have been found in infected root canals, usually in combinations involving many species in primary infections and a few ones in secondary/persistent infections. Endodontic bacteria fall into 9 of the 13 phyla that have oral representatives* (Fig. 15-10). Fungi and archaea have been only occasionally found in endodontic infections.

Endodontic infections develop in a previously sterile place that does not contain a normal microbiota. Any species found has the potential to be an endodontic pathogen or at least play a role in the ecology of the endodontic microbial community. Culture and molecular studies reveal only prevalence of species; consequently, only association can be inferred. Causation is usually surmised on the basis of both frequency of detection and potential pathogenicity (in animal models or association with other human diseases), and several species have emerged as candidate or putative endodontic pathogens. The following sections discuss specific aspects of each type of endodontic infection.

PRIMARY INTRARADICULAR INFECTION

Microbial Composition and Diversity

Primary intraradicular infection is infection of the necrotic pulp tissue (Fig. 15-11). Participating microorganisms can have been involved in earlier stages of pulp invasion (usually via caries) that culminated in inflammation and further necrosis, or they can be latecomers that took advantage of the environmental conditions in the root canal after pulp necrosis.

Primary infections are characterized by a mixed community conspicuously dominated by anaerobic bacteria. The number of bacterial cells may vary from 10^3 to 10^8 per root canal.[220,265,287,306] Molecular studies have disclosed a mean of 10 to 20 species/phylotypes per infected canal.[162,208,250,261] Canals of teeth with sinus tracts exhibit a mean number of 17 species.[208] The size of the apical periodontitis lesion has been shown to be proportional to the number of bacterial species and cells in the root canal.[208,260,287] A molecular study[208] demonstrated that the number of taxa per canal was clearly in direct proportion to the lesion size: small lesions (<5 mm) harbored about 12 taxa, lesions from 5 to less than 10 mm harbored 16 taxa, and lesions over 10 mm harbored about 20 species. Some canals associated with large lesions may harbor even more than 40 taxa[208]; the larger the lesion, the higher the bacterial diversity and density in the canal.

The most prevalent named bacterial species detected in primary infections, including abscessed cases, belong to diverse genera of gram-negative (*Fusobacterium, Dialister, Porphyro-*

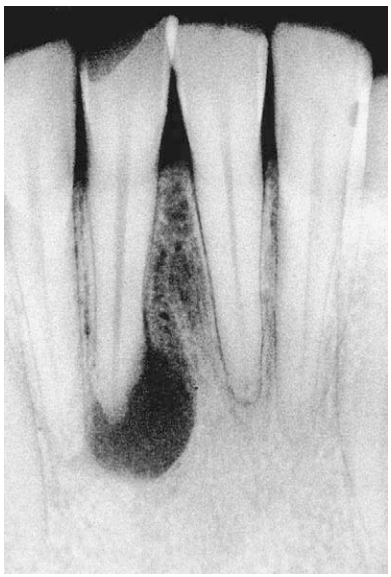

FIG. 15-11 Apical periodontitis due to primary intraradicular infection. Pulp is necrotic and lesion size is usually directly proportional to complexity of the microbiota involved.

monas, Prevotella, Tannerella, Treponema, Campylobacter, and *Veillonella*) and gram-positive (*Parvimonas, Filifactor, Pseudoramibacter, Olsenella, Actinomyces, Peptostreptococcus, Streptococcus, Propionibacterium,* and *Eubacterium*) bacteria.* Bacterial prevalence in primary infections may vary from study to study as a function of several factors, such as sensitivity and specificity of the detection and identification methods, sampling technique, geographic location, and accuracy or divergence in clinical diagnosis and disease classification. Even so, the species most frequently detected are expected to be the same in most well-conducted studies. Figs. 15-12 to 15-14 display the most frequently detected species associated with chronic apical periodontitis, acute apical periodontitis, and acute apical abscesses, respectively, as revealed by studies from the authors' group using a highly sensitive molecular biology technique.

About 40% to 55% of the endodontic microbiota in primary infections is composed of species still uncultivated.[162,219] A molecular study revealed that 55% and 40% of the taxa detected in association with chronic apical periodontitis and acute apical abscesses, respectively, were uncultivated phylotypes.[219] As for their abundance in these infections, as-yet-uncultivated phylotypes corresponded to 38% and 30% of the clones sequenced from samples of chronic apical periodontitis and abscesses, respectively.[219] Molecular studies investigating the breadth of bacterial diversity in infected root canals have disclosed the occurrence of uncultivated phylotypes belonging to several genera, including *Synergistes, Dialister, Prevotella, Solobacterium, Olsenella, Fusobacterium, Eubacterium, Megasphaera, Veillonella,* and *Selenomonas,* as well as phylotypes related to the family *Lachnospiraceae* or the TM7 phylum.† Some uncultivated phylotypes can even be among the most prevalent bacteria in primary intraradicular infections, and others may be associated with pain.[219] Two of the most prevalent such phylotypes found in endodontic infections include *Synergistes* clone BA121 and *Bacteroidetes* clone X083.[207,208,251,253,255] Detection of these phylotypes in samples from endodontic infections suggests that they can be previously unrecognized bacteria that play a role in the pathogenesis of different forms of apical periodontitis. The fact that they have not yet been cultivated and phenotypically characterized does not mean that they are not important.

Symptomatic Infections

Acute apical periodontitis and acute apical abscesses are typical examples of symptomatic endodontic infections. In these cases, the infection is located in the canal, but it has also reached the periradicular tissues and, in abscessed cases, can spread to other anatomic spaces. Acute apical abscesses are caused by bacteria that egress the infected root canal and invade the periradicular tissues to establish an extraradicular infection and evoke purulent inflammation. Clinically, the disease leads to pain and/or swelling and has the potential to diffuse to sinuses and other facial spaces of the head and neck to form a cellulitis or other complications (Fig. 15-15). The microbiota involved in endodontic abscesses is mixed and dominated by anaerobic bacteria[47,115,122,219,261] (see Fig. 15-14). Direct comparisons using molecular technology reveal an average of 12 to 18 taxa per abscess case, compared to 7 to 12 taxa present in root canals from chronic cases.[219,261] Uncultivated phylotypes constitute approximately 40% of the taxa found in abscesses and collectively represent more than 30% of the 16S rRNA gene sequences retrieved in clone libraries.[219]

Whereas microbial causation of apical periodontitis is well established, there is no strong evidence disclosing specific involvement of a single species with any particular sign or symptom of apical periodontitis. Some gram-negative anaerobic bacteria have been suggested to be involved with symptomatic lesions,* but the same species may also be present in somewhat similar frequencies in asymptomatic cases,† so factors other than the mere presence of a given putative pathogenic species may play a role in the etiology of symptomatic endodontic infections.[232,237] These factors could include differences in virulence ability among strains of the same species; bacterial interactions resulting in additive or synergistic effects among species in mixed infections; number of bacterial cells (load); environmental cues regulating expression of virulence factors; host resistance; and concomitant herpesvirus infection. Association of some or all of these factors (instead of an isolated event) is likely to determine the occurrence and intensity of symptoms.[232,237]

Cross-sectional studies suggest that bacterial succession occurs before symptoms arise.[261] At a given moment during the endodontic infectious process, the microbiota may reach a certain degree of pathogenicity that elicits acute inflammation at the periradicular tissues, with consequent development of pain and sometimes swelling. Molecular studies using DGGE or T-RFLP analysis revealed that the structure of the endodontic bacterial communities in symptomatic teeth is significantly different from that of asymptomatic teeth.[261] Differences are represented by different dominant species in the communities and larger numbers of species in symptomatic cases. A shift in the structure of the microbial community is likely to occur before appearance of symptoms. Such a shift is probably due to the arrival of new pathogenic species or variations and rearrangements in the number of members of the bacterial community. Differences in the type and load of dominant species and the resulting bacterial interactions may affect virulence of the whole bacterial community. This is in agreement with the community-as-a-pathogen concept discussed earlier.

Geographic Influence

Findings from laboratories in different countries are often quite different regarding the prevalence of the species involved in endodontic infections. Although these differences may be attributed to variations in identification methodologies, a geographic influence in the composition of the root canal microbiota has been suspected. Studies using molecular biology techniques directly compared the endodontic microbiota of patients residing in different geographic locations and suggested that significant differences in the prevalence of some important species can actually exist.[14,204,241] In a more holistic approach, analysis of the bacterial community profiles of the microbiota associated with acute apical abscesses from the United States and Brazilian patients also revealed a geography-related pattern, with several species being exclusive for each

location and others shared by the two locations, showing great differences in prevalence.[143] The factors that can lead to differences in the composition of the endodontic microbiota and the impact of these differences on therapy, particularly in abscessed cases requiring systemic antibiotic therapy, remain elusive.

Spatial Distribution of the Microbiota—Anatomy of Infection

Knowledge of microbial location and organization within the root canal system assumes special importance to understanding the disease process and establishing effective antimicrobial therapeutic strategies. Most of the knowledge of the structure of the endodontic microbiota comes from morphologic studies,[161,167,227,257] but these do not usually provide information about bacterial identity and numbers. Consequently, it is not possible to delineate the role of the visualized bacteria in the disease process. Because every bacterial cell observed in the root canal system might be an endodontic pathogen, findings from morphologic studies should be used to understand the topography of the root canal infection and establish thera-

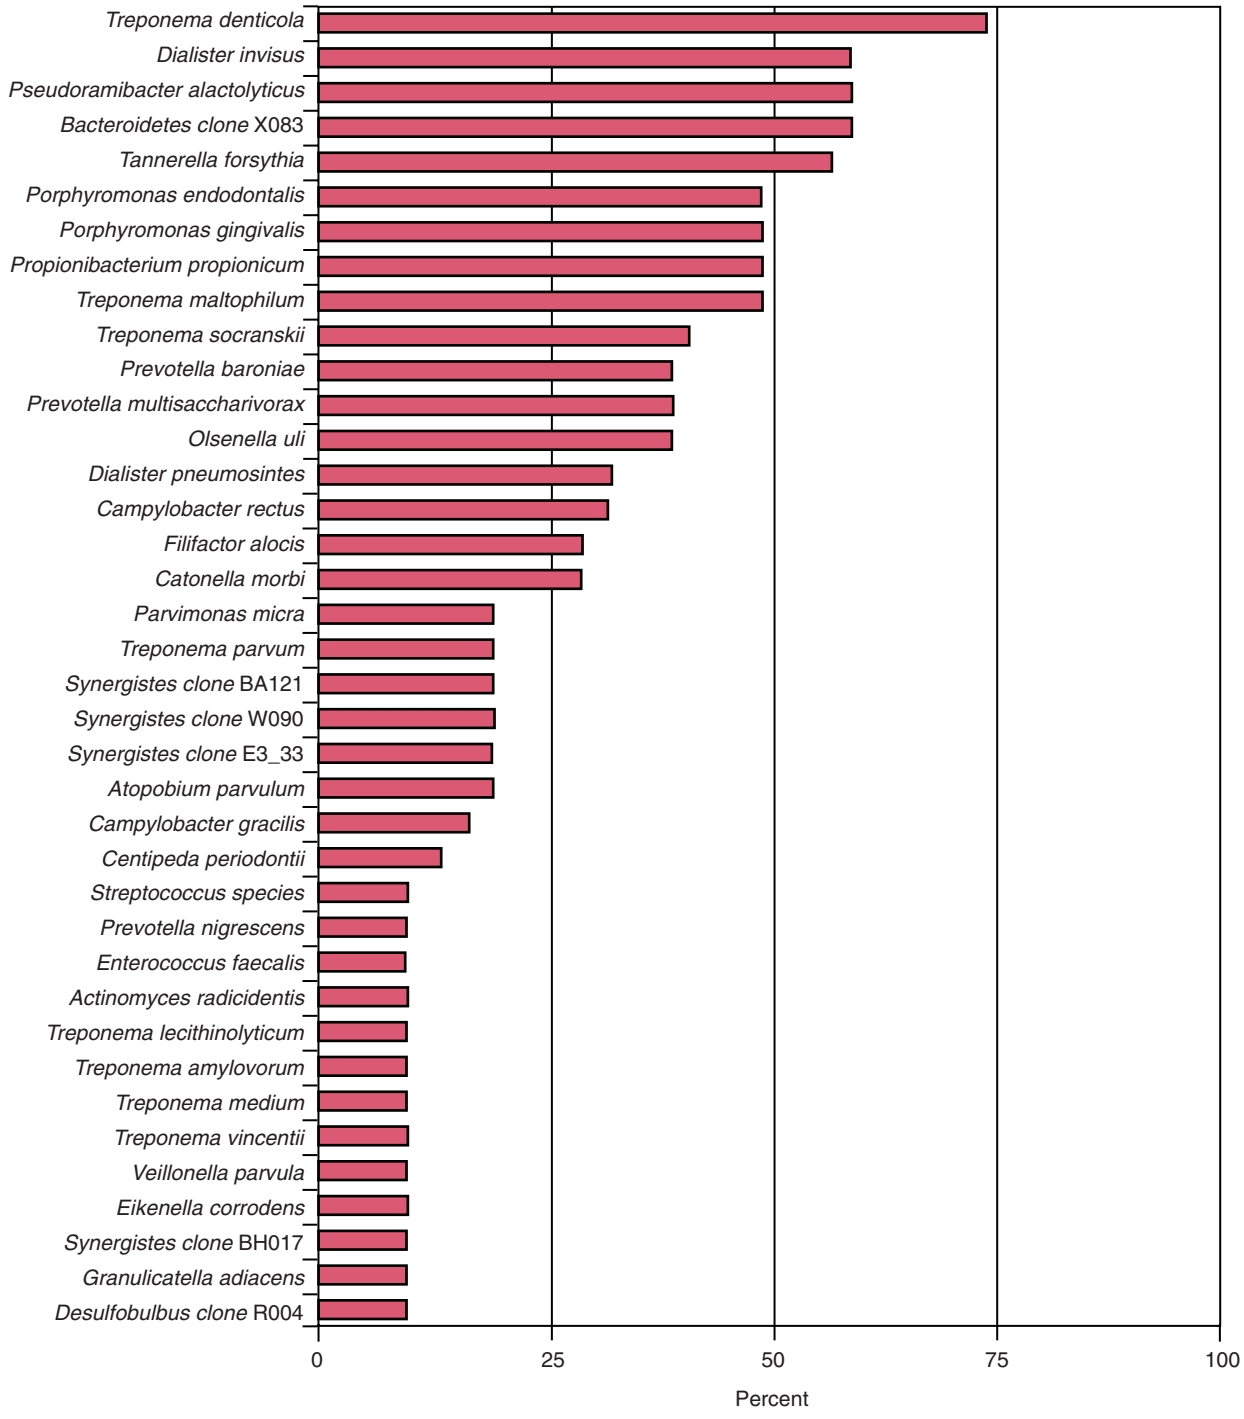

FIG. 15-13 Prevalence of bacteria detected in primary infections of teeth with acute apical periodontitis. Data from the authors' studies using a taxon-specific nested-polymerase chain reaction protocol. *(From references 207, 211, 250, and 253.)*

peutic measures in an attempt to completely eradicate the infection or at least reduce the bacterial load to thresholds compatible with periradicular tissue healing.

Again, mounting evidence suggests that apical periodontitis, like caries and periodontal diseases, is also a biofilm-induced disease. Morphologic studies have shown that the root canal microbiota in primary infections is dominated by bacterial morphotypes that include cocci, rods, filaments, and spirilla (spirochetes) (Fig. 15-16), and fungal cells are sporadically found[227,257] (Fig. 15-17). Bacteria colonizing the root canal system usually grow in sessile biofilms adhered to the dentinal walls and also as coaggregates (cells with distinct morphologies), aggregates (cells with the same morphology), and planktonic cells suspended in the fluid phase of the main canal[161,167,257] (Fig. 15-18). Lateral canals and isthmuses connecting main canals may be clogged with bacterial cells primarily organized in biofilms[166,202] (Figs. 15-19 and 15-20).

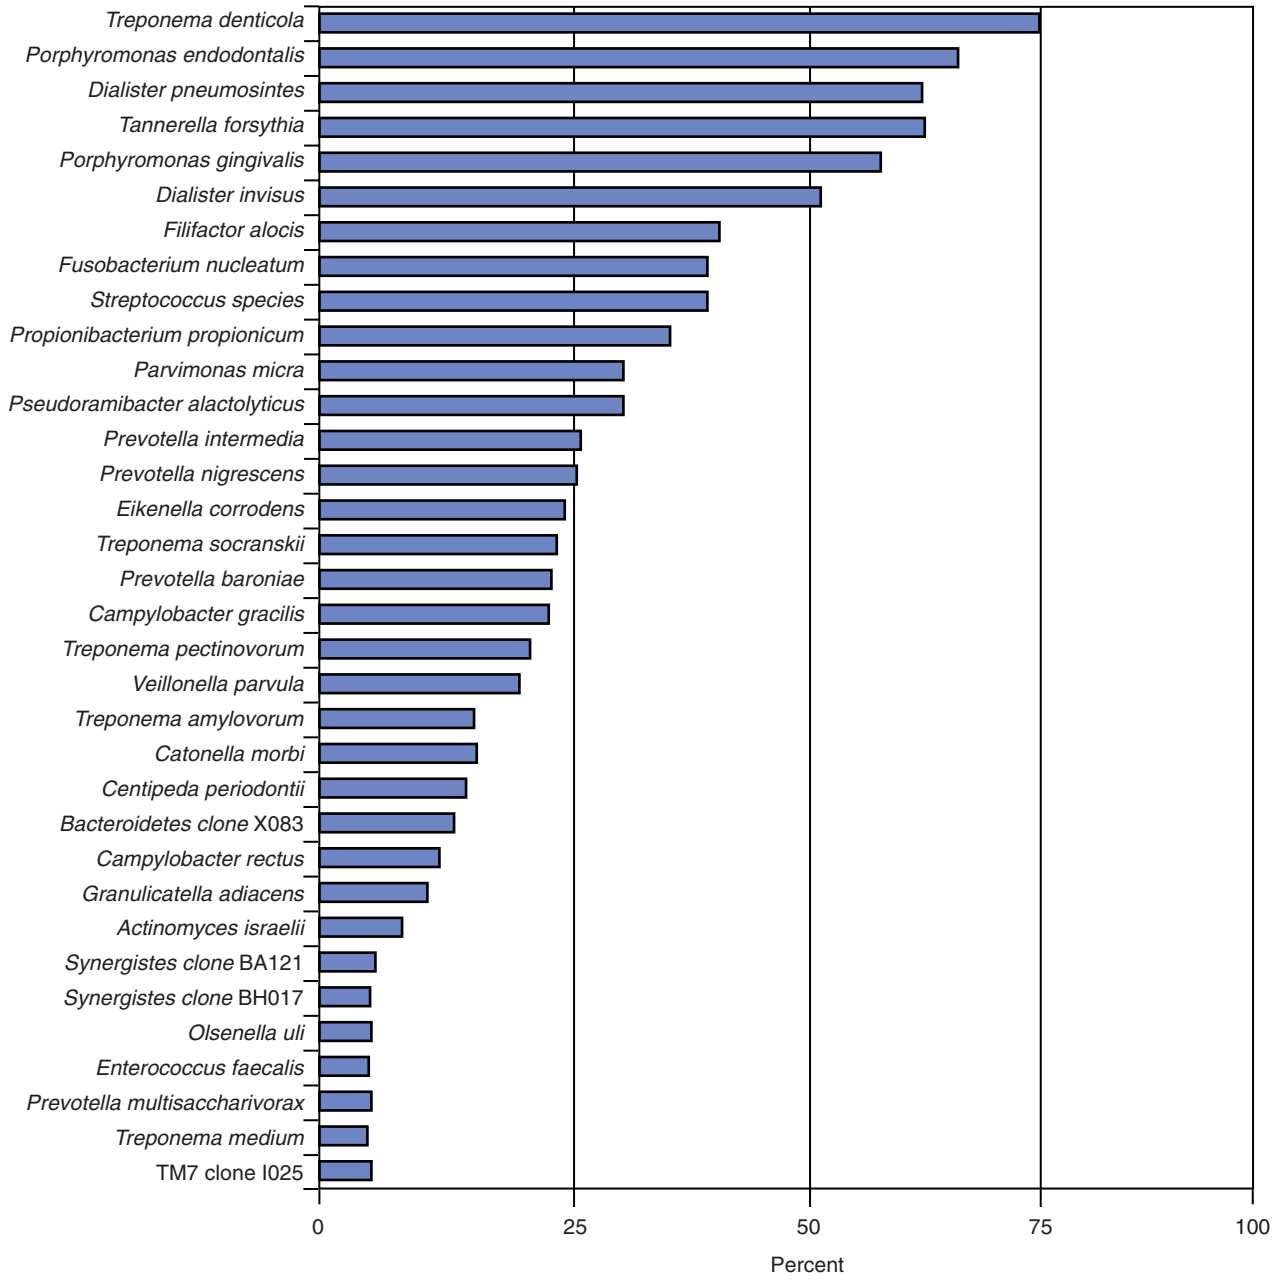

FIG. 15-14 Prevalence of bacteria detected in primary infections of teeth with acute apical abscesses. Data from the authors' studies using a taxon-specific nested-polymerase chain reaction protocol. *(From references 207, 211, 250, and 253.)*

Bacterial cells from endodontic biofilms are very often seen penetrating the dentinal tubules (Fig. 15-21). The diameter of dentinal tubules is large enough to permit penetration of most oral bacteria. It has been reported that dentinal tubule infection can occur in about 70% to 80% of the teeth evincing apical periodontitis lesions.[149,193] A shallow penetration is more common; bacterial cells can be observed reaching approximately 300 µm in some teeth[257] (Fig. 15-22). Dividing cells can be frequently observed within tubules in in situ investigations[257] (see Fig. 15-22), indicating that bacteria can derive nutrients within tubules, probably from degrading odontoblastic processes, denatured collagen, bacterial cells that die during the course of infection, and intracanal fluids that enter the tubules by capillarity.

Several putative endodontic pathogens have been shown to be capable of penetrating dentinal tubules in vitro, including *Porphyromonas endodontalis, Porphyromonas gingivalis, Fusobacterium nucleatum, Actinomyces israelii, Propionibacterium acnes, Enterococcus faecalis, Candida albicans,* and streptococci.[142,191,239,258,310] In their clinical study, Peters et al.[193] isolated and identified bacteria present in root dentin at different depths, and the most common isolates belonged to the genera *Prevotella, Porphyromonas, Fusobacterium, Veillonella, Peptostreptococcus, Eubacterium, Actinomyces,* lactobacilli, and strep-

FIG. 15-15 Acute apical abscess. The infection has spread to other anatomic spaces to form cellulitis.

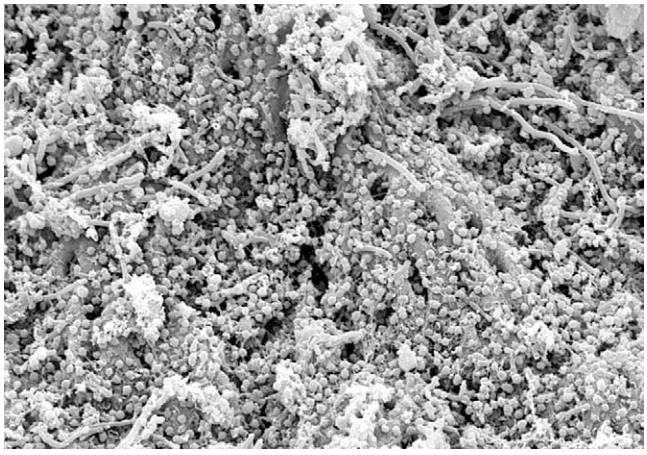

FIG. 15-16 Mixed bacterial population colonizing the root canal wall. Cocci are the predominant forms, but rods, filaments, and spirochetes are also observed. In some areas, coccoid cells are relatively apart from each other (×2200). *(From Siqueira JF Jr, Rôças IN, Lopes HP: Patterns of microbial colonization in primary root canal infections.* Oral Surg Oral Med Oral Pathol Oral Radiol Endod *93:174, 2002.)*

tococci. Using immunohistologic analysis, Matsuo et al.[149] observed the intratubular occurrence of *F. nucleatum, Pseudoramibacter alactolyticus, Eubacterium nodatum, Lactobacillus casei,* and *Parvimonas micra* inside dentinal tubules from the canal walls of extracted infected teeth with apical periodontitis.

Whereas bacteria present as planktonic cells in the main root canal may be easily accessed and eliminated by instruments and substances used during treatment, those organized in biofilms attached to the canal walls or located into isthmuses, lateral canals, and dentinal tubules are definitely more difficult to reach and may require special therapeutic strategies to be eradicated.

A daughter cell is growing on the surface of the mother cell *(insets)* (insets: bottom ×2700, top ×3500). *(From Siqueira JF Jr, Sen BH: Fungi in endodontic infections.* Oral Surg Oral Med Oral Pathol Oral Radiol Endod *97:632, 2004.)*

Microbial Ecology and the Root Canal Ecosystem

A root canal with necrotic pulp provides a space for bacterial colonization and affords bacteria a moist, warm, nutritious, and anaerobic environment, which is by and large protected from the host defenses because of lack of active blood circulation in the necrotic pulp tissue. Also, the root canal walls are nonshedding surfaces conducive to persistent colonization and formation of complex communities. The necrotic root canal might be considered a fertile environment for bacterial growth, and colonization not a difficult task for virtually all oral bacterial species. Although a large number of bacterial species (about 100 to 200) can be found in the oral cavity of a particular individual,[187] only a limited assortment of these species (about 10 to 40) is consistently selected out for growth and survival within a root canal containing necrotic pulp tissue from the same individual. This indicates that ecological determinants operate in the necrotic canal and dictate which species will succeed in colonizing this previously sterile environment. The major ecological factors that determine the composition of the root canal microbiota include oxygen tension, type and amount of available nutrients, and bacterial interactions. Other factors such as temperature, pH, and receptors for adhesins may also be involved.

The root canal infection is a dynamic process, and different bacterial species apparently dominate at different stages. Shifts in the composition of the microbiota are largely due to changes in environmental conditions, particularly in regard to oxygen tension and nutrient availability. In the very initial phases of the pulpal infectious process, facultative bacteria predominate.[63] After a few days or weeks, oxygen is depleted within the root canal as a result of pulp necrosis and consumption by facultative bacteria. Further oxygen supply is interrupted with loss of blood circulation in the necrotic pulp. An anaerobic milieu develops and is highly conducive to survival and growth of obligate anaerobic bacteria. With the passage of time, anaer-

obic conditions become even more pronounced, particularly in the apical third of the root canal; as a consequence, anaerobes will dominate the microbiota, outnumbering facultative bacteria (Fig. 15-23).

The main sources of nutrients for bacteria colonizing the root canal system include: (1) the necrotic pulp tissue; (2) proteins and glycoproteins from tissue fluids and exudate that seep into the root canal system via apical and lateral foramens; (3) components of saliva that may coronally penetrate into the root canal; and (4) products of the metabolism of other bacteria. Because the largest amount of nutrients is available in the main canal, the most voluminous part of the root canal system, most of the infecting microbiota (particularly fastidious anaerobic species) is expected to be located in this region. Bacterial species that can best utilize and compete for nutrients in the root canal system will succeed in colonization.

In addition to being influenced by variations in oxygen levels, shifts in the microbiota colonizing the root canal system can also be dependent upon the dynamics of nutrient utilization. Saccharolytic species dominate the very early stages of the infectious process but are soon outnumbered by asaccharolytic species, which will dominate later stages.[289] Even though the necrotic pulp tissue can be regarded as a finite source of nutrients to bacteria, given the small volume of tissue that is gradually degraded, induction of periradicular inflammation guarantees a sustainable source of nutrients, particularly in the form of proteins and glycoproteins present in the exudate that seep into the canal. At this stage of the infectious process, bacteria that have a proteolytic capacity or establish a cooperative interaction with those that can utilize this substrate in the metabolism start to dominate. Therefore, as the infectious process reaches the stage of induction of periradicular inflammation, proteins become the principal nutrient source, particularly in the apical part of the canal, favoring the establishment of anaerobic species that utilize peptides and/or amino acids in their metabolism (see Fig. 15-23).

Because primary endodontic infections are usually characterized by mixed communities, different bacterial species are in close proximity with one another, and interactions become inevitable. Thus, establishment of certain species in the root canal is also influenced by interactions with other species. In this regard, early colonizers play an important role in dictating which species will live along with them in the community. Bacterial interactions can be positive or negative. Positive interactions enhance the survival capacity of the interacting bacteria and enable different species to coexist in habitats where neither could exist alone. For instance, interbacterial nutritional interactions are important ecological determinants that result in higher metabolic efficiency of the whole community. Nutritional interactions are mainly represented by food webs, including utilization of metabolic end products from one species by another and bacterial cooperation for the

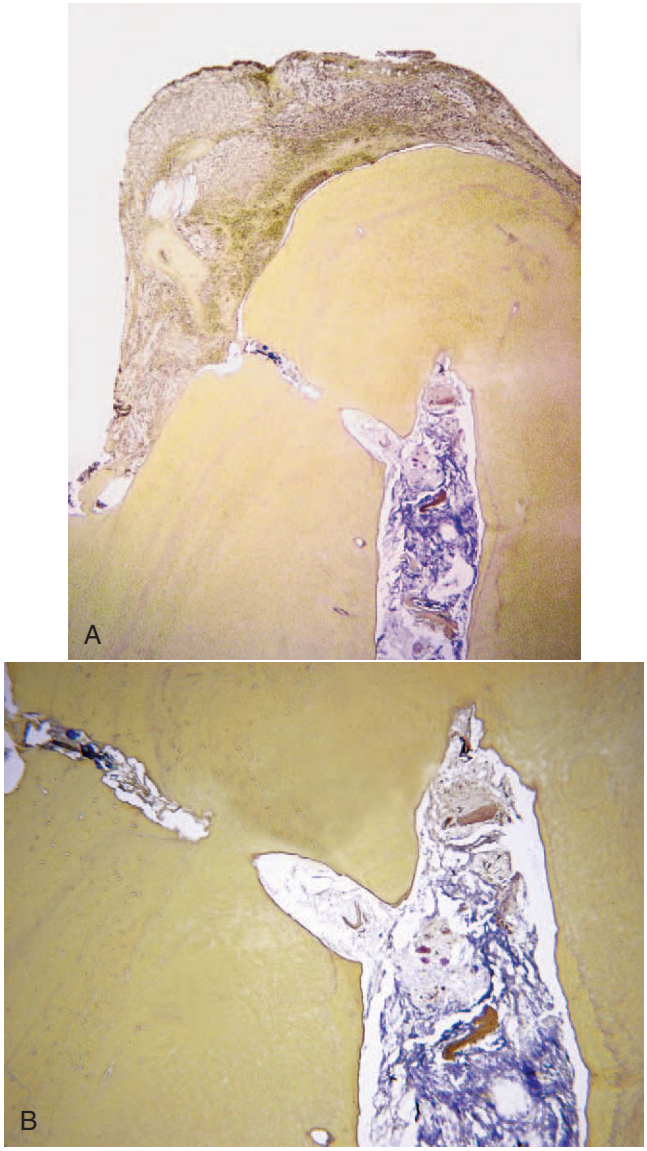

FIG. 15-19 A, Bacterial biofilm in the necrotic canal and in an apical ramification contiguous to inflamed periradicular tissues (×25). **B,** Higher magnification of **A** (×100). Sections stained with a Taylor-modified Brown and Brenn technique. *(Courtesy Dr. Domenico Ricucci.)*

breakdown of complex host-derived substrates. Fig. 15-24 displays a complex array of interbacterial nutritional interactions that can take place in infected root canals, where the growth of some species can be dependent upon products of metabolism of other species. Moreover, one species can provide growth conditions favorable to another—for example, by reducing oxygen tension in the environment and favoring the establishment of anaerobes, or by releasing some proteinases that can provide protection from host defenses. Negative interactions in turn act as feedback mechanisms that limit population densities. Examples include competition (for nutrients and space) and amensalism (when one species produces a substance that inhibits another species).

Many species adhere directly to host surfaces, other species adhere to bacteria already attached to the surface. The latter is called *coaggregation* and is a highly specific phenomenon with regard to the partners involved.[117] Coaggregations differ from aggregations and agglutinations in that the latter two interactions occur between genetically identical cells.[118] A given pair of species can attach to each other by means of specific receptor-adhesin interactions, which are usually lectinlike interactions (attachment of a specific protein on the surface of one species to a specific carbohydrate on the surface of the other). Coaggregation can favor colonization of host surfaces and also facilitate metabolic interactions between the partners. Coaggregation has been demonstrated for several pairs of bacterial taxa found in endodontic infections.[114]

Other Microorganisms in Endodontic Infections

Fungi

Fungi are eukaryotic microorganisms that may colonize the oral cavity, especially *Candida* species, but they have been only occasionally detected in primary intraradicular infections.[60,126,159,259] One molecular study[16] has reported the occurrence of *C. albicans* in 21% of samples from primarily infected canals.

Archaea

Archaea comprise a highly diverse group of prokaryotes distinct from bacteria. Members of this domain have been traditionally recognized as extremophiles, but some of these microorganisms have also been found to flourish in nonextreme environments, including the human body.[59] To date, no member of the *Archaea* domain has been described as a human pathogen. Although one study failed to detect archaea in samples from primary endodontic infections,[254] other studies detected a *Methanobrevibacter oralis*–like phylotype in some primarily infected canals.[305,307]

Viruses

Viruses are not cells but inanimate particles composed of a nucleic acid molecule (DNA or RNA) and a protein coat. On their own, they have no metabolism and need to infect living cells to use the cell's machinery to replicate the viral genome. Because viruses require viable host cells to infect and replicate themselves, they cannot thrive in the root canal with necrotic pulp. Viruses have been reported to occur in the root canal only in noninflamed vital pulps of patients infected with the human immunodeficiency virus.[78] Human cytomegalovirus (HCMV) and Epstein-Barr virus (EBV) have been detected in apical periodontitis lesions,[215] where living host cells are present. It has been hypothesized that HCMV and EBV may be implicated in the pathogenesis of apical periodontitis as a direct result of virus infection and replication or as a result of virally induced impairment of local host defenses, which might give rise to overgrowth of pathogenic bacteria in the very apical part of the root canal.[273] Bacterial challenge emanating from the canals may cause an influx of virus-infected cells into the periradicular tissues. Reactivation of HCMV and/or EBV by tissue injury induced by bacteria may evoke impairment of host immune response in the periradicular microenvironment, changing the potential of local defense cells to mount an adequate response against infectious agents. Herpesvirus-infected inflammatory cells are stimulated to release proinflammatory

cytokines,[157,313] and evidence of HCMV and/or EBV infection has been more frequently observed in symptomatic apical periodontitis lesions,[214,216] large lesions,[215,216] and lesions from HIV-positive patients.[217] However, the role of herpesviruses in the pathogenesis of apical periodontitis has still to be elucidated.

PERSISTENT/SECONDARY ENDODONTIC INFECTIONS

As defined earlier in this chapter, persistent intraradicular infections are caused by microorganisms that resisted intracanal antimicrobial procedures and survived in the treated canal. Involved microorganisms are remnants of a primary or secondary infection. The latter in turn is caused by microorganisms that at some time entered the root canal system secondary to professional intervention. The moment can be during treatment, between appointments, or even after root canal filling. In any circumstance, if penetrating microorganisms manage to adapt themselves to the new environment, surviving and flourishing, a secondary infection is established. Species involved can be oral microorganisms or not, depending on the source of secondary infection.

Persistent and secondary infections are for the most part clinically indistinguishable. Exceptions include infectious complications (such as an apical abscess) arising after the treatment of noninfected vital pulps or cases in which apical periodontitis was absent at the time of treatment but present on the follow-up radiograph. Both situations are typical examples of secondary infections. Both persistent and secondary infections can be responsible for several clinical problems, including persistent exudation, persistent symptoms, interappointment flare-ups, and failure of the endodontic treatment, characterized by a posttreatment apical periodontitis lesion.

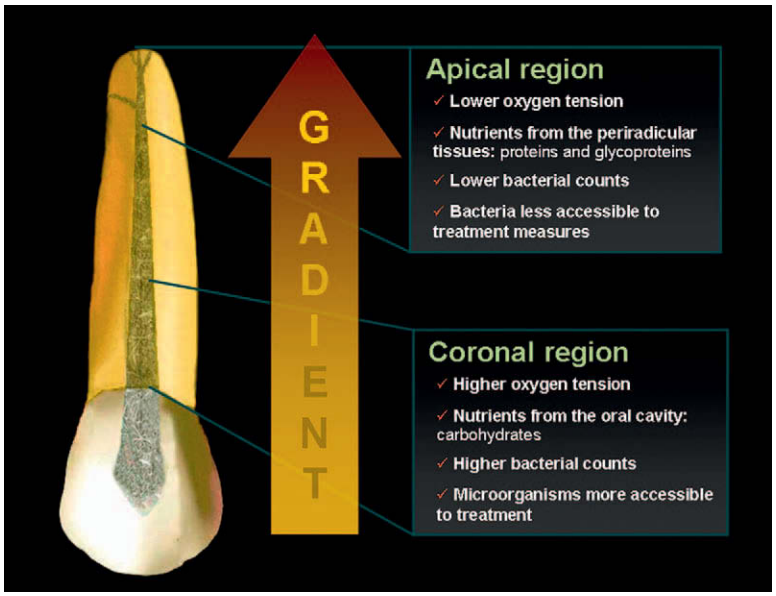

FIG. 15-23 Ecological conditions in different areas of the root canal. A gradient of oxygen tension and nutrients (type and availability) is formed. Consequently, the microbiota residing in different parts can also differ in diversity, density, and accessibility to treatment procedures.

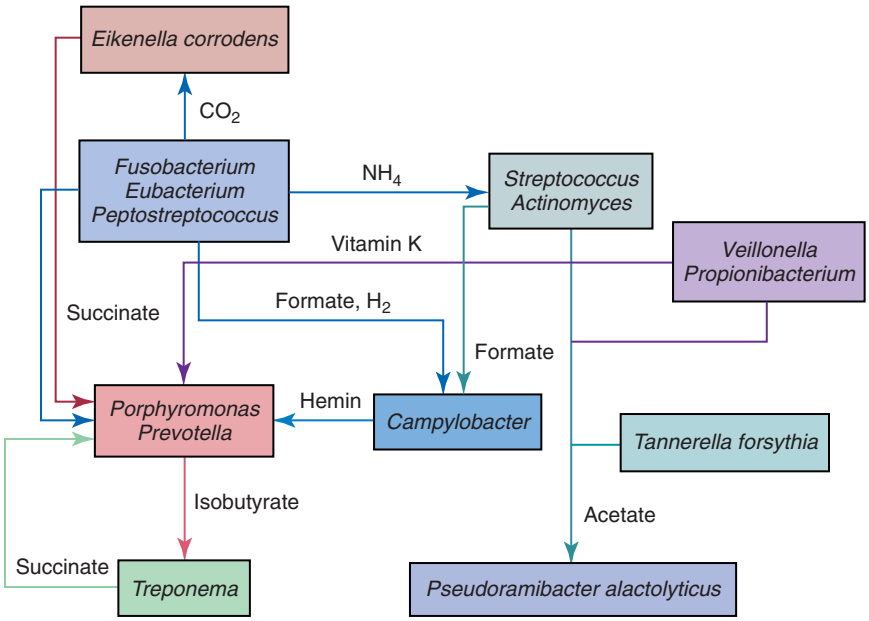

FIG. 15-24 Interbacterial nutritional interactions that can take place in infected root canals where growth of some species can be dependent upon products of metabolism of other species.

Secondary/Persistent Infections and Treatment Failure

Persistent or secondary intraradicular infections are the major causes of endodontic treatment failure (Fig. 15-25). This statement is supported by two strong evidence-based arguments. First, it has been demonstrated that there is an increased risk of adverse treatment outcome when bacteria are present in the canal at the time of filling.[64,267,308] Second, most (if not all) root canal–treated teeth evincing persistent apical periodontitis lesions have been demonstrated to harbor an intraradicular infection.* Based on these arguments, studies investigating bacteria remaining in the root canals at the filling stage serve the purpose of disclosing species that have the potential to influence the treatment outcome (*outcome into perspective*). On the other hand, studies dealing with the microbiota of root canal–treated teeth evincing apical periodontitis serve to show the association of species with treatment failure, since the microorganisms detected are likely to be participating in the etiology of persistent disease (*outcome already established*).

*References 134, 135, 197, 206, 221, 252, and 290.

Bacteria at the Root Canal–Filling Stage

Diligent antimicrobial treatment may still fail to completely eliminate bacteria from the infected root canal system. This is because persisting bacteria are either resistant or inaccessible to treatment procedures. Whatever the cause of persistence, bacterial diversity and density are substantially reduced after treatment. Root canal samples positive for bacterial growth after chemomechanical procedures followed or not by intracanal medication have been shown to harbor 1 to 5 bacterial

FIG. 15-25 Posttreatment apical periodontitis lesions in root canal–treated teeth. In poorly treated canals, the microbiota is similar to primary infections. In cases apparently well treated, fewer species are found. Regardless of treatment quality, persistent or secondary intraradicular infections are the main causative agents of endodontic treatment failure.

species per case, and the number of bacterial cells usually varies from 10^2 to 10^5 per sample.*

No single species has been significantly found to persist after treatment procedures. Gram-negative bacteria, which are common members of primary infections, are usually eliminated. Exceptions include some anaerobic rods, such as *F. nucleatum, Prevotella* species, and *Campylobacter rectus,* which are among the species found in postinstrumentation or postmedication samples.† Most studies on this subject have clearly revealed that when bacteria resist treatment procedures, gram-positive bacteria are more frequently present. Gram-positive facultatives or anaerobes often detected in these samples include streptococci, *P. micra, Actinomyces* species, *Propionibacterium* species, *P. alactolyticus,* lactobacilli, *E. faecalis,* and *Olsenella uli.*‡ This gives support to the notion that gram-positive bacteria can be more resistant to antimicrobial treatment measures and have the ability to adapt to the harsh environmental conditions in instrumented and medicated root canals. About 40% of the taxa found in posttreatment samples are as-yet-uncultivated bacteria,[220] indicating that along with other reasons (such as inaccessibility to sampling or low bacterial levels), attainment of negative cultures after treatment procedures does not necessarily imply sterility.

Bacteria persisting in the root canal after chemomechanical procedures or intracanal medication will not always maintain an infectious process. This statement is supported by evidence that some apical periodontitis lesions healed even after bacteria were found in the canal at the filling stage.[64,267] There are some possible explanations:

- Residual bacteria may die after filling because of toxic effects of the filling material, access denied to nutrients, or disruption of bacterial ecology.
- Residual bacteria may be present in quantities and virulence subcritical to sustaining periradicular inflammation.
- Residual bacteria remain in locations where access to periradicular tissues is denied.

Bacteria that resist intracanal procedures and are present in the canal at the time of filling can influence the outcome of the endodontic treatment provided they:

- Have the ability to withstand periods of nutrient scarcity, scavenging for low traces of nutrients and/or assuming a dormant state or a state of low metabolic activity, to prosper again when the nutrient source is reestablished
- Resist treatment-induced disturbances in the ecology of the bacterial community, including disruption of quorum-sensing systems, food webs, genetic exchanges, and disorganization of protective biofilm structures
- Reach a critical population density (load) necessary to inflict damage to the host
- Have unrestrained access to the periradicular tissues through apical/lateral foramina or iatrogenic root perforations
- Possess virulence attributes that are expressed in the modified environment and reach concentrations adequate to directly or indirectly induce damage to the periradicular tissues

In this context, it should not be forgotten that host resistance to infection is also an important and probably decisive counteracting factor.

Microbiota in Root Canal–Treated Teeth

The microbiota in root canal–treated teeth with apical periodontitis also exhibits decreased diversity in comparison to primary infections. Canals apparently well treated harbor one to five species, but the number of species in canals with inadequate treatment can reach up to 10 to 30 species, which is very similar to untreated canals (see Fig. 15-25).[197,209,221,252,290] The number of bacterial cells in treated teeth varies from 10^3 to 10^7 per canal.[190,225]

Several culture and molecular biology studies have revealed that *E. faecalis* is the most frequent species in root canal–treated teeth, with prevalence values reaching up to 90% of cases* (Fig. 15-26). Root canal–treated teeth are about nine times more likely to harbor *E. faecalis* than cases of primary infections.[211] This suggests that this species can be inhibited by other members of a mixed bacterial consortium commonly present in primary infections, and that the bleak environmental conditions within filled root canals do not prevent its survival. The fact that *E. faecalis* has been commonly recovered from cases treated in multiple visits and/or in teeth left open for drainage[266] suggests that this species may be a secondary invader that succeeds in colonizing the canal, resists treatment, and causes a secondary infection that then becomes persistent.

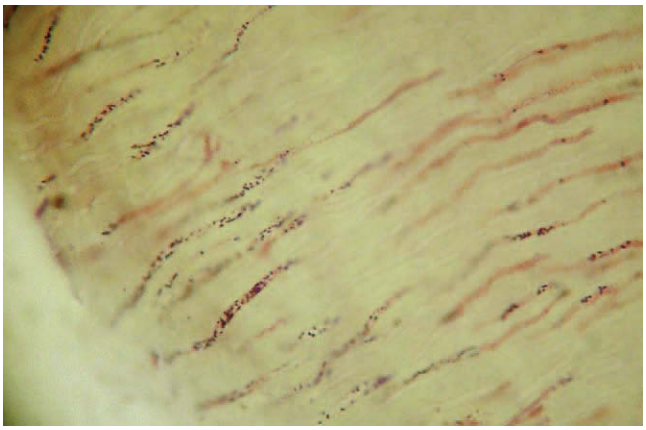

FIG. 15-27 Dentinal tubule infection by *Enterococcus faecalis* in dog's teeth after experimental infection. Notice that cells invaded the entire extent of some tubules up to the cementum (Brown and Brenn staining, ×1000).

For a given microorganism to survive in treated canals, it has to resist intracanal disinfection procedures and adapt to the harsh environmental conditions caused by treatment. The ability of *E. faecalis* to penetrate dentinal tubules, sometimes to a deep extent[88,239] (Fig. 15-27), can enable it to escape the action of endodontic instruments and irrigants used during chemomechanical preparation.[88,238] Moreover, its ability to form biofilms in root canals can be important for its resistance to and persistence after intracanal antimicrobial procedures.[53] *Enterococcus faecalis* is also resistant to calcium hydroxide[32]; such an ability to resist high pH values seems to be related to a functioning proton pump that drives protons into the cell to acidify the cytoplasm.[62] Unlike most putative endodontic pathogens frequently found in primary infections, *E. faecalis* may colonize root canals in single infections,[290] and such relative independence of living without deriving nutrients from other bacteria can be extremely important for its establishment in treated root canals. Finally, environmental cues can regulate gene expression in *E. faecalis,* affording this bacterium the ability to adapt to varying (and adverse) conditions.[107] Indeed, *E. faecalis* can enter a so-called viable but non-cultivable (VBNC) state,[136] which is a survival mechanism adopted by several bacteria when exposed to unfavorable environmental conditions.[137] In VBNC state, bacteria lose the ability to grow in culture media but maintain viability and pathogenicity and sometimes can resume division when optimal environmental conditions are restored. Studies have demonstrated that *E. faecalis* has the ability to survive in environments with scarcity of nutrients and then flourish when the nutrient source is reestablished.[66] It also has the capacity to recover from a prolonged starvation state in obturated canals,[226] suggesting that viable cells of this species entombed at the time of root filling may provide a long-term nidus for subsequent infection.

Taken together, all these properties help explain the significantly high prevalence of *E. faecalis* in root canal–treated teeth. Although association of this species with posttreatment disease is suggested by epidemiologic studies and supported by the species attributes that allow it to survive under unfavorable environmental conditions, causation is not proven. In fact, the status of *E. faecalis* as the main causative agent of endodontic failures has been questioned by the following findings from studies carried out in independent laboratories:

- Despite being easily cultivated, *E. faecalis* is not detected in all studies evaluating the microbiota of root canal–treated teeth with posttreatment disease.[39,213]
- Even when present, *E. faecalis* is rarely one of the most dominant species in retreatment cases.[205,209,221]
- *E. faecalis* has been found not to be more prevalent in root canal–treated teeth with lesions when compared to treated teeth with no lesions.[111,324]

Other bacteria found in root canal–treated teeth with apical periodontitis include streptococci and some fastidious anaerobic bacterial species: *P. alactolyticus, Propionibacterium propionicum, Filifactor alocis, Dialister pneumosintes, Dialister invisus, Tannerella forsythia, P. micra, Prevotella intermedia,* and *Treponema denticola** (Fig. 15-28). Uncultivated phylotypes correspond to 55% of the taxa detected in treated canals, and collectively they can also be in high proportions, corresponding to about half of the 16S rRNA gene sequences retrieved in clone libraries.[221] Some still uncultivated phylotypes, such as *Bacteroidetes* clone X083 and *Synergistes* clone BA121, can be among the most prevalent taxa in treated canals[205,221] (see Fig. 15-28). As-yet-uncultivated bacteria can also dominate the community, helping explain why culture studies failed to detect bacteria in some treated root canals.

The bacterial community profiles in treated cases vary from individual to individual, indicating that distinct bacterial combinations can play a role in treatment failure.[209,221] All these findings strongly suggest that the microbiota of root canal–treated teeth with apical periodontitis is more complex than previously anticipated by culture studies.

Fungi are only occasionally found in primary infections, but *Candida* species have been detected in root canal–treated teeth in up to 18% of the cases.† Fungi gain access to root canals via contamination during endodontic therapy (secondary infection) or they overgrow after inefficient intracanal antimicrobial procedures that cause an imbalance in the primary endodontic microbiota.[264] *Candida albicans* is by far the most commonly detected fungal species in root canal–treated teeth. This species has several properties that can be involved in persistence following treatment, including its ability to colonize and invade dentin[228,229,258] and resistance to calcium hydroxide.[309,311]

EXTRARADICULAR INFECTIONS

Apical periodontitis lesions are formed in response to intraradicular infection and by and large constitute an effective barrier against spread of the infection to the alveolar bone and other body sites. In most situations, apical periodontitis inflammatory lesions succeed in preventing microorganisms from invading the periradicular tissues. Nevertheless, in some specific circumstances, microorganisms can overcome this defense barrier and establish an extraradicular infection. The most common form of extraradicular infection is the acute apical abscess, characterized by purulent inflammation in the periradicular tissues in response to a massive egress of virulent

*References 82, 158, 197, 205, 209, 221, 252, 253, and 290.

†References 39, 60, 158, 159, 190, 197, 252, and 290.

bacteria from the root canal. There is, however, another form of extraradicular infection which, unlike the acute abscess, is usually characterized by absence of overt symptoms. This condition entails the establishment of microorganisms in the periradicular tissues, either by adherence to the apical external root surface in the form of biofilm structures[169,297] or by formation of cohesive actinomycotic colonies within the body of the inflammatory lesion.[92] These extraradicular microorganisms have been discussed as one of the etiologies of persistence of apical periodontitis lesions in spite of diligent root canal treatment.[234,299]

Certain situations permit intraradicular bacteria to reach the periradicular tissues and establish an extraradicular infection.[235] Some may be:

- A result of direct advance of some bacterial species that overcome host defenses concentrated near or beyond the apical foramen, an extension of the intraradicular infectious process, or penetration into the lumen of pocket (bay) cysts which are in direct communication with the apical foramen. The borderline between the infecting endodontic microbiota and the host defenses is often located intraradicularly, short of or at the apical foramen. In some cases, however, microorganisms may reach the periradicular tissues, and the borderline is then situated extraradicularly, beyond the boundaries of the apical foramen (Fig. 15-29). In the latter situation, the whole infectious process would be a continuum composed of an intraradicular and an extraradicular segment, in which the former fosters the latter (see Fig. 15-29). It has been suggested that in some cases, the extraradicular segment becomes independent of the intraradicular component of the infectious process.
- Due to bacterial persistence in the apical periodontitis lesion after remission of acute apical abscesses. The acute apical abscess is for the most part clearly dependent on the intraradicular infection; once the intraradicular infection is properly controlled by root canal treatment or tooth extraction and drainage of pus is achieved, the extraradicular infection is handled by the host defenses and usually subsides. Nonetheless, it should be appreciated that in some rare cases, bacteria that have participated in acute apical abscesses may persist in the periradicular tissues following resolution of the acute response and establish a persistent extraradicular infection associated with chronic periradicular inflammation, usually associated with an actively draining sinus tract.
- A sequel to apical extrusion of debris during root canal instrumentation (particularly after overinstrumentation). Bacteria embedded in dentinal chips can be physically protected from the host defense cells and therefore can persist in the periradicular tissues and sustain periradicular inflammation. The virulence and quantity of the involved bacteria, as well as the host's ability to deal with infection, will be decisive factors dictating whether an extraradicular infection will develop or not.

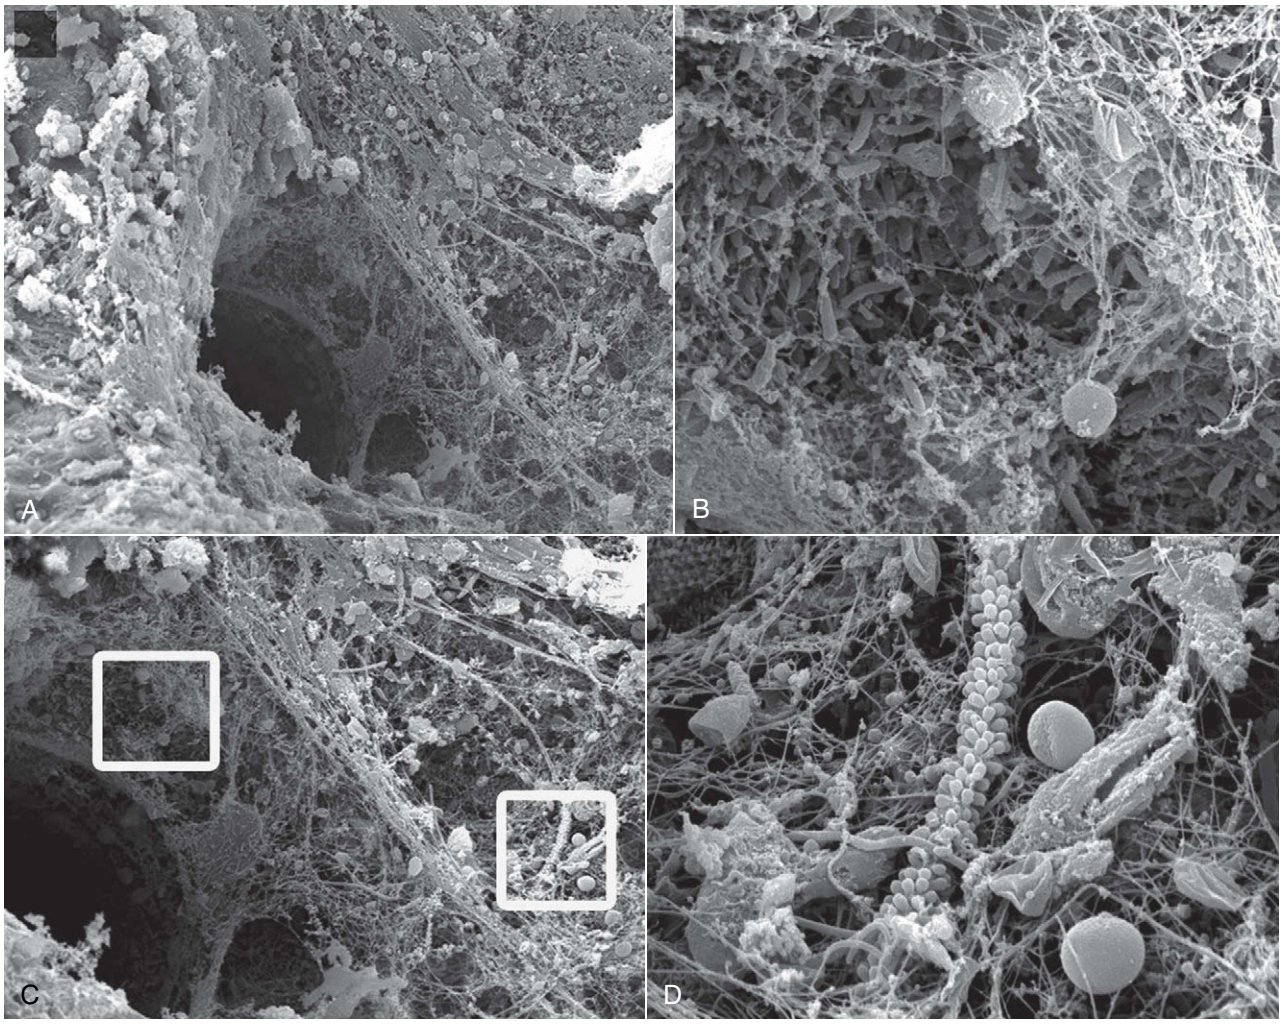

FIG. 15-29 Scanning electron micrograph showing extensive bacterial colonization in the very apical part of the canal, near and at the apical foramen (**A-B,** ×550 and ×850, respectively). **C,** Higher magnification of *left inset* in **B** showing a bacterial biofilm adhered to the very apical canal walls (×3700). **D,** Higher magnification of *right inset* in **B** showing a fully developed "corn cob" in tissue meshwork adjacent to the apical foramen (×4000). *(Modified from Siqueira JF Jr, Lopes HP: Bacteria on the apical root surfaces of untreated teeth with periradicular lesions: a scanning electron microscopy study.* Int Endod J *34:216, 2001.)*

Conceivably, the extraradicular infection can be dependent on or independent of the intraradicular infection.[234] The acute apical abscess is the main example of dependent extraradicular infection. Independent extraradicular infections would be those that are no longer fostered by the intraradicular infection and can persist even after successful eradication of the latter. So far, it has been suggested that the main bacterial species implicated in independent extraradicular infections are *Actinomyces* species and *P. propionicum,* in a pathologic entity named *apical* (or periapical, periradicular) *actinomycosis*[33,92,270,291] (Fig. 15-30). These bacteria form cohesive colonies that may be collectively resistant to phagocytosis.[65] Existence of apical actinomycosis as a self-sustained pathologic entity, no longer nurtured by the intraradicular infection, and its involvement as an exclusive cause of treatment failure is speculative and remains to be proven.[202,247]

Except for apical actinomycosis and cases evincing sinus tracts, it is still controversial whether chronic apical periodontitis lesions can harbor bacteria for very long beyond initial tissue invasion.[11] Studies using culture-dependent[283,298,315] or culture-independent molecular biology methods, such as checkerboard hybridization[76,285] and FISH,[284] have reported the extraradicular occurrence of a complex microbiota associated with apical periodontitis lesions that do not respond favorably to the root canal treatment. Anaerobic bacteria have been reported to be the dominant microorganisms in several of those lesions.[283,285] Apart from a discussion about whether contamination can be effectively prevented during surgical sampling of periradicular lesions, these studies did not evaluate the bacteriologic conditions of the apical part of the root canal. This makes it difficult to ascertain whether extraradicular infections were dependent on or independent of an intraradicular infection.

The incidence of extraradicular infections in untreated teeth is conceivably low,[167,243] which is congruent with the high success rate of nonsurgical root canal treatment.[269] Even in root canal–treated teeth with recalcitrant lesions in which a higher incidence of extraradicular bacteria has been reported,

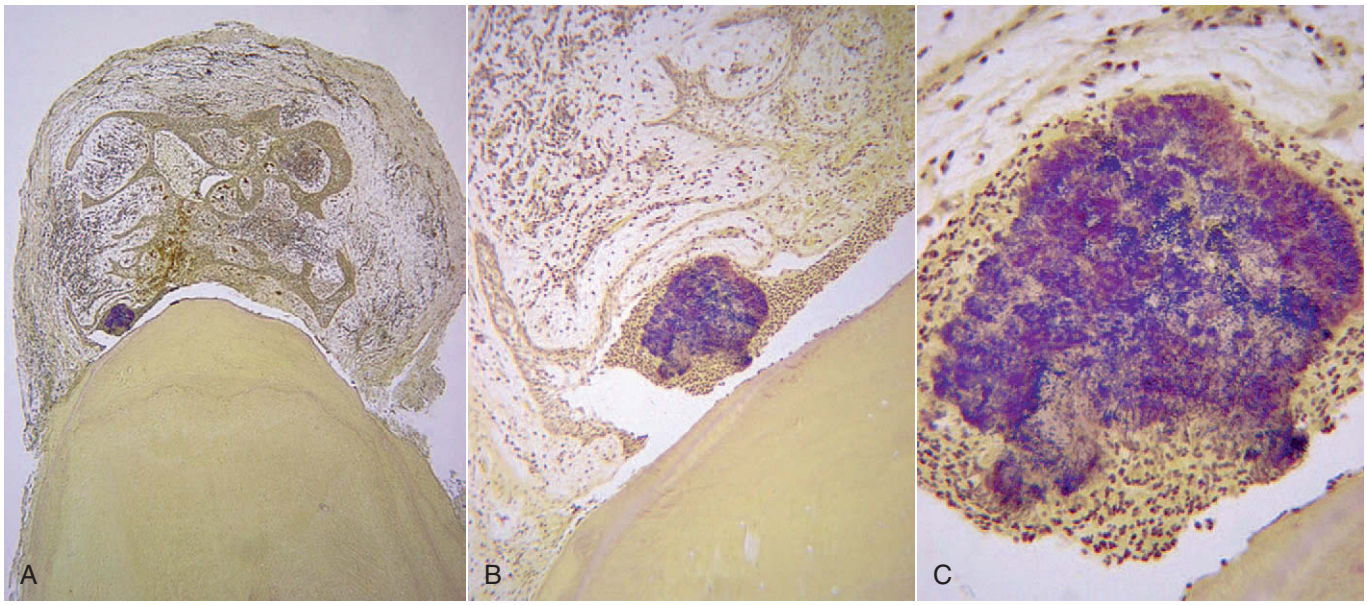

FIG. 15-30 Bacterial aggregate in an epithelialized periradicular lesion, suggestive of actinomycosis. This case presented a severe flare-up in the past, but the tooth was asymptomatic at the time of extraction. **A,** Section not passing through the canal; note cyst cavity and bacterial aggregation on the *left* (×25). **B,** Detail of area with colony (×100). **C,** Higher magnification of colony, which is surrounded by neutrophils (×400). a high rate of healing following retreatment[269] indicates that the major cause of posttreatment disease is located within the root canal system, characterizing a persistent or secondary intraradicular infection. This has been confirmed by studies investigating the microbiologic conditions of root canals associated with persistent apical periodontitis.[158,197,209,252,290] Based on such data, it is reasonable to assume that most extraradicular infections observed in association with root canal–treated teeth must have been fostered by an intraradicular infection.

THE FOCAL INFECTION THEORY

Focal infection consists of an infectious disorder caused by microorganisms or their products that have disseminated from a distant body site (focus of infection).[179] Microorganisms from an infected oral site might spontaneously or after dental procedures gain entry into the blood circulation and cause disease in remote sites. The relationship of oral infections and systemic diseases is not a new issue; in 400 BC, Hippocrates reported that a patient was cured of arthritis after tooth extraction.

In a paper published in 1891, Miller described several human diseases, including non-oral diseases, which had been traced to the action of oral microorganisms.[154] He did not necessarily recommend extracting teeth considered to be a focus of infection, and indeed suggested treatment of infected root canals. Conservative dentistry suffered a severe attack at the beginning of the 20th century, after spread of the concept of oral sepsis into the medical literature by the English physician William Hunter in 1900.[103] Hunter believed that oral sepsis was responsible for several infectious diseases in the body, including osteomyelitis, gastritis, middle-ear suppurations, tonsillitis, endocarditis, meningitis, nephritis, and other septic conditions.[104] In 1900, he wrote:

> *The more I study it [oral sepsis as a cause of medical diseases] the more impressed I am, at once with its importance, and with the extraordinary neglect with which it is treated alike by physicians and surgeons.… I confess I think it urgent, in the interests of the many sufferers from gastritis as well as in the interests of those suffering from pyogenic conditions generally, that some similar steps be taken with regard to the mouth—the chief channel of access, in my judgement, of all pyogenic infections.*[103]

In 1911, he stressed the oral sepsis concept still more emphatically and attacked American dentists:

> *It is an all-important matter of sepsis and antisepsis that concerns every branch of the medical profession, and concerns very closely the public health of the community.… My clinical experience satisfies me that if oral sepsis could be successfully excluded, the other channels by which medical sepsis gains entrance into the body might almost be ignored.… No one has probably had more reason than I have had to admire the sheer ingenuity and mechanical skill constantly displayed by the dental surgeon. Such are the fruits of this baneful so-called "conservative dentistry." … The title that would best describe the dentistry here referred to would be that of "septic dentistry." Conservative it is, but only in one sense. It conserves the sepsis which it produces by the gold work it places over and around the teeth, by the satisfaction which it gives the patient, by the pride which the dentist responsible for it feels in his "high-class American" work, and by his inability or unwillingness to recognise the septic effects which it produces.*[104]

As a result of the focal infection theory, the avoidance of conservative dentistry in favor of tooth extractions was what

followed in dentistry for years. Fortunately, improvements in dental treatment (including root canal therapy), accompanied by advances in epidemiologic and biologic research giving scientific support to treatment modalities, significantly contributed to rescuing the fate of the dental profession. In 1952, an editorial in the *Journal of the American Medical Association* heralded the apparent end of the focal infection theory as it was acknowledged at that time:

> *After exerting a tremendous influence on the practice of medicine for a generation, the theory of focal infection in the past 10 or 15 years has fallen in part into disfavor. This has been due partly to the following observations that seem to discredit it: 1) Many patients with diseases presumably caused by foci of infection have not been relieved of their symptoms by removal of the foci; 2) many patients with these same systemic diseases have no evident focus of infection; 3) foci of infection are, according to some statistical studies, as common in apparently healthy persons as in those with disease.*[274]

Nevertheless, the last 2 decades have witnessed a revived interest in the focal infection theory, thanks to reports from epidemiologic studies suggesting the involvement of oral microorganisms with systemic diseases.[150,292] Although a plethora of focal infections having the oral cavity as their suspected source have been described, the most documented examples are bacterial endocarditis,[22] brain abscess,[132] and orthopedic joint infections.[179] Oral bacteria have also been implicated in aspiration pneumonia,[224] preterm low birth weight,[170] and coronary heart disease.[18] Infected root canals and apical periodontitis lesions have long been suggested to be potential foci of infection. Once again the focal infection concept is knocking on our doors. Fortunately, this time it can be evaluated and discussed on a scientific basis and has to go through the scrutiny of scientific methods.

To cause a focal disease, bacteria must travel from the focus of infection to a distant body site. This occurs via bacteremia, a condition in which viable bacteria are present in the blood circulation. There is no evidence showing that bacteremia spontaneously arises from infected root canals associated with a chronic apical periodontitis lesion. On the other hand, bacteremia can occur in cases of acute apical abscesses and during the treatment of infected root canals or periradicular surgery.* It has been shown that it is far more probable that bacteremia occurs if root canal procedures are performed beyond the apical foramen than when maintained within the root canal.[21] Bender et al.[21] reported that the incidence of bacteremia was zero if the instrumentation remained within the canal and 15% if it extended beyond the apical foramen. Even so, the bacteremia following endodontic procedures was demonstrated to last no longer than 10 minutes, as a result of competent clearance of bacteria from within the circulation. Using improved anaerobic cultivation methods, Baumgartner et al.[12,13] revealed that nonsurgical root canal treatment resulted in a lower incidence of bacteremia (3%, as a result of overinstrumentation) than surgical flap reflection (83%), periradicular curettage (33%), or tooth extraction (100%). In a study that performed intentional instrumentation beyond the apex, a 34% to 54% incidence of bacteremia was reported.[108]

However, it has been demonstrated that bacteremia can occur even if instrumentation is maintained within the root canal system. Debelian et al.[49] investigated the incidence of bacteremia following endodontic treatment of teeth with apical periodontitis lesions. In the treatment of half of the patients, the first three reamers (sizes 15, 20, and 25) were used to a level 2 mm beyond the root apex, while in the other half, instrumentation ended inside the root canal, 1 mm short of the apex. Bacteremia was observed in 54% of the cases where instrumentation through the foramen occurred and in 31% of the cases where instrumentation was confined to the canals. No statistically significant difference was found when the frequency of bacteremias in the two groups was compared. This may be explained by the fact that all instrumentation techniques induce apical extrusion of debris, some more than others, even when instrumentation is confined to the interior of the canal.[4,102,140,201] If debris is infected, bacteria are propelled into the periradicular tissues and then can enter the circulation. In a study where instrumentation was accomplished short of the apical foramen and patency files were not utilized,[223] culture analysis revealed detectable bacteremia in 30% of the patients who had no positive preoperative control blood sample.

There is no doubt that root canal procedures can induce bacteremia. The questions now are at what magnitude (number of bacterial cells in the blood) bacteremia occurs, how long it persists, and whether endodontic bacteria can cause disease at distant sites. It is very difficult to prove that a given oral microorganism is the causative agent of a focal infection. Although it has been demonstrated that the microbial species present in the blood of patients undergoing root canal treatment are of the same clonal types as those present in their root canals,[48] such findings only mean root canal treatment can cause bacteremia, not that microorganisms from the root canal cause disease in remote sites of the body. For bacteria present in the bloodstream to reach other body sites and induce disease, they must (1) survive the host defenses in the blood vessels as well as in the distant anatomic site, (2) encounter predisposing conditions in the distant site for their attachment and further colonization, (3) reach sufficient numbers to induce disease, and (4) possess an array of virulence factors that can inflict direct or indirect damage to the host tissues.

Establishing a causal link between oral disease and disorders in remote parts of the body depends on some important factors. Perhaps one of the most important is determining whether the microorganism associated with the medical disorder is genotypically the same as the suspected oral microorganism. In addition, the onset of the medical disease should follow the onset of the oral disease. In cases where a dental procedure is suspected of causing bacteremia, the onset of the medical disease should be within the incubation period.[271]

It is apparent from well-conducted studies that oral bacteria are rarely a cause of systemic disease.[179] Periodontal pathogens seldom cause endocarditis, with about 100 reported cases due to *Aggregatibacter actinomycetemcomitans,* two due to *Prevotella oralis,* one due to *Prevotella bivia,* one due to black-pigmented anaerobic bacteria, and five due to *Veillonella* species.[175,189] Except for *A. actinomycetemcomitans,* which has been infrequently found in endodontic infections,[256] the other

*References 12, 13, 21, 50, 131, and 163.

species have been isolated from infected root canals or apical abscesses. Obligate anaerobic bacteria from the oral cavity do not appear to survive well in other body locations, and viridans group streptococci, considered the principal oral culprits in endocarditis, are not primary pathogens but rather opportunistic bacteria that usually require altered biologic tissues to induce disease.[175]

Culture-independent techniques for bacterial identification have revealed previously unsuspected degrees of diversity in the oral microbiota.[119,185] Since many oral (and endodontic) bacteria remain to be cultivated and then fully characterized, their pathogenicity and involvement in causation of disease have yet to be elucidated. A study using molecular technology revealed a large amount of bacterial DNA in blood specimens from healthy individuals,[168] and many of the DNA sequences detected were from uncultivated and unknown bacteria. The presence of bacterial DNA in the blood has important implications for a possible role of previously uncharacterized bacterial species in some diseases, sometimes distant from the focus of infection. It would appear that to date, no molecular study has been performed to detect the occurrence of uncultivated bacterial phylotypes from the oral cavity in bacteremias following endodontic procedures. In addition, no study has evaluated the presence of those phylotypes in remote diseases in the body. Therefore, future research is warranted to ascertain whether uncultivated bacteria from the oral cavity can be involved in focal diseases.

Although there is no definitive evidence that bacteria from infected root canals can cause systemic diseases after bacteremia, there is a potential risk in certain patients, so it would be prudent to avoid situations that could predispose to bacteremias, such as overinstrumentation. Overinstrumentation induces damage to the periradicular tissues, affecting cells, extracellular matrix, and vessels; when it occurs during preparation of infected root canals, large numbers of bacteria can also be carried into the periradicular tissues. Bacteria introduced into periradicular tissues can enter injured vessels, and a bacteremia ensues. It has been postulated that lymphatics and not blood vessels (where the pressure gradient is outward and not inward after trauma) may be the primary means of entry of oral bacteria into the blood.[179] In addition to a higher risk of bacteremia, as alluded to earlier, bacteria pushed into the periradicular tissues during overinstrumentation may cause postoperative pain or even the failure of root canal treatment.[235] For all these reasons, overinstrumentation should be avoided.

The focal infection theory has remained controversial owing to the lack of indisputable evidence regarding the causal relationship between endodontic infections and other medical conditions. A cross-sectional study[72] revealed that there was no association between coronary heart disease and root canal–treated teeth or teeth with apical periodontitis. Nonsurgical endodontics is perhaps the least likely dental treatment procedure to produce a significant bacteremia in either incidence or magnitude.[179]

One should bear in mind that bacteremia can occur naturally as a result of normal daily activities, including toothbrushing and mastication.[8,87,139] Because of the 1000 to 8000 times greater chance of any bacteremia originating from normal daily activities, determining whether bacteremia has emanated from an endodontic intervention or a time before or after it is impossible.[179] Whatever the origin, bacteremias are usually transient. Detection of bacteria after dental procedures is significant after 10 minutes, and some reports indicate that positive blood cultures can be detected for as long as 30 minutes after the procedure.[9,96,138,198,199] However, bacteremia caused by some pathogenic species has been observed to persist for at least 60 minutes after brushing and extraction without antibiotic prophylaxis.[139]

In the absence of clear evidence regarding the effects of bacteremia in some compromised patients, and before elucidation of the speculative involvement of uncultivated bacteria, empirical consensus indicates that antibiotic prophylaxis should be performed in patients at risk of developing infective endocarditis. Antibiotic prophylaxis should also be considered for immunosuppressed patients, individuals with indwelling catheters, or patients with orthopedic prosthetic devices. Such individuals may receive some benefit from antibiotic prophylaxis, although there is unclear evidence in this regard.[175]

TREATMENT OF ENDODONTIC INFECTIONS—RATIONALE

The ultimate goal of endodontic treatment is either to prevent the development of apical periodontitis or, in cases where disease is present, to create adequate conditions for periradicular tissue healing. Taking into account the microbial etiology of apical periodontitis, the logical goals of the endodontic treatment are then to eliminate or at least substantially reduce the microbial population within the root canal system (through disinfection means) and to prevent microorganisms from infecting or reinfecting the root canal or the periradicular tissues (through aseptic means and a tight coronal seal provided by both the root canal filling and the permanent coronal restoration). The success of the endodontic treatment will depend on how effective the clinician is in accomplishing these goals.

Inasmuch as apical periodontitis has a polymicrobial etiology, bacterial community profiles significantly vary from one individual to another,[219] and differences are even more pronounced when samples are taken from different geographical locations,[143,204] endodontic infections should be treated using a broad-spectrum, nonspecific antimicrobial strategy with the potential to reach the most likely members of the endodontic bacterial community.

The privileged anatomic localization of the root canal system places bacteria entrenched in it beyond the reach of the host's defenses. Endodontic infections can only be treated by means of professional intervention using both chemical and mechanical procedures. The main steps of endodontic treatment involved with infection control are represented by the chemomechanical preparation and the interappointment medication. In this regard, the chemomechanical preparation is of paramount importance for root canal disinfection, since instruments and irrigants act primarily on the main canal, which is the most voluminous area of the system and consequently harbors the largest numbers of bacterial cells. Bacterial elimination from the root canal is carried out by means of the mechanical action of instruments, the flow and backflow of the irrigant solution, and the antibacterial effects of irrigants. Several irrigants have been proposed over the years, but sodium hypochlorite (NaOCl) remains the most widely used, although

studies have revealed that instrumentation and irrigation with NaOCl per se do not suffice to predictably render root canals free of cultivable bacteria. About 40% to 60% of canals are still positive for bacterial presence after chemomechanical preparation using different NaOCl concentrations.* Chlorhexidine has been proposed as an alternative, but clinical studies showed that it is not superior to NaOCl with regard to antibacterial effectiveness.[265,306]

Because residual bacteria can adversely affect treatment outcome,[64,267] the use of an interappointment medication has been recommended to complement the antibacterial effects of chemomechanical procedures and eliminate persisting bacteria.[151,245,268] Calcium hydroxide is arguably the most used intracanal medication. Addition of other antimicrobial mixing substances can enhance the effectiveness of calcium hydroxide.[244] Studies have shown that intracanal medication with a calcium hydroxide paste may be necessary to supplement the antibacterial effects of chemomechanical procedures and predictably render root canals free of cultivable bacteria before filling.[230,240,245,246,268]

FASCIAL SPACE INFECTIONS

If bacteria from the infected root canal gain entry into the periradicular tissues and the immune system is unable to suppress the invasion, an otherwise healthy patient eventually shows signs and symptoms of an acute apical abscess, which can in turn evolve to cellulitis (see Fig. 15-15). Clinically, the patient experiences swelling and mild to severe pain. Depending on the relationship of the apices of the involved tooth to the muscular attachments, the swelling may be localized to the vestibule or extend into a fascial space. The patient may also have systemic manifestations, such as fever, chills, lymphadenopathy, headache, and nausea. Because the reaction to the infection may occur very quickly, the involved tooth may or may not show radiographic evidence of a widened periodontal ligament space. In most cases, the tooth elicits a positive response to percussion, and the periradicular area is tender to palpation. The tooth is serving as a *focus of infection* because it leads to periradicular infection and secondary (i.e., metastatic) spread to the fascial spaces of the head and neck, resulting in cellulitis and systemic signs and symptoms of infection.

In such cases, treatment involves incision for drainage and root canal treatment of the involved tooth to remove the source of the infection. Antibiotic therapy may be indicated with compromised host resistance, the presence of systemic symptoms, or fascial space involvement. Fascial space infections of odontogenic origin are infections that have spread into the fascial spaces from the periradicular area of a tooth, the focus of infection. They are *not* examples of the theory of focal infection, which describes the dissemination of bacteria or their products from a distant focus of infection.

Fascial spaces are potential anatomic areas that exist between the fascia and underlying organs and other tissues. During infection, these spaces are formed as a result of the spread of purulent exudate. The spread of infections of odontogenic origin into the fascial spaces of the head and neck is determined by the location of the root end of the involved tooth in relation to its overlying buccal or lingual cortical plate and the relationship of the apex to the attachment of a muscle (Fig. 15-31, *A*). For example, if the source of the infection is a mandibular molar and the apices of the molar lie closer to the lingual cortical plate and above the attachment of the mylohyoid muscle of the floor of the mouth, the purulent exudate breaks through the lingual cortical plate into the sublingual space. If the apices lie below the attachment of the mylohyoid muscle, the infection spreads into the submandibular space.

As described by Hohl et al.,[100] the fascial spaces of the head and neck can be categorized into four anatomic groups:

- The mandible and below
- The cheek and lateral face
- The pharyngeal and cervical areas
- The midface

Swellings of and below the mandible include six anatomic areas or fascial spaces:

- The buccal vestibule
- The body of the mandible
- The mental space
- The submental space
- The sublingual space
- The submandibular space

The *mandibular buccal vestibule* is the anatomic area between the buccal cortical plate, the overlying alveolar mucosa, and the buccinator muscle (posterior) or the mentalis muscle (anterior) (see Figs. 15-31, *B* and *C*). In this case, the source of the infection is a mandibular posterior or anterior tooth in which the purulent exudate breaks through the buccal cortical plate, and the apex or apices of the involved tooth lie above the attachment of the buccinator or mentalis muscle, respectively.

The *space of the body of the mandible* is the potential anatomic area between the buccal or lingual cortical plate and its overlying periosteum. The source of infection is a mandibular tooth in which the purulent exudate has broken through the overlying cortical plate but not yet perforated the overlying periosteum. Involvement of this space can also occur as a result of a postsurgical infection.

The *mental space* (Fig. 15-31, *D*) is the potential bilateral anatomic area of the chin that lies between the mentalis muscle superiorly and the platysma muscle inferiorly. The source of the infection is an anterior tooth in which the purulent exudate breaks through the buccal cortical plate, and the apex of the tooth lies below the attachment of the mentalis muscle.

The *submental space* (Fig. 15-31, *E*) is the potential anatomic area between the mylohyoid muscle superiorly and the platysma muscle inferiorly. The source of the infection is an anterior tooth in which the purulent exudate breaks through the lingual cortical plate, and the apex of the tooth lies below the attachment of the mylohyoid muscle.

The *sublingual space* (Fig. 15-31, *F*) is the potential anatomic area between the oral mucosa of the floor of the mouth superiorly and the mylohyoid muscle inferiorly. The lateral boundaries of the space are the lingual surfaces of the mandible. The source of infection is any mandibular tooth in which the purulent exudate breaks through the lingual cortical plate, and the apex or apices of the tooth lie above the attachment of the mylohyoid muscle.

The *submandibular space* (Fig. 15-31, *G*) is the potential space between the mylohyoid muscle superiorly and the

platysma muscle inferiorly. The source of infection is a posterior tooth, usually a molar, in which the purulent exudate breaks through the lingual cortical plate, and the apices of the tooth lie below the attachment of the mylohyoid muscle. If the submental, sublingual, and submandibular spaces are involved at the same time, a diagnosis of Ludwig's angina is made. This life-threatening cellulitis can advance into the pharyngeal and cervical spaces, resulting in airway obstruction.

Swellings of the lateral face and cheek include four anatomic areas or fascial spaces:

- The buccal vestibule of the maxilla
- The buccal space
- The submasseteric space
- The temporal space

Anatomically, the *buccal vestibular space* (Fig. 15-31, *H*) is the area between the buccal cortical plate, the overlying mucosa, and the buccinator muscle. The superior extent of the space is the attachment of the buccinator muscle to the zygomatic process. The source of infection is a maxillary posterior tooth in which the purulent exudate breaks through the buccal cortical plate, and the apex of the tooth lies below the attachment of the buccinator muscle.

The *buccal space* (Fig. 15-31, *I*) is the potential space between the lateral surface of the buccinator muscle and the medial surface of the skin of the cheek. The superior extent of the space is the attachment of the buccinator muscle to the zygomatic arch, whereas the inferior and posterior boundaries are the attachment of the buccinator to the inferior border of the mandible and the anterior margin of the masseter muscle, respectively. The source of the infection can be either a posterior mandibular or maxillary tooth in which the purulent exudate breaks through the buccal cortical plate, and the apex or apices of the tooth lie above the attachment of the buccinator muscle (i.e., maxilla) or below the attachment of the buccinator muscle (i.e., mandible).

As the name implies, the *submasseteric space* (Fig. 15-31, *J*) is the potential space between the lateral surface of the ramus of the mandible and the medial surface of the masseter muscle. The source of the infection is usually an impacted third molar in which the purulent exudate breaks through the lingual cortical plate, and the apices of the tooth lie very close to or within the space.

The *temporal space* (Fig. 15-31, *K*) is divided into two compartments by the temporalis muscle. The *deep temporal space* is the potential space between the lateral surface of the skull and the medial surface of the temporalis muscle; the *superficial temporal space* lies between the temporalis muscle and its overlying fascia. The deep or superficial temporal spaces are involved indirectly if an infection spreads superiorly from the inferior pterygomandibular or submasseteric spaces, respectively.

Swellings of the pharyngeal and cervical areas include the following fascial spaces:

- The pterygomandibular space
- The parapharyngeal spaces
- The cervical spaces

The *pterygomandibular space* (Fig. 15-31, *L*) is the potential space between the lateral surface of the medial pterygoid muscle and the medial surface of the ramus of the mandible. The superior extent of the space is the lateral pterygoid muscle. The source of the infection is mandibular second or third molars in which the purulent exudate drains directly into the space. In addition, contaminated inferior alveolar nerve injections can lead to infection of the space.

The *parapharyngeal spaces* comprise the lateral pharyngeal and retropharyngeal spaces (Fig. 15-31, *M*). The *lateral pharyngeal space* is bilateral and lies between the lateral surface of the medial pterygoid muscle and the posterior surface of the superior constrictor muscle. The superior and inferior margins of the space are the base of the skull and the hyoid bone, respectively, and the posterior margin is the *carotid space,* or sheath, which contains the common carotid artery, internal jugular vein, and the vagus nerve. Anatomically, the *retropharyngeal space* lies between the anterior surface of the prevertebral fascia and the posterior surface of the superior constrictor muscle and extends inferiorly into the retroesophageal space, which extends into the posterior compartment of the mediastinum. The pharyngeal spaces usually become involved as a result of secondary spread of infection from other fascial spaces or directly from a peritonsillar abscess.

The cervical spaces comprise the pretracheal, retrovisceral, danger, and prevertebral spaces (Fig. 15-31, *N*). The *pretracheal space* is the potential space surrounding the trachea. It extends from the thyroid cartilage inferiorly into the superior portion of the anterior compartment of the mediastinum to the level of the aortic arch. Because of its anatomic location, odontogenic infections do not spread to the pretracheal space. The *retrovisceral space* comprises the retropharyngeal space superiorly and the retroesophageal space inferiorly. The space extends from the base of the skull into the posterior compartment of the mediastinum to a level between vertebrae C6 and T4. The *danger space* (i.e., space 4)[85] is the potential space between the alar and prevertebral fascia. Because this space is composed of loose connective tissue, it is considered an actual anatomic space extending from the base of the skull into the posterior compartment of the mediastinum to a level corresponding to the diaphragm. The *prevertebral space* is the potential space surrounding the vertebral column. As such, it extends from vertebra C1 to the coccyx. A retrospective study showed that 71% of cases in which the mediastinum was involved arose from the spread of infection from the retrovisceral space (21% from the carotid space and 8% from the pretracheal space).[130]

Swellings of the midface consist of four anatomic areas and spaces:

1. The palate
2. The base of the upper lip
3. The canine spaces
4. The periorbital spaces

Odontogenic infections can spread into the areas between the palate and its overlying periosteum and mucosa and the base of the upper lip, which lies superior to the orbicularis oris muscle, even though these areas are not considered actual fascial spaces. The source of infection of the palate is any of the maxillary teeth in which the apex of the involved tooth lies close to the palate. The source of infection of the base of the upper lip is a maxillary central incisor in which the apex lies close to the buccal cortical plate and above the attachment of the orbicularis oris muscle.

The *canine,* or *infraorbital, space* (Fig. 15-31, *O*) is the potential space between the levator anguli oris muscle inferiorly and the levator labii superioris muscle superiorly. The source of infection is the maxillary canine or first premolar in

which the purulent exudate breaks through the buccal cortical plate, and the apex of the tooth lies above the attachment of the levator anguli oris muscle.

The *periorbital space* (see Fig. 15-31, *O*) is the potential space that lies deep to the orbicularis oculi muscle. This space becomes involved through the spread of infection from the canine or buccal spaces. Infections of the midface can be very dangerous because they can result in *cavernous sinus thrombosis,* a life-threatening infection in which a thrombus formed in the cavernous sinus breaks free, resulting in blockage of an artery or the spread of infection. Under normal conditions, the angular and ophthalmic veins and the pterygoid plexus of veins flow into the facial and external jugular veins. If an infection has spread into the midfacial area, however, edema and resultant increased pressure from the inflammatory response cause the blood to back up into the cavernous sinus. Once in the sinus, the blood stagnates and clots. The resultant infected thrombi remain in the cavernous sinus or escape into the circulation.[171,323]

MANAGEMENT OF ABSCESSES AND CELLULITIS

The two most important elements of effective patient management are correct diagnosis and removal of the cause by controlling the endodontic infection. In an otherwise healthy patient, chemomechanical preparation of the infected root canals and incision for drainage of periradicular swelling usually prompt rapid improvement in clinical signs and symptoms. The majority of cases of endodontic infections can be treated effectively without the use of adjunctive antibiotics. The appropriate treatment is removal of the cause of the inflammatory condition.

Antibiotics are *not* recommended for irreversible pulpitis, acute apical periodontitis, draining sinus tracts, after endodontic surgery, to prevent flare-ups, or after incision for drainage of a localized swelling (without cellulitis, fever, or lymphadenopathy).[70,99,165,196,312] When the ratio of risk to benefit is considered in these situations, antibiotic use may put the patient at risk for side effects of the antimicrobial agent and select for resistant microorganisms. Analgesics (not antibiotics) are indicated for the treatment of pain.

Antibiotics in conjunction with appropriate endodontic treatment are recommended for progressive or persistent infections with systemic signs and symptoms such as fever (100° F [37.8° C]), malaise, cellulitis, unexplained trismus, and progressive or persistent swelling (or both). In such cases, antibiotic therapy is indicated as an adjunct to effective débridement of the root canal system, which is the reservoir of microorganisms. In addition, aggressive incision for drainage is indicated for any infection marked by cellulitis. Incision for drainage is indicated whether the cellulitis is indurated or fluctuant. It is important to provide a pathway of drainage to prevent further spread of the abscess and/or cellulitis. An incision for drainage allows decompression of the increased tissue pressure associated with edema and provides significant pain relief. Furthermore, the incision provides a draining pathway not only for bacteria and their products but also for the inflammatory mediators associated with the spread of cellulitis.

A minimum inhibitory concentration of antibiotic may not reach the source of the infection because of decreased blood flow and because the antibiotic must diffuse through the edematous fluid and pus. Drainage of edematous fluid and purulent exudate improves circulation to the tissues associated with an abscess or cellulitis, providing better delivery of the antibiotic to the area. Placement of a drain may not be indicated for localized fluctuant swellings if complete evacuation of the purulent exudate is believed to have occurred.

For effective drainage, a stab incision is made through the periosteum in the most dependent site of the swelling. The incision must be long enough to allow blunt dissection using a curved hemostat or periosteal elevator under the periosteum for drainage of pockets of inflammatory exudate. A rubber dam drain or a Penrose drain is indicated for any patient with a progressive abscess or cellulitis to maintain an open pathway for drainage. Patients should improve rapidly after removal of the cause of the infection and drainage.

Patients with cellulitis should be followed on a daily basis to ensure that the infection is resolving. The best practical guide for determining the duration of antibiotic therapy is clinical improvement of the patient. When clinical evidence indicates that the infection is certain to resolve or is resolved, antibiotics should be administered for no longer than 1 or 2 days more.

Endodontic treatment should be completed as soon as possible after the incision for drainage. The drain usually can be removed 1 or 2 days after improvement. If no significant clinical improvement occurs, the diagnosis and treatment must be reviewed carefully. Consultation with a specialist and referral may be indicated for severe infections or persistent infections. Likewise, patients requiring extraoral drainage should be referred to a clinician trained in the technique.

SYSTEMIC ANTIBIOTICS FOR ENDODONTIC INFECTIONS

A hundred years ago, infectious diseases were the major recognized causes of death in the world. The advent of antibiotics resulted in a significant decline in the incidence of life-threatening infections and heralded a new era in the therapy of infectious diseases, but the enthusiasm generated turned out to be premature. Over the years, microbial evolutionary responses to the selective pressure exerted by antibiotics have resulted in microbial species resistant to virtually every known antibiotic agent.[93] The rapid emergence of resistant microbial strains comes as a consequence of the astonishing power of natural selection among microorganisms. If a given member of a microbial community possesses genes of resistance against a certain antibiotic and the community is persistently exposed to the drug, the resistant microorganism is selected to emerge and multiply in detriment of the susceptible portion of community. The emergence of multidrug-resistant strains of several bacterial species capable of causing life-threatening infections has been reported.[93,144,188,296,316] Antibiotic resistance among obligately anaerobic bacteria is increasing, with resistance to penicillins, clindamycin, and cephalosporins noted at community hospitals and major medical centers.[94,95]

Among oral bacteria, there have been a handful of reports on emerging resistance to commonly used antibiotics. Resistance has been found in *F. nucleatum* strains for penicillin, amoxicillin, and metronidazole, in *P. intermedia* for tetracy-

cline and amoxicillin, and in *A. actinomycetemcomitans* for amoxicillin and azithromycin.[124,303] Macrolides (erythromycin and azithromycin) have presented decreased activity against *Fusobacterium* and nonpigmented *Prevotella* species.[97,123,124] Production of beta-lactamase by oral bacteria has also been reported, with the most prominent beta-lactamase-producing bacteria belonging to the anaerobic genus *Prevotella*.[24,31,68,91,304] Kuriyama et al.[123] revealed that beta-lactamase production was detected in 36% of the black-pigmented *Prevotella* and 32% of the nonpigmented *Prevotella* species isolated from pus samples of oral abscesses. Susceptibility of *Prevotella* strains to several cephalosporins, erythromycin, and azithromycin has been found to correlate with amoxicillin susceptibility; amoxicillin-resistant strains can be similarly resistant to these other antibiotics.[124] This finding suggests that there is little value in the use of oral cephalosporins and macrolides in managing endodontic abscesses, particularly when penicillin-resistant strains are evident. Other enzyme-producing oral anaerobic species include strains of *F. nucleatum, P. acnes, Actinomyces* species, and *Peptostreptococcus* species.[31,68,91,304] Facultative bacteria such as *Capnocytophaga* and *Neisseria* species have also been detected among the beta-lactamase producers.[91] Bacteria that produce beta-lactamases protect not only themselves but also other penicillin-susceptible bacteria present in a mixed community by releasing free beta-lactamase into the environment.[29]

Overuse and misuse of antibiotics has been considered the major cause for the emergence of multidrug-resistant strains. Improper use of antibiotics includes use in cases with no infection, erroneous choice of the agent, dosage and/or duration of therapy, and excessive use in prophylaxis.[177,178] Antibiotics are used in clinical practice far more often than necessary. Antibiotic therapy is actually warranted in about 20% of the individuals who are seen for clinical infectious disease, but they are prescribed up to 80% of the time. To complicate matters further, in up to 50% of cases, recommended agents, doses, or duration of therapy are incorrect.[144]

The appalling rise in the frequency of multidrug resistance among leading pathogens should cause great concern and incite a commitment to act carefully and responsibly. A single erroneous use of antibiotics can be a significant contribution to the current scenario of increasing microbial resistance. Diseases that were effectively treated in the past with a given antibiotic may now require the use of another drug, usually more expensive and potentially more toxic, to achieve effective antimicrobial treatment. Unfortunately, even the new drug may not be effective.

Antibiotics are defined as naturally occurring substances of microbial origin or similar synthetic (or semisynthetic) substances that have antimicrobial activity in low concentrations and inhibit the growth of or kill selective microorganisms. The purpose of antibiotic therapy is to aid the host defenses in controlling and eliminating microorganisms that temporarily have overwhelmed the host defense mechanisms.[177] Based on the earlier discussion, it becomes clear that the most important decision making in antibiotic therapy is not so much *which* antibiotic should be employed but *whether* antibiotics should be used at all.[176] One should bear in mind that antibiotics are very useful drugs classically used to treat or help treat infectious disease and provide prophylaxis in carefully selected cases.

The vast majority of infections of endodontic origin are treated without the need for antibiotics. As mentioned, the absence of blood circulation in a necrotic pulp prevents antibiotics from reaching and eliminating microorganisms present in the root canal system, so the source of infection is often unaffected by systemic antibiotic therapy. Antibiotics can, however, help impede spread of the infection and development of focal infections in medically compromised patients and be a valuable adjunct for managing selected cases of endodontic infection. In addition to the indications for systemic antibiotics discussed earlier for acute abscesses and cellulitis, antibiotics are also prescribed for prophylaxis in medically compromised patients during routine endodontic therapy, in some cases of persistent exudation not resolved after revision of intracanal procedures, and replantation of avulsed teeth.

Selection of antibiotics in clinical practice is either empirical or based on the results of microbial susceptibility tests. For diseases with known microbial causes, empirical therapy may be used. This is especially applicable to infections of endodontic origin, because culture-dependent antimicrobial tests of anaerobic bacteria can take too long to provide results about their susceptibility to antibiotics (7 to 14 days). Therefore, it is preferable to opt for an antimicrobial agent whose spectrum of action includes the most commonly detected bacteria. Most of the bacterial species involved with endodontic infections, including abscesses, are susceptible to penicillins,[17,106,115,124] which make them first-line drugs of choice. Since the use of antibiotics is restricted to severe infections or prophylaxis, it seems prudent to use amoxicillin, a semisynthetic penicillin with a broad spectrum of antimicrobial activity. In more serious cases, including life-threatening conditions, combining amoxicillin with clavulanic acid or metronidazole may be required to achieve optimum antimicrobial effects as a result of the extended spectrum of action to include penicillin-resistant strains.[124] In patients allergic to penicillins or in cases refractory to amoxicillin therapy, clindamycin is indicated. Clindamycin has strong antimicrobial activity against oral anaerobes.[122,124,125]

To sum up, the risk/benefit ratio should be always weighed before prescribing antibiotics. Appropriately selected patients will benefit from systemically administered antibiotics. A restrictive and conservative use of antibiotics is highly recommended in endodontic practice, but indiscriminate use (including cases of pulpitis—no infection!) is contrary to sound clinical practice. This may cause a selective pressure and consequent overgrowth of intrinsically resistant bacteria, predisposing patients to secondary and superinfections and rendering drugs ineffective against potentially fatal medical infectious diseases. Future generations will thank us for today's conscientious and judicious use of antibiotics.

ACKNOWLEDGMENT

The authors acknowledge the outstanding work of Drs. J. Craig Baumgartner and Jeffrey W. Hutter in previous editions of this text. The sections on fascial space infections and management of abscesses and cellulitis were built upon their foundation work.

- Overview of Clinical Revascularization Cases
- Example of a Revascularization Protocol
- Clinical Measures of Treatment Outcome

OVERVIEW OF REGENERATIVE DENTISTRY

From a biologic perspective, the goal of endodontics is to prevent or treat apical periodontitis. An optimal way to accomplish this goal is to either maintain pulpal health in cases of pulpal inflammation or to regenerate healthy pulpal tissue in cases of pulpal necrosis. Thus, there is considerable interest in research and clinical studies aimed towards regeneration of a functional and healthy pulp-dentin complex.[68,109] This chapter will review the current status of regenerative endodontic procedures with an emphasis on biologic principles and the advantages and limitations of currently available clinical procedures.

The history of dentistry has largely involved the prosthetic replacement of lost or diseased tissues, including endodontic obturation of root canal systems with inert materials (see Chapter 10). In contrast, the goal of regenerative dentistry is to induce biologic replacement of dental tissues and their supporting structures. The potential for regenerative dentistry is in large part due to advancements in biologic therapies that apply growth and differentiation factors which hasten or induce natural biologic regeneration. Many of these concepts have emerged from the burgeoning field of tissue engineering, which emphasizes the spatial assembly of distinct stem cells, growth factors/morphogens, and scaffolds to form a functional tissue or organ.[62]

Pioneering work supporting the concept of regenerating dental tissues was reported more than 50 years ago when Dr. B.W. Hermann described the application of calcium hydroxide ($Ca[OH]_2$) for vital pulp therapy,[47] and Professor Nygaard-Østby evaluated a revascularization method for reestablishing a pulp-dentin complex in permanent teeth with pulpal necrosis (see later).[82] Over the last several decades, the scope and clinical application of regenerative dental procedures has continuously advanced to now include guided tissue or bone regeneration (GTR, GBR) procedures and distraction osteogenesis,[15,17,86] the application of platelet-rich plasma for bone augmentation,[60] Emdogain for regeneration of periodontal tissues,[44] recombinant human bone morphogenic protein (rhBMP) for augmentation of bone,[34] and preclinical trials on the use of fibroblast growth factor 2 (FGF-2) for periodontal tissue regeneration.[118] At the beginning of the 21st century, we are seeing the potential of these therapies for dental practice, including endodontics. For example, pulp, dentin, and enamel can be regenerated using scaffold material and stem cells,[29,51,141] and tooth crowns can be regenerated using the primordium of embryonic oral epithelium and adult bone-marrow stem cells.[87] Adult bone marrow stem cells are capable of differentiating directly into ameloblasts when mixed with embryonic epithelial cells,[49] dissociated cells from tooth germs can be mixed with agar and collagen (i.e., scaffolds) to form crown, root, and periodontal structures in adult hosts,[49,71] and postnatal stem cells isolated from extracted wisdom teeth can be used to regenerate tooth roots and periodontal ligaments that can support synthetic crowns.[113] Regenerative dental procedures are emerging as a vital, evolving field of dental care.

Overview of Regenerative Endodontics

Regenerative endodontics has been defined as biologically based procedures designed to replace damaged structures such as dentin, root structures, and cells of the pulp-dentin complex.[68] Similar to most rapidly evolving fields, the scope and depth of basic research has outpaced the translation of this knowledge into clinical trials and established dental procedures. It is important to review both basic and clinical studies for a full understanding of the scope, limitations, and potential of this field. To understand the implications of preclinical research for clinical practice, it is important to briefly review the development of teeth.

The forming tooth progresses through a succession of morphologic stages—bud, cap, and bell—resulting in the formation of the crown, root, and periodontium (see also Chapter 12). Tooth development is regulated by a series of reciprocal interactions involving both ectodermal and mesenchymal stem cells.[119] Ectodermal stem cells differentiate into ameloblasts, and mesenchymal stem cells, also known as *ectomesenchymal stem cells* owing to their neural crest origin, differentiate into odontoblasts. One important requirement for regeneration of pulp tissues is to obtain stem cells capable of differentiating into odontoblasts.

Stem cells are often viewed as relatively undifferentiated cells capable of self-renewal/expansion (i.e., can divide many times) and able to differentiate into specialized cell types. The range of differentiation ("potency") is an important property of stem cells and serves as the basis for classifying cells as *totipotent*—capable of differentiating into any cell type—or *pluripotent, multipotent,* or *unipotent*—characterizing more restricted abilities for differentiation. In general, considerable research has focused on totipotent embryonic stem cells that have maximal capacity for differentiation, but ethical, legal, and medical (tissue-rejection) issues can render these cell types unsuitable for clinical development.[68] In contrast, postnatal (i.e., adult) stem cells are more readily available, are already applied in clinical practice (e.g., bone marrow transplants, etc.), and when used in an autologous application, will not induce immune responses such as tissue rejection. Many of these stem cells appear to satisfy criteria for multipotency, since they can differentiate into cells that express phenotypic markers for odontoblasts, neurons, and muscle or adipose cells.[52]

Nakahara has summarized potential methods for regenerating an entire tooth. The first approach, incorporating principles of tissue engineering, involves seeding appropriate stem cells onto scaffolding materials, such as has been used for periodontal regeneration.[70] This approach may be controlled by the addition of specific growth factors and/or signaling molecules. The second approach involves replicating the natural developmental processes of embryonic tooth formation. In this approach, artificial tooth germs are transplanted into the bodies of animal hosts where there is enough blood flow to support tissue formation. Although either approach may evolve into a method capable of generating entire teeth, it should be appreciated that the natural development of permanent human teeth takes years to complete. Regenerating an entire tooth from a patient's own stem cells may not be clinically practical.

One alternative approach would be to regenerate a functional pulp-dentin complex *within* a patient's existing permanent tooth. This would restore natural functions, such as formation of replacement dentin and maintenance of tissue immunity and neural sensation, to teeth that otherwise would require endodontic obturation with inert materials or possibly extraction. One key advantage is that the pulp occupies a relatively small volume (about 0.1 to 2 ml) and, compared to complex organs such as the heart or liver, has a relatively simple cytoarchitecture that can be approximated as a core of loose connective tissue surrounded by a layer of odontoblasts attached to dentin. From a tissue-engineering perspective, the dental pulp may be a relatively easier tissue to regenerate.

PRECLINICAL STUDIES ON REGENERATIVE ENDODONTICS

Applying the principles of tissue engineering to the development of regenerative endodontic procedures requires research on the correct spatial assembly of distinct stem cells, growth factors/morphogens, and scaffolds to form a functional pulp-dentin complex.[42,62,74] In this section, we will review each of these critical components in turn.

Stem Cells

As described earlier, dental pulp can be viewed as a core of innervated and vascularized loose connective tissue surrounded by a layer of odontoblasts. The major cell type of this core region is the fibroblast. Together with blood vessels, lymphatics, and neurons, this core tissue is embedded in an extracellular matrix consisting of collagen and other fiber types (see also Chapter 12). Pulpal mesenchymal stem cells are thought to be localized in the perivascular region and the cell-rich zone of Hohl adjacent to the odontoblastic layer; both have been proposed to serve as cell sources for replacement odontoblasts.[32,106] Thus, several cell types must be developed in order to form this core of loose connective tissue. The regeneration of loose connective tissue has been proposed to be similar to the process of the granulation phase of wound healing, with the local release of angiogenic growth factors such as vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) playing key roles in coordinating angiogenesis and the development of loose connective tissue.[8] Interestingly, platelet-rich plasma has about a three- to sixfold increase in VEGF and PDGF and has been reported to increase rates of wound healing.[8,81,94,132] Additional studies have demonstrated that the application of recombinant human VEGF substantially increases the degree of revascularization of human dental pulp slices implanted into immunocompromised mice.[36] Given the large existing knowledge base on the regeneration of loose connective tissue, recent research has mainly focused on generation of the surrounding layer of odontoblasts.

At least five different types of postnatal mesenchymal stem cells have been reported to differentiate into odontoblast-like cells, including dental pulp stem cells (DPSC),[39] stem cells of human exfoliated deciduous teeth (SHED),[66] stem cells of the apical papilla (SCAP),[113,114] dental follicle progenitor cells (DFPC),[67] and bone marrow-derived mesenchymal stem cells (BMMSC).[12] Although many of these studies involve human samples collected from patients younger than 25 years of age, it should be noted that multipotent stem cells have been collected from the pulps of patients as old as 41.[50] Regenerative procedures may be applicable to at least young and middle-aged patients. To our knowledge, no study has evaluated the formation of odontoblast-like cells from patients older than 50 years of age, and this represents an important gap in knowledge. The identification of a differentiated cell as an odontoblast is not always straightforward, since this cell is similar to osteoblasts in the formation of mineralized nodules and in the expression of several proteins such as dentin sialoprotein (DSP), although DSP levels are nearly 400 times greater in odontoblasts than osteoblasts.[131] Measuring only one or two characteristics of a cell might not conclusively identify whether the resulting cell is a true odontoblast. Even among odontoblasts, the phenotype varies in cells located in the apical (squa-

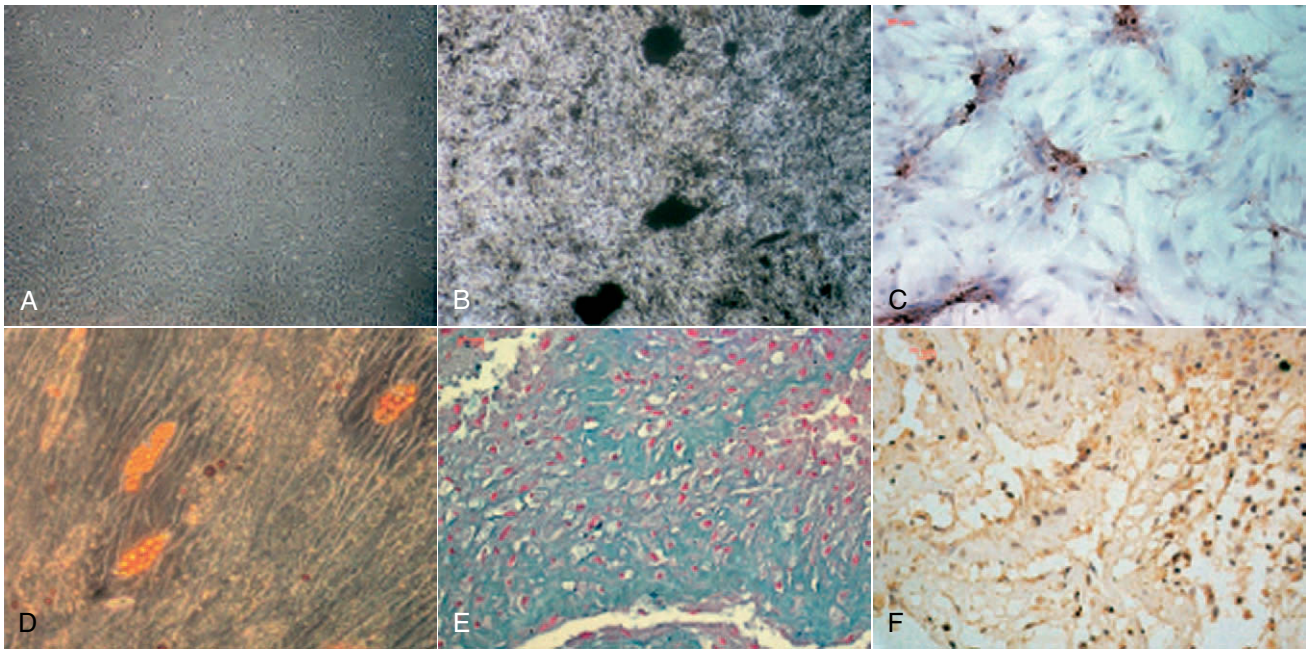

FIG. 16-1 Multilineage differentiation capacity of human dental pulp cells (DPCs). **A,** DPCs cultured in control medium (×40). Differentiation into odontoblast-like cells was shown by the deposition of a mineralized matrix indicated by von Kossa stain (**B;** ×100) and by the positive immunostaining of DSP (**C;** ×200). **D,** Adipogenic differentiation was shown by the accumulation of neutral lipid vacuoles stainable with Oil Red O (×100). Chondrogenic differentiation was shown by the secretion of cartilage-specific proteoglycans stainable with Alcian blue (**E;** ×400) and by the positive immunostaining of collagen type II (**F;** ×400). *(From Wei X, Ling J, Wu L, et al: Expression of mineralization markers in dental pulp cells.* J Endod *33:703, 2007.)*

mous shape) versus coronal (tall columnar) pulpal tissue. Importantly, molecular studies have identified many of the genes selectively expressed in odontoblasts,[64,89,90] and this knowledge is expected to aid future studies characterizing the conditions necessary for mesenchymal cells of multiple origins to differentiate into true odontoblasts. It is likely that definitive cellular identification depends upon both the morphology of the cell and an assessment of the expression of multiple genes. For accuracy, we will refer to cells that express mineralized nodules and DSP as *odontoblast-like*.

Growth Factors/Morphogens

Several growth factors have been evaluated for their ability to trigger the differentiation of selected mesenchymal stem cell populations into odontoblast-like cells. Interestingly, several case studies have reported that patients taking long-term corticosteroids often present with dramatic reduction of the radiographic size of the pulp chamber and up to a fivefold increase in the thickness of the predentin layer.[77,136] Although these patients were medically complex patients (e.g., renal failure) taking multiple drugs, the use of corticosteroids appeared to be associated with the observed increased activity of human odontoblasts. More recent studies have extended this general observation by demonstrating that the application of dexamethasone greatly increased the differentiation of human dental pulp cells into odontoblast-like cells.[54,131] This was particularly evident when dexamethasone was combined with 1,25-dihydroxyvitamin D_3.[54] Merely changing the composition of growth factors completely altered the differentiation of these cells, with the same population of cells able to express markers of odontoblasts, chondrocytes, or adipocytes, depending on their exposure to different combinations of growth factors (Fig. 16-1).[131] Such findings emphasize the importance of growth factors in guiding the differentiation of these cells. Other studies have evaluated growth factors administered alone or in various combinations for promoting differentiation of odontoblast-like cells (Table 16-1).

Several of the approaches listed in Table 16-1 have immediate clinical implications. First, it is unlikely that a single growth factor will result in maximal differentiation, so combinations of growth factors may be required for evaluation in clinical trials. Related to this point, many of the studied growth factors (e.g., dexamethasone, insulin) are drugs already approved for human use in other medical/dental applications. Second, the demonstration that statins promote the differentiation of an odontoblast-like phenotype suggests that patients clinically taking statins may also have narrowing of the pulp chamber space, similar to the findings previously described for corticosteroids. This would be an important future area of research. Third, clinicians have long used demineralized human bone to augment healing after surgical procedures.[95] Demineralized human bone is thought to contain a natural combination of appropriate growth factors and scaffolds, thereby providing an appropriate environment for osteoblast differentiation or function. Extending this concept, several research groups have demonstrated that demineralized human dentin has significant benefit for promoting the differentiation of odontoblast-like cells.* Although human dentin contains many types of noncollagenous proteins, it is notable that transforming growth factor

Dentin matrix protein 1	Rat dental pulp	Odontoblast-like	In vivo	Almushayt et al., 2006[1]

β 1 (TGF-β1) is the only TGF subtype detectable in human dentin.[144] Moreover, the application of ethylenediamine tetraacetic acid (EDTA) strongly exposed immunoreactive TGF-β1 from human dentin, with appreciably smaller activities released after treatment with $Ca(OH)_2$, sodium hypochlorite (NaOCl), mineral trioxide aggregate (MTA), or citric acid.[38,122,144] Moreover, dentin contains additional noncollagenous proteins that promote odontoblast differentiation[1] or angiogenesis.[97] Collectively these findings suggest that future clinical regenerative trials should evaluate whether an EDTA irrigation of the dentinal walls prior to an endodontic regenerative procedure results in improved clinical outcomes.

Scaffolds

An important component of tissue engineering is a physical scaffold.[76,104] Tissues are organized as three-dimensional structures, and appropriate scaffolding is necessary to (1) provide a spatially correct position of cell location and (2) regulate differentiation, proliferation, or metabolism. It is known that extracellular matrix molecules control the differentiation of stem cells,[16,138] and an appropriate scaffold might selectively bind and localize cells,[128] contain growth factors,[137] and undergo biodegradation over time.[142] Thus, a scaffold is far more than a simple lattice to contain cells.

Scaffolds can be classified as either natural or synthetic. Examples of natural scaffolds include collagen,[55,73] glycosaminoglycans, demineralized or native dentin matrix,[10,40,55,72,127] and fibrin. From the perspective of focusing on practical clinical applications, platelet-rich plasma (PRP) appears to satisfy several of these criteria. PRP is autologous, fairly easy to prepare in a dental setting, rich in growth factors, degrades over time, and forms a three-dimensional fibrin matrix.[8,9,57,85] In addition, these properties may play a role in the reported outcomes of classical revascularization methods applied to patients (see later).

The second major category of scaffolds is based upon synthetic materials. Examples include polylactic acid (PLA), polyglycolic acid (PGA), polylactic-coglycolic acid (PLGA),

polyepsilon caprolactone,[140] hydroxyapatite/tricalcium phosphate,[4] bioceramics,[139] titanium (in some[143] but not all studies[126]), and hydrogels such as alginate[28,35] or variants of polyethylene glycol (PEG). Moreover, the combination of scaffolds with certain growth factors/morphogens appears to be an important combination for optimal generation of an odontoblast-like cell. This is a critical domain of research for the development of regenerative endodontics as a predictable clinical procedure.

Delivery System

Even with selection of the appropriate cell source, growth factors, and scaffold, the resultant mixture must be delivered in a spatially appropriate fashion into the space of the root canal system. For example, nearly all cells of the body are within 0.1 to 1 mm of a blood vessel in order to maintain adequate diffusion of oxygen and nutrients.[37,46] If one were to inject cells along the entire coronal-apical extent of a root canal system, the vast majority of cells would be expected to succumb to tissue hypoxia. One alternative approach would be to inject a cell/scaffold/growth-factor mixture into the apical 1 mm of the root canal system and then "back-fill" the root canal system with a scaffold/growth-factor combination. Since dental pulp can be approximated as a loose connective tissue core surrounded by a layer of odontoblasts, the spatial arrangement of cells and growth factors within the scaffold may be particularly important to promote odontogenesis without having complete calcification of the root canal system. The questions require additional research effort.

Summary of Basic Research on Regenerative Endodontics

Regeneration of a functional pulp-dentin complex relies on the foundation of tissue engineering and can be viewed as a function of the spatially correct delivery of appropriate stem cells and growth factors embedded within a scaffold. Although considerable research has used in vitro cell-culture methods to identify key factors regulating the differentiation of odontoblast-like cells, it should be noted that emerging studies conducted in animal models are quite promising for regeneration of this pulp tissue. A recent preclinical study involved surgical placement of human root tips filled with various human stem cell/growth factor/scaffold combinations into immunocompromised mice.[51] This model permits histologic analysis of neovascularization as well as the differentiation and mineralization activity of newly formed odontoblasts. The use of human cells in a mouse model permits histologic confirmation that the resulting odontoblast-like cells were of human origin. These novel findings provide strong evidence that either human SCAP or DPSC cell sources, on a PLGA scaffold, were able to regenerate a vascularized tissue that had histologic evidence for odontoblast-like cell differentiation and the spatially appropriate formation of dentin-like material onto the root canal walls (Fig. 16-2). Although no specific growth factors were added to this mixture, it is important to note that the root canal walls were treated with 17% EDTA, an irrigant known to expose endogenous growth-factor proteins embedded in the dentinal walls.[38] This and related

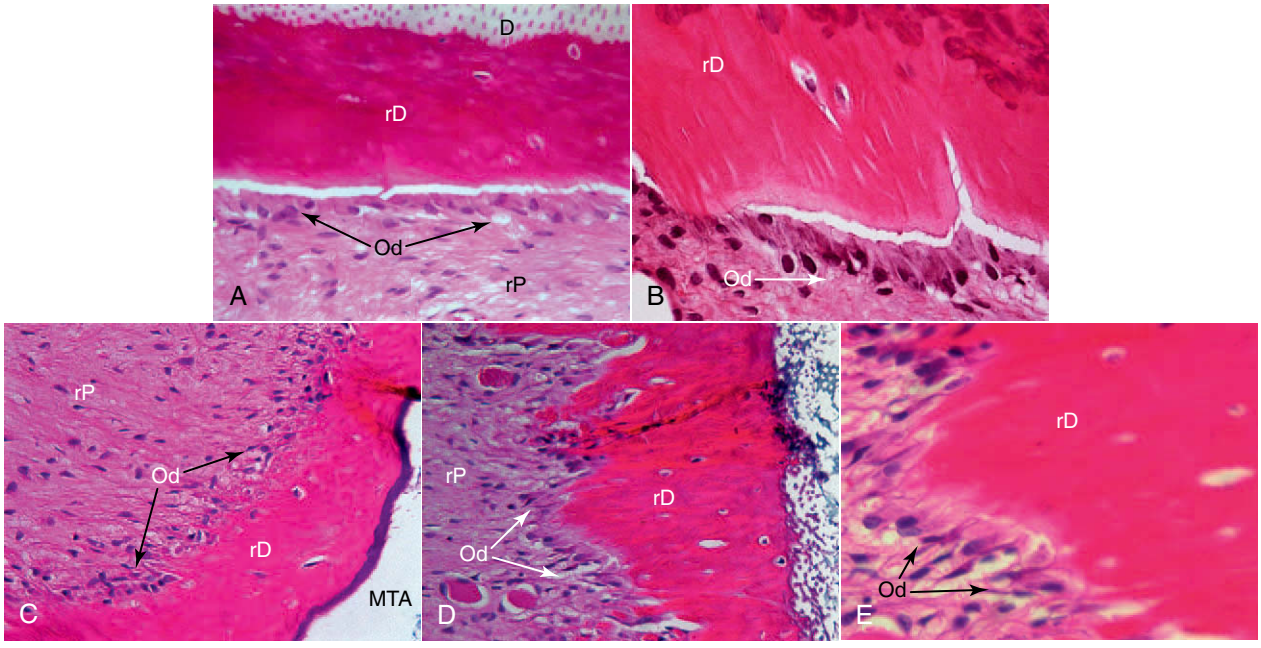

FIG. 16-2 Histologic analysis of a preclinical experiment evaluating regeneration of pulp tissue using dental pulp stem cells (DPSC) implanted with a resorbable polylactic-coglycolic acid (PLGA) scaffold into human root segments that were sealed on the coronal side with mineral trioxide aggregate (MTA) and implanted into immunocompromised mice for 4 months. *D,* Original dentin; *rD,* regenerated dentin-like tissue; *rP,* regenerated pulplike tissue. *Green arrows* in **A** indicate rD; *blue arrows* in **A** indicate the entrance of blood supply; *blue arrow* in **B** and **C** indicate the thin layer of rD under MTA cement; *blue arrows* in **F** and **G** indicate the junction of D and rD; *black arrow* in **G** indicates well-aligned odontoblast-like cells. [Epub ahead of print].)*

studies provide strong impetus for clinical translational research evaluating various potential regenerative endodontic therapies.

CLINICAL STUDIES ON REGENERATIVE ENDODONTICS

To date, no published clinical trials have fully incorporated the tissue-engineering concepts described. Instead, studies over the last 50 years have focused on revascularization techniques, which share some features with the principles of regenerative tissue engineering. The key distinction is that in contrast to the focused delivery of cells/growth factors/scaffolds employed in tissue-engineering approaches, revascularization focuses on triggering bleeding into an empty root canal space with the hope that this will trigger a process similar to the role of the blood clot in triggering wound healing in surgical procedures.[82] These revascularization case series will be reviewed in this section.

Historical Development of the Field

Nearly 50 years ago, Nygaard-Østby evaluated whether pulp tissue could be regenerated in root canal systems. His approach was based on the known importance of the formation of a blood clot in wound healing[82,83] and involved laceration of the periapical tissue with an endodontic file. His first case series reported on nine patients aged 21 to 42 and a total of 17 teeth; there was a 13-day to 3-year follow-up prior to tooth extraction and histologic analysis.[82] Some of the cases had vital pulp tissue. In these cases, there was an aseptic access, the pulp was extirpated, and the apex was overinstrumented to evoke bleeding. Then the canals were obturated with Kloroperka N-O paste and a gutta-percha point. In the teeth with necrotic pulp tissue, the procedure was the same as in the teeth with vital pulp tissue, but the canals were irrigated and had interappointment treatment with sulfathiazole and 4% formaldehyde. Teeth were then extracted, and both clinical and histologic findings were reported (Fig. 16-3). In general, apical inflammation from

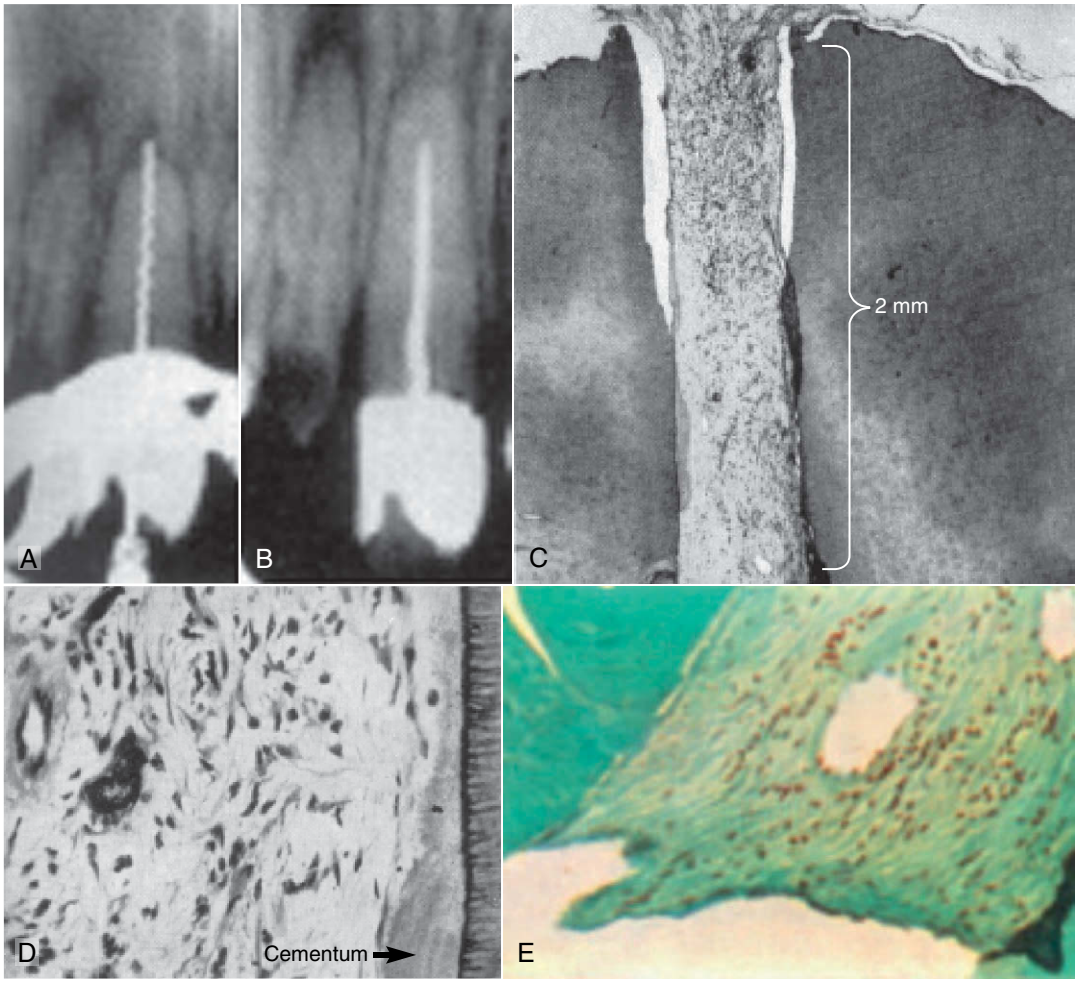

FIG. 16-3 Radiographic and histologic findings from a central incisor with a necrotic pulp, from Nygaard-Østby.[82] **A,** Evidence of a file going beyond the apex. There is also evidence of a radiolucency in the apical area. **B,** Second radiograph at 14 months, taken shortly before tooth was extracted, showing the short fill. **C,** Histologic section of same tooth, showing fibrous connective tissue has grown into the apical 2 mm of the tooth. **D,** Higher magnification *(upper right)* shows evidence of what appears to be cementum deposition on the canal wall and fibrous connective tissue in the pulp space. **E,** Evidence of collagen bundles in the canal space. *(From Nygaard-Østby B: The role of the blood clot in endodontic therapy: an experimental histologic study.* Acta Odontol Scand *19:323, 1961.)*

the overinstrumentation resolved by about 2 weeks. At the 1-month postoperative time point, the periodontal ligament tissue was healed. At 10 months, periapical bone was still being formed. The blood clot in the root canal systems gradually was replaced with granulation tissue, and then fibrous connective tissue. However, the growth of this tissue into the root canals was incomplete, and there was also histologic evidence of variable resorption of the dentinal walls along with the deposition of cementum. No newly formed dentin was observed. In his second case series on 47 teeth, histologic evidence of an ingrowth of vascularized fibrous connective tissue was observed in 80% (28 of 35) of teeth with vital pulps but only 8% (1 of 12) of teeth with necrotic pulps.[83] Although newly mineralized tissue was evident on some dentinal walls, it appeared to be cementum and not newly formed dentin. This finding of cementum deposition is consistent with recent histologic studies using contemporary revascularization procedures.[129] Taken together, most* but not all[101] studies of this period suggested that it is possible to create an environment that favors ingrowth of connective tissue into the débrided root canal system that is capable of depositing mineralized tissue on canal walls. However, the extent of tissue ingrowth was limited in most cases to the apical 2 to 3 mm of the root canal system, the mineralized tissue was often described as cementum, and inflammatory elements and/or resorption were also reported. These findings clearly did not replicate the pulp-dentin complex, and research in this area gradually subsided.

Clinical Procedures Related to Regenerative Endodontics

Since the report of this original body of research, there have been substantial fundamental advances in our understanding of canal disinfection, coronal microleakage, and the entire field of regenerative medicine. The development of these technologies and a new knowledge base has resulted in a recent surge in the publication of clinical procedures typically applied to immaturely developed (i.e., open apex) permanent teeth with a diagnosis of pulpal necrosis. With these publications has come some controversy regarding the terminology that should be used to describe the clinical procedure and outcomes. There are several procedures designed to treat the incompletely formed root that occur following endodontic procedures. *Apexification* is defined as a method to induce a calcified barrier in a root with an open apex or the continued apical development of an incompletely formed root in teeth with necrotic pulp tissue.[2] This is distinct from revascularization, since apexification does not attempt to regain vital tissue in the canal space. Rather, the outcome of an apexification procedure is establishment of an apical barrier against which an obturating material may be placed. A second term, *apexogenesis,* is defined as a vital pulp therapy procedure performed to encourage continued physiologic development and formation of the root end.[2] An important distinction is that apexogenesis is indicated for teeth in which there has been no loss of vascularity, thus no need to "revascularize" the canal space. Another term used to describe root development is *maturogenesis*.[133] In that the desired outcome of revascularization procedures is to set the stage for *physiologic root development,* the term that best describes revascularization outcomes.

*References 30, 65, 79, 80, 82, 83, and 116.

Revascularization can be broadly defined as the restoration of vascularity to a tissue or organ.[5] The use of this term was recently discussed in a letter to the editor of the *Journal of Endodontics*.[53] The authors stated that the term *revascularization* does not completely address the desired outcomes of regenerative endodontic procedures, because the desired outcome is regeneration of the pulp-dentin complex, rather than just revascularization of the canal space. Further, they suggested that "induced or guided tissue generation and regeneration" would be more appropriate terminology. Others have observed that "Guided tissue regeneration has some merit except that … we do not know what tissue fills the pulp space."[123] Given the lack of clinical and histologic evidence, it is difficult to settle on consistent terminology, and the ongoing development and application of tissue-engineering principles makes this a moving target that is likely to change with development of new clinical procedures. It is important to note that basic research and preclinical studies have identified many of the critical issues for regenerative endodontic procedures, yet case studies published to date continue to use revascularization methods coupled with recent advances in canal disinfection and new materials (e.g., MTA) that minimize the potential for coronal microleakage. Thus, this is a dynamic period of development of this class of procedures.

There have been numerous recent case reports and case series on revascularization of the necrotic pulp space. Investigators and clinicians have used a variety of medicaments to disinfect the canal space. These include a triple antibiotic paste (a 1 : 1 : 1 mixture of ciprofloxacin/metronidazole/minocycline) or variation thereof,[14,58,59,92,121] $Ca(OH)_2$ alone or in combination with antibiotics,[21,22,59] and formocresol.[103]

The triple antibiotic paste—because its use has been reported in a number of case reports and case series and because it is less commonly used in dentistry than $Ca(OH)_2$ and formocresol—deserves additional review. The development of the triple antibiotic paste was led in large part by Hoshino and colleagues.[48,100] They demonstrated the effectiveness of combinations of antibiotics (and in particular the high efficacy of the combination of ciprofloxacin, metronidazole, and minocycline) in eradicating bacteria from the infected dentin of root canals. Astute practitioners realized that the triple antibiotic paste could be a valuable adjunct for revascularization procedures, since it could be used to create an environment favorable for the ingrowth of vasculature and regenerative cells by reducing or eradicating bacteria in the canal space of teeth with necrotic pulps and incompletely formed apices. The efficacy of the triple antibiotic paste in disinfecting necrotic root canal systems has been demonstrated in a preclinical model.[134] In this dog study, 60 teeth were accessed and infected by sealing dental plaque and sterile saline on a cotton pellet into the pulp chamber for 6 weeks. By the end of this period, each premolar was radiographically confirmed to have apical periodontitis. The canals were then sampled at three time points: before and after irrigation with 1.25% NaOCl, and 2 weeks after the delivery of the triple antibiotic paste into the root canal system using a Lentulo spiral. Before irrigation, all of the teeth had positive cultures for anaerobic bacteria, with a mean colony forming unit (CFU) count of 1.7×10^8. After irrigation with 1.25% NaOCl, 10% of the teeth sampled cultured bacteria free. The mean colony-forming unit (CFU) count was 1.4×10^4, or an approximate

10,000-fold reduction in viable bacteria. After dressing with the triple antibiotic paste for 2 weeks, 70% of the teeth sampled cultured bacteria free. The mean CFU count was only 26, which is about another 1000-fold drop in bacteria. This study provides strong support for the effectiveness of the triple antibiotic paste in disinfection of immature teeth with apical periodontitis.

Related dog studies sought to determine how best to create a matrix, or scaffold, onto which stem cells could grow in the canal system.[120] Using a protocol similar to that described earlier, immature dog teeth that were infected and confirmed to have developed apical periodontitis were then disinfected with the triple antibiotic paste. At the revascularization step, teeth were randomized into four groups: (1) no further treatment, (2) stimulation of bleeding into the canals, (3) placement of collagen solution in the canals, (4) placement of a mixture of collagen solution and blood. A fifth group of teeth that were not infected were left for natural development. The teeth were radiographically monitored for 3 months, at which time the dogs were sacrificed for histologic examination. In the teeth where nothing was done to create bleeding into the canal, there was evidence of persistent apical radiolucency and a lack of further development in root length and root wall thickness. Histologic sections from these teeth demonstrated persistent apical inflammation and thin root walls. In teeth where a blood clot was formed in the canal system, there was radiographic evidence of resolution of the apical pathosis and an increase in root length and root wall thickness. Histologic sections demonstrated healing of the apical area, including bone and periodontal ligament, ingrowth of tissue into the root canal system, and thickening of the root walls. Findings indicated that there was a trend toward more vital tissue within the canal lumens for roots in which blood clot was formed after disinfection with triple antibiotic paste. In addition, the results suggest the importance of inclusion of a blood clot to improve chances of revascularization. The fibrin polymer of the blood clot likely served as a matrix, or scaffold, for stem cell growth, thus enhancing the likelihood of tissue regeneration. Collectively, these two preclinical studies provide evidence for the efficacy of triple antibiotic paste and suggest the importance of a scaffold in promoting tissue ingrowth.

Prior to reviewing the techniques used for revascularization, it is important to consider the relative advantages and limitations of revascularization compared to other options for treatment of the immature tooth with necrotic pulp (see also Chapter 23). There are several challenges clinicians face when presented with an incompletely formed root in need of endodontic treatment. Because the apex is not fully developed and often has a blunderbuss shape, cleaning and shaping of the apical portion of the root canal system can be difficult. The process is further complicated by the presence of thin, fragile dentinal walls that may be prone to fracture during instrumentation or obturation. In addition, the open apex increases the risk of extruding material into the periradicular tissues. Traditionally an immature tooth with an open apex is treated by apexification, which involves creating an apical barrier to prevent extrusion. In many cases, this entails an involved, long-term treatment with $Ca(OH)_2$, resulting in the formation of a hard-tissue apical barrier.[25,26,33,45,115] However, a disadvantage of the traditional apexification procedures is that the short-term[98] or long-term[6,7] use of $Ca(OH)_2$ can reduce root strength. This finding is consistent with a large case series using the traditional apexification protocol; it showed that a major reason for tooth loss following apexification was root fracture.[24] The advent of one-step apexification,[23,41] by creation of artificial barriers using materials such as MTA,[102,135] has greatly decreased the number of appointments and time to completion. One-step apexification, however, does not generally result in further root development.[13,31] A primary advantage of revascularization procedures in these cases is the greater likelihood there will be an increase in root length and root wall thickness.

Overview of Clinical Revascularization Cases

To date, only case reports and case series on endodontic revascularization treatment are available; no randomized controlled clinical trials have been published. Although case series do not provide definitive evidence to support a given treatment modality, they do have the advantage of being conducted in actual patients and thus provide a higher level of evidence than preclinical studies. While techniques for endodontic revascularization have varied in published case reports and case series (Table 16-2 for a summary and Figs. 16-4 to 16-8), there have been some consistent features worth noting. Nearly all reported cases involve patients 8 to 18 years old and teeth with immature apices. Age may be an important issue, since some studies suggest that younger patients have a greater healing capacity or stem cell regenerative potential.[3,27,63,69,84] Moreover, the large diameter of the immature (open) apex may foster the ingrowth of tissue into the root canal space and may be indicative of a rich source of mesenchymal stem cells of the apical papilla (SCAP; see Fig. 16-4).[56,113,114] These tissues are likely lacerated during the evoked bleeding step and constitute one likely source of mesenchymal stem cells delivered into the root canal space. Another consistent finding reported in nearly every case is the lack of instrumentation of the dentinal walls related to concerns about the potential fracture of these thin, incompletely developed roots. The lack of instrumentation would be expected to have the benefit of avoiding generation of a smear layer that could occlude the dentinal walls or tubules. In addition, NaOCl, alone or in combination with other irrigants, was used to disinfect the canal space. In a majority of cases, a combination of triple antibiotic or NaOCl was left in the canal space for a period of days to weeks, so the disinfection protocol was primarily a chemical method rather than the chemomechanical approach used in conventional nonsurgical endodontic therapy. In most cases, a blood clot formed in the canal. The formation of a blood clot might serve as a protein scaffold, permitting three-dimensional ingrowth of tissue.

Nearly all of these reports noted continued thickening of the root walls and subsequent apical closure. An example of increased root length and thickening of root walls is seen in Fig. 16-6.[92] Because of the lack of histology in these clinical cases, it should be recognized that radiographic findings of continued root wall thickness does not necessarily indicate that dentin was formed. Based on histologic results from preclinical studies, it is possible that the radiographic appearance of increased root wall thickness might be due to ingrowth of cementum, bone, or a dentin-like material.* It should also be noted in some of the case reports[21,58,59] that although the teeth

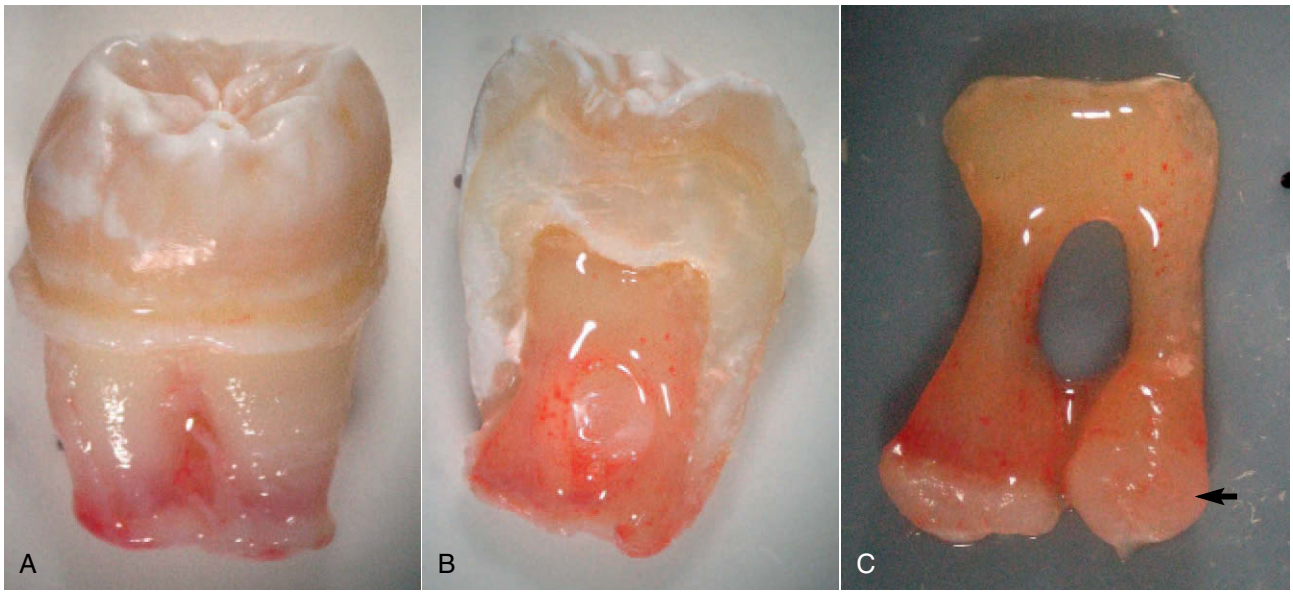

FIG. 16-4 A-C, Dissection of an immature permanent tooth indicating the extent of the apical papilla. Note that this structure is likely lacerated during the evoked bleeding step of revascularization cases and thus cells from this structure, including mesenchymal stem cells of the apical papilla (SCAP), are likely to be delivered into the root canal space. Arrow in **C** denotes junction of apical papilla and dental pulp. *(Courtesy Dr. Michael Henry.)*

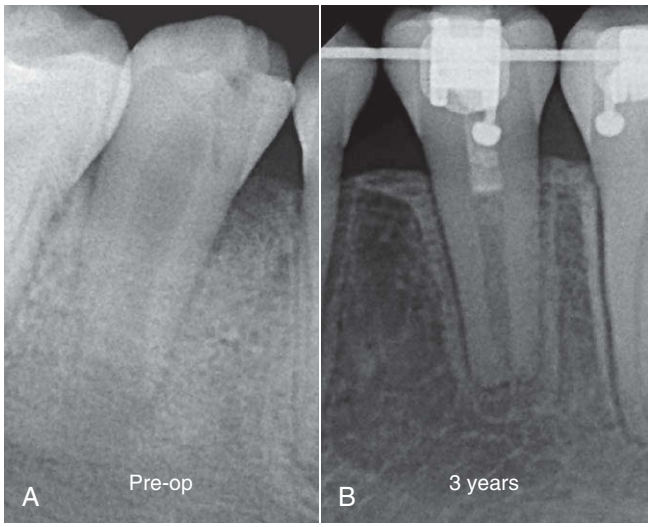

FIG. 16-5 Revascularization case of a 14-year-old female patient with a diagnosis of pulpal necrosis secondary to dens invaginatus. The tooth was isolated, accessed, and irrigated with 2.5% sodium hypochlorite and 2% chlorhexidine, followed by placement of a mixture of ciprofloxacin, metronidazole, and minocycline for 96 days. Upon recall, symptoms had subsided, the tooth was isolated, and the triple antibiotic paste was removed by irrigation. Bleeding was established, and the root canal system was sealed with white mineral trioxide aggregate and a composite restoration. *(Courtesy Dr. Sandra Madison.)*

were nonresponsive to pulp testing, vital tissue was identified in the apical portion of the canal space. In these cases, necrotic tissue was removed until bleeding was observed, then the canals were disinfected with antibiotic paste[58,59] or $Ca(OH)_2$.[21] One could argue that by leaving vital pulp tissue in the apical segment of the canal, the resulting progression of root formation is more similar to apexogenesis than revascularization. Although the biologic process may differ between the revascularization and apexogenesis cases presented in these case reports, the goals of the procedures are similarly advantageous and significant. In both procedures, there is healing of the periradicular tissues and a progression of root development in a tooth that would otherwise have had a progression of pulpal and periradicular pathosis.

A retrospective study has compared the radiographic changes in 48 revascularization cases to 40 control cases.[18] Although published revascularization cases have been treated with varying clinical protocols, they can be grouped by method of canal disinfection—namely, triple antibiotic paste, $Ca(OH)_2$ treatment, or formocresol treatment. This study applied a mathematical image-correction procedure that permitted the comparison of nonstandardized radiographs with subsequent statistical analysis of radiographic outcomes. The percent change in root dimensions was first compared in two negative control groups (nonsurgical root canal treatment [NSRCT] and MTA apexification) predicted to have little to no change in root dimensions. This provides an internal test that the mathematical analysis was appropriate. The results indicate that these two negative control groups had minimal measured changes in root length (Fig. 16-9) or root width (Fig. 16-10), with the anticipated finding that instrumentation with files of greater taper resulted in a slight but detectable loss of apical root width. The results indicated that revascularization treatment with either the triple antibiotic paste or $Ca(OH)_2$ produced significantly greater increases in root length compared with either the MTA or NSRCT control groups. The formocresol group differed only in comparison to the MTA apexification control group. In terms of changes in root width (see Fig. 16-10), treatment with the triple antibiotic paste produced significantly greater increases in dentin wall thickness compared with the MTA and NSRCT control groups. Treatment

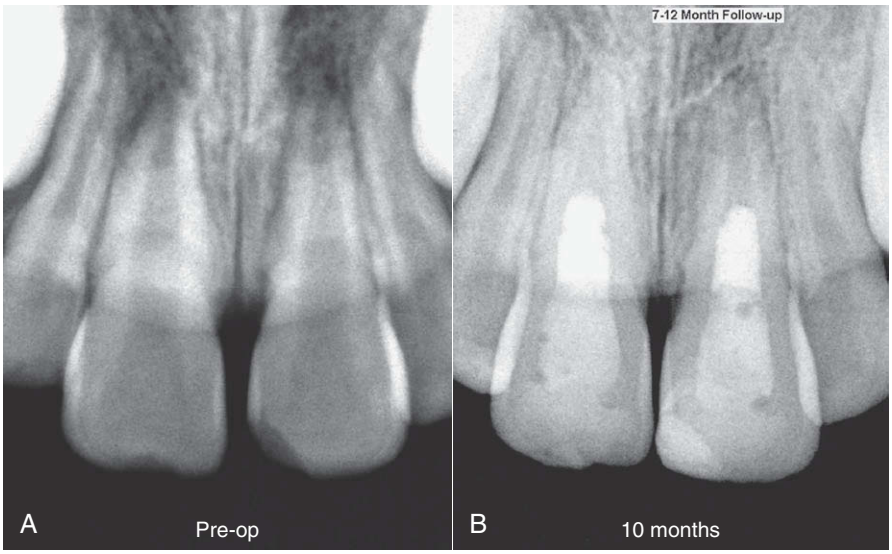

FIG. 16-6 Revascularization case for treating an 8-year-old female patient with a diagnosis of pulpal necrosis secondary to dental trauma (lateral luxation with +2 class fracture of teeth #8 and #9). The teeth were isolated, accessed, and irrigated with 5% sodium hypochlorite and 2% chlorhexidine, followed by placement of a mixture of ciprofloxacin, metronidazole, and minocycline for 21 days. Upon recall, symptoms had subsided, the teeth were isolated, and the triple antibiotic paste was removed by irrigation. Bleeding was established in both teeth, and the root canal systems were sealed with white mineral trioxide aggregate and a composite restoration. *(Courtesy Dr. Alan Law.)*

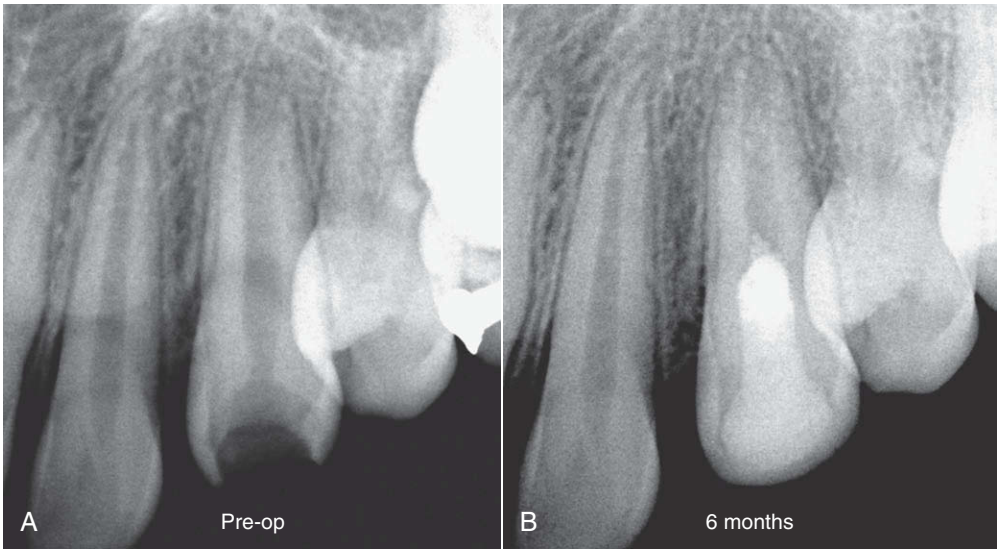

FIG. 16-7 Revascularization case illustrating treatment delivered to a 13-year-old female patient with a diagnosis of pulpal necrosis secondary to caries, with an unspecified prior history of trauma. The tooth was isolated, accessed, and irrigated with 5% sodium hypochlorite and 0.12% chlorhexidine, followed by placement of a mixture of ciprofloxacin, metronidazole, and minocycline for 21 days. Upon recall, the tooth was isolated, and the triple antibiotic paste was removed by irrigation. Bleeding was established in both teeth, and the root canal system was sealed with white mineral trioxide aggregate and a composite restoration. *(Courtesy Dr. Alan Law.)*

with $Ca(OH)_2$ or formocresol resulted in significantly greater change in dentinal wall thickness compared with the NSRCT group, but no differences were observed between these medicaments and the MTA apexification group. Finally, the triple antibiotic paste produced significantly greater differences in dentinal wall thickness compared with either the $Ca(OH)_2$ or formocresol groups. In general, the formocresol group showed the smallest improvement in root length and thickness. Secondary analyses indicated that a 12- to 18-month recall is probably the minimal time to judge radiographic evidence of root development, although later time points (36 months) often demonstrate continued root development. Another secondary analysis indicated that the location of $Ca(OH)_2$ placement appeared to be a strong predictor of radiographic outcome. When $Ca(OH)_2$ placement was restricted to the coronal half of the root canal, the increase in root wall thick-

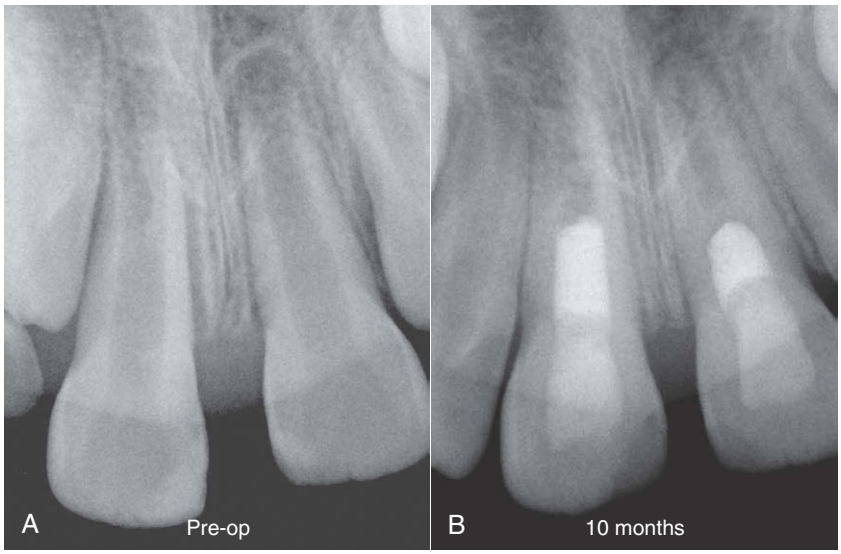

FIG. 16-8 Revascularization case illustrating treatment delivered to a 9-year-old male patient with a diagnosis of pulpal necrosis secondary to trauma, with a class 3 fracture in tooth #8 and a class 2 fracture in tooth #9. The patient reported moderate to severe pain in both teeth. The teeth were isolated, accessed, and irrigated with 5% sodium hypochlorite, followed by placement of a mixture of ciprofloxacin, metronidazole, and minocycline for 55 days. Upon recall, the teeth were isolated, and the triple antibiotic paste was removed by irrigation. Bleeding was established in tooth #9 but not in tooth #8, where CollaCote was placed prior to mineral trioxide aggregate (MTA). The root canal systems were sealed with white MTA and a composite restoration. *(Courtesy Dr. Alan Law.)*

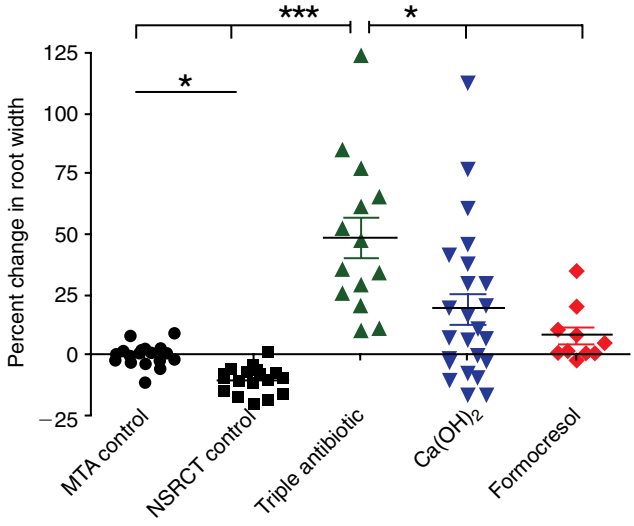

FIG. 16-9 Retrospective analysis of the percentage of change in root length from preoperative image to postoperative image, measured from the cementoenamel junction (CEJ) to the root apex in 40 control patients and in 48 patients following a revascularization procedure. ***$P < 0.001$ versus mineral trioxide aggregate (MTA) apexification control group (n = 20) and NSRCT control group (n = 20). $P < 0.05$ versus MTA control group only. Median values for each group are depicted by horizontal line, and individual cases are indicated by the corresponding symbol. *(From Bose R, Nummikoski P, Hargreaves K: A retrospective evaluation of radiographic outcomes in immature teeth with necrotic root canal systems treated with regenerative endodontic procedures.* J Endod *35:1343, 2009.)*

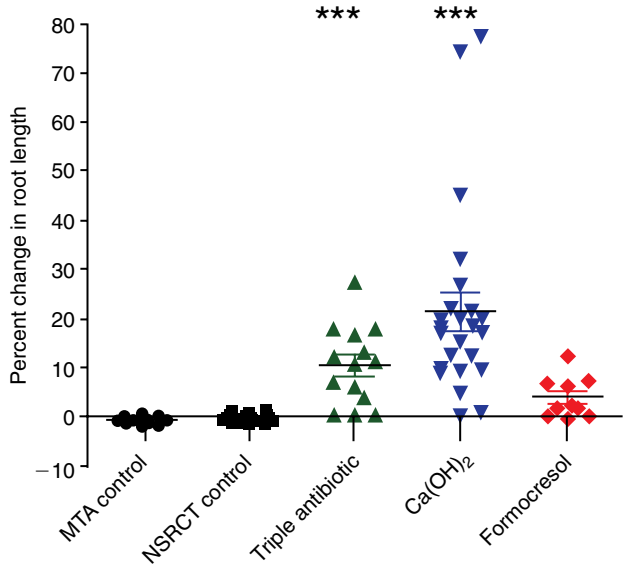

FIG. 16-10 Retrospective analysis of the percentage of change in dentinal wall thickness from preoperative image to postoperative image, measured at the apical third of the root (position of apical third defined in the preoperative image) in 40 control patients and in 48 patients following a revascularization procedure. ***$P < 0.001$ versus mineral trioxide aggregate (MTA) apexification control group and NSRCT control group. $P < 0.05$ versus NSRCT control group only. $P < 0.05$ versus Calcium hydroxide ($Ca[OH]_2$) and formocresol groups. $P < 0.05$ versus NSRCT control group only. *(From Bose R, Nummikoski P, Hargreaves K: A retrospective evaluation of radiographic outcomes in immature teeth with necrotic root canal systems treated with regenerative endodontic procedures.* J Endod *35:1343, 2009.)*

ness was 55%, compared to a 3% increase when it was placed in the apical half of the root canal system. This might be due to residual $Ca(OH)_2$ having a cytotoxic interaction with stem cells. Although prospective randomized clinical trials with standardized radiographic assessment are clearly required, the results of this retrospective study are consistent with a robust outcome of revascularization procedures, particularly when medicated with either a triple antibiotic paste or a $Ca(OH)_2$ medicament. The demonstration of continued root development does not reveal whether this radiopaque material is dentin, cementum, or bone, so given the known reliance of stem cells on an appropriate scaffold and growth factor combination, this will be an important focus for future research efforts.

Example of a Revascularization Protocol

Based on current research, several considerations can be reviewed when considering a protocol for revascularization treatment. The first issue is case selection; the best available evidence indicates that this treatment should be considered for the incompletely developed permanent tooth that has an open apex and is negative to pulpal responsiveness testing. Although the ultimate goal of this approach is to develop a tissue engineering–based method of pulpal regeneration in the fully developed permanent tooth, it should be recognized that current revascularization protocols have not been developed or evaluated for these more challenging cases. Informed consent issues should include the number of appointments (at least two), the possible adverse effects (primarily potential minocycline staining of the crown), the potential lack of response to treatment and alternative treatments, and possible posttreatment symptoms. Clinical staining of the crown and any root structure above the gingival margin appears to be due to the presence of minocycline. This can be minimized by using a delivery system that restricts the drug below the cementoenamel junction (CEJ). When it does occur, it can often be reduced or eliminated by a walking bleach method with sodium perborate. Likely alternative treatments would include MTA apexification, no treatment, or extraction.

At the first appointment (Fig. 16-11, *A-E*), the treatment alternatives, risks, and potential benefits should be described to the patient and guardian after collecting clinical information and establishing pulpal and periradicular diagnoses. Following informed consent, the tooth is anesthetized, isolated, and accessed. Minimal instrumentation should be accomplished, but the use of a small file to "scout" the root canal system and determine working length is important. If sensation is experienced within the canal system, this may suggest that some residual vital pulp tissue remains.[59] The root canal system is copiously and slowly irrigated with 20 ml of NaOCl followed by 20 ml of 0.12% to 2% chlorhexidine (CHX). Since canal disinfection relies considerably on chemical irrigants, it is important to place the needle into the apical third and irrigate using needles with a closed end and side-port vents (e.g., Max-I-Probe needles), together with a slow rate of infusion, to help to reduce any irrigants passing through the open apex. The root canal system is then dried with sterile paper points, and the antimicrobial medicament is delivered into the root canal space. The best available evidence would support the use of either a triple antibiotic paste or $Ca(OH)_2$. Both medicaments have been shown to be effective (see Figs. 16-9 and 16-10). The triple antibiotic paste has the advantage of being a very effective antibiotic combination against odontogenic microorganisms[48,100]; its efficacy is supported by several case studies.[18] This combination is not approved by the U.S. Food and Drug Administration (FDA), however, and carries a potential for minocycline staining of the crown. Alternatively, $Ca(OH)_2$ has the advantage of being widely available and is a commonly used medicament, but it may be cytotoxic to stem cells.[14,18,20] After antimicrobial medicament is placed, the tooth is then sealed with a sterile sponge and a temporary filling (e.g., Cavit), and the patient is discharged for 3 to 4 weeks.

At the second appointment (see Fig. 16-11, *F-J*), the patient is evaluated for resolution of any signs or symptoms of an acute infection (e.g., swelling, sinus tract pain, etc.) that may have been present at the first appointment. The antimicrobial treatment is repeated if resolution has not occurred.[20,59] In most cases, the acute signs and symptoms have resolved. Since revascularization-induced bleeding will be evoked at this appointment, the tooth should not be anesthetized with a local anesthetic containing a vasoconstrictor. Instead, 3% mepivacaine can be used, which will facilitate the ability to trigger bleeding into the root canal system.[93] Following isolation and reestablishment of coronal access, the tooth should be copiously and slowly irrigated with 20 ml NaOCl, possibly together with gentle agitation with a small hand file to remove the antimicrobial medicament. After drying the canal system with sterile paper points, a file is placed a few mm beyond the apical foramen, and the apical tissue is lacerated with bleeding up to 3 mm from the CEJ. A small piece of Colla-Plug may be inserted into the root canal system to serve as a resorbable matrix to restrict the positioning of the MTA. About 3 mm of MTA is then placed, followed by a restoration. A 12- to 18-month recall should be considered as the earliest time point to conduct the clinical examination and evaluate continued radiographic improvement in root development.[18]

Clinical Measures of Treatment Outcome

The goal of nonsurgical root canal treatment is to maintain or restore the health of periradicular tissues. The goals of revascularization procedures extend beyond those of nonsurgical root canal treatment in that there is an additional objective of regaining vital, functioning tissue capable of supporting continued root development in cases of the immature permanent tooth with a necrotic root canal system. The measures of success for revascularization are not only radiographic evidence of periradicular health but also radiographic and other clinical evidence of functioning vital tissue in the canal space. Radiographic evidence of functioning pulp (or pulplike) tissue would include continued root growth, both in length and wall thickness. These findings have been shown in many published cases. Other measures of the presence of vital, functioning tissue in the canal space include laser Doppler blood flowmetry[117]; pulp testing involving heat, cold, and electricity[91]; and lack of signs or symptoms. The ideal clinical outcome is an asymptomatic tooth that does not require retreatment, but to validate that regenerative endodontic techniques are truly effective, nonsubjective vitality-assessment methods are essential.

It is worth noting that the published revascularization cases have shown increased root wall thickness that is limited to the

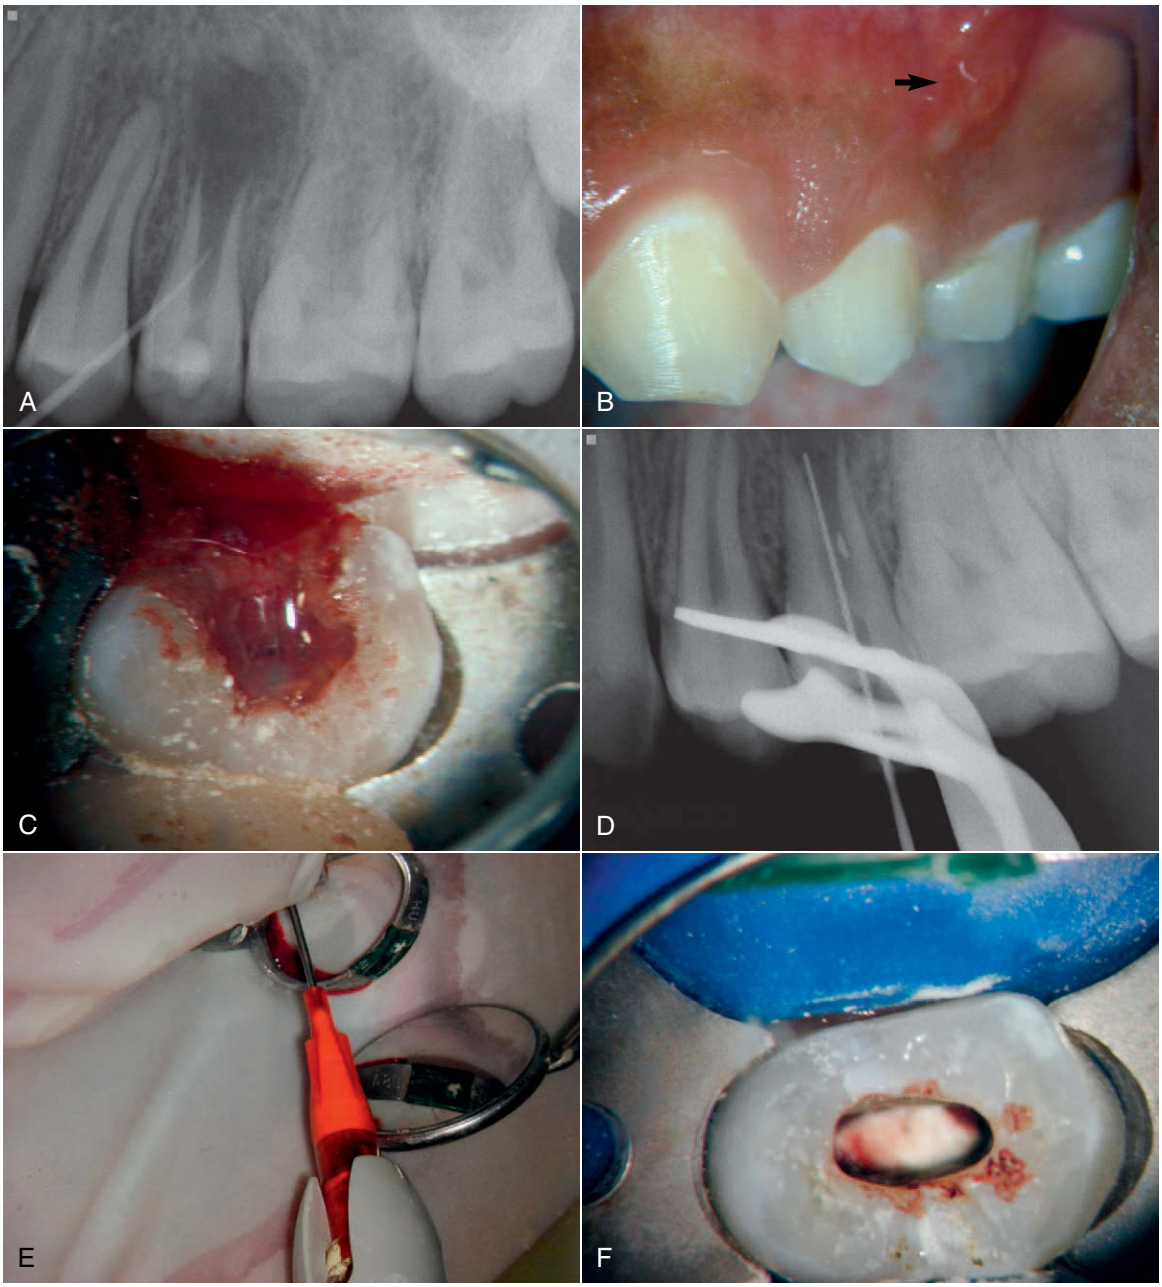

FIG. 16-11 Example of a revascularization protocol. First appointment: Clinical examination revealed a sinus tract **(A),** soft-tissue swelling that required an incision for drainage **(B),** and purulent/hemorrhagic exudates upon access **(C-D).** A working length file was placed into the root canal system, and the tooth was slowly irrigated with 20 ml of 5.25% sodium hypochlorite (NaOCl) and 20 ml of 0.12% chlorhexidine using a Max-I-Probe needle inserted to the apical third. **E,** The canals were dried and medicated by a triple antibiotic paste (a 1:1:1 mixture of ciprofloxacin/metronidazole/minocycline) using a Centrix syringe that facilitates delivery below the cementoenamel junction (CEJ). The patient returned 1 month later. The tooth was isolated, accessed, and the medicament removed by slow irrigation with NaOCl. CollaPlug was placed below the CEJ **(F)** to serve as a matrix to position the mineral trioxide aggregate coronal to the blood clot **(G).**

Continued

midroot and apical root. There has been no demonstration of increased root thickness in the cervical area, an area shown to be prone to fracture in immature teeth with a history of trauma and subsequent endodontic treatment.[24] Future clinical studies should focus on extending revascularization into the cervical area, potentially strengthening this area and decreasing the risk of root fracture.

SUMMARY

The field of regenerative endodontics is rapidly advancing. It is based upon the principles of tissue engineering, namely the spatial delivery of appropriate cells, scaffolds, and growth factors. Similar to most rapidly developing fields, the preclinical area of research has outpaced translational clinical studies.

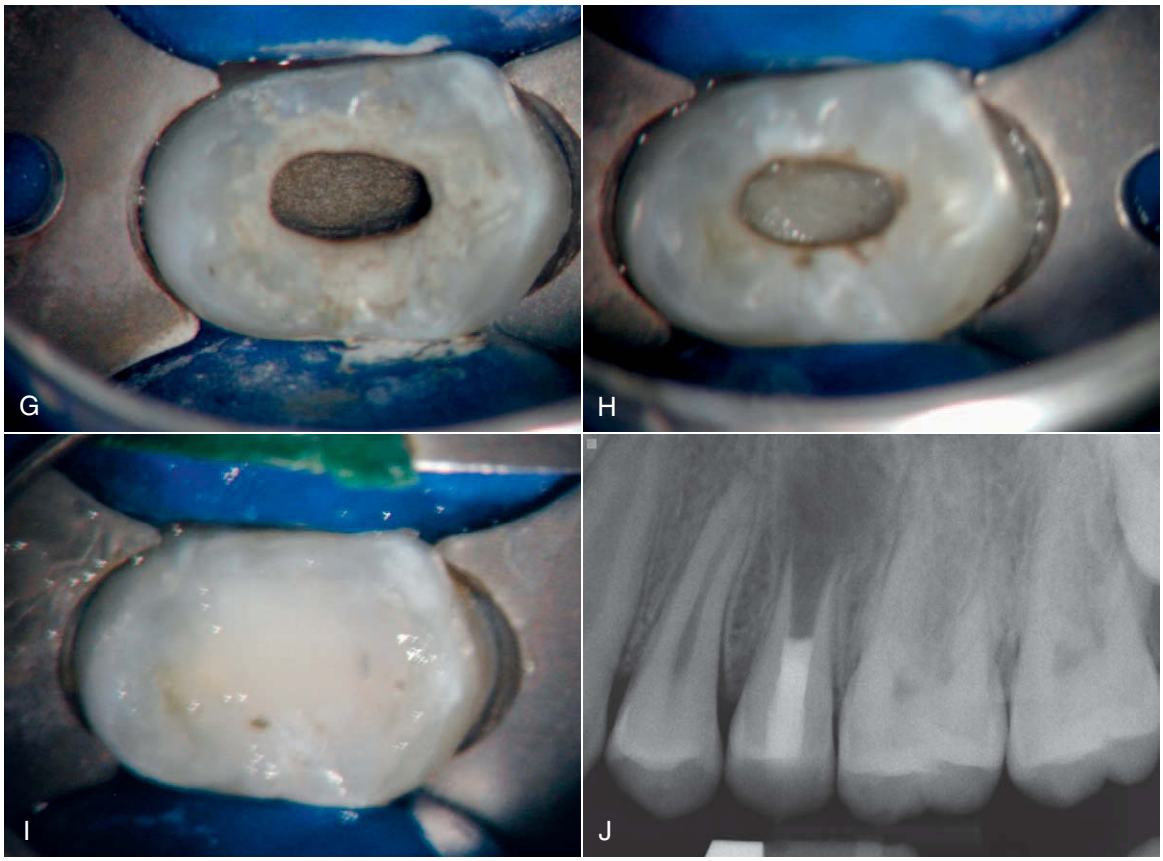

FIG. 16-11, cont'd The tooth was then sealed with a layer of Fuji II **(H)** and a composite **(I-J).** *(Courtesy Dr. Anibal Diogenes.)*

Preclinical studies have identified several mesenchymal stem cell sources capable of differentiating into odontoblast-like cells, as well as candidate scaffolds and growth factors capable of guiding this development. The initial preclinical animal studies indicate that an approach using human stem cells implanted into a human root in an immunocompromised mouse provides a useful model for evaluating combinations of stem cells/scaffolds/growth factors for regenerating the pulp-dentin complex. It is likely that this combined approach of in vitro and in vivo preclinical research will greatly advance our understanding of the conditions necessary to regenerate a functional pulp-dentin complex.

To date, none of the published clinical studies fully engage the concepts of tissue engineering. Instead, these studies are best described as revascularization procedures that attempt to regenerate biologic tissues within the root canal space, without necessarily replicating the pulp-dentin complex. Discussion about the requirements of an appropriate scaffold and growth factor was begun in the 1960s by Nygaard-Østby,[82] who had no access to our contemporary instruments, materials, and the entire knowledge base of tissue engineering. Although clinical revascularization procedures do not constitute the ideal regenerative treatment, it is important to note that they do generate a scaffold (fibrin) and growth factors (from platelets and access to proteins embedded in the dentinal walls), and the clinical outcome results in continued radiographic root development of the immature permanent tooth with a diagnosis of pulpal necrosis. Thus, a revascularization procedure provides a very real treatment of high value in cases with an otherwise poor prognosis. Histologic analyses of revascularization procedures conducted in patients[82,83] or animals[78,96,129] suggests that the increase in root dimensions is often due to deposition of cementum-like material, dentin, or bone.

Future clinical research will likely focus on translating basic research findings into improved regenerative procedures. For example, the formation of a cementum-like material on the dentinal walls may lead to studies evaluating benefits of revascularization procedures for overall tooth resistance to fracture. In addition, it is clear that the multipotent nature of many mesenchymal stem cell types could contribute to the finding of cementum deposition. Controlled differentiation into odontoblasts is an important area of research and amenable to tissue-engineering concepts. The development of delivery systems that permit structural reinforcement of the cervical area (or ideally, the pulp chamber) might provide clinical opportunities to regenerate lost tooth structure, thereby permitting natural teeth to be retained instead of possible fracture or extraction. Finally, the ultimate and long-term goal for regenerative endodontic procedures should be to treat the fully formed permanent tooth. Although this situation is more complex than the immature tooth with an open apex and a ready source of stem cells, it provides the unique potential of saving the natural dentition while restoring the sensory, immunologic, and defensive properties of the pulp-dentin complex.

CHAPTER 17

The Role of Endodontics After Dental Traumatic Injuries

ASGEIR SIGURDSSON, MARTIN TROPE, and NOAH CHIVIAN

CHAPTER OUTLINE

UNIQUE ASPECTS OF DENTAL TRAUMA
MOST COMMON TYPES OF DENTAL TRAUMA
- Crown fractures
- Crown-Root Fractures
- Root Fractures
- Luxation Injuries and Avulsion

FOLLOW-UP AFTER DENTAL TRAUMA
RADIOGRAPHIC EXAMINATIONS
CROWN FRACTURES
- Crown Infraction
- Uncomplicated Crown Fracture
- Treatment
- Complicated Crown Fracture
- Treatment
- Vital Pulp Therapy: Requirements for Success
- Treatment Methods
- Treatment of the Nonvital Pulp

CROWN-ROOT FRACTURE
ROOT FRACTURE
- Diagnosis and Clinical Presentation
- Treatment
- Healing Patterns
- Treatment of Complications

LUXATION INJURIES
- Definitions
- Incidence
- Treatment
- Biologic Consequences

CLINICAL MANAGEMENT OF THE AVULSED TOOTH
- Consequences of Tooth Avulsion
- Treatment Objectives
- Clinical Management
- Diagnosis and Treatment Planning

PREPARATION OF THE ROOT
- Extraoral Dry Time Less Than 60 Minutes
- Extraoral Dry Time More Than 60 Minutes

PREPARATION OF THE SOCKET
SPLINTING
MANAGEMENT OF THE SOFT TISSUES
ADJUNCTIVE THERAPY
- Second Visit

ENDODONTIC TREATMENT
- Extraoral Time Less Than 60 Minutes
- Extraoral Time More Than 60 Minutes

TEMPORARY RESTORATION
- Root Filling Visit

PERMANENT RESTORATION
- Follow-Up Care

A traumatic injury to the tooth results in damage to many dental and periradicular structures, making the management and consequences of these injuries multifactorial. Knowledge of the interrelating healing patterns of these tissues is essential.

This chapter will concentrate on the role of the dentinopulpal complex in the pathogenesis of disease subsequent to dentinal trauma and how treatment of this complex can contribute to favorable healing after an injury.

UNIQUE ASPECTS OF DENTAL TRAUMA

Most dental trauma occurs in the 7- to 12-year-old age group and is mainly due to falls and accidents near home or school.[23,132] It occurs primarily in the anterior region of the mouth, affecting the maxillary more than the mandibular jaw.[28] Serious accidents like automobile crashes can affect any tooth and occur in all age ranges. In many cases, after a traumatic dental injury, endodontic treatment is provided to caries-free, single-rooted, young permanent teeth. If quick and correct treatment for these teeth is provided after injury, the potential for a successful endodontic outcome is very good.

MOST COMMON TYPES OF DENTAL TRAUMA

Crown Fractures

Most crown fractures occur in young, caries-free anterior teeth.[88,98] This makes maintaining or regaining pulp vitality essential. Luckily, vital pulp therapy supports a good prognosis in these situations if correct treatment and follow-up procedures are carefully followed.

Crown-Root Fractures

Crown-root fractures are first treated periodontally to ensure there is a sufficient and good margin for the restoration to be possible. If the tooth can be maintained from a periodontal point of view, the pulp is treated as with a crown fracture.

Root Fractures

A surprisingly large number of pulps in root-fractured teeth will survive this rather dramatic injury. In almost every case, the apical segment stays vital, and in many cases, the coronal segment stays vital or regains vitality subsequent to the injury. If the coronal segment permanently loses vitality, it should be treated as an immature permanent tooth with nonvital pulp. *The apical segment rarely needs treatment.*

Luxation Injuries and Avulsion

Luxation injuries and avulsion often result in pulp necrosis and damage to the cemental protective layer of the root. The potential complication of pulp infection in a root that has lost its cemental protective layer makes these injuries potentially catastrophic. Correct emergency and follow-up evaluation, which may include timely endodontic treatment, is critical.

FOLLOW-UP AFTER DENTAL TRAUMA

The reader is referred to Chapter 1 for specific descriptions of pulp tests, but a few general statements about pulp tests on traumatized teeth may be helpful in trying to interpret the results.

For decades, controversy has surrounded the validity of thermal and electric tests on traumatized teeth. Only generalized impressions may be gained from these tests following a traumatic injury. They are in reality sensitivity tests for nerve function and do not indicate the presence or absence of blood circulation within the pulpal space. It is assumed that subsequent to traumatic injury, the conduction capability of the nerve endings and/or sensory receptors is sufficiently deranged to inhibit the nerve impulse from an electric or thermal stimulus. This makes the traumatized tooth vulnerable to false-negative readings from such tests.[112]

Teeth that give a response at the initial examination cannot be assumed to be healthy and continue to give a response over time. Teeth that yield no response cannot be assumed to have necrotic pulps, because they may give a response at later follow-up visits. It has been demonstrated that it may take as long as 9 months for normal blood flow to return to the coronal pulp of a traumatized fully formed tooth. As circulation is restored, the responsiveness to pulp tests returns.[66]

The transition from no response to a response at a subsequent test may be considered a sign of a healing pulp. The repetitious finding of responses may be taken as a sign of a healthy pulp. The transition from a response to no response may be taken as an indication that the pulp is probably undergoing degeneration, and therefore an intervention in the form of endodontic treatment might be indicated. The persistence of no response would suggest that the pulp has been irreversibly damaged, but even this is not absolute.[30]

Thermal and electric pulp tests of all anterior teeth (canine to canine) of the maxillary and mandibular jaws should be performed at the time of the initial examination and carefully recorded to establish a baseline for comparison with subsequent repeated tests in later months. These tests should be repeated at 3 weeks, at 3, 6, and 12 months, and at yearly intervals following the trauma. The purpose of the tests is to establish a trend as to the physiologic status of the pulps of these teeth. Particularly in traumatized teeth, carbon dioxide snow (CO_2, −78° C) or dichlorodifluoromethane (−40° C) placed on the incisal third of the facial surface gives more accurate responses than a water-ice pencil[64,65] (Fig. 17-1). The intense cold seems to penetrate the tooth and covering splints or restorations and reach the deeper areas of the tooth. Neither the dry ice nor the dichlorodifluoromethane spray forms ice water, which could disperse over adjacent teeth or gingiva to give a false-positive response. In trauma evaluation, there is no question that using water-ice pencils should be avoided because of this. Dichlorodifluoromethane spray is a very inexpensive alternative to CO_2 snow; how cold it is will give much more reliable responses than water ice. The electric pulp test relies on electric impulses directly stimulating the nerves of the pulp. These tests have limited value in young teeth but are useful in cases where the dentinal tubules are closed and do not allow dentinal fluid to flow in them. This situation is typical of teeth in elderly patients or in traumatized teeth that are undergoing premature sclerosis. In these situations, the thermal tests that rely on fluid flow in the tubules cannot be used, and the electric pulp test becomes important.

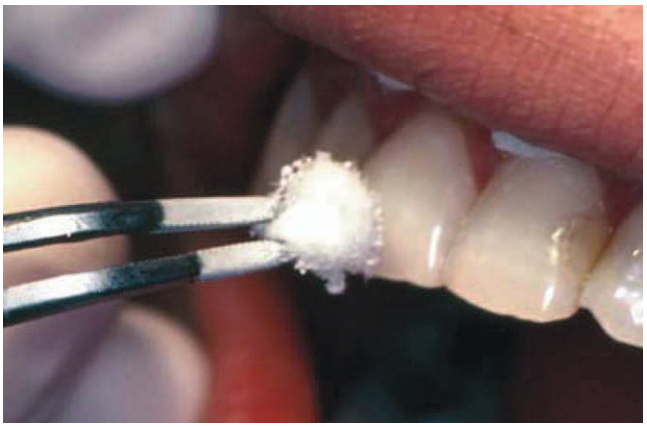

FIG. 17-1 Difluorodichloromethane (−40° F [−40° C]) gas is sprayed on a cotton pellet and then placed on the incisal edge of the maxillary incisor.

Laser Doppler flowmetry (LDF) was introduced in the early 1970s for measurement of blood flow in the retina.[81] The technique has also been used to assess blood flow in other tissue systems such as skin and renal cortex. It utilizes a beam of infrared (780 to 820 nm) or near-infrared (632.8 nm) light that is directed into the tissue by optical fibers. As light enters the tissue, it is scattered by moving red blood cells and stationary tissue cells. Photons that interact with moving red blood cells are scattered, and the frequency shifts according to the Doppler principle. Photons that interact with stationary tissue cells are scattered but not Doppler shifted. A portion of the light is returned to a photodetector, and a signal is produced (Fig. 17-2).

Attempts have been made to use LDF technology for pulp vitality diagnosis in traumatized teeth, because this would provide a more accurate reading of the vitality status of the

FIG. 17-2 Laser Doppler machine. *(Courtesy Moor Instruments, Devon, United Kingdom.)*

pulp.[103,164,165] Studies have shown promising results, indicating that laser Doppler can detect blood flow more consistently and earlier than the standard vitality tests would be expected to render a response. In a study on young dogs, laser Doppler was able to correctly detect blood flow as early as 2 to 3 weeks after avulsion of an immature tooth and at the same time indicate no flow in those which would remain necrotic.[165]

Presently the cost of a laser Doppler flowmetry machine limits its use in private dental offices; these are used primarily in hospitals and teaching institutions.

RADIOGRAPHIC EXAMINATIONS

Radiographs are essential tools in the thorough examination of traumatized hard tissues. They may reveal root fractures, subgingival crown fractures, tooth displacements, bone fractures, resorptions of the root, and adjacent bone or foreign objects. One radiograph will be insufficient in most dental trauma cases. In their new guidelines for the management of traumatic dental injuries, the International Association of Dental Traumatology (IADT) has recommended taking at least four different radiographs for almost every injury.[58-60] Those four include a direct 90-degree on the axis of the tooth, two with different vertical angulations, and one occlusal film (Fig. 17-3). Multiple radiographs will increase the likelihood of diagnosing root fractures, apical translocations, and other possible injuries.

Early detection of root resorption is extremely difficult on dental radiographs, however. The radiodensity of the root requires that a significant amount of root substance is removed to cause enough contrast on the radiograph to allow it to be detected. Thus only resorptive defects on the mesial or distal aspects of the root can be predictably detected after some time, but the facial and palatal or lingual aspects are much harder to see. To overcome these difficulties, it is essential to take as many different horizontal angled radiographs as feasible in cases of suspected root resorption. One should also carefully evaluate the adjacent bone for resorption[153] (Fig. 17-4), discussed in more detail later.

New radiographic techniques like tuned-aperture computed tomography (TACT) and cross-sectional CT scans have shown promise in improving the clinician's ability to diagnose root resorption (see also Chapter 29).[105]

FIG. 17-3 An occlusal film of a luxation injury of central incisors. Both were diagnosed to be laterally luxated with apical translocation. Note that the left central is completely obliterated and has a history of being luxated some years prior.

In instances of soft-tissue laceration, it is advisable to radiograph the injured area prior to suturing to be sure that no foreign objects have been embedded. A soft-tissue radiograph with a normal-sized film briefly exposed at reduced kilovoltage should reveal the presence of many foreign substances, including tooth fragments (Fig. 17-5).

In reviewing the films of traumatized teeth, special attention should be directed to the dimension of the root canal space, the degree of apical closure of the root, the proximity of fractures to the pulp, and the relationship of root fractures to the alveolar crest. Whereas conventional periapical films are generally useful, an occlusal or Panorex film can supplement them when the clinician is looking for bone fractures, dislocation of teeth, or the presence of foreign objects.

CROWN FRACTURES

As already mentioned, the primary aim from an endodontic point of view is to maintain pulp vitality after crown fractures.

Crown Infraction

Crown infraction can be defined as an incomplete fracture or crack of enamel, without loss of tooth structure.[16]

Biologic Consequences

Crown infractions are injuries that carry little danger of resulting in pulp necrosis. Meticulous follow-up over a 5-year period is the most important endodontic preventive measure in these cases. If at any follow-up examination, the reaction to sensitivity tests changes, or if on radiographic assessment, signs of

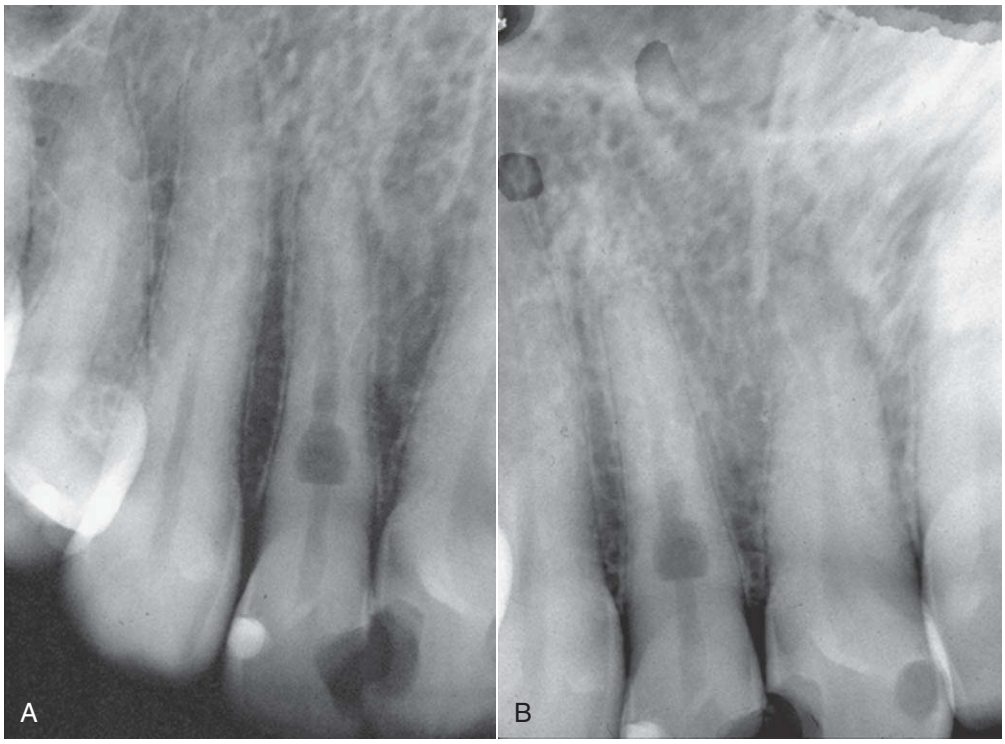

FIG. 17-4 Angled radiographs to show internal resorption. Radiographs from two different horizontal projections depict **(A)** the lesion within the confines of the root canal on both views and **(B)** the adjacent bone intact on both views.

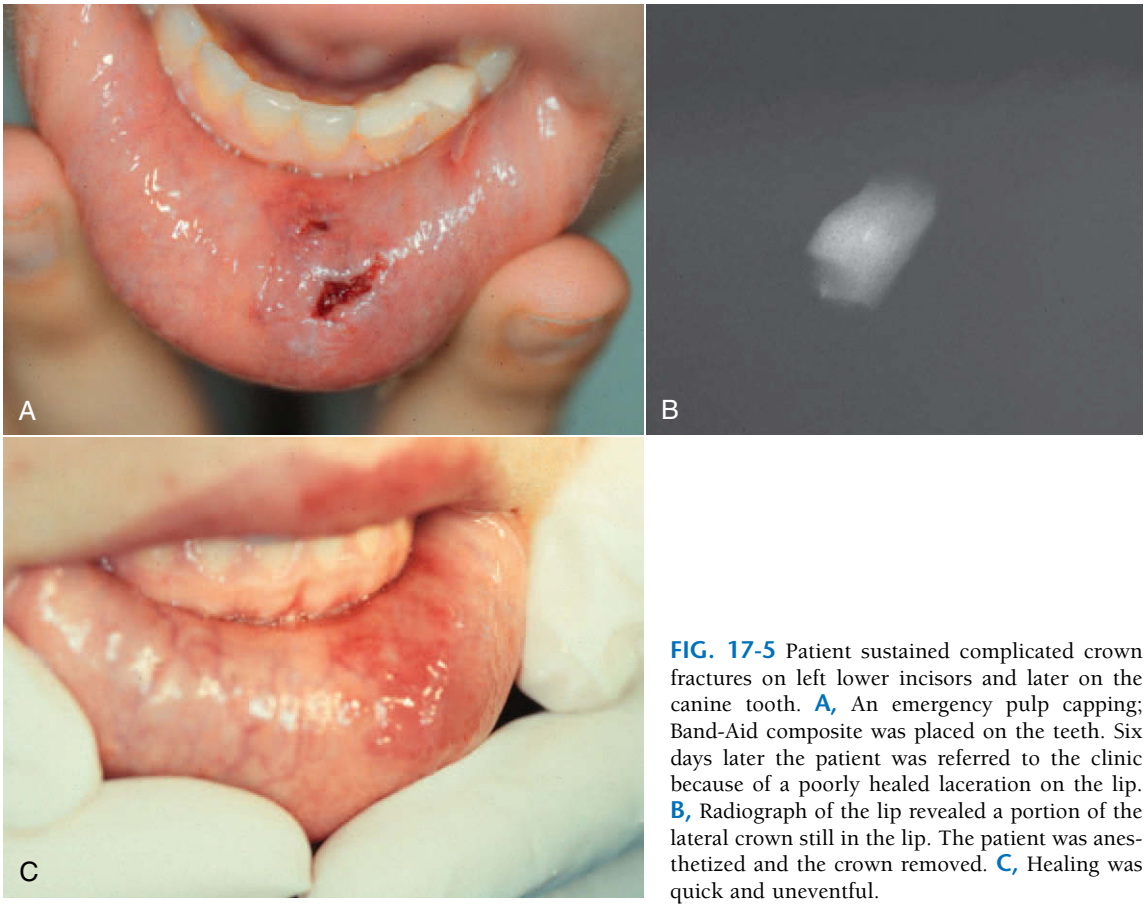

FIG. 17-5 Patient sustained complicated crown fractures on left lower incisors and later on the canine tooth. **A,** An emergency pulp capping; Band-Aid composite was placed on the teeth. Six days later the patient was referred to the clinic because of a poorly healed laceration on the lip. **B,** Radiograph of the lip revealed a portion of the lateral crown still in the lip. The patient was anesthetized and the crown removed. **C,** Healing was quick and uneventful.

apical or periradicular periodontitis develop or the root appears to have stopped development or is obliterating, endodontic intervention should be considered.

Uncomplicated Crown Fracture

Uncomplicated crown fracture can be defined as fracture of the enamel only or enamel and dentin without pulp exposure.[16]

Incidence

This injury is likely to be the most commonly reported dental injury. It is estimated to account for at least a third to half of all reported dental trauma.

Biologic Consequences

Uncomplicated crown fractures are also injuries that have little danger of resulting in pulp necrosis. In fact, the biggest danger to the health of the pulp is through iatrogenic causes during the esthetic restoration of these teeth.

Treatment

There are two key issues in the treatment of crown fractures. First, all exposed dental tubules need to be closed as soon as reasonably possible. If the broken-off piece is not available, or if it is not possible to reattach it and there is no time to do a full composite restoration at the time of the emergency appointment, a composite Band-Aid or temporary coverage should be placed on all exposed dentin. This is to prevent any ingress of bacteria into the tubules as well as to reduce the patient's discomfort. The second issue is the remaining dentin thickness. Several studies have confirmed that if the remaining dentin is more than 0.5 mm thick, the tooth can be restored with the restoration of choice, including etching and bonding, and no special attention needs to be given to the pulp.[3,41,54,105,140] If, however, the remaining dentin is less than this thickness, a protective layer of hard-setting calcium hydroxide in the deepest part of the dentin exposure does reduce, if not completely prevent, the reactive inflammation of the underling pulp, which is a significantly different reaction compared to the negative reaction to composite bonding systems.[3,41,54,105,140]

Complicated Crown Fracture

A *complicated crown fracture* involves enamel, dentin, and pulp[1] (Fig. 17-6).

Incidence

Complicated crown fractures occur in 0.9% to 13% of all dental injuries.[38,119,142]

Biologic Consequences

A crown fracture involving the pulp, if left untreated, will always result in pulp necrosis.[90] However, the manner and time sequence in which the pulp becomes necrotic allows a great deal of potential for successful intervention to maintain pulp vitality. The first reaction after the injury is hemorrhage and local inflammation (Fig. 17-7).

Subsequent inflammatory changes are usually proliferative but can be destructive over time. A proliferative reaction is favored in traumatic injuries, since the fractured surface is usually flat, allowing salivary rinsing with little chance of impaction of contaminated debris. Unless impaction of contaminated debris is obvious, it is expected that in the first 24 hours after the injury, a proliferative response with inflammation extending not more than 2 mm into the pulp will be present[43,47,75] (see Fig. 17-7). In time, the bacterial challenge will result in local pulpal necrosis and a slow apical progression of the pulpal inflammation (Fig. 17-8).

Treatment

Treatment options for complicated crown fracture are (1) vital pulp therapy, comprising pulp capping, partial pulpotomy, or full pulpotomy; or (2) pulpectomy. Choice of treatment depends on the stage of development of the tooth, the time between trauma and treatment, concomitant periodontal injury, and restorative treatment plan.

Stage of Development of the Tooth

Loss of vitality in an immature tooth can have catastrophic consequences. Root canal treatment on a tooth with a blunderbuss canal is time consuming and difficult. It is probably more important that necrosis of an immature tooth leaves it with thin dentinal walls that are susceptible to fracture both during and after the apexification procedure.[91] Every effort must be made to keep the tooth vital, at least until the apex and cervical root have completed their development.

Removal of the pulp in a mature tooth is not as significant as in an immature tooth, since a pulpectomy in a mature tooth has an extremely high success rate.[131] However, it has been

FIG. 17-6 Complicated crown fracture involving enamel, dentin, and pulp.

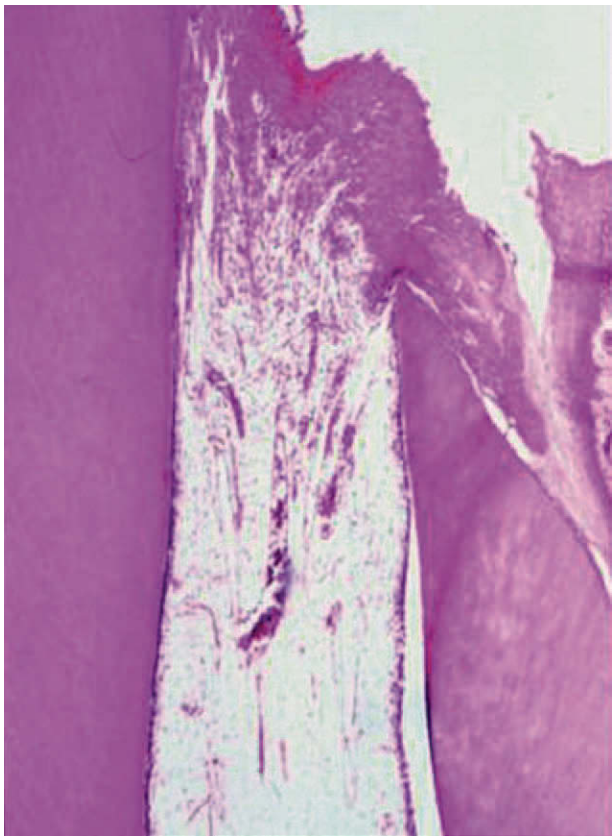

FIG. 17-7 Histologic appearance of the pulp within 24 hours of a traumatic exposure. The pulp proliferated over the exposed dentinal tubules. There is approximately 1.5 mm of inflamed pulp below the surface of the fracture.

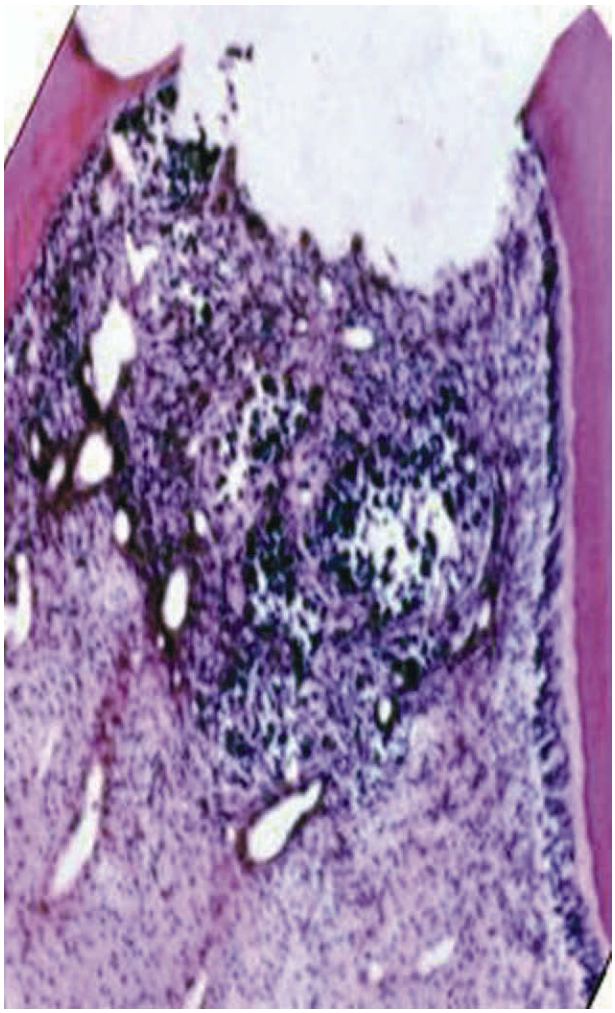

FIG. 17-8 Histologic appearance of the pulp days after a traumatic exposure. Superficial necrosis above a zone of inflamed pulp is seen.

shown that under optimal conditions, vital pulp therapy (rather than removal) on a mature tooth can be carried out successfully.[101,161] Therefore, this form of therapy can be an option under certain circumstances, even though a pulpectomy is the treatment which affords the most predictable success.

In an immature tooth, vital pulp therapy should always be attempted if at all feasible because of the tremendous advantages of maintaining the vital pulp.

Time Between Trauma and Treatment

For 48 hours after a traumatic injury, the initial reaction of the pulp is proliferative, with no more than a 2-mm depth of pulpal inflammation (see Fig. 17-8). After 48 hours, chances of direct bacterial contamination of the pulp increase, with the zone of inflammation progressing apically[47]; as time passes, the likelihood of successfully maintaining a healthy pulp decreases.

Concomitant Attachment Damage

A periodontal injury will compromise the nutritional supply of the pulp. This fact is particularly important in mature teeth, where the chance of pulp survival is not as good as for immature teeth.[14,53]

Restorative Treatment Plan

Unlike an immature tooth where the benefits of maintaining vitality of the pulp are so great, in a mature tooth, pulpectomy is a viable treatment option. As pointed out, if performed under optimal conditions, vital pulp therapy after traumatic exposures can be successful. If the restorative treatment plan is simple and a composite resin restoration will suffice as the permanent restoration, this treatment option should be given serious consideration. If a more complex restoration is to be placed (e.g., a crown or bridge abutment), pulpectomy may be the more predictable treatment method.

Vital Pulp Therapy: Requirements for Success

Vital pulp therapy has an extremely high success rate if the following requirements can be adhered to:

- *Treatment of a noninflamed pulp*. Treatment of a healthy pulp has been shown to be an essential requirement for successful therapy.[141,151] Vital pulp therapy of the inflamed pulp yields an inferior success rate,[141,151] so the optimal time for treatment is in the first 24 hours when pulp inflammation is superficial. As time between the injury and therapy increases, pulp removal must be extended apically to ensure that noninflamed pulp has been reached.

- *Bacteria-tight seal*. In our opinion, this requirement is the most critical factor for successful treatment.[141] Challenge by bacteria during the healing phase will cause failure (see also Chapter 15).[40] If the exposed pulp is effectively sealed from bacterial leakage, successful healing of the pulp with a hard-tissue barrier will occur independent of the dressing placed on the pulp.[41,73]
- *Pulp dressing*. Calcium hydroxide is still the most common dressing used for vital pulp therapy. Its main advantage is that it is antibacterial[37,130] and will disinfect the superficial pulp. Pure calcium hydroxide will cause necrosis of about 1.5 mm of pulp tissue, which removes superficial layers of inflamed pulp if present[102] (Fig. 17-9). The high pH (12.5) of calcium hydroxide causes a liquefaction necrosis in the most superficial layers.[123] The toxicity of calcium hydroxide appears to be neutralized as the deeper layers of pulp are affected, causing a coagulative necrosis at the junction of the necrotic and vital pulp, resulting in only mild irritation. This mild irritation will initiate an inflammatory response, and in the absence of bacteria,[123] the pulp will heal with a hard-tissue barrier (Fig. 17-10).[122,123] Hard-setting calcium hydroxide will not cause necrosis to the superficial layers of pulp but has also been shown to initiate healing with a hard-tissue barrier.[139,148]

A major disadvantage of calcium hydroxide is that it does not seal the fractured surface. Therefore, an additional material must be used to ensure that the pulp is not challenged by bacteria, particularly during the critical healing phase.

Many materials such as zinc oxide eugenol[25,151] tricalcium phosphate,[77] and composite resin 24 have been proposed as medicaments for vital pulp therapy. None to this date have afforded the predictability of calcium hydroxide used in conjunction with a well-sealed coronal restoration.[54,94,128,140] In a dog study, for example, pulps capped directly with various adhesive agents showed moderate to severe inflammatory reactions, with progressive extension of tissue necrosis with time and total absence of continuous hard-tissue bridge formation.[94] Application of a calcium hydroxide–based material was characterized by inflammatory cell infiltration, limited tissue necrosis, and partial to complete hard-tissue bridging.[94] In a similar study on human teeth in vivo, it was found that Scotchbond Multi-Purpose Plus caused inflammatory changes when applied directly to exposed pulp tissue, but direct capping with Dycal followed by sealing with Scotchbond Multi-Purpose Plus showed favorable results in pulp tissue.[140]

Mineral trioxide aggregate (MTA) has been shown to be a good pulp capping agent.[55,106,109,163] It has a high pH similar to calcium hydroxide when unset[145] and after setting will create an excellent bacteria-tight seal.[146] It is also hard enough to act as a base for a final restoration.[145] Yet MTA does not enjoy the same popularity as calcium hydroxide as a pulp capping agent in treatment of traumatic exposures. There are probably three main reasons. The first is likely to be that because MTA needs a moist environment for at least 6 hours to set properly, the treatment becomes a two-step procedure, compared with a one-step procedure for other medicaments. Using MTA as a pulp capping agent thus necessitates that a wet cotton pellet be placed over it until it is set, and then the permanent restoration can be fabricated at a later time. The second likely reason is that originally, MTA was gray in color and reported to cause discoloration in the tooth crown when used as capping agent in anterior teeth.[35] To counter this discoloration problem, a new white version of MTA was marketed a few years ago. Initially there were some concerns that the pulp did not respond to the white version as favorably as it had to the gray one.[110] Comparatively few studies have been done comparing the white MTA to the grey one, but most have indicated that the pulp seems to react as well to one as the other.[84,106,120] Further studies are warranted to compare the two formulations

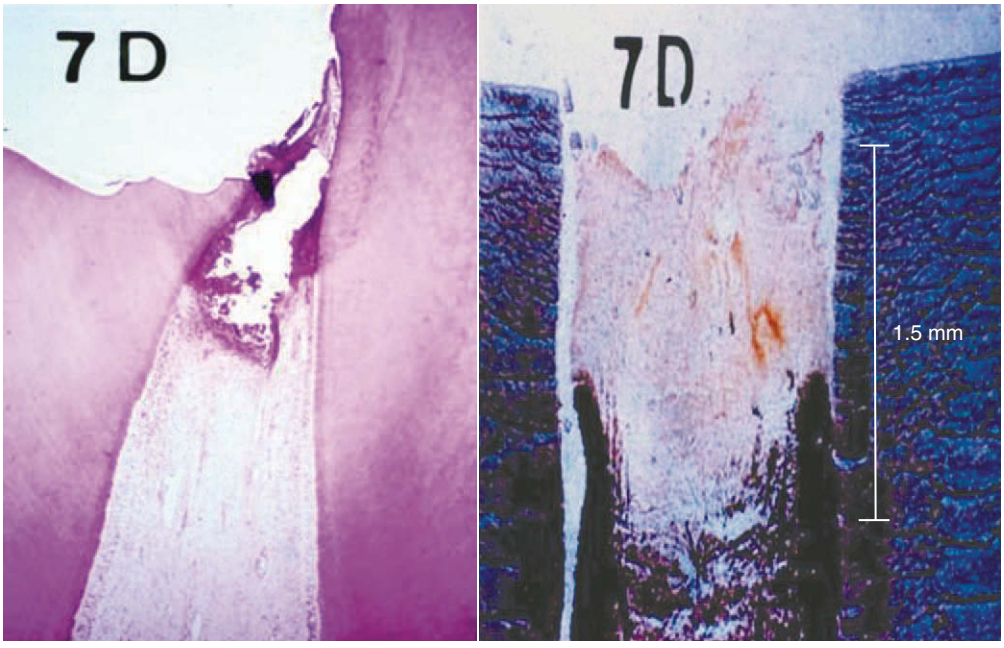

FIG. 17-9 Pulp necrosis of 1.5 mm as a result of the high pH of calcium hydroxide.

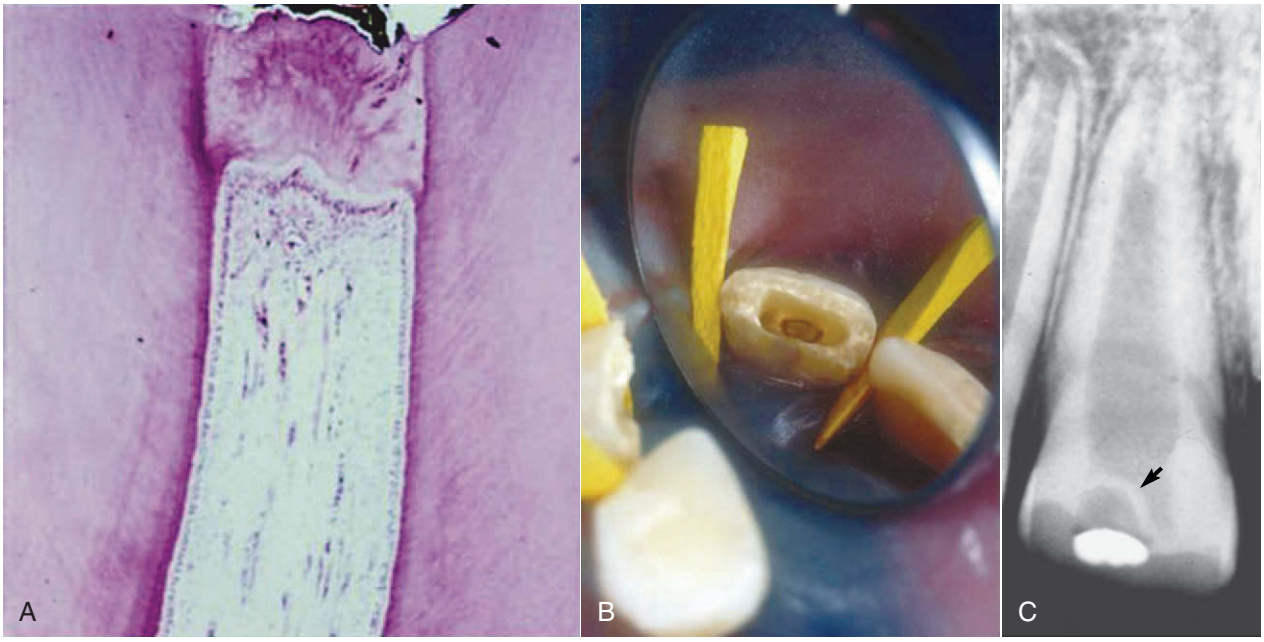

FIG. 17-10 Hard-tissue barrier after calcium hydroxide partial pulpotomy. **A,** Histologic appearance of replacement odontoblasts and a hard-tissue barrier. **B,** Clinical appearance of the barrier on removal of the coronal restoration 3 months after placement of the calcium hydroxide. **C,** Radiographic appearance of the hard-tissue barrier.

of MTA to fully elucidate the concerns raised regarding possible differences.[4] The third—and probably most common—reason why MTA is not as widely used as it could be is its relatively high cost.

Treatment Methods

Pulp Capping

Pulp capping implies placing the dressing directly onto the pulp exposure without any removal of the soft tissue.[24]

INDICATIONS

None; the success rate of this procedure (80%)[62,114] compared to partial pulpotomy (95%)[43] indicates that a superficial pulp cap should not be considered after traumatic pulp exposures. The lower success rate is not difficult to understand, since superficial inflammation develops soon after the traumatic exposure. If the treatment is at the superficial level, a number of inflamed (rather than healthy) pulps will be treated, lowering the potential for success. In addition, a bacteria-tight coronal seal is much more difficult to attain in superficial pulp capping, since there is no depth to the cavity to aid in creating the seal, as there is with a partial pulpotomy.

Partial Pulpotomy

Partial pulpotomy implies the removal of coronal pulp tissue to the level of healthy pulp. Knowledge of the reaction of the pulp after a traumatic injury makes it possible to accurately determine this level. This procedure is commonly called the *Cvek pulpotomy*.

INDICATIONS

As with pulp capping.

TECHNIQUE

Anesthesia, possibly without a vasoconstrictor, rubber dam placement, and superficial disinfection are performed. A 1- to 2-mm deep cavity is prepared into the pulp, using a high-speed handpiece with a sterile diamond bur of appropriate size with copious water coolant[70] (Fig. 17-11). A slow-speed bur or spoon excavator should be avoided. If bleeding is excessive, the pulp is amputated deeper until only moderate hemorrhage is seen. Excess blood is carefully removed by rinsing with sterile saline and the area dried with a sterile cotton pellet. Use of 5% sodium hypochlorite (NaOCl; bleach) has been recommended to rinse the pulpal wound.[41] The bleach will cause a chemical amputation of the blood coagulum, remove damaged pulp cells, dentin chips, and other debris, and provides hemorrhage control with minimal damage to the "normal" pulp tissue underneath.

Care must be taken not to allow a blood clot to develop; this will compromise the prognosis.[43,122] A thin layer of pure calcium hydroxide is mixed with sterile saline or anesthetic solution to a thick mix and carefully placed onto the pulp stump. If the pulp size does not permit additional loss of pulp tissue, a commercial hard-setting calcium hydroxide can be used.[139] The prepared cavity is filled with a material with the best chance of a bacteria-tight seal (zinc oxide eugenol or glass ionomer cement) to a level flush with the fractured surface. The material in the pulpal cavity and all exposed dentinal tubules are etched and restored with bonded composite resin. Alternatively, after hemostasis is obtained, the pulp can be capped with MTA, a wet cotton pellet placed on top if it, and the access temporized for the appropriate time. The cotton pellet then needs to be removed as early as possible and the tooth then restored with composite restoration.

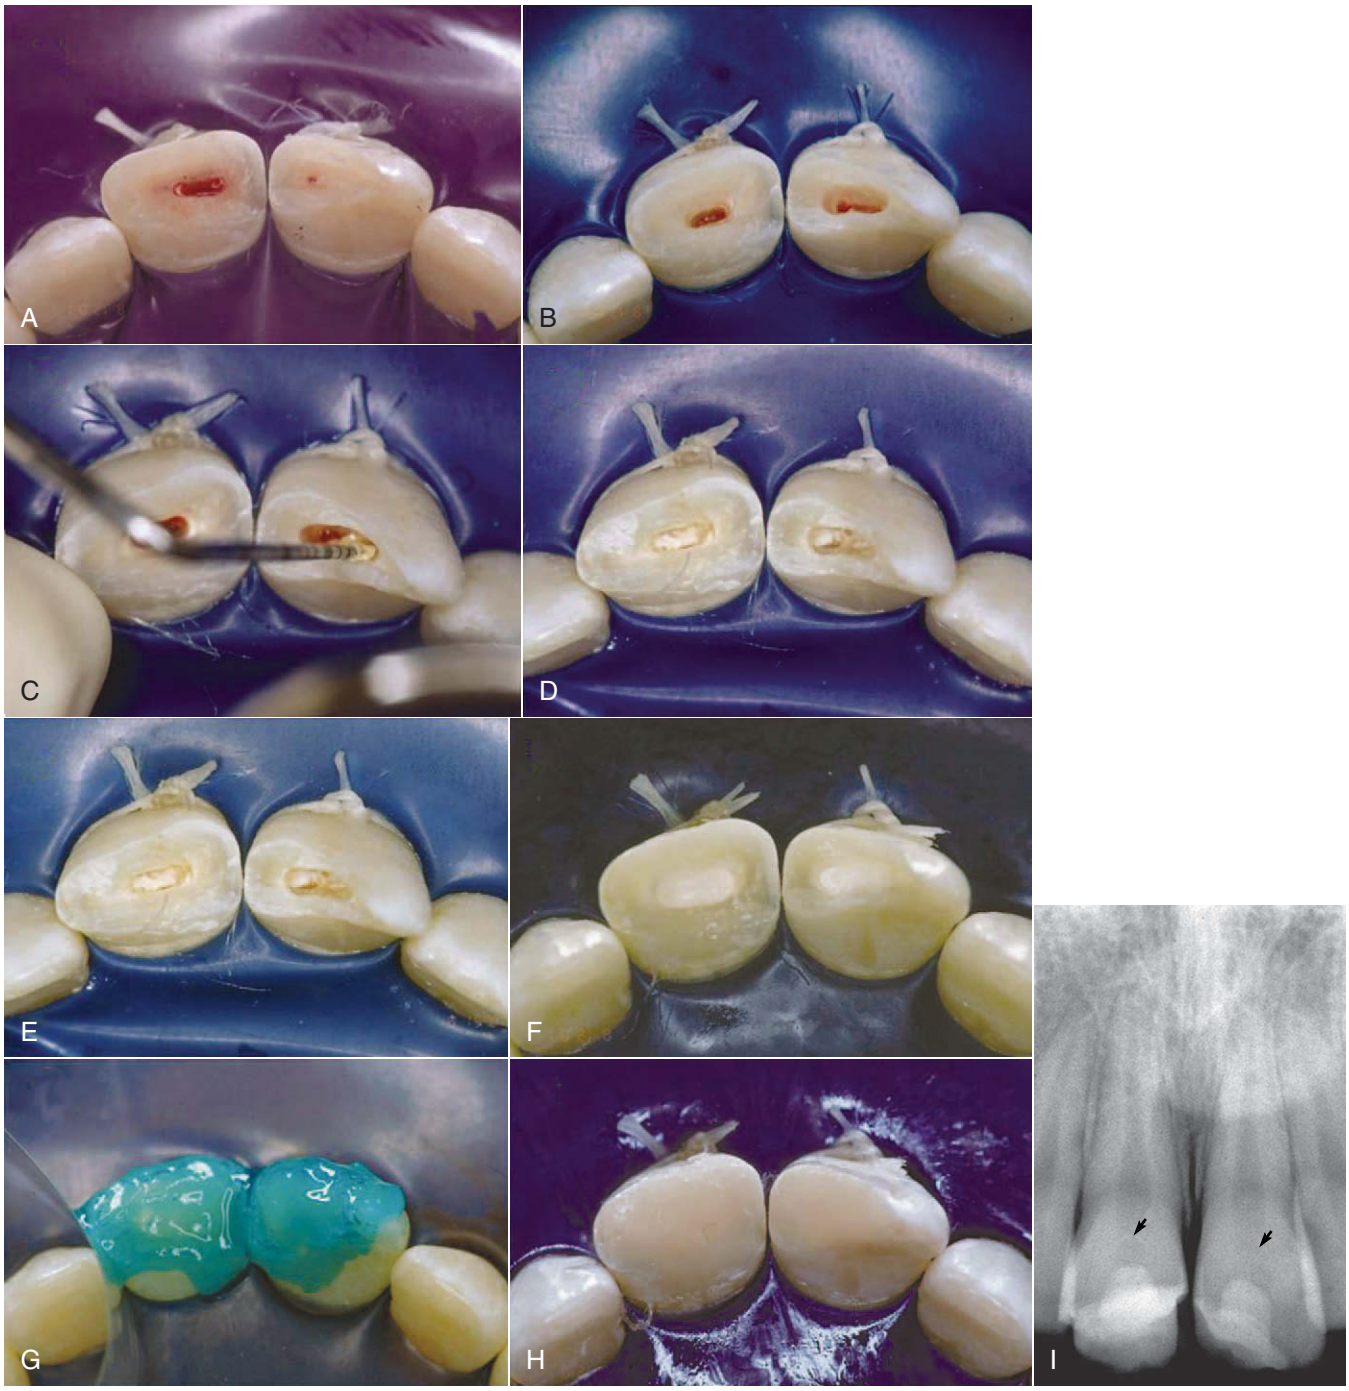

FIG. 17-11 Cvek partial pulpotomy. **A,** The fractured teeth are cleaned and disinfected; a rubber dam is placed. **B,** Cavities are prepared at high speed with a round diamond bur 1 to 2 mm into the pulpal tissue. **C,** Calcium hydroxide on a plugger **(D)** is placed on the soft tissue of the pulp. **E,** Care is taken to avoid smearing the walls of the preparation with the calcium hydroxide. **F,** Cavity preparations are filled with glass ionomer cement. **G,** Exposed dentin is etched and **(H)** then covered with composite resin. **I,** Radiograph exposed 6 months later shows formation of hard-tissue barriers in both teeth. *(Courtesy Dr. Alessandra Ritter.)*

FOLLOW-UP

As with pulp capping. Emphasis is placed on evidence of maintenance of responses to sensitivity tests and radiographic evidence of continued root development (Fig. 17-12).

PROGNOSIS

This method affords many advantages over pulp capping. Superficial inflamed pulp is removed during preparation of the pulpal cavity. Calcium hydroxide disinfects dentin and pulp and removes additional pulpal inflammation. Most impor-

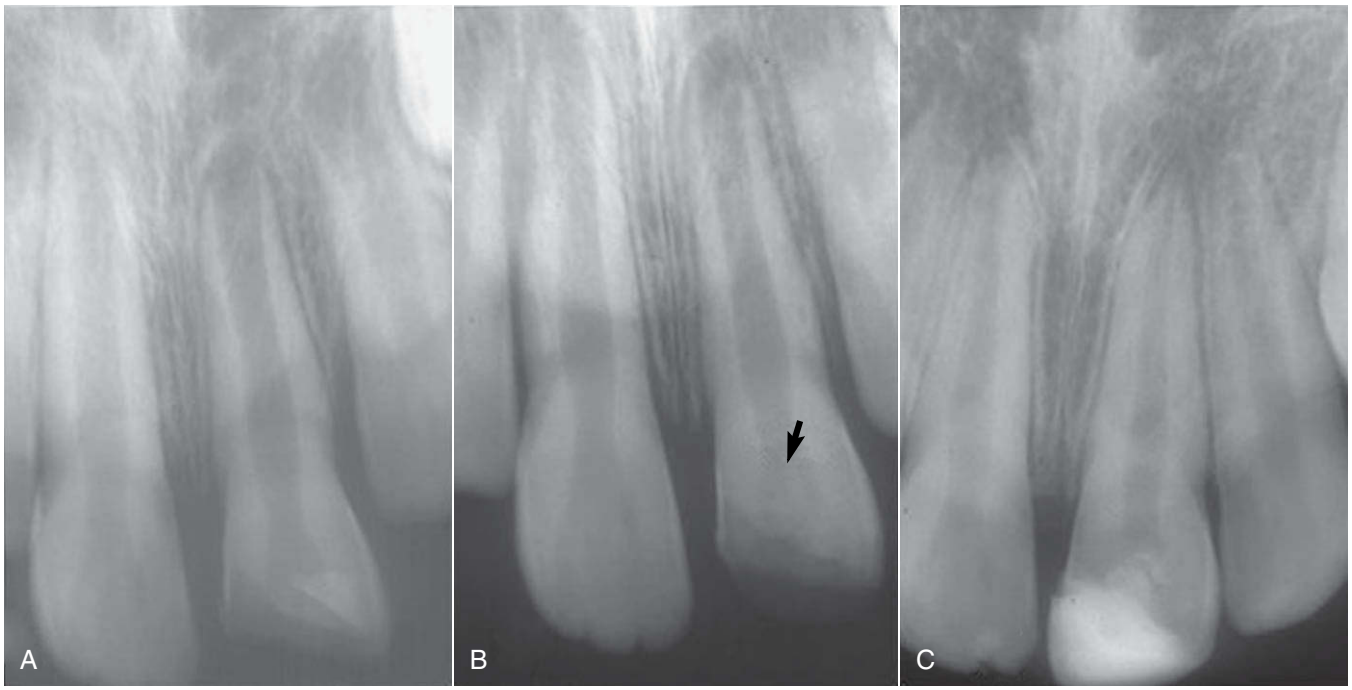

FIG. 17-12 Continued root development after partial pulpotomy. **A,** Radiograph of immature tooth with a complicated crown fracture. **B,** At the time of placement of calcium hydroxide after partial pulpotomy. **C,** Follow-up radiograph confirming that the pulp maintained vitality and the root continued to develop.

tantly, space is provided for a material that can provide a bacteria-tight seal to allow pulpal healing with hard tissue under optimal conditions. Additionally, coronal pulp remains, which allows sensitivity testing to be carried out at the follow-up visits. Prognosis is extremely good (94% to 96%).[43,63]

Full Pulpotomy

This procedure involves removal of the entire coronal pulp to a level of the root orifices. This level of pulp amputation is chosen arbitrarily because of its anatomic convenience. Since inflamed pulp sometimes extends past the canal orifices into the root pulp, many mistakes are made that result in treatment of an inflamed rather than noninflamed pulp.

INDICATIONS

Full pulpotomy is indicated when it is anticipated that the pulp is inflamed to the deeper levels of the coronal pulp. Traumatic exposures after more than 72 hours or a carious exposure of a young tooth with partially developed apex are two examples of when this treatment may be indicated. Because of the likelihood that the dressing will be placed on an inflamed pulp, full pulpotomy is contraindicated in mature teeth. Benefits only outweigh risks for this treatment form in the immature tooth with incompletely formed apices and thin dentinal walls.

TECHNIQUE

The procedure begins with anesthesia, rubber dam placement, and superficial disinfection as with pulp capping and partial pulpotomy. The coronal pulp is removed as in partial pulpotomy but to the level of the root orifices. Calcium hydroxide dressing, a bacteria-tight seal, and a coronal restoration are carried out as with partial pulpotomy.

FOLLOW-UP

As with pulp capping and partial pulpotomy. A major disadvantage of this treatment method is that sensitivity testing is not possible owing to the loss of coronal pulp, so radiographic follow-up is extremely important to assess for signs of apical periodontitis and ensure the continuation of root formation.

PROGNOSIS

Since the cervical pulpotomy is performed on pulps, which are expected to have deep inflammation, and the site of pulp amputation is arbitrary, many more mistakes are made that lead to treatment of the inflamed pulp. Consequently the prognosis, which is in the range of 75%, is poorer than partial pulpotomy.[67] Because of the inability to evaluate pulp status after full pulpotomy, some authors have recommended pulpectomy routinely after the roots have fully formed (Fig. 17-13). This philosophy is based on the pulpectomy procedure having a success rate in the range of 95%, whereas if apical periodontitis develops, the prognosis of root canal treatment drops significantly to about 80%.[125,131]

Pulpectomy

Pulpectomy implies removal of the entire pulp to the level of the apical foramen.

INDICATIONS

Pulpectomy is indicated in complicated crown fracture of mature teeth if conditions are not ideal for vital pulp therapy or it is foreseeable that restoring the tooth will require a post placement. This procedure is no different from root canal treatment of a vital nontraumatized tooth.

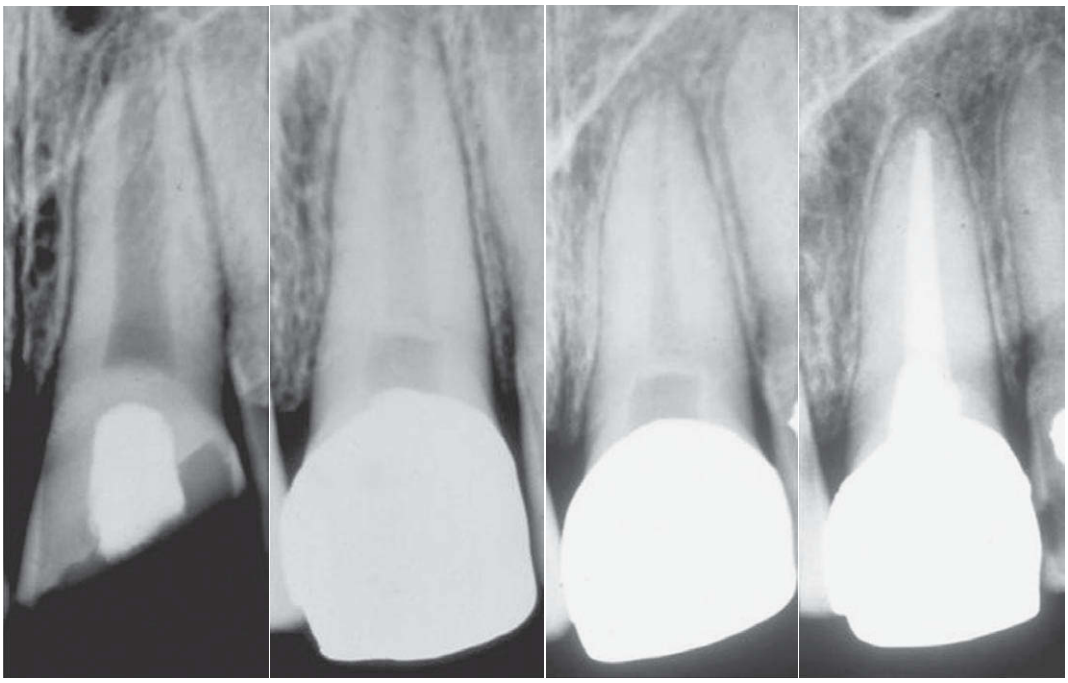

FIG. 17-13 Successful pulpotomy followed by a pulpectomy at 18 months. *(Courtesy Dr. Leif Tronstad.)*

Treatment of the Nonvital Pulp

Immature Tooth: Apexification

INDICATIONS

This procedure should be performed in teeth with open apices and thin dentinal walls in which standard instrumentation techniques cannot create an apical stop to facilitate effective root canal filling.

BIOLOGIC CONSEQUENCES

A nonvital immature tooth presents a number of difficulties for adequate endodontic treatment. The canal is often wider apically than coronally, necessitating the use of a filling technique with softened filling material to mold it to the shape of the apical part of the canal. Since the apex is extremely wide, no barrier exists to stop this softened material from moving into and traumatizing the apical periodontal tissues. Also, the lack of apical stop and extrusion of material through the canal might result in a canal that is underfilled and susceptible to leakage. An additional problem in immature teeth with thin dentinal walls is their susceptibility to fracture, both during and after treatment.[44]

These problems are overcome by stimulating the formation of a hard-tissue barrier to allow for optimal filling of the canal and reinforcing the weakened root against fracture, both during and after apexification.[93,143]

TECHNIQUE

Disinfection of the Canal In the vast majority of cases, nonvital teeth are infected,[29,127] so the first phase of treatment is to disinfect the root canal system to ensure periapical healing.[37,48] The canal length is estimated with a parallel preoperative radiograph, and after access to the canals is prepared, a file is placed to this estimated length. When the length has been confirmed radiographically, very light filing (because of the thin dentinal walls) is performed with copious irrigation with 0.5% NaOCl.[49,136] A lower strength of NaOCl is used because of the increased danger of placing the agent through the apex in immature teeth. The increased volume of irrigant used compensates for this lower concentration of NaOCl. An irrigation needle that can passively reach close to the apical length is useful in disinfecting the canals of these immature teeth. The canal is dried with paper points and a creamy mix of calcium hydroxide (toothpaste thickness) spun into the canal with a Lentulo spiral instrument (Fig. 17-14). Additional disinfecting action of calcium hydroxide is effective after its application for at least 1 week,[130] so the continuation of treatment can take

FIG. 17-14 Creamy mix of calcium hydroxide on a Lentulo spiral instrument ready for placement into the canal.

place any time after 1 week. Further treatment should not be delayed more than 1 month, since the calcium hydroxide could be washed out by tissue fluids through the open apex, leaving the canal susceptible to reinfection.

HARD-TISSUE APICAL BARRIER

Traditional Method Formation of the hard-tissue barrier at the apex requires a similar environment to that required for hard-tissue formation in vital pulp therapy: a mild inflammatory stimulus to initiate healing and a bacteria-free environment to ensure that inflammation is not progressive.

As with vital pulp therapy, calcium hydroxide is used for this procedure.[44,76,78] Pure calcium hydroxide powder is mixed with sterile saline (or anesthetic solution) to a thick (powdery) consistency (Fig. 17-15). The calcium hydroxide is packed against the apical soft tissue with a plugger or thick point to initiate hard-tissue formation. This step is followed by backfilling with calcium hydroxide to completely fill the canal. The calcium hydroxide is meticulously removed from the access cavity to the level of the root orifices and a well-sealing temporary filling placed in the access cavity. A radiograph is taken, and the canal should appear to have become calcified, indicating that the entire canal has been filled with the calcium hydroxide (Fig. 17-16). Because calcium hydroxide washout is evaluated by its relative radiodensity in the canal, it is prudent to use a calcium hydroxide mixture without the addition of a radiopaquer such as barium sulphate. These additives do not wash out as readily as calcium hydroxide, so if they are present in the canal, evaluation of washout is impossible.

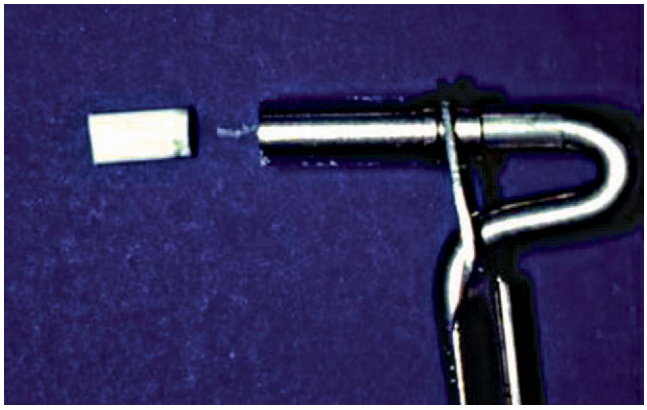

FIG. 17-15 Thick mix of calcium hydroxide.

At 3-month intervals, a radiograph is exposed to evaluate whether a hard-tissue barrier has formed and if the calcium hydroxide has washed out of the canal. This is assessed to have occurred if the canal can be seen again radiographically. If no washout is evident, it can be left intact for another 3 months. Excessive calcium hydroxide dressing changes should be avoided if at all possible, since the initial toxicity of the material is thought to delay healing.[95]

When completion of a hard-tissue barrier is suspected, the calcium hydroxide should be washed out of the canal with NaOCl. A file of a size that can easily reach the apex can be used to gently probe for a stop at the apex. When a hard-tissue barrier is indicated radiographically and can be probed with an instrument, the canal is ready for filling.

MTA BARRIER

The creation of a physiologic hard-tissue barrier, while quite predictable, takes anywhere from 3 to 18 months with calcium hydroxide. The disadvantages of this long time period are that

FIG. 17-16 A-B, Root canal that "disappears" after placement of a thick mix of pure calcium hydroxide and then over time washes out again. (*Courtesy Dr. Cecilia Bourguignon.*)

the patient is required to present for treatment multiple times, and the tooth may fracture during treatment before the thin, weak roots can be strengthened. In addition, one study has indicated that long-term treatment with calcium hydroxide may weaken the roots and make them even more susceptible to fracture.[19]

MTA has been used to create a hard-tissue barrier quickly after disinfection (see earlier in the section Traditional Method) of the canal (Fig. 17-17). Calcium sulphate is pushed through the apex to provide a resorbable extraradicular barrier against which to pack the MTA. The MTA is mixed and placed into the apical 3 to 4 mm of the canal in a manner similar to the placement of calcium hydroxide. A wet cotton pellet should be placed against the MTA and left for at least 6 hours. After the MTA is fully set, the entire canal is then filled with a root filling material. Some clinicians have suggested that the filling can be placed immediately, since the tissue fluids of the open apex will probably provide enough moisture to ensure that the MTA will set sufficiently. The cervical canal is then reinforced with composite resin to below the marginal bone level as described later (see Fig. 17-17).

A number of case reports have been published using this MTA apical barrier technique,[68,80,100] and it has steadily gained popularity with clinicians. Presently, no prospective long-term

outcome study is available comparing its success rate with the traditional calcium hydroxide technique.

Filling the Root Canal Since the apical diameter is larger than the coronal diameter of most of these canals, a softened filling technique is indicated in these teeth (see Chapter 10). Care must be taken to avoid excessive lateral force during filling, owing to the thin walls of the root. If the hard-tissue barrier was produced by long-term calcium hydroxide therapy, it consists of irregularly arranged layers of coagulated soft tissue, calcified tissue, and cementum-like tissue (Fig. 17-18). Included also are islands of soft connective tissue, giving the barrier a "Swiss cheese" consistency.[31,45] Because of the irregular nature of the barrier, it is not unusual for cement or softened filling material to be pushed through it into the apical tissues during filling (Fig. 17-19). Formation of the hard-tissue barrier might be some distance short of the radiographic apex. This is because it forms wherever the calcium hydroxide contacts vital tissue. In teeth with wide, open apices, vital tissue can survive and proliferate from the periodontal ligament a few millimeters into the root canal. Filling should be completed to the level of the hard-tissue barrier and not forced toward the radiographic apex.

Reinforcement of Thin Dentinal Walls The apexification procedure has become a predictably successful procedure (see Prognosis),[61] but the thin dentinal walls still present a clinical problem. Should secondary injuries occur, teeth with thin dentinal walls are more susceptible to fractures that render them unrestorable.[51,147] It has been reported that approximately 30% of these teeth will fracture during or after endodontic treatment.[93] Consequently, some clinicians have questioned the advisability of the apexification procedure and have opted for more radical treatment procedures, including extraction followed by extensive restorative procedures such as dental implants. Studies have shown that intracoronal bonded restorations can internally strengthen endodontically treated teeth and increase their resistance to fracture.[69,91] Thus after root filling, the material should be removed to below the

FIG. 17-19 Root filing with a soft technique after calcium hydroxide apexification. Sealer and softened filling material is expressed through the "Swiss cheese" holes in the barrier.

marginal bone level and a bonded resin filling placed (see Fig. 17-17).

Follow-Up Routine recall evaluation should be performed to determine success in the prevention or treatment of apical periodontitis. Restorative procedures should be assessed to ensure that they in no way promote root fractures.

Prognosis Periapical healing and the formation of a hard-tissue barrier occurs predictably with long-term calcium hydroxide treatment (79% to 96%).[44,93] However, long-term survival is jeopardized by the fracture potential of the thin dentinal walls of these teeth. It is expected that the newer techniques of internally strengthening the teeth described earlier will increase their long-term survivability.

Pulp Revascularization Regeneration of a necrotic pulp has been considered possible only after avulsion of an immature permanent tooth that was reimplanted within 40 minutes (see later). The advantages of pulp revascularization lie in the possibility of further root development and reinforcement of dentinal walls by deposition of hard tissue, thus strengthening the root against fracture (see also Chapter 16). After reimplantation of an avulsed immature tooth, a unique set of circumstances exists that allows regeneration to take place. The young tooth has an open apex and is short, which allows new tissue to grow into the pulp space relatively quickly. The pulp is necrotic but usually neither degenerated nor infected, so it will act as a matrix into which the new tissue can grow. It

has been experimentally shown that the apical part of a pulp may remain vital and after reimplantation proliferate coronally, replacing the necrotized portion of the pulp.[26,107,134] Because in most cases, the crown of the tooth is intact and caries-free, bacterial penetration into the pulp space through cracks[97] and defects will be a slow process. The race between new tissue growth and infection of the pulp space favors the new tissue.

Regeneration of pulp tissue in a necrotic infected tooth with apical periodontitis has been thought up to now to be impossible.[104] However, if it is possible to create an environment similar to that described for the avulsed tooth, regeneration will probably occur. If the canal is effectively disinfected, a matrix into which new tissue can grow is provided, and coronal access is effectively sealed. Regeneration should occur as in an avulsed immature tooth.

Banchs and Trope[25] wrote one of the first case reports that suggest it may be possible to replicate the unique circumstances of an avulsed tooth. The case (Fig. 17-20) describes the treatment of an immature second mandibular premolar with radiographic and clinical signs of apical periodontitis along with a sinus tract. The canal was disinfected without mechanical instrumentation but with copious irrigation with 5.25% NaOCl, and the patient was prescribed a mixture of antibiotics consisting of equal amounts of ciprofloxacin, metronidazole, and minocycline for 3 weeks.[82]

After rinsing out the antibody mixture after three weeks, a blood clot was produced to the level of the cementoenamel junction to provide a matrix for ingrowth of new tissue; this was followed by a deep coronal restoration to provide a bacteria-tight seal. Clinical and radiographic evidence of healing appeared as early as 22 days, the large radiolucency

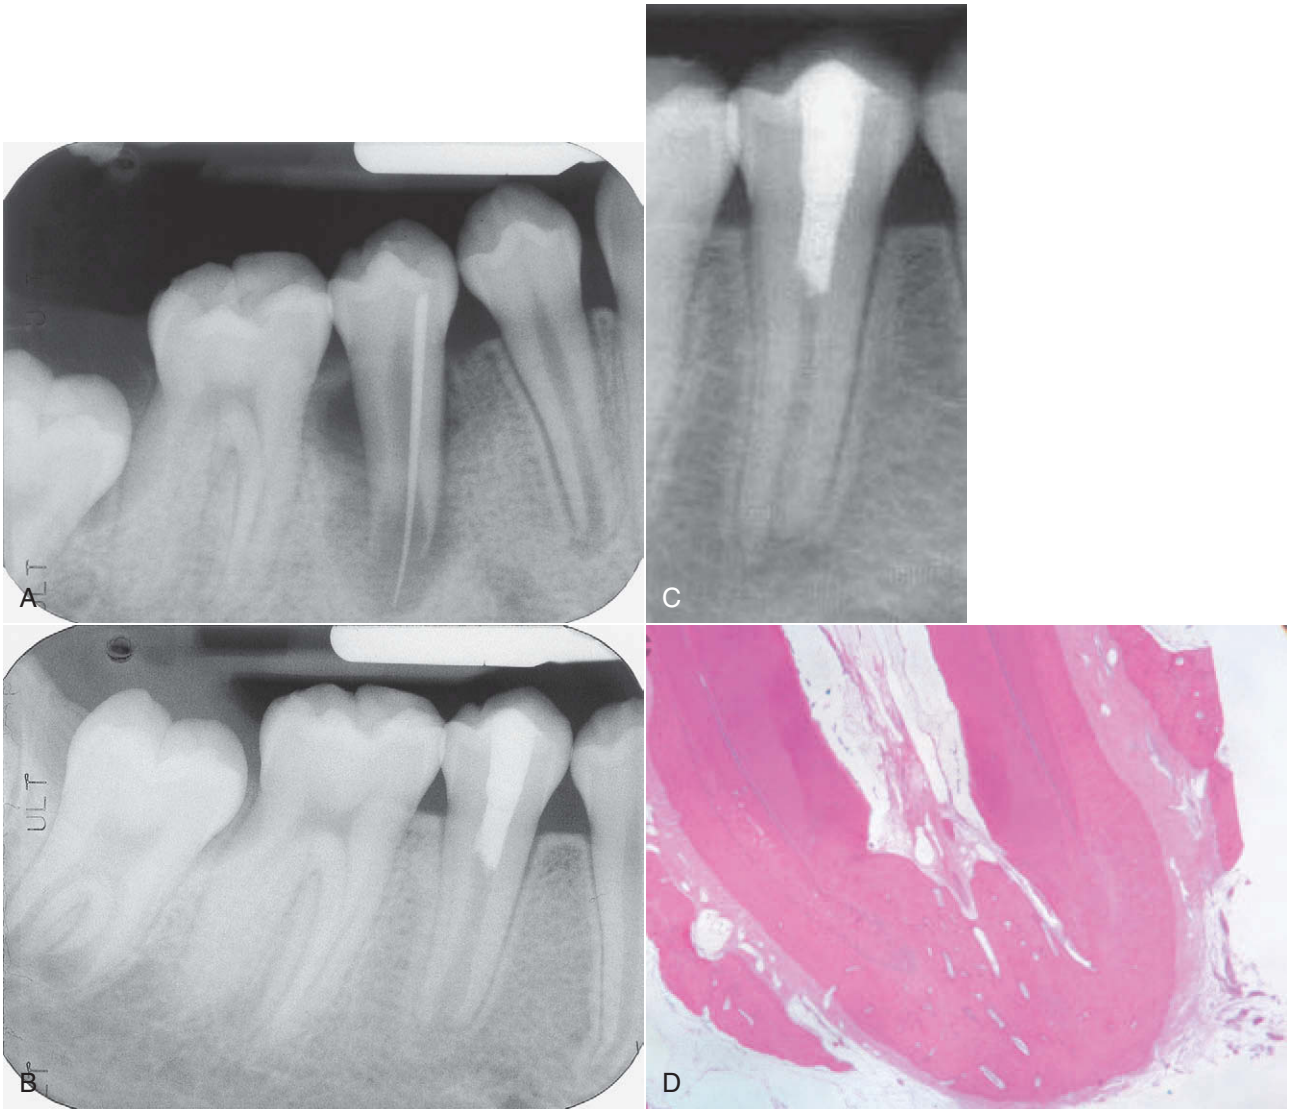

FIG. 17-20 A, Preoperative radiograph showing an immature root with periradicular periodontitis and a traced sinus tract to the apex of the root. **B,** Radiographic checkup 7 months after treatment that included application of a mixture of ciprofloxacin, metronidazole, and minocycline. **C,** At 24-month checkup, showing continued root development both in length and width of the root. **D,** Histologic slide from Thibodeau et al.[144] showing thickened root walls, apical development, and healing of apical periodontitis in a dog tooth where a periapical lesion had been created in an immature tooth.

had disappeared within 2 months, and at the 24-month recall it was obvious that the root walls were thick and development of the root below the restoration was similar to the adjacent and contralateral teeth. More recently, published cases and case series reports have further supported that it is possible to have ingrowths of tissue followed by new apposition of dentin and continuation of root formation.[89,144] Studies have also confirmed the potent antibacterial properties of the triantibiotic paste used in these cases. Studies are underway to find a synthetic matrix which will act as a more predictable scaffold for new ingrowth of tissue than the blood clot that was used in these examples.[144,162] The procedure described here can be attempted in most cases, and if after 3 months there are no signs of regeneration, then the more traditional treatment methods can be initiated.

Mature Tooth

Conventional endodontic therapy.

CROWN-ROOT FRACTURE

Crown-root fracture is a periodontal rather than an endodontic challenge. The tooth must be treated periodontally to enable a well-sealed coronal restoration. This could be accomplished by simple gingivectomy if the extent of the root component of the fracture is large. Alternatively, the tooth could be orthodontically or surgically extruded such that the exposed surface of the root fracture is treatable. Once the feasibility of the coronal restoration is assured, the particular crown fracture is treated as previously described.

ROOT FRACTURE

Root fracture implies fracture of the cementum, dentin, and pulp. These injuries are relatively infrequent, occurring in less than 3% of all dental injuries.[166] Immature teeth with vital pulps rarely sustain horizontal root fractures.[7] When a root fractures horizontally, the coronal segment is displaced to a varying degree, but generally the apical segment is not displaced. Because the apical pulpal circulation is not disrupted, pulp necrosis in the apical segment is extremely rare. Permanent pulpal necrosis of the coronal segment, requiring endodontic treatment, occurs in about 25% of cases.[8,9,86]

Diagnosis and Clinical Presentation

Clinical presentation is similar to that of luxation injuries. The extent of displacement of the coronal segment is usually indicative of the location of the fracture and can vary from none, simulating a concussion injury (apical fracture), to severe, simulating an extrusive luxation (cervical fracture).

Radiographic examination for root fractures is extremely important. Since root fractures are usually oblique (facial to palatal) (Fig. 17-21), one periapical radiograph may easily miss its presence. It is imperative to take at least three angled radiographs (45, 90, 110 degrees) so that at least at one angulation, the x-ray beam will pass directly through the fracture line to make it visible on the radiograph (Fig. 17-22).

Treatment

Emergency treatment involves repositioning the segments into close proximity as much as possible. In the case of severe displacement of the coronal segment, its apical extension is frequently lodged in (if not perforating through) the cortical bone facial to the tooth. Forcing the crown facially will not be possible, and the two segments will not be properly aligned. The only way to accomplish reapproximation of the two segments is to release the coronal segment from the bone by gently pulling it slightly downward with finger pressure or extraction forceps, and then once it is loose, rotate it back to its original position (Fig. 17-23). The traditionally recommended[113] splinting protocol has been changed from 2 to 4 months with rigid splinting to a semirigid splint to adjacent teeth for 2 to 4 weeks.[18] If a long time has elapsed between the injury and treatment, it will likely not be possible to reposition the segments close to their original position, compromising the long-term prognosis for the tooth.

FIG. 17-21 Extracted root after a root fracture. Note the oblique angle of the fracture.

Healing Patterns

Investigators[20] have described four types of responses to root fractures:

1. *Healing with calcified tissue.* Radiographically, the fracture line is discernible, but the fragments are in close contact (Fig. 17-24, *A*).
2. *Healing with interproximal connective tissue.* Radiographically, the fragments appear separated by a narrow radiolucent line, and the fractured edges appear rounded (see Fig. 17-24, *B*).
3. *Healing with interproximal bone and connective tissue.* Radiographically, the fragments are separated by a distinct bony ridge (see Fig. 17-24, *C*).
4. *Interproximal inflammatory tissue without healing.* Radiographically, a widening of the fracture line and/or a developing radiolucency corresponding to the fracture line becomes apparent (see Fig. 17-24, *D*).

The first three types of healing patterns are considered successful. The teeth are usually asymptomatic and respond posi-

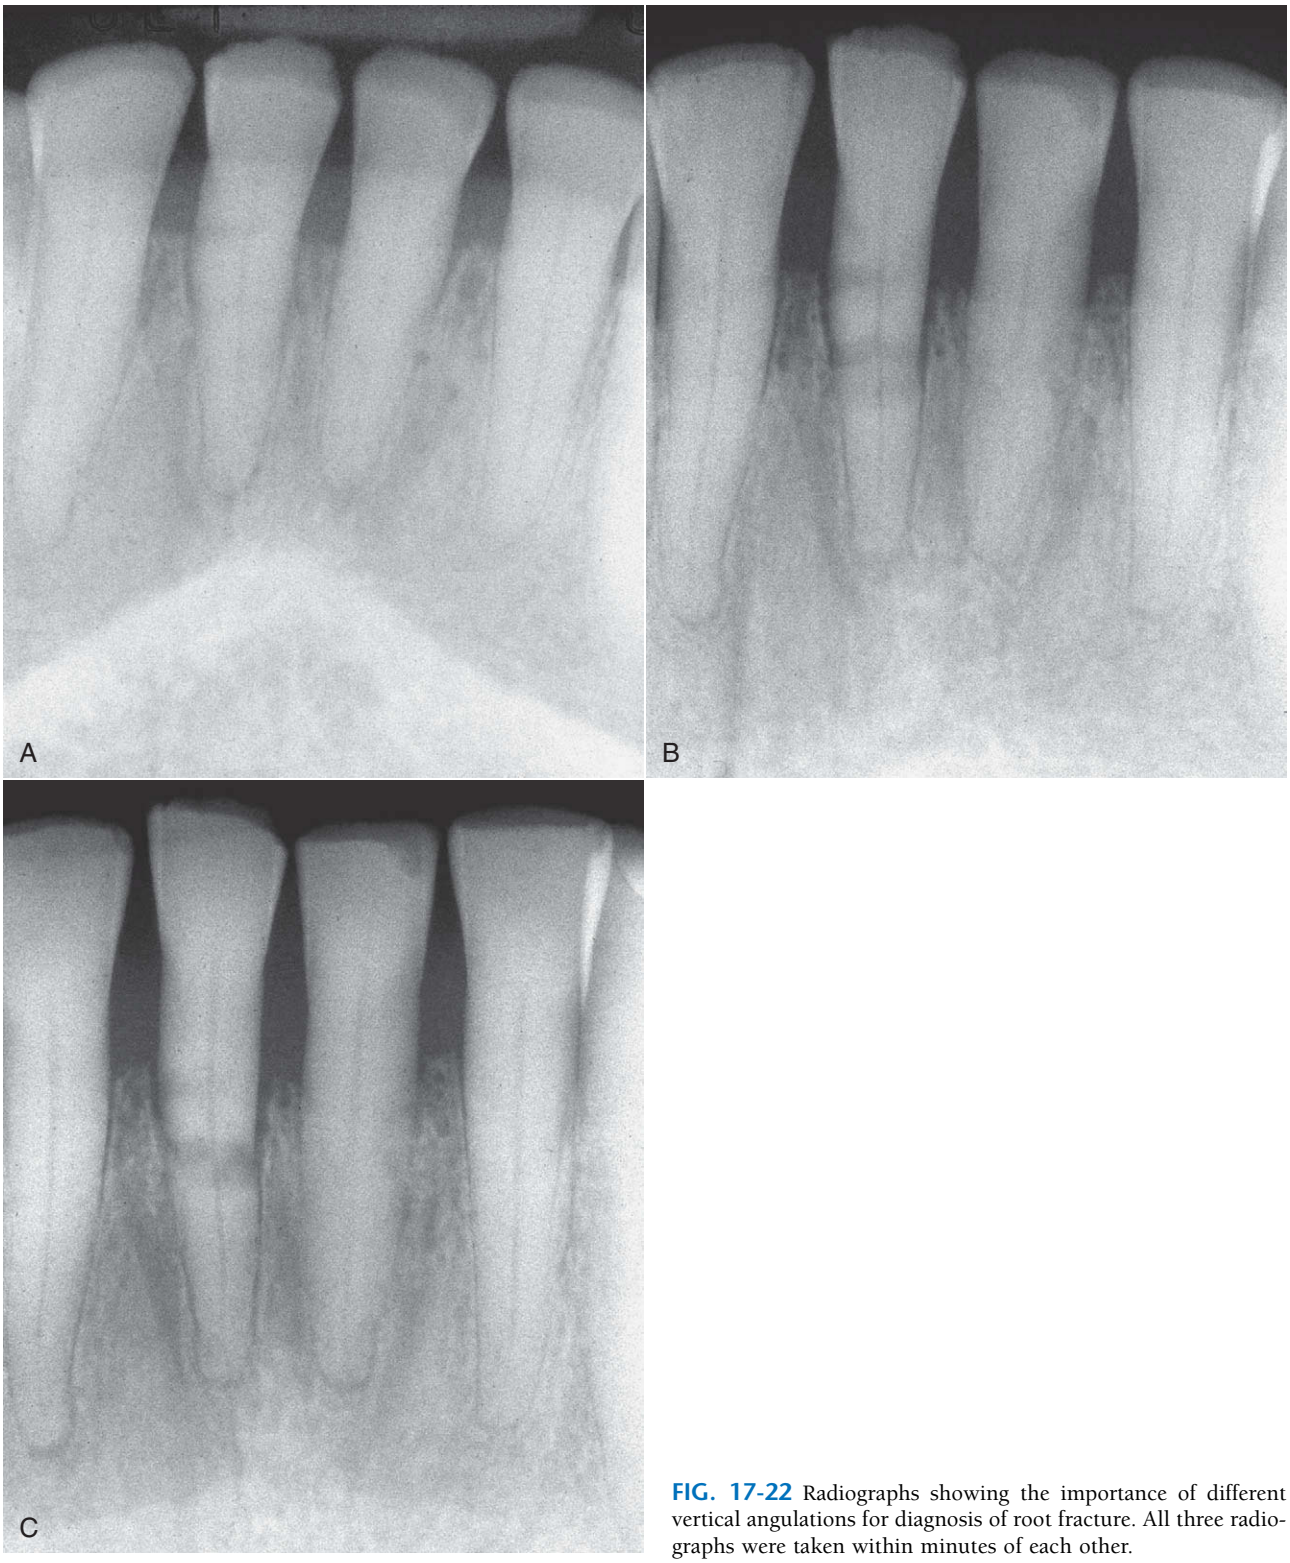

FIG. 17-22 Radiographs showing the importance of different vertical angulations for diagnosis of root fracture. All three radiographs were taken within minutes of each other.

tively to sensitivity testing. Coronal yellowing is possible because calcific metamorphosis of the coronal segment is not unusual[87,166] (see Fig. 17-29).

The fourth type of root fracture response is typical when the coronal segment loses its vitality. The infective products in the coronal pulp cause an inflammatory response and typical radiolucencies at the fracture line[20] (see Fig. 17-24, *D*).

Treatment of Complications

Coronal Root Fractures

Historically it had been thought that fractures in the cervical segment had a poor prognosis, and extraction of the coronal segment was recommended. Research does not support this treatment; in fact, if these coronal segments are adequately

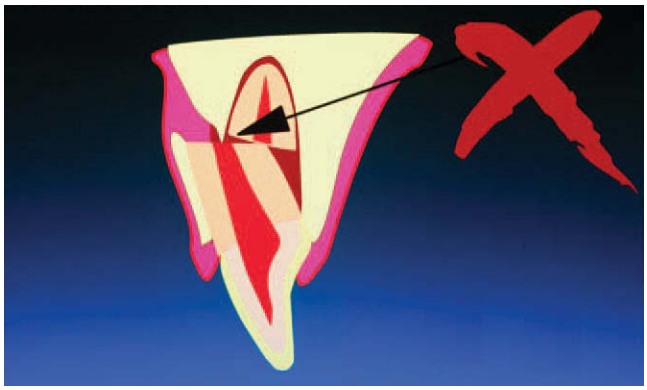

FIG. 17-23 Figure of facial root fracture manipulated back into place.

splinted, chances of healing do not differ from midroot or apical fractures (Fig. 17-25).[166] However, if the fracture occurs at the level of or coronal to the crest of the alveolar bone, the prognosis is extremely poor.

If reapproximation of the fractured segments is not possible, extraction of the coronal segment is indicated. The level of fracture and length of the remaining root are evaluated for restorability. If the apical root segment is long enough, gentle orthodontic eruption of this segment can be carried out to enable a restoration to be fabricated.

Midroot and Apical Root Fractures

Permanent pulpal necrosis occurs in 25% of root fractures.[45,86] Initially it is likely that in many cases the pulp in the coronal segment becomes necrotic after the injury, but then because of a very large apical opening in the coronal segment, revascularization is possible if the segments are well reapproximated. In the vast majority of cases, permanent necrosis occurs in the coronal segment, with only the apical segment remaining vital. Therefore, endodontic treatment is indicated in the coronal root segment unless periapical pathology is seen in the apical segment. In most cases, the pulpal lumen is wide at the apical extent of the coronal segment so that long-term calcium hydroxide treatment or an MTA apical plug is indicated (see Apexification). The coronal segment is filled after a hard-tissue barrier has formed apically in the coronal segment and periradicular healing has taken place.

In rare cases when both the coronal and apical pulp are necrotic, treatment is more complicated. Endodontic treatment through the fracture is extremely difficult. Endodontic manipulations, medicaments, and filling materials all have a detrimental effect on healing of the fracture site. If healing of the fracture has been complete and followed by necrosis of the apical segment, the prognosis is much improved.

In more apical root fractures, necrotic apical segments can be surgically removed. This is a viable treatment if the remaining coronal root segment is long enough to provide adequate periodontal support. Removal of the apical segment in midroot fractures leaves the coronal segment with a compromised attachment; endodontic implants have been used to provide additional support to the tooth.

Follow-Up

After the splinting period is completed, follow-up is as with all dental traumatic injuries: at 3, 6, and 12 months and yearly thereafter.

Prognosis

Factors that influence repair include:

1. Degree of dislocation and mobility of the coronal fragment are extremely important in determining outcome.[7,17,87,137,166] Increased dislocation and coronal fragment mobility result in a poorer prognosis.
2. Immature teeth are seldom involved in root fractures, but in the unlikely event they are, the prognosis is good.[17,85]
3. Quality of treatment is vital to successful repair. Prognosis improves with quick treatment, close reduction of the root segments, and semirigid splinting for 2 to 4 weeks.[18]

Complications are pulp necrosis and root canal obliteration. Pulp necrosis can be treated successfully[45,86] by treating the coronal segment with calcium hydroxide to stimulate hard-tissue barrier formation. Root canal obliteration is common if the root segment (coronal or apical) remains vital.

LUXATION INJURIES

Definitions

Types of luxation injury:

1. *Concussion* implies no displacement, normal mobility, and sensitivity to percussion.
2. *Subluxation* implies sensitivity to percussion, increased mobility, and no displacement.
3. *Lateral luxation* implies displacement labially, lingually, distally, or incisally.
4. *Extrusive luxation* implies displacement in a coronal direction.
5. *Intrusive luxation* implies displacement in an apical direction into the alveolus.

Definitions 1 through 5 describe injuries of increasing magnitude in terms of intensity of the injury and subsequent sequelae.

Incidence

Luxation injuries as a group are the most common of all dental injuries, with reported incidences ranging from 30% to 44%.[50]

Treatment

Teeth that are concussed or subluxated do not need any immediate treatment. Responses to vitality tests should be investigated and noted. Even after mild injury such as subluxation, the pulp might be unresponsive to vitality tests for several weeks if not months.[133] When the pulp is unresponsive initially after the trauma, patients should be recalled on a regular basis and monitored for any additional signs of infection of the root canal (see later).

Teeth with lateral and extrusive luxation should be repositioned as soon as possible. In lateral luxation, the apex might be perforating the facial bone plate, and the tooth has to first be slightly and gently pulled down to loosen the hold prior to repositioning it in its original position. Current IADT

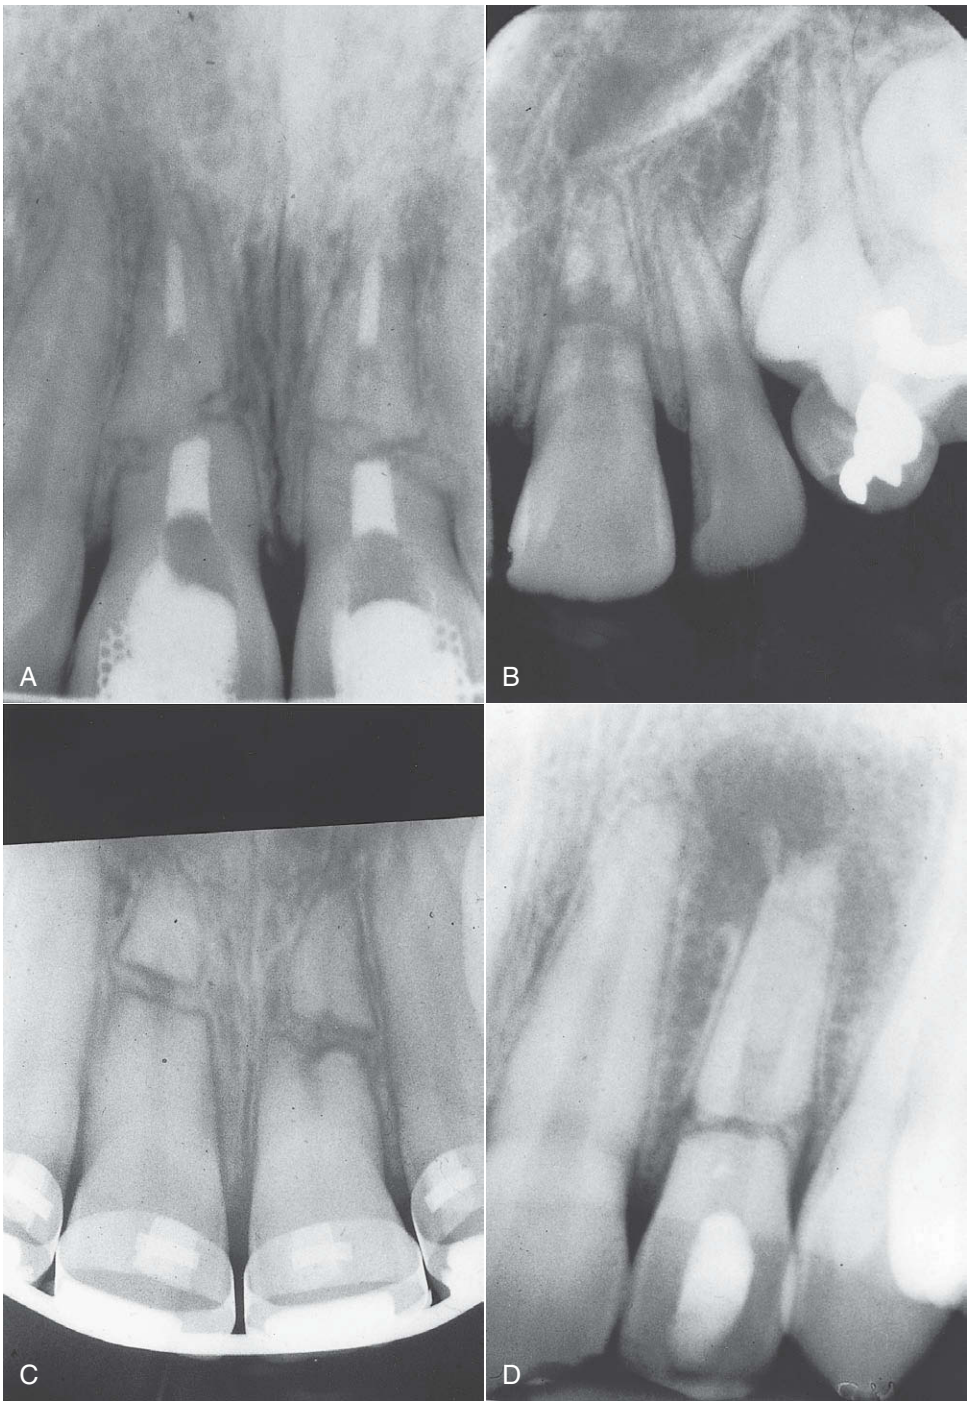

FIG. 17-24 Healing patterns after horizontal root fractures. **A,** Healing with calcified tissue. **B,** Healing with interproximal connective tissue. **C,** Healing with bone and connective tissue. **D,** Interproximal connective tissue without healing.

guidelines call for 2 weeks of physiologic splinting in cases of extrusion luxation and 4 weeks for lateral luxation. Decision on root canal therapy follows the guidelines for avulsion (see later). If the tooth has a fully formed apex and was diagnosed to have moved into (if not through) the cortical plate (apical translocation), there is a good likelihood of the pulp being devitalized, so endodontic treatment should be initiated as early as 2 weeks after the injury. If the apex is still not fully formed, waiting for signs of revascularization is strongly recommended.

Permanent teeth that are intruded are not likely to spontaneously re-erupt, especially if the apex is fully formed.[92] Alternative treatment like orthodontic extrusion or immediate surgical reposition should therefore be considered. If orthodontic extrusion is planned for an intruded tooth, it should be initiated as soon as possible, delaying no more than 2 to 3 weeks post trauma. There are only a few studies that have evaluated the true efficacy of this approach. One study[157] using a dog model indicated that severely intruded teeth showed

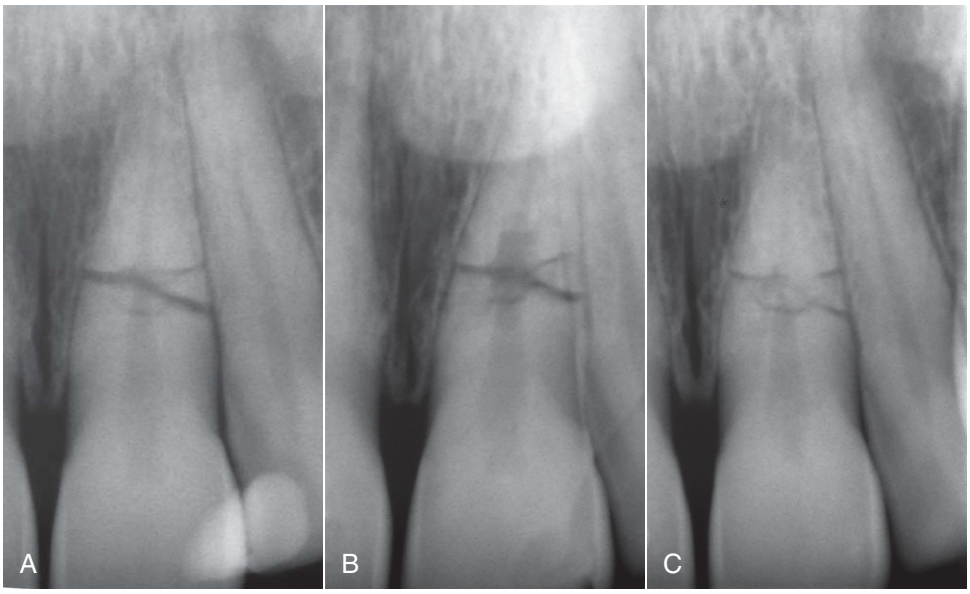

FIG. 17-25 Internal root resorption in the root fracture area; tooth was diagnosed with compound midroot fracture. **A,** Coronal portion was repositioned and then splinted to the lateral incisor with a composite splint. **B,** At 6-month recall, the pulp responded normally to cold, but an internal root-resorptive defect was noted on radiograph. No treatment was indicated, because the pulp did respond normally to vitality tests. **C,** At 42-month recall, the tooth was still asymptomatic, and the pulp still responded to vitality tests. The resorptive defect had healed, and signs of dystrophic calcifications were evident in the apical and coronal segments.

signs of ankylosis as early as 11 to 13 days after the trauma, despite initiation of orthodontic movement 5 to 7 days after the injury.

For the surgical approach, one study[42] (using a dog model) concluded that "a careful immediate surgical repositioning of a severely intruded permanent tooth with complete root formation has many advantages with few disadvantages." Another investigation,[52] a retrospective study of 58 intruded human teeth, indicated that surgical repositioning resulted in a predictable outcome, with only five of the teeth being lost over the observation period. However, it was also observed that less surgical manipulation positively influenced the healing. If an intruded tooth is immediately reimplanted, it should be splinted for at least 4 weeks, but in most cases the splint needs to be left on the tooth longer.

Biologic Consequences

Luxation injuries result in damage to the attachment apparatus (periodontal ligament and cemental layer), the severity of which is dependent on the type of injury sustained (concussion least, intrusion most). The apical neurovascular supply to the pulp is also affected to varying degrees, resulting in an altered or nonvital tooth.

Healing can be favorable or unfavorable. Favorable healing after a luxation injury occurs if the initial physical damage to the root surface and the resultant inflammatory response to the damaged external root surface is again covered with cementum. An unfavorable response occurs when there is direct attachment of bone to the root, with the root ultimately being replaced by bone.

There are two resorption responses in which the pulp plays an essential role:

1. In *external* inflammatory root resorption, the *necrotic infected pulp* provides the stimulus for periodontal inflammation in the ligament space. If the cementum has been damaged, the inflammatory stimulators in the pulp space are able to diffuse through the dentinal tubules and stimulate an inflammatory response over large areas of the periodontal ligament. Because of the lack of cemental protection, the periodontal inflammation will include root resorption as well as the expected bone resorption.
2. With *internal* inflammatory root resorption, the inflamed pulp is the tissue involved in resorbing the root structure. The pathogenesis of internal root resorption is not completely understood. Here it is thought that coronal necrotic infected pulp provides a stimulus for a pulpal inflammation in the more apical parts of the remaining vital pulp.[7] If the internal root surface has lost its precemental protection during an injury, internal root resorption will occur in the area adjacent to the inflamed pulp. Thus, both the necrotic infected pulp and the inflamed pulp contribute to this type of root resorption.

External Root Resorption

CAUSED BY AN INJURY (ALONE) TO THE EXTERNAL ROOT SURFACE

If an injury harms the attachment, the byproducts of this mechanical damage stimulate an inflammatory response. The healing response is dependent on the extent of the initial damage.

Localized Injury: Healing With Cementum When the injury is localized (e.g., after concussion or subluxation injury), mechanical damage to the cementum occurs, resulting in a

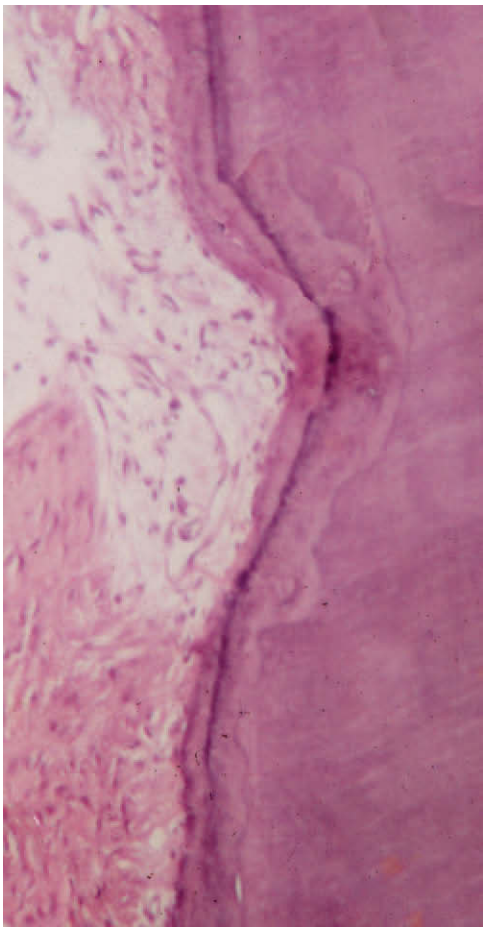

FIG. 17-26 Histologic section showing previous root resorptive defect healed with new cementum and periodontal ligament.

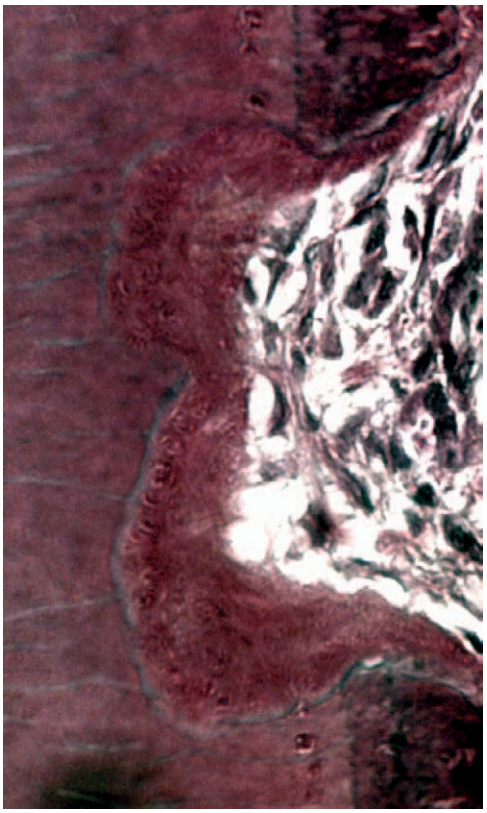

FIG. 17-27 Histologic appearance of osseous replacement. There is direct contact between bone and root structure. Resorptive defects are seen in the bone and root tissue, which is the normal physiologic process of bone turnover. The resorptive defects will be filled by new bone and additional areas resorbed. In this way the entire root will be replaced by bone at a rate dependent on the metabolic rate of the patient.

local inflammatory response and a localized area of root resorption. If no further inflammatory stimulus is present, periodontal healing and root surface repair will occur within 14 days[71] (Fig. 17-26). The resorption is localized to the area of mechanical damage, and treatment is not required, since it is free of symptoms and not even visualized radiographically in most cases. In a minority of cases, however, small radiolucencies can be seen on the root surface if the radiograph is taken at a specific angle. It is important to avoid misinterpreting these cases as progressive. The pulp is not involved. If the pulp responds to sensitivity tests, this is a clue that no treatment should be performed. A wait-and-see attitude can allow spontaneous healing to take place. It is important to realize that in the initial stages, radiolucency could be followed by spontaneous repair, and endodontic treatment should *not* be initiated.

Diffuse Injury: Healing by Osseous Replacement When the traumatic injury is severe (e.g., intrusive luxation or avulsion with extended dry time), involving diffuse damage on more than 20% of the root surface, an abnormal attachment can occur after healing takes place.[96] The initial reaction as always is inflammation, in response to the severe mechanical damage to the root surface. After the initial inflammatory response, a diffuse area of root surface devoid of cementum results. Cells in the vicinity of the denuded root now compete to repopulate it. Often cells which are precursors of bone, rather than the slower-moving periodontal ligament cells, will move across from the socket wall and populate the damaged root. Bone comes into contact with the root without an intermediate attachment apparatus. This phenomenon is termed *dentoalveolar ankylosis*.[96] However, the ankylosis and osseous replacement that follows cannot be reversed and can be considered a physiologic process, since bone resorbs and reforms throughout life. Thus root is resorbed by osteoclasts, but in the reforming stage, bone is laid down instead of dentin, slowly replacing the root with bone. This process is termed *osseous replacement*[152] (Fig. 17-27). The initial inflammation to remove the mechanical debris of the traumatic injury is a pathologic response that in the authors' opinion may be reversed. In these traumatic cases, however, the resorptive phase includes the root (Fig. 17-28).

Treatment Treatment strategies for limiting the effect of the traumatic injury to the periodontal structures are outside the scope of this chapter, but in general this involves minimizing the initial inflammatory response to the injury. The initial inflammation is destructive in nature and will increase the surface area of root to be covered in the healing phase.[21] The smaller the surface area to be covered by new cementum, the higher the chances of favorable repair.

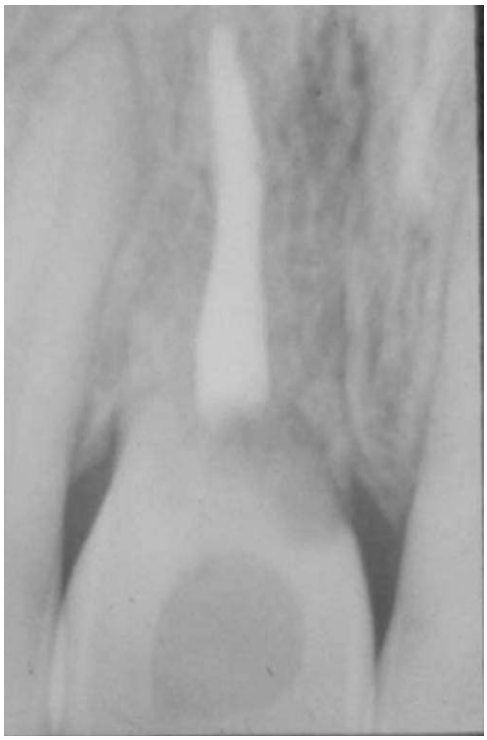

FIG. 17-28 Radiographic appearance of osseous replacement. The root acquires the radiographic appearance of the surrounding bone (without a lamina dura). Note that radiolucencies typical of active inflammation are not present.

A study has indicated that if Ledermix, a drug combining corticosteroid and tetracycline, is placed in the root canal immediately after a severe trauma where osseous replacement was expected, favorable healing will occur at a very high rate.[36] In a more recent study, it was shown that triamcinolone (the corticosteroid portion of the Ledermix paste) was as effective as Ledermix at inhibiting external root resorption.[39] Both these studies were done on young dogs and need to be replicated in human studies.

CAUSED BY AN INJURY TO THE EXTERNAL ROOT SURFACE AND INFLAMMATORY STIUMLUS IN THE ROOT CANAL

Recognized inflammatory stimuli that cause root resorption are pressure, pulp space infection, and sulcular infection. This chapter is focused on pulp space infection. Other chapters in this text deal with orthodontic and periodontal issues (see Chapters 18 and 23).

CONSEQUENCES OF APICAL NEUROVASCULAR SUPPLY DAMAGE

Pulp Canal Obliteration (Calcification) *Pulp canal obliteration* is common after luxation injuries (Fig. 17-29). The frequency of pulp canal obliteration appears inversely proportional to pulp necrosis. The exact mechanism of pulp canal obliteration is unknown. It has been theorized that the sympathetic/parasympathetic control of blood flow to the odontoblasts is altered, resulting in uncontrolled reparative dentin.[7,15] Another theory is that hemorrhage and blood clot formation in the pulp after injury is a nidus for subsequent calcification if the pulp remains vital.[7,15] Pulp canal obliteration can usually be diagnosed within the first year after injury[11] and was found to be more frequent in teeth with open apices (>0.7 mm radiographically), in teeth with extrusive and lateral luxation injuries, and in teeth that have been rigidly splinted.[11]

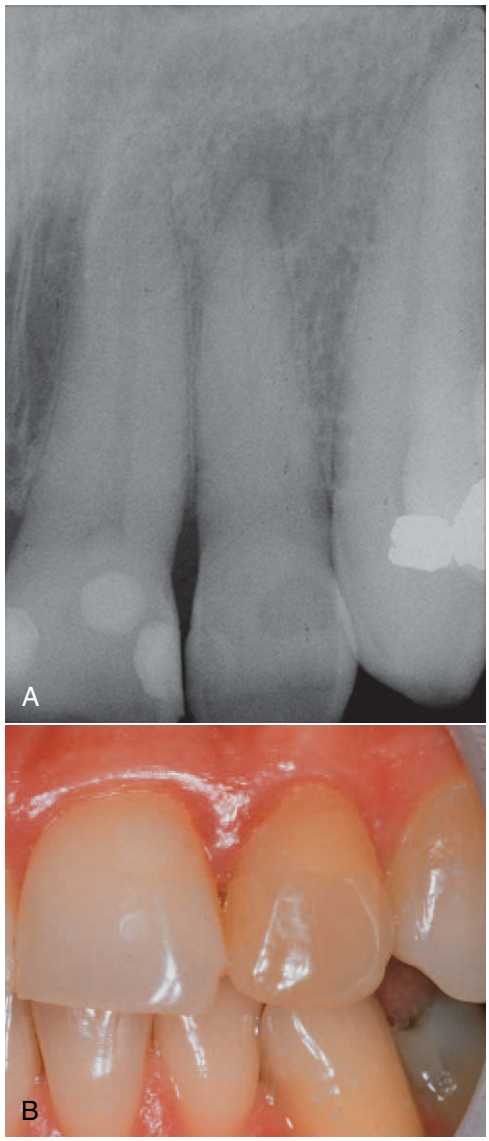

FIG. 17-29 A, Pulp canal calcification after a luxation injury. Radiographic appearance of a calcified maxillary lateral incisor; note that despite calcification, it has now become necrotic and infected, evident by the periapical lesion. **B,** The typical yellow appearance of the tooth caused by thickened dentin in the pulp chamber.

Pulp Necrosis The factors most important for the development of pulp necrosis are type of injury (concussion least, intrusion most) and the stage of root development (mature apex > immature apex).[10] Pulp necrosis will most likely lead to infection of the root canal system, with problematic consequences.

Pulp Space Infection Pulp space infection in conjunction with damage to the external root surface results in periradicular root

FIG. 17-30 Inflammatory root resorption caused by a pulp space infection. Note the radiolucencies in the root and surrounding bone. *(Courtesy Dr. Fred Barnett.)*

and bone resorption and will continue in its active state as long as the pulpal stimulus (infection) remains. When the root loses its cemental protection, lateral periodontitis with root resorption can result (Fig. 17-30).

To have pulp space infection, the pulp must first become necrotic. Necrosis will occur after a fairly serious injury in which displacement of the tooth results in severing of the apical blood vessels. In mature teeth, pulp regeneration cannot occur and usually by 3 weeks, the necrotic pulp will become infected. For details of the typical bacterial contents of a traumatized necrotic pulp, the reader is referred to Chapter 15 or Bergenholtz.[29] Because a serious injury is required for pulp necrosis, it is usual that areas of cemental covering of the root are also affected, resulting in loss of its protective (insulating) quality. Now bacterial toxins can pass through the dentinal tubules and stimulate an inflammatory response in the periodontal ligament. The result is resorption of the root and bone. The periodontal infiltrate consists of granulation tissue with lymphocytes, plasma cells, and polymorphonuclear leukocytes. Multinucleated giant cells resorb the denuded root surface, and this continues until the stimulus (pulp space bacteria) is removed[149] (Fig. 17-31). Radiographically the resorption is observed as progressive radiolucent areas of the root and adjacent bone (see Fig. 17-30).

Treatment Assessing attachment damage due to the traumatic injury and minimizing the subsequent inflammation should be the focus of the emergency visit. The clinician's attention to pulp space infection should ideally be 7 to 10 days after the injury.[155,156] Root canal disinfection removes the stimulus to the periradicular inflammation, thus the resorption will stop.[71,155,156] In most cases a new attachment will form, but if a large area of root is affected, osseous replacement can result

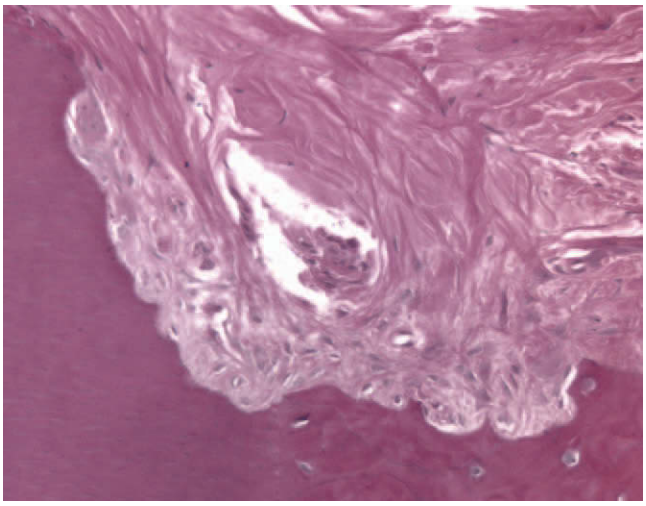

FIG. 17-31 Histologic appearance of multinucleated osteoclasts (dentinoclasts) resorbing the dentin of the root.

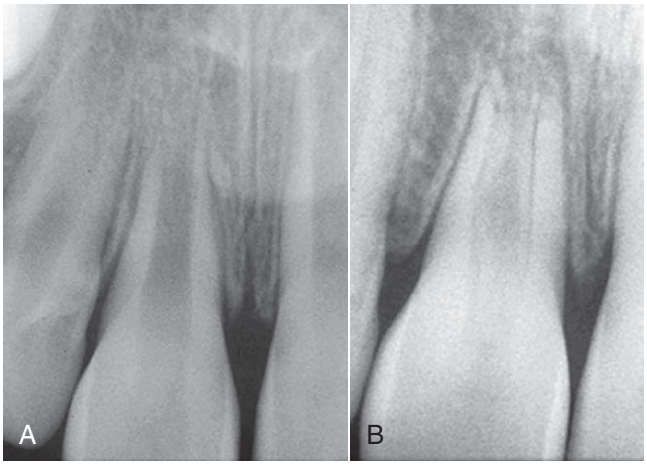

FIG. 17-32 Revascularization of immature root. A tooth with an open apex was replanted soon after the avulsion. The checkup radiograph 12 years later confirms that regrowth has taken place into the pulp chamber. It appears that a bone plug has grown in, and new periodontal ligament has formed, with a lamina dura within the pulp canal. *(Courtesy Dr. Cecilia Bourguignon.)*

by the mechanism already described. Again, treatment principles include prevention of pulp space infection or elimination of the bacteria if they are present in the pulp space.

1. Prevention of pulp space infection
   a. *Reestablish the vitality of the pulp.* If the pulp stays vital, the canal will be free of bacteria, and external inflammatory root resorption will not occur. In severe injuries where vitality has been lost, it is possible under some circumstances to promote revascularization of the pulp. Revascularization is possible in young teeth with incompletely formed apices if replaced in their original position within 60 minutes of the injury[46] (Fig. 17-32). If the tooth has been avulsed, soaking it in doxycycline for 5 minutes or covering the root with minocycline powder before replantation has been shown to double or triple the

revascularization rate.[46,116] Even under the best conditions, however, revascularization will fail to occur on many occasions, and a diagnostic dilemma results. If the pulp revascularizes, external root resorption will not occur, and the root will continue to develop and strengthen. If the pulp becomes necrotic and infected, the subsequent external inflammatory root resorption that develops could result in loss of the tooth in a very short time. At present, the diagnostic tools available cannot detect a vital pulp in this situation before approximately 6 months after successful revascularization. This period of time is obviously unacceptable, since by that time the teeth that have not revascularized could be lost to the resorption process. Recently the laser Doppler flowmeter or the pulse oximeter have been shown to have diagnostic potential for the detection of revascularization in immature teeth (see Fig. 17-4). These devices appear to detect the presence of vital tissue in the pulp space by 4 weeks after the traumatic injury.[165]

b. *Prevent root canal infection by root canal treatment at 7 to 10 days*. In teeth with closed apices, revascularization cannot occur. These teeth should be endodontically treated within 7 to 10 days of the injury before the ischemically necrosed pulp becomes infected.[155,156] Theoretically, treating teeth within this time period can be considered equivalent to treating a tooth with a vital pulp, and the endodontic treatment could be completed in one visit if possible. However, efficient treatment is extremely difficult so soon after a serious traumatic injury, and in the authors' opinion it is beneficial to start the endodontic treatment with chemomechanical preparation, after which an intracanal dressing with a creamy mix of calcium hydroxide is placed[155] (see Fig. 17-14). The clinician can now fill the canal at his/her convenience after periodontal healing of the injury is complete—approximately 1 month after the instrumentation visit. There appears to be no necessity for long-term calcium hydroxide treatment in cases where the endodontic treatment is started within 10 days of the injury.[155]

2. *Eliminate pulp space infection*. When root canal treatment is initiated later than 10 days after the accident, or if active external inflammatory resorption is observed, the preferred antibacterial protocol consists of microbial control followed by long-term dressing with densely packed calcium hydroxide.[156] Calcium hydroxide can effect an alkaline pH in the surrounding dentinal tubules (Fig. 17-33), kill bacteria, and neutralize endotoxin, a potent inflammatory stimulator.

The first visit consists of the microbial control phase, with cleaning and shaping of the canal and the placement of a creamy mix of calcium hydroxide using a Lentulo spiral. The patient is seen in approximately 1 month, at which time the canal is filled with a dense mix of calcium hydroxide. Once filled, the canal should appear radiographically to be calcified, since the radiodensity of calcium hydroxide in the canal is usually similar to the surrounding dentin (see Fig. 17-16). A radiograph is then exposed at 3-month intervals. At each visit the tooth is tested for symptoms of periodontitis. In addition to stopping the resorptive process, calcium hydroxide washout is assessed. Since the root surface is so radiodense as to make assessment of healing difficult, the adjacent bone healing is assessed. If adjacent bone has healed, it is assumed that the resorptive process has stopped in the root as well; then the canal can be obturated with the permanent root filling material (Fig. 17-34).

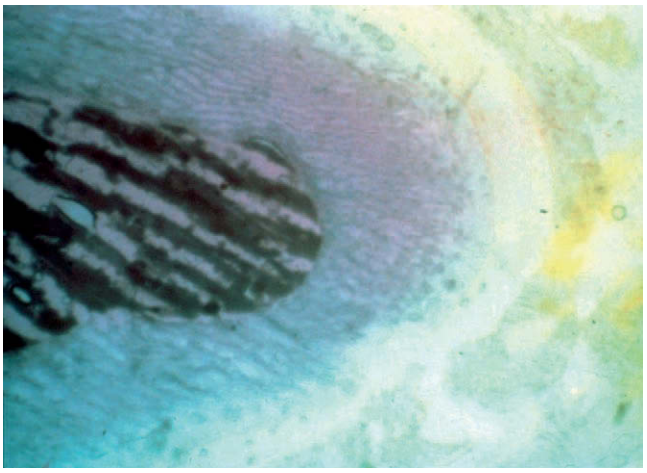

FIG. 17-33 High pH of calcium hydroxide. The root was filled with calcium hydroxide and then cut in cross section. A pH indication shows the high pH in the canal and surrounding root, whereas the surrounding tissue is a neutral pH.

Internal Root Resorption

Internal root resorption is rare in permanent teeth. Internal resorption is characterized by an oval-shaped enlargement of the root canal space.[16] External resorption, which is much more common, is often misdiagnosed as internal resorption.

ETIOLOGY

Internal root resorption is characterized by resorption of the internal aspect of the root by multinucleated giant cells

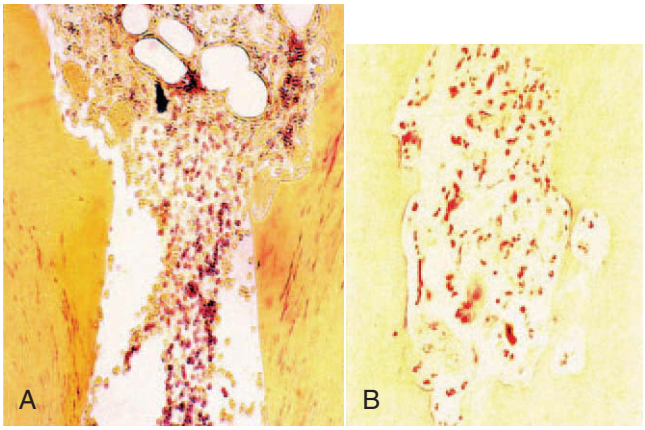

FIG. 17-35 Histologic appearance of internal root resorption. **A,** Section stained with Brown and Brenn. Bacteria are seen (in the dentinal tubules) communicating between the necrotic coronal segment and the apical granulomatous tissue and resorbing cells. **B,** An area of active internal root resorption. (*Courtesy Dr. Leif Tronstad.*)

adjacent to the granulation tissue in the pulp (Fig. 17-35). Chronic inflammatory tissue is common in the pulp, but only rarely does it result in resorption. There are different theories on the origin of the pulpal granulation tissue involved in internal resorption. The most logical explanation is that it is inflamed pulp tissue due to an infected coronal pulp space. Communication between the coronal necrotic tissue and the vital pulp is through appropriately oriented dentinal tubules[159] (see Fig. 17-35). One investigator reports[159] that resorption of the dentin is frequently associated with deposition of hard tissue resembling bone or cementum and not dentin. He postulates that the resorbing tissue is not of pulpal origin but is "metaplastic" tissue derived from the pulpal invasion of macrophage-like cells. Others[138] concluded that the pulp tissue was replaced by periodontium-like connective tissue when internal resorption was present. In addition to the requirement of the presence of granulation tissue, root resorption takes place only if the odontoblastic layer and predentin are lost or altered.[149]

Reasons for the loss of predentin adjacent to the granulation tissue are not obvious. Trauma frequently has been suggested as a cause.[124,160] Another reason for the loss of predentin might be extreme heat produced when cutting on dentin without an adequate water spray. The heat presumably would destroy the predentin layer, and if later the coronal aspect of the pulp becomes infected, the bacterial products could initiate the typical inflammation in conjunction with resorbing giant cells in the vital pulp adjacent to the denuded root surface. Internal root resorption has been produced experimentally by the application of diathermy.[159]

CLINICAL MANIFESTATIONS

Internal root resorption is usually asymptomatic and is first recognized clinically through routine radiographs. For internal resorption to be active, at least part of the pulp must be vital. The coronal portion of the pulp is often necrotic, whereas the apical pulp that includes the internal resorptive defect can remain vital. Therefore, a negative sensitivity test result does not rule out active internal resorption. It is also possible that

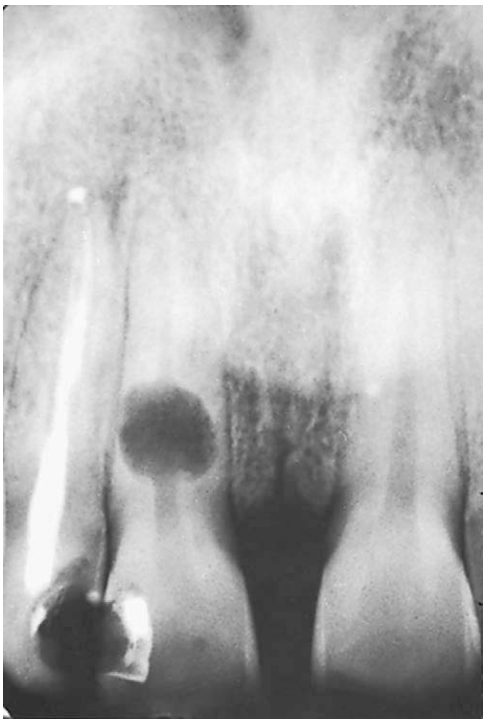

FIG. 17-36 A maxillary incisor with internal root resorption. Uniform enlargement of the pulp space is apparent. Outline of the canal cannot be seen in the resorptive defect.

the pulp becomes nonvital after a period of active resorption, giving a negative sensitivity test, radiographic signs of internal resorption, and radiographic signs of apical inflammation. Traditionally, the pink tooth has been thought pathognomonic of internal root resorption. The pink color is due to the granulation tissue in the coronal dentin undermining the crown enamel. The pink tooth can also be a feature of subepithelial external inflammatory root resorption, which must be ruled out before a diagnosis of internal root resorption is made.

RADIOGRAPHIC APPEARANCE

The usual radiographic presentation of internal root resorption is a fairly uniform radiolucent enlargement of the pulp canal (Fig. 17-36). Because the resorption is initiated in the root canal, the resorptive defect includes some part of the root canal space, so the original outline of the root canal is distorted.

HISTOLOGIC APPEARANCE

Like that of other inflammatory resorptive defects, the histologic picture of internal resorption is granulation tissue with multinucleated giant cells (see Fig. 17-35). An area of necrotic pulp is found coronal to the granulation tissue. Dentinal tubules containing microorganisms and communicating between the necrotic zone and the granulation tissue can sometimes be seen[129,149,156,159] (see Fig. 17-35). Unlike external root resorption, the adjacent bone is not affected with internal root resorption.

TREATMENT

Treatment of internal root resorption is conceptually very easy. Since the resorptive defect is the result of the inflamed pulp, and the blood supply to the tissue is through the apical

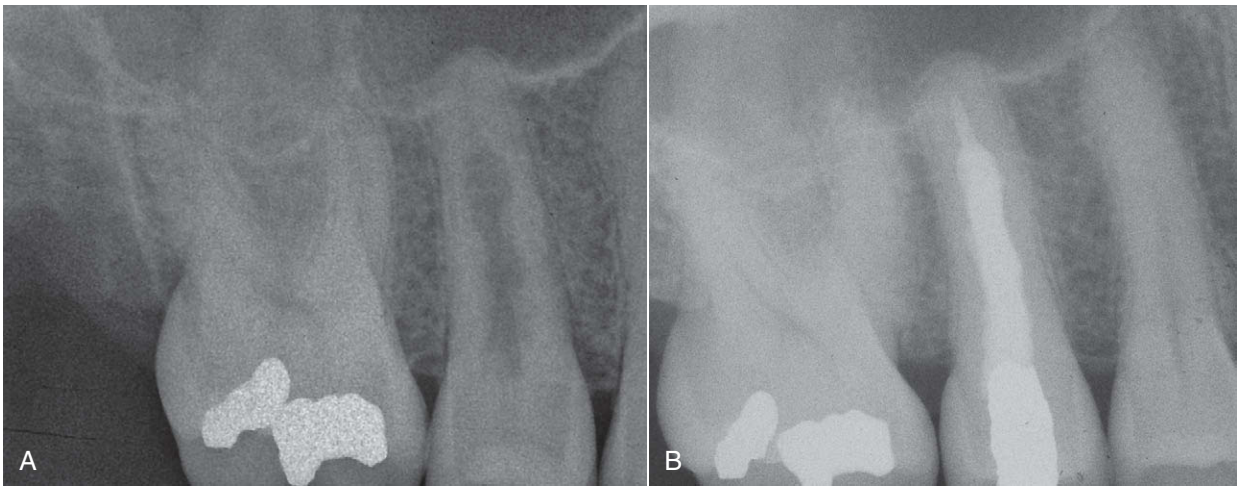

FIG. 17-37 A, Internal root resorption in a maxillary premolar with a history of trauma 7 years prior to the diagnosis (patient's head slammed against side window during an automobile accident). **B,** Three-year follow-up radiograph after endodontic treatment.

foramina, endodontic treatment that effectively removes the blood supply to the resorbing cells is the treatment approach. After adequate anesthesia is obtained, the canal apical to the internal defect is explored, and a working length short of the radiographic apex is used. The apical canal is thoroughly cleaned and shaped to ensure that the blood supply to the tissue resorbing the root is cut off.

By completion of the root canal instrumentation, it should be possible to obtain a blood-free and dry canal with paper points. Calcium hydroxide is spun into the canal to facilitate the removal of the tissue in the irregular defect at the next visit. At the second visit, the tooth and defect are filled with a warm gutta-percha technique (Fig. 17-37).

Diagnostic Features of External versus Internal Root Resorption

It is often very difficult to distinguish external from internal root resorption, so misdiagnosis and incorrect treatment may result. What follows is a list of typical diagnostic features of each resorptive type.

RADIOGRAPHIC FEATURES

A change of angulation of x-rays should give a fairly good indication of whether a resorptive defect is internal or external. A lesion of internal origin appears close to the canal, whatever the angle of the x-ray (see Fig. 17-36). A defect on the external aspect of the root moves away from the canal as the angulation changes (Fig. 17-38). By using the buccal-object rule, it is usually possible to distinguish whether the external root defect is buccal or lingual-palatal.

With internal resorption, the outline of the root canal is usually distorted, and the root canal and the radiolucent resorptive defect appear contiguous (see Fig. 17-36). When the defect is external, the root canal outline appears normal and can usually be seen "running through" the radiolucent defect (Fig. 17-39).

External inflammatory root resorption is always accompanied by resorption of the bone in addition to the root (Fig. 17-40); radiolucencies will be apparent in the root and the adjacent bone. Internal root resorption does not involve the bone, and as a rule the radiolucency is confined to the root (see Fig. 17-36). On rare occasions if the internal defect perforates the root, the bone adjacent to it is resorbed and appears radiolucent on the radiograph.

VITALITY TESTING

External inflammatory resorption in the apical and lateral aspects of the root involves an infected pulp space, so no response to sensitivity tests supports the diagnosis. However, since subepithelial external root resorption does not involve the pulp (the bacteria are thought to originate in the sulcus of the tooth), a normal response to sensitivity testing is usually associated with this type of resorption. Internal root resorption usually occurs in teeth with vital pulps and responses to sensitivity testing. In teeth that exhibit internal root resorption, it is common to register a no-response to sensitivity testing, since often the coronal pulp has been removed or is necrotic, and the active resorbing cells are more apical in the canal. Also, the pulp might have become necrotic after active resorption took place.

PINK SPOT

With apical and lateral external root resorption, the pulp is nonvital, so the granulation tissue that produces the pink spot is not present in these cases. For subepithelial external (Fig. 17-41) and internal root resorption, the pink spot due to the granulation tissue undermining the enamel is a possible sign.

Summary of Possible Diagnostic Features

- External inflammatory root resorption due to pulp infection.
  Apical. No response of the pulp to thermal or electric stimuli, with or without a history of trauma.
  Lateral. History of trauma, no response of the pulp to thermal or electric stimuli, lesion moves on angled x-rays, root canal visualized radiographically overlying the defect, bony radiolucency also apparent.
- Subepithelial external inflammatory due to sulcular infection. History of trauma (often forgotten or its long-

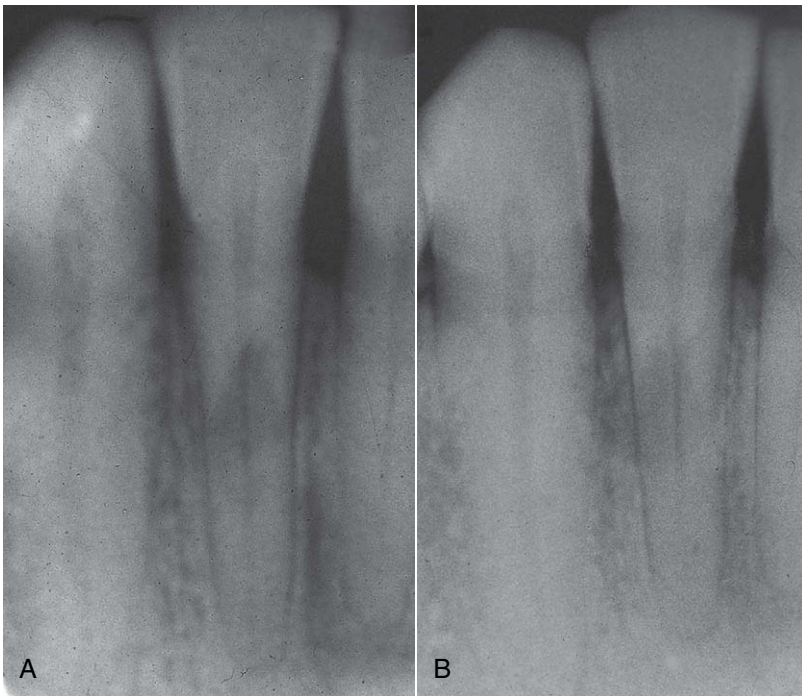

FIG. 17-38 External root resorption. Radiographs from two different horizontal projections depict movement of the lesion to outside the confines of the root canal.

FIG. 17-39 External root resorption on a mandibular premolar 6 years after completing orthodontic treatment. Note the mottled appearance of the resorptive defect and the outline of the root canal within the defect.

FIG. 17-40 Mandibular molar with subepithelial external inflammatory resorption on its mesial aspect. Note the small opening into the root and the extensive resorption in the dentin; however, the pulp is not exposed. Also note that a resorptive defect is present in the adjacent bone, appearing on the radiograph as similar to an infra-bony pocket.

term risks not appreciated by the patient), positive pulp sensitivity test, lesion located at the attachment level of the tooth, lesion moves on angled x-rays, root canal outline is undistorted and can be visualized radiographically, crestal bony defect associated with the lesion, pink spot possible.

- Internal root resorption. History of trauma, crown preparation, or pulpotomy; responsive pulp to thermal or electric stimuli likely, may occur at any location along the root canal (not only attachment level); lesion stays associated with the root canal on angled x-rays, radiolucency contained in the root without an adjacent bony defect; pink spot possible.

The majority of misdiagnoses of resorptive defects are made between subepithelial external and internal root resorptions. The diagnosis should always be confirmed while treatment is proceeding. If root canal therapy is the treatment of choice for an apparent internal root resorption, the bleeding within the canal should cease quickly after pulp extirpation, since the blood supply of the granulation tissue is the apical blood vessels. If bleeding continues during treatment—and particularly if it is still present at the second visit—the source of the blood supply is external, and treatment for perforating external resorption should be carried out. On obturation, it

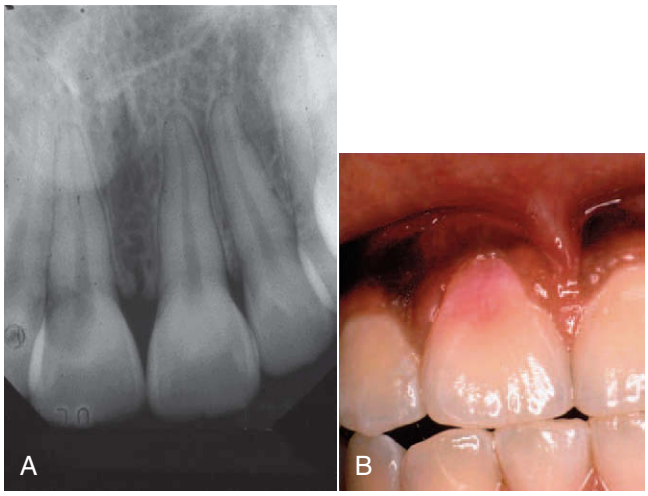

FIG. 17-41 Pink spot of subepithelial external inflammatory root resorption. **A,** Radiographic appearance. **B,** Clinical appearance.

should be possible to fill the entire canal from within in internal resorption. Failure to achieve this should make the clinician suspicious of an external lesion that is perforating the root. Finally, if the blood supply of an internal resorption defect is removed on pulp extirpation, any continuation of the resorptive process on recall radiographs should alert the clinician to the possibility that an external resorptive defect was misdiagnosed.

CLINICAL MANAGEMENT OF THE AVULSED TOOTH

Favorable healing after an avulsion injury requires quick emergency intervention followed by evaluation and possible treatment at decisive times during the healing phase. The urgency of the emergency visit and the multidisciplinary nature of follow-up evaluations require that both the lay public and clinicians from many dental disciplines be knowledgeable about the treatment strategies involved.

Consequences of Tooth Avulsion

Tooth avulsion results in attachment damage and pulp necrosis. The tooth is "separated" from the socket due mainly to tearing of the periodontal ligament that leaves viable periodontal ligament cells on most of the root surface. In addition, small and localized cemental damage occurs from the crushing of the tooth against the socket.

If the periodontal ligament left attached to the root surface does not dry out, the consequences of tooth avulsion are usually minimal.[12,135] The hydrated periodontal ligament cells will maintain their viability and repair after replantation, with minimal destructive inflammation as a byproduct. Since the areas of the crushing injury are localized, inflammation stimulated by the damaged tissues will be correspondingly limited, and favorable healing with new replacement cementum is likely to occur after the initial inflammation subsides (see Fig. 17-26).

If excessive drying occurs before replantation, the damaged periodontal ligament cells will elicit a severe inflammatory response over a diffuse area on the root surface. Unlike the situation described earlier where the area to be repaired after the initial inflammatory response is small, here a large area of root surface is affected that must be repaired by new tissue. The slower-moving cementoblasts cannot cover the entire root surface in time, and it is likely that in certain areas, bone will attach directly onto the root surface. In time through physiologic bone recontouring, the entire root will be replaced by bone. As earlier noted, this has been termed *osseous replacement* or *replacement resorption*[21,153] (see Figs. 17-27, 17-28).

Pulpal necrosis always occurs after an avulsion injury. Although a necrotic pulp itself is not of consequence, the necrotic tissue is extremely susceptible to bacterial contamination. If revascularization does not occur or effective endodontic therapy is not carried out, the pulp space will inevitably become infected. The combination of bacteria in the root canal and cemental damage on the external surface of the root results in an external inflammatory resorption that can be very serious and lead to rapid loss of the tooth[149] (see Fig. 17-30).

The consequences after tooth avulsion appear directly related to the severity and surface area of the inflammation on the root surface and resultant damaged root surface that must be repaired. Treatment strategies should always be considered in the context of limiting the extent of the periradicular inflammation, thus tipping the balance toward favorable (cemental) rather than unfavorable (osseous replacement or inflammatory resorption) responses.

Treatment Objectives

Treatment is directed at avoiding or minimizing resultant inflammation due to the two main consequences of the avulsed tooth: attachment damage and pulpal infection.

Attachment damage as a direct result of the avulsion injury cannot be avoided. However, considerable additional damage can occur to the periodontal ligament in the time that the tooth is out of the mouth (primarily because of drying). Treatment is directed at minimizing this damage (and the resultant inflammation) so that the fewest possible complications result. When severe additional damage cannot be avoided, and osseous replacement of the root is considered certain, steps are taken to slow the replacement of the root by bone to maintain the tooth in the mouth for as long as possible.

In the open apex tooth, all efforts are made to promote revascularization of the pulp, thus avoiding pulp space infection. When revascularization fails (in the open apex tooth) or is not possible (in the closed apex tooth), all treatment efforts are made to prevent or eliminate toxins from the root canal space.

Clinical Management

Emergency Treatment at the Accident Site

Replant if possible or place in an appropriate storage medium. As mentioned, damage to the attachment apparatus that occurred during the initial injury is unavoidable but usually minimal. However, all efforts are made to minimize necrosis of the remaining periodontal ligament while the tooth is out of the mouth. Pulpal sequels are not a concern initially and are dealt with at a later stage of treatment.

The single most important factor to assure a favorable outcome after replantation is the speed with which the tooth is replanted.[16,22] Of utmost importance is the prevention of

drying, which causes loss of normal physiologic metabolism and morphology of the periodontal ligament cells.[22,135] Every effort should be made to replant the tooth within the first 15 to 20 minutes.[27] This usually requires emergency personnel at the site of the injury with some knowledge of treatment protocol. The clinician should communicate clearly with the person at the site of the accident. Ideally this information should have been given at an earlier time as an educational offering to, for example, school nurses or athletic trainers; failing this, the information can be given over the phone. The aim is to replant a clean tooth with an undamaged root surface as gently as possible, after which the patient should be brought to the office immediately. If doubt exists that the tooth can be replanted adequately, the tooth should quickly be stored in an appropriate medium until the patient can get to the dental office for replantation. Suggested storage media in order of preference are milk, saliva (either in the vestibule of the mouth or in a container into which the patient expectorates), physiologic saline, and water.[79] Water is the least desirable storage medium because the hypotonic environment causes rapid cell lysis and increased inflammation on replantation.[33,34]

Cell culture media in specialized transport containers such as Hank's Balanced Salt Solution (HBSS) have shown superior ability to maintain the viability of the periodontal ligament fibers for extended periods.[154] Presently they are considered impractical, since they need to be present at the accident site before the injury occurs, but if we consider that more than 60% of avulsion injuries occur close to home or school,[74] it should be beneficial to have these media available in emergency kits at these sites. It would also be advantageous to have them in ambulances and in the kits of emergency response personnel who are likely to treat the more serious injuries where teeth might otherwise be sacrificed to a more serious life-threatening situation.

Management in the Dental Office

EMERGENCY VISIT

Prepare socket, prepare root, replant, construct a functional splint, and administer local and systemic antibiotics.

Recognizing that a dental injury might be secondary to a more serious injury is essential. The attending dental clinician is likely to be the first health care provider the patient sees after a head injury, so ruling out any injuries to the brain (e.g., concussion) and/or central nervous system (CNS) in general is paramount. If on examination a CNS injury is suspected, immediate referral to the appropriate expert is the first priority above and beyond the dental injury. Once a CNS injury has been ruled out, the focus of the emergency visit is the attachment apparatus. The aim is to replant the tooth with a minimum of irreversibly damaged cells (that will cause inflammation) and the maximal number of periodontal ligament cells that have the potential to regenerate and repair the damaged root surface.

Diagnosis and Treatment Planning

If the tooth was replanted at the site of injury, a complete history is taken to assess the likelihood of a favorable outcome. The position of the replanted tooth is assessed and adjusted if necessary. On rare occasions, the tooth may be gently removed to prepare the root to increase the chances of a favorable outcome (see later).

If the patient presents with the tooth out of the mouth, the storage medium should be evaluated and the tooth placed in a more appropriate medium if required. Hank's Balanced Salt Solution is presently considered the best medium for this purpose. Milk or physiologic saline is also appropriate for storage purposes.

The medical and accident history is taken and a clinical exam carried out, with emphasis on questions about when, how, and where the injury occurred.

The clinical examination should include an examination of the socket to ascertain whether it is intact and suitable for replantation. The socket is gently rinsed with saline, and when cleared of the clot and debris, its walls are examined directly for the presence, absence, or collapse of the socket wall. The socket and surrounding areas including the soft tissues should be radiographed. Three vertical angulations are required for diagnosis of the presence of a horizontal root fracture in adjacent teeth.[16] The remaining teeth in both the upper and lower jaws should be examined for injuries such as crown fractures. Any soft-tissue lacerations should be noted and if tooth fragments are missing, explored.

PREPARATION OF THE ROOT

Preparation of the root is dependent on the maturity of the tooth (open versus closed apex) and on the dry time of the tooth before it was placed in a storage medium. A dry time of 60 minutes is considered the point where survival of root periodontal ligament cells is unlikely.

Extraoral Dry Time Less Than 60 Minutes

Closed Apex

The root should be rinsed of debris with water or saline and replanted in as gentle a fashion as possible.

If the tooth has a closed apex, revascularization is not possible,[46] but because the tooth was dry for less than 60 minutes (replanted or placed in appropriate medium), the chance for periodontal healing exists. Most importantly, the chance of a severe inflammatory response at the time of replantation is lessened. A dry time of less than 15 to 20 minutes is considered optimal, where periodontal healing would be expected.[12,27,135]

A continuing challenge is the treatment of the tooth that has been dry for more than 20 minutes (periodontal cell survival is assured) but less than 60 minutes (periodontal cell survival unlikely). In these cases, logic suggests that the root surface consists of some cells with the potential to regenerate and some that will act as inflammatory stimulators.

Open Apex

Gently rinse off debris, soak in doxycycline for 5 minutes or cover with minocycline, replant.

In an open-apex tooth, revascularization of the pulp as well as continued root development is possible (see Fig. 17-32). Investigators[46] found in monkeys that soaking the tooth in doxycycline (1 mg in approximately 20 ml of physiologic saline) for 5 minutes before replantation significantly enhanced complete revascularization. This result was confirmed later in dogs by other investigators.[116,165] A study found that covering the root with minocycline (Arestin, OraPharma, Inc,

Warminster, PA), which attaches to the root for approximately 15 days, further increased the revascularization rate in dogs.[116] Although animal studies do not provide us with a prediction of the rate of revascularization in humans, it is reasonable to expect that the same enhancement of revascularization that occurred in two animal species will occur in humans as well. As with the tooth with the closed apex, the open-apex tooth is then gently rinsed and replanted.

Extraoral Dry Time More Than 60 Minutes

Closed Apex

Remove the periodontal ligament by placing in acid for 5 minutes, soak in fluoride, replant.

When the root has been dry for 60 minutes or more, survival of the periodontal ligament cells is not expected.[22,135] In such cases, the root should be prepared to be as resistant to resorption as possible (attempting to slow the osseous replacement process). These teeth should be soaked in acid for 5 minutes to remove all remaining periodontal ligament and thus remove the tissue that will initiate the inflammatory response on replantation. The tooth should then be soaked in 2% stannous fluoride for 5 minutes and replanted.[32,126] A few years ago, studies were published that indicated that Emdogain (enamel matrix protein, Andover, MA) could be beneficial in teeth with extended extra oral dry times, not only to make the root more resistant to resorption but possibly to stimulate the formation of new periodontal ligament from the socket[57,83] (see Fig. 17-8). Unfortunately, more recent studies have shown that the positive effect of Emdogain is only temporary, and most of these teeth start to resorb after a few years.[121]

If the tooth has been dry for more than 60 minutes and no consideration is given to preserving the periodontal ligament, the endodontics may be performed extraorally. In the case of a tooth with a closed apex, no advantage exists to this additional step at the emergency visit. However, in a tooth with an open apex, endodontic treatment performed after replantation involves a long-term apexification procedure. In these cases, completing the root canal treatment extraorally, where a seal in the blunderbuss apex is easier to achieve, may be advantageous. When endodontic treatment is performed extraorally, it must be performed aseptically with the utmost care to achieve a root canal system that is thoroughly disinfected.

Open Apex

Replant? If yes, treat as with closed-apex tooth. Endodontic treatment may be performed out of the mouth.

Since these teeth are in young patients in whom facial development is usually incomplete, many pediatric clinicians consider the prognosis to be so poor and the potential complications of an ankylosed tooth so severe, that they recommend these teeth not be replanted. Considerable debate exists as to whether it would be beneficial to replant the root even though it will inevitably be lost due to osseous replacement. If the patients are followed carefully and the root submerged by decoronation procedure at the appropriate time,[6,56,60] the height, and more importantly the width, of the alveolar bone will be maintained, allowing for easier permanent restoration at the appropriate time when the child's facial development is complete.

PREPARATION OF THE SOCKET

The socket should be left undisturbed before replantation.[16] Emphasis is placed on removal of obstacles within the socket to facilitate replacement of the tooth into the socket.[71] It should be lightly aspirated if a blood clot is present. If the alveolar bone has collapsed or may interfere with replantation, a blunt instrument should be inserted carefully into the socket in an attempt to reposition the wall.

SPLINTING

A splinting technique that allows physiologic movement of the tooth during healing and is in place for a minimal time period results in a decreased incidence of ankylosis.[3,13,71] Semirigid (physiologic) fixation for 1 to 2 weeks is recommended.[3,5,60] The splint should allow movement of the tooth, should have no memory (so the tooth is not moved during healing), and should not impinge on the gingiva and/or prevent maintenance of oral hygiene in the area. Many splints satisfy the requirements of an acceptable splint. A new titanium trauma splint (TTS) has recently been shown to be particularly effective and easy to use[158] (Fig. 17-42). After the splint is in place, a radiograph should be exposed to verify the positioning of the tooth and as a preoperative reference for further treatment and follow-up. When the tooth is in the best possible position, adjusting the bite to ensure that it has not been splinted in a position causing traumatic occlusion is important. One week is sufficient to create periodontal support to maintain the avulsed tooth in position.[152] Therefore, the splint should be removed after 1 to 2 weeks. The only exception is with avulsion in conjunction with alveolar fractures, for which 4 to 8 weeks is the suggested time of splinting.[152]

MANAGEMENT OF THE SOFT TISSUES

Soft-tissue lacerations of the socket gingiva should be tightly sutured. Lacerations of the lip are fairly common with these types of injuries. The clinician should approach lip lacerations with some caution; a plastic surgery consult might be prudent. If these lacerations are sutured, care must be taken to clean the wound thoroughly beforehand because dirt or even minute

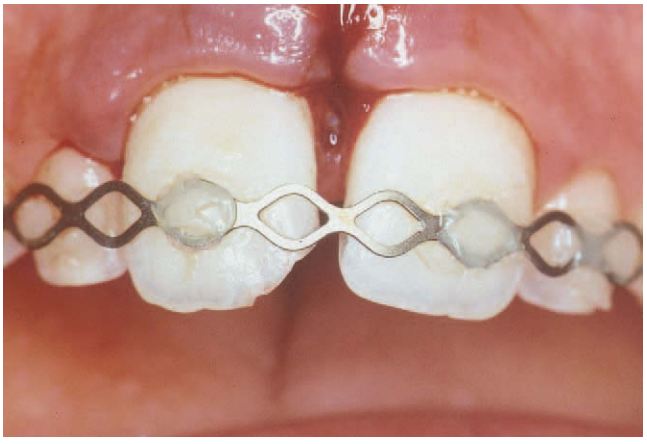

FIG. 17-42 Titanium trauma splint (TTS) in place.

tooth fragments left in the wound affect healing and the esthetic result.

ADJUNCTIVE THERAPY

Systemic antibiotics given at the time of replantation and prior to endodontic treatment are effective in preventing bacterial invasion of the necrotic pulp and therefore subsequent inflammatory resorption.[72] Tetracycline has the additional benefit of decreasing root resorption by affecting the motility of the osteoclasts and reducing the effectiveness of collagenase.[117] The administration of systemic antibiotics is recommended, beginning at the emergency visit and continuing until the splint is removed.[72] For patients not susceptible to tetracycline staining, the antibiotic of choice is doxycycline twice daily for 7 days at the appropriate dosage for patient age and weight.[117,118] Penicillin V 1000 mg as a loading dose, followed by 500 mg 4 times daily for 7 days has also been shown to be beneficial. The bacterial content of the sulcus also should be controlled during the healing phase. In addition to stressing to the patient the need for adequate oral hygiene, the use of chlorhexidine rinses for 7 to 10 days are helpful.

As stated previously, a recent series of studies by our research group found great benefit in removal of the pulp contents at the emergency visit and placing Ledermix or corticosteroid into the root canal.[36,39] Apparently the use of the medicament was able to shut down the inflammatory response after replantation to allow for more favorable healing compared to those teeth that did not have the medicament.

The need for analgesics should be assessed on an individual case basis. The use of pain medication stronger than nonprescription nonsteroidal antiinflammatory drugs (NSAIDs) is unusual. The patient should be sent to a physician for consultation regarding a tetanus booster within 48 hours of the initial visit.

Second Visit

This visit should take place 1 to 2 weeks after the trauma. At the emergency visit, emphasis was placed on the preservation and healing of the attachment apparatus. The focus of this visit is the prevention or elimination of potential irritants from the root canal space. These irritants, if present, provide the stimulus for the progression of the inflammatory response, bone and root resorption. Also at this visit, the course of systemic antibiotics is completed; the chlorhexidine rinses can be stopped. At this appointment the splint is removed; the tooth might still have class I or class II mobility after splint removal, but all indications are that it will continue to heal better without the splint.[3]

ENDODONTIC TREATMENT

Extraoral Time Less Than 60 Minutes

Closed Apex

Initiate endodontic treatment after 1 to 2 weeks. In cases where endodontic treatment is delayed or signs of resorption are present, treat with long-term calcium hydroxide treatment before obturation.

No chance exists for revascularization of these teeth, therefore endodontic treatment should be initiated at the second visit 7 to 10 days later.[14,46] If therapy is initiated at this optimum time, the pulp should be necrotic without (or with minimal) infection.[99,155] Endodontic therapy with an effective interappointment antibacterial agent[155] over a relatively short period (1 to 2 weeks) is sufficient to ensure effective disinfection of the canal.[130] Long-term calcium hydroxide treatment should always be considered when the injury occurred more than 2 weeks before initiation of the endodontic treatment or especially if radiographic evidence of resorption is present.[155]

The root canal is thoroughly cleaned and shaped, irrigated, and then filled with a thick (powdery) mix of calcium hydroxide and sterile saline (anesthetic solution is also an acceptable vehicle) (see Fig. 17-15). The canal is obturated when a radiographically intact periodontal membrane can be demonstrated around the root (see Fig. 17-34). Calcium hydroxide is an effective antibacterial agent[37,130] and favorably influences the local environment at the resorption site, theoretically promoting healing.[150] It also changes the environment in the dentin to a more alkaline pH, which may slow the action of the resorptive cells and promote hard-tissue formation.[150] However, the changing of the calcium hydroxide should be kept to a minimum (not more than every 3 months) because it has a necrotizing effect on the cells attempting to repopulate the damaged root surface.[95]

Calcium hydroxide is considered the drug of choice in the prevention and treatment of inflammatory root resorption, but it is not the only medicament recommended in these cases. Some attempts have been made not only to remove the stimulus for the resorbing cells but also to affect them directly. The antibiotic-corticosteroid paste, Ledermix (DENTSPLY [Australia], Melbourne, Australia), is effective in treating inflammatory root resorption by inhibiting the spread of dentinoclasts[111] without damaging the periodontal ligament; however, its ability to diffuse through human tooth root has been demonstrated,[1] and its release and diffusion is enhanced when used in combination with calcium hydroxide paste.[2]

Open Apex

Avoid endodontic treatment, and look for signs of revascularization. At the first sign of an infected pulp, initiate apexification procedure.

Teeth with open apices have the potential to revascularize and continue root development; initial treatment is directed toward reestablishing blood supply[46,116,164] (Fig. 17-43). The initiation of endodontic treatment is avoided if at all possible, unless definite signs of pulp necrosis (e.g., periradicular inflammation) are present. An accurate diagnosis of pulp vitality is extremely challenging in these cases. After trauma, a diagnosis of necrotic pulp is particularly undesirable, because infection in these teeth is potentially more harmful due to cemental damage accompanying the traumatic injury. External inflammatory root resorption can be extremely rapid in these young teeth, because the tubules are wide and allow irritants to move freely to the external surface of the root.[46,164]

Patients are recalled every 3 to 4 weeks for pulp vitality testing. Studies indicate that thermal tests with carbon dioxide snow (−78° C) or difluorodichloromethane (−50° C) placed at the incisal edge or pulp horn are the best methods of sensitivity testing, particularly in young permanent teeth.[64,65,108] One of these two tests must be included in the pulp vitality testing. Recent reports confirm the superiority of the laser Doppler

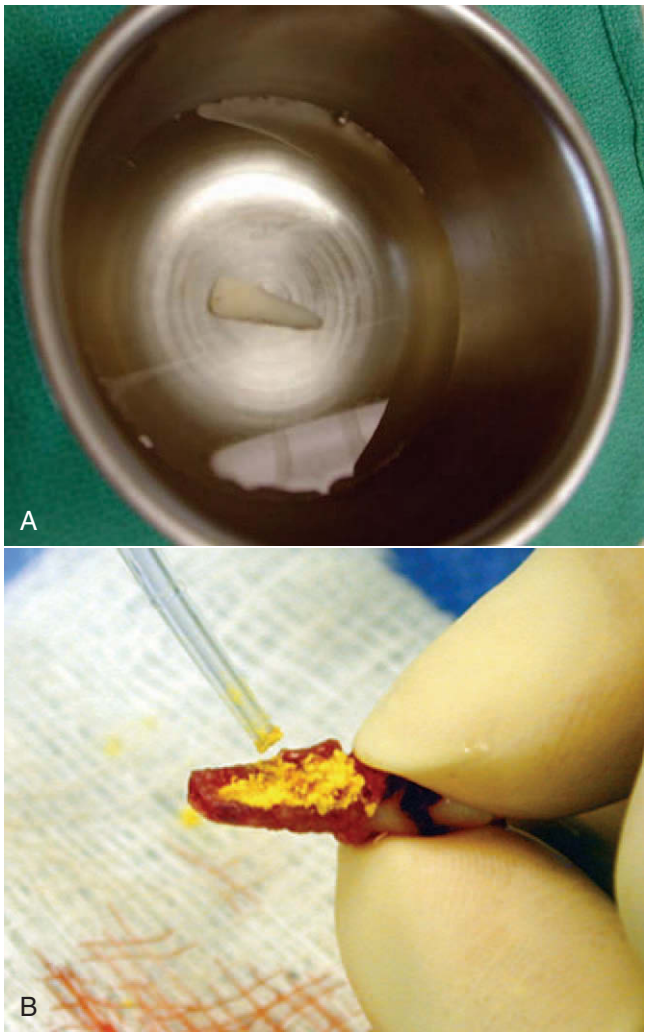

FIG. 17-43 A, Avulsed tooth soaking in doxycycline. **B,** Minocycline powder placed on the root surface before replantation.

flowmeter in the diagnosis of revascularization of traumatized immature teeth[165]; however, the cost of such an instrument precludes its use in the average dental office. Radiographic (apical breakdown and/or signs of lateral root resorption) and clinical (pain to percussion and palpation) signs of pulp pathosis are carefully assessed. At the first sign of pathosis, endodontic treatment should be initiated, and after disinfection of the root canal space an apexification procedure should be carried out.

Extraoral Time More Than 60 Minutes

Closed Apex

As with more than 60 minutes dry time.

These teeth are treated endodontically in the same way as those teeth that had an extraoral time of less than 60 minutes.

Open Apex (If Replanted)

If endodontic treatment was not performed out of the mouth, initiate apexification procedure.

The chance of revascularization in these teeth is extremely poor,[153,156] so no attempt is made to revitalize them. An apexification procedure is initiated at the second visit if root canal treatment was not performed at the emergency visit. If endodontic treatment was performed at the emergency visit, the second visit is a recall visit to assess initial healing only.

TEMPORARY RESTORATION

Effectively sealing the coronal access is essential to prevent infection of the canal between visits. Recommended temporary restorations are reinforced zinc oxide eugenol cement, acid etch composite resin, or glass ionomer cement. The depth of the temporary restoration is critical to its sealability. A depth of at least 4 mm is recommended, so a cotton pellet should not be placed; the temporary restoration is placed directly onto the calcium hydroxide in the access cavity. Calcium hydroxide should first be removed from the walls of the access cavity before placing the temporary restoration, because it is soluble and will wash out when it comes into contact with saliva, leaving a defective temporary restoration.

After initiation of the root canal treatment, the splint is removed. If time does not permit complete removal of the splint at this visit, the resin tacks are smoothed so as not to irritate the soft tissues; the remaining resin is removed at a later appointment.

At this appointment, healing is usually sufficient to perform a detailed clinical examination on the teeth surrounding the avulsed tooth. Pulp vitality tests, reaction to percussion and palpation, and periodontal probing measurements should be carefully recorded for reference at follow-up visits.

Root Filling Visit

At the clinician's convenience or following long-term calcium hydroxide therapy, when an intact lamina dura is traced.

If the endodontic treatment was initiated 1 to 2 weeks after the avulsion and a thorough examination confirms normality, filling of the root canal at this visit is acceptable. Long-term use of calcium hydroxide is also a proven option for these cases. If endodontic treatment was initiated more than 2 weeks after the avulsion or active resorption is visible, the pulp space must first be disinfected before root filling. Traditionally, the reestablishment of a lamina dura (see Fig. 17-34) is a radiographic sign that the canal bacteria have been controlled. When an intact lamina dura can be traced throughout, root filling can take place.

The canal is cleaned, shaped, and irrigated under strict asepsis (i.e., a rubber dam). After completion of cleaning and shaping, the canal can be filled.

PERMANENT RESTORATION

Much evidence exists that coronal leakage caused by defective temporary and permanent restorations results in a clinically relevant amount of bacterial contamination of the root canal after root filling.[115] Therefore, the tooth should receive a permanent restoration as soon as possible. The depth of restoration is important for a tight seal, so the deepest restoration possible should be made. A post should be avoided if possible. Because most avulsions occur in the anterior region of the mouth where esthetics is important, composite resins combined with dentin bonding agents are recommended in these cases.

Follow-Up Care

Follow-up evaluations should take place at 3 months, 6 months, and yearly for at least 5 years. If osseous replacement is identified (see Fig. 17-28), a more closely monitored follow-up schedule is indicated. In the case of inflammatory root resorption (see Fig. 17-30), a new attempt at disinfection of the root canal space by standard retreatment might reverse the process. Teeth adjacent to and surrounding the avulsed tooth or teeth may show pathologic changes long after the initial accident, so these teeth too should be tested at follow-up visits and the results compared to those collected soon after the accident.

CHAPTER 18

Endodontic and Periodontal Interrelationships

DAVID G. KERNS and GERALD N. GLICKMAN

CHAPTER OUTLINE

INTERCOMMUNICATION BETWEEN PULPAL AND PERIODONTAL TISSUE
INFLUENCE OF PULPAL PATHOLOGIC CONDITION ON THE PERIODONTIUM
INFLUENCE OF PERIODONTAL INFLAMMATION ON THE PULP
THEORETIC PATHWAYS OF OSSEOUS LESION FORMATION
- Primary Endodontic Lesions
- Primary Endodontic Lesions With Secondary Periodontal Involvement
- Primary Periodontal Lesions
- Primary Periodontal Lesions With Secondary Endodontic Involvement
- True Combined Lesions
- Concomitant Pulpal and Periodontal Lesions

DIFFERENTIAL DIAGNOSIS
- Lateral Periodontal Cysts

TREATMENT ALTERNATIVES
- Forced Eruption or Extrusion

The interrelationships between pulpal and periodontal disease primarily occur by way of the intimate anatomic and vascular connections between the pulp and the periodontium; these interrelationships have been traditionally demonstrated using radiographic, histologic, and clinical criteria. Pulpal and periodontal problems are responsible for more than 50% of tooth mortality.[16] Diagnosis is often challenging because these diseases have been primarily studied as separate entities, and each primary disease may mimic clinical characteristics of the other disease. Some studies suggest that these two diseases may have etiologic influences on the progression of the other disorder. Pulp tissue succumbs to degeneration by way of a multitude of insults such as caries, restorative procedures, chemical and thermal insults, trauma, and periodontal disease. When products from pulp degeneration reach the supporting periodontium, rapid inflammatory responses can ensue that are characterized by bone loss, tooth mobility, and sometimes sinus tract formation. If this occurs in the apical region, a periradicular lesion forms. If this occurs with crestal extension of the inflammation, a retrograde periodontitis or reverse pocket is formed. However, the lesion formed has little anatomic similarity to a periodontally induced defect.

Periodontal disease, by contrast, is a slowly progressing disease that may have a gradually atrophic effect on the dental pulp. A periodontal lesion is used to denote an inflammatory process in the periodontal tissues resulting from dental plaque accumulation on the external tooth surfaces. Research has shown that periodontitis is characterized by the presence of localized inflammation or tissue infarction, a decrease in cells, resorption, fibrosis, and coagulation necrosis.* Dystrophic calcification may cause some degeneration in the pulp and further influence periodontal disease. In addition, periodontal treatments such as deep root planing or curettage, use of localized medicaments, and gingival injury or wounding may accelerate further pulpal inflammation and provoke the interrelated disease process.[70,76,77]

In recent years, periodontal disease has been shown to be related to (and possibly even the cause of) pulpal disease, and pulpal disease may cause periodontal lesions that behave differently from chronic destructive periodontitis. The effects of periodontal disease on the pulp and the potential for healing of certain periodontal lesions after endodontic therapy have been documented extensively.† This chapter discusses the intercommunications between pulpal and periodontal tissues, the effects of pulpal disease on the periodontium, periodontal disease and its effects on the pulp, and the classification, differential diagnosis, and management and prognosis of endodontic and periodontal problems.

TABLE 18-1

Incidence of Furcation Canals

Investigators	Techniques	Incidence
Rubach and Mitchell (1965)[65]	Sectioned teeth	45%
Lowman et al. (1973)[52]	Dissecting microscope	Maxillary molars 59% Mandibular molars 55%
Burch and Hulen (1974)[13]	Radiopaque dye	Accessory furcal canals 76%
Vertucci and Williams (1974)[81]	Hematoxylin dye	46%
Kirkham (1975)[43]	Radiopaque dye	23%
Gutmann (1978)[33]	Safranin dye	Maxillary molars 28.4% Mandibular molars 27.4%

INTERCOMMUNICATION BETWEEN PULPAL AND PERIODONTAL TISSUE

Several possible channels between the pulp and periodontium that lead to the interaction of the disease process in both tissues have been suggested. These include neural (i.e., reflex) pathways, lateral canals, dentinal tubules, palatogingival grooves, periodontal ligament, alveolar bone, apical foramina, and common vasculolymphatic drainage pathways. The most interconnected and evidenced relationship between the two tissues is by way of the vascular system, as illustrated anatomically by the presence of the apical foramen, lateral (i.e., accessory) canals, and dentinal tubules.* These communications, when they exist, may serve as potential paths for inflammatory reciprocity.[13,33,45,47,52,65]

The apical foramen is the most direct route of communication to the periodontium, but by no means is it the only location where pulpal and periodontal tissues communicate with each other. Lateral and accessory canals, mainly in the apical area and in the furcation of molars, also connect the dental pulp with the periodontal ligament. Table 18-1 lists the incidence of furcation canals. These have been suggested as a direct pathway between pulp and periodontium and typically contain connective tissue and vessels that connect the circulatory system of the pulp with that of the periodontium. Research has demonstrated that inflammation in the interradicular periodontal tissues may develop following induction of pulpal inflammation.[69,70] Serial sectioning of 74 teeth has revealed 45% of accessory canals are present primarily in the apical region.[65] More significantly, lateral accessory canals in eight teeth were located more coronally on the roots. Among them, connection of the accessory canals with periodontal pockets was microscopically demonstrable in five of the specimens. One investigator introduced safranin dye into 102 molar teeth that were placed in a vacuum chamber and found 28% of the teeth had furcation canals, although only 10% of the total group exhibited canals on the lateral root surface.[33]

In addition to the apical foramen and lateral accessory canals, dentinal tubules have also been suggested as another common pathway between periodontium and pulpal tissue. Dentinal tubules contain cytoplasmic extensions or odontoblastic processes that extend from the odontoblasts at the pulpodentin interface to the dentinoenamel junction (DEJ) or the cementodentinal junction (CDJ). It has been reported that the pulp chamber can communicate with the external root surface by way of dentinal tubules, especially when the cementum is denuded.[33,85]

Palatogingival grooves are developmental anomalies of the maxillary incisor teeth, with lateral incisors more often affected than central incisors (4.4% versus 0.28%, respectively).[84] These usually begin in the central fossa, cross the cingulum, and extend apically with varying distances. Generally, the incidence of palatogingival grooves ranges from 1.9% to 8.5%.[26,84] Investigators[26] reported that 0.5% of the teeth examined had a palatogingival groove extension to the root apex, thus contributing to an endodontic pathologic condition. Bilateral buccal radicular grooves have also been reported on maxillary incisors.[41]

Perforation of the root creates a communication between the root canal system and the periodontal ligament. This may occur as a result of overinstrumentation during endodontic procedures, internal or external root resorption, or caries invading through the floor of the pulp chamber. The prognosis for teeth with root perforation is usually determined by the location of the perforation, the time left unsealed, the ability to seal the perforation, the chance of building new attachments, and the accessibility of the remaining root canals. Teeth that have perforations in the middle or apical third of the root have the greatest chance of healing. The closer the perforation is to the gingival sulcus, particularly into the coronal third of the root or the furcation region, the greater the likelihood of apical migration of the gingival epithelium in initiation of a periodontal lesion.[4]

A vertical root fracture can produce a "halo" effect around the tooth radiographically.[63] Deep periodontal pocketing and localized destruction of alveolar bone are often related to long-standing root fractures. The fractured root can mimic a radiographic profile of occlusal trauma, with localized loss of lamina dura, altered trabecular pattern, and a widened periodontal ligament. The fracture site provides a portal of entry for irritants from the root canal system to the surrounding periodontal ligament. Vertical root fractures have contributed to the progression of periodontal destruction in the presence of apparently successful endodontic tooth therapy and overall periodontal site stability.[64]

INFLUENCE OF PULPAL PATHOLOGIC CONDITION ON THE PERIODONTIUM

Pulpal pathosis as a cause of periodontal disease has received much attention during the last decade. Pulpal degeneration results in necrotic debris, bacterial byproducts, and other toxic irritants that can move toward the apical foramen, causing periodontal tissue destruction apically and potentially migrating toward the gingival margin. Investigators termed this *retrograde periodontitis* to differentiate the process from *marginal*

*References 7, 18, 45, 52, 67, and 77.

periodontitis, in which the disease proceeds physically from the gingival margin toward the root apex. When pulpal disease progresses beyond the confines of the tooth, inflammation extends and affects the adjacent periodontal attachment apparatus.[73] This inflammatory process often results in dysfunction of the periodontal ligament and resorption of alveolar bone, cementum, and even dentin. The endodontic infection has been regarded as a local modifying risk factor for periodontitis progression if left untreated.[23] It is believed that an unresolved periapical infection could sustain endodontic pathogen growth, and infectious products would egress into the periodontium by way of the apex and lateral or accessory canals, as well as encourage osteoclastic activity. These may aggravate periodontal pocket formation and bone loss and impair wound healing to accelerate further periodontal disease development and progression. In addition, the medicaments (e.g., high concentrations of calcium hydroxide, corticosteroids, antibiotics) used for root canal therapy can irritate the periodontal attachment apparatus.[10,11] The nature and extent of periodontal destruction depend on several factors, including virulence of the irritating stimuli present in the root canal system (e.g., microbiota, medications, foreign body reactions), duration of the disease, and host defense mechanisms.[16] The rare prevalence of endodontic-periodontal lesions argues that periradicular pathoses in general have little effect on localized inflammatory bone resorption, given that few combined lesions are seen in cases of apical periodontitis.

The ability of the periodontium to regenerate lost attachment apparatus on pulpless teeth has been questioned, especially if these teeth contain a root canal filling and have been denuded of cementum. One investigator suggested that endodontically treated teeth may not respond as well as untreated teeth to periodontal procedures. He found 60% osseous regeneration of periodontal defects in teeth not treated endodontically, compared with 33% defect fill in endodontically treated teeth.[66] However, in a monkey study, others reported that all tissue of the periodontium had a potential for regeneration after periodontal surgery, regardless of the status of the pulp (vital, filled, medicated, or open).[20] Another study reported that pulpal status has little influence on initial cementogenesis and that substances leaching from certain root canal filling materials do not alter deposition of new cementum.[61]

Although endodontic infections have been highly correlated with deeper periodontal pockets and furcation involvement in mandibular molars, the causal relationship between the two pathoses has not yet been established.[39] It has been suggested that endodontic treatment should occur before treatment of furcation lesions (i.e., bone regeneration) to ensure successful results. Extensive evidence is lacking to prove this hypothesis, but there is general agreement that with the proper endodontic treatment, periodontal disease of pulpal origin should heal. The question of whether endodontic infections play a significant role in affecting the health of the periodontium remains to be further elucidated.[57]

INFLUENCE OF PERIODONTAL INFLAMMATION ON THE PULP

Clinically, it is not uncommon to observe an advanced periodontitis spreading to the apical foramen, with associated pulp necrosis. It is also recognized that infection from a periodontal pocket may spread to the pulp through accessory canals, which occur most often in the furcation and closer to the apex of teeth. Investigators proved that pulpitis and pulp necrosis can occur as a result of periodontal inflammation involving accessory and apical canals.[65] In addition, bacterial products and toxins may also gain access to the pulp by way of exposed dentinal tubules. The pulpal reaction is influenced not only by the stages of periodontal disease but also by the type of periodontal treatment, such as scaling, root planing, and administration of medication.[32] Inflammatory lesions of varying severity and necrotic pulp tissue are usually found in teeth with large canals or in cases where periodontal breakdown has extended to the apex.[32] One investigator stated that during periodontal therapy, the blood vessels supplying the pulp by way of accessory canals may be damaged.[85] Another animal study found that 70% of root specimens examined showed no pathologic changes despite the fact that 30% to 40% of the periodontal attachment was lost.[8] The remaining 30% of roots displayed only small inflammatory cell infiltrates or formation of reparative dentin or both in areas where pulp was adjacent to root exposed through periodontal destruction. These tissue changes were frequently associated with root surface resorption, suggesting that dentinal tubules must be uncovered before irritation can be transmitted.

These observations suggest that the presence of an intact cementum layer is important for the protection of the pulp from toxic elements produced by the plaque microbiota, so periodontal disease and periodontal treatments should be regarded as potential causes of pulpitis and pulpal necrosis. It has also been reported that the pulps of teeth with longstanding periodontal disease develop fibrosis and various forms of mineralization. Canals associated with periodontally involved teeth were reported to be narrower than canals of teeth that were not periodontally involved. This result is thought to be a reparative process rather than an inflammatory response.[7,49]

Although consensus supports the influence a degenerating or inflamed pulp can have on the periodontium, not all researchers agree about the effect of periodontal disease on the pulp. Specifically, inflammatory alterations and localized pulp necrosis have been observed adjacent to lateral canals in roots exposed by periodontal disease.[65,69,70] Additional studies have failed to confirm a direct correlation between periodontal disease and pulp tissue changes.[19,56,79] When pathologic changes occur in the pulp as a result of periodontal disease, the pulp usually does not degenerate so long as the main canal is not involved.[48] It seems plausible to assume that periodontal disease rarely jeopardizes the vital function of the pulp. Generally, if the blood supply through the apical foramen remains intact, the pulp is usually capable of withstanding physiologic insults induced by periodontal disease.

THEORETIC PATHWAYS OF OSSEOUS LESION FORMATION

For the clinician, the close relationship between pulpal and periodontal disease is reasonably established on clinical and radiographic levels. Because interpretations vary as to which came first (the proverbial "chicken or egg" controversy), clinical data gathering in endodontic and periodontal problems is often complex, requiring medical history review, pulp vitality testing, pocket and furcation probing, tooth mobility

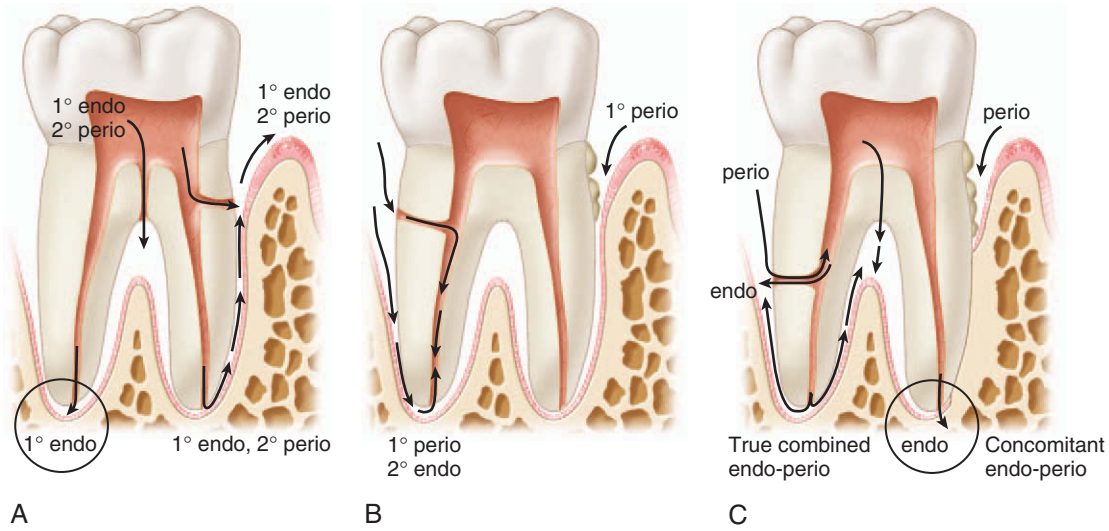

FIG. 18-1 Endodontic and periodontal pathways. **A,** Endodontic lesions. The pathway of inflammation is through the apical foramen, furcation canals, and lateral accessory canals to the periodontium. This results in a primary endodontic lesion, sometimes progressing toward secondary periodontal involvement. **B,** Periodontal lesions. This is the progression of periodontitis by way of lateral canal and apex to induce a secondary endodontic lesion. **C,** True combined endodontic and periodontal lesion and concomitant endodontic and periodontal lesions.

determinations, and critical examination of radiographs. When formulating a differential diagnosis, the clinician should first consider both the periodontal and pulpal status of the affected tooth. If an interrelationship in disease entities exists, appropriate treatment must be rendered to remove true causative factors and enhance the prognosis for tooth retention.[72] Fig. 18-1 lists interrelationships between pulpal and periodontal disease.

Primary Endodontic Lesions

Disease processes of the dental pulp frequently involve inflammatory changes. Caries, restorative procedures, and traumatic injuries are the most common causes. Typically, endodontic lesions resorb bone apically and laterally and destroy the attachment apparatus adjacent to a nonvital tooth. Inflammatory processes in the periodontium occurring as a result of root canal infection not only may be localized at the apex but also may appear along the lateral aspects of the root (Fig. 18-2) and in furcation areas of two- and three-rooted teeth (Fig. 18-3).

The emergence of these processes may be associated with clinical signs of inflammation: pain, tenderness to pressure and percussion, increased tooth mobility, and swelling of the marginal gingiva, simulating a periodontal abscess. The suppurative process may cause a sinus tract along the periodontal ligament space or through patent channels (including the apical foramen and lateral accessory canals). This usually results in a narrow opening of the sinus tract into the gingival sulcus and pocket that can be easily traced with a gutta-percha cone or a periodontal probe. Such a tract can readily be probed down to the tooth apex, where no increased probing depth would otherwise exist around the tooth. In multirooted teeth, a periodontal ligament sinus tract can drain off into the furcation area and resemble a Grade III "through-and-through" furcation defect resulting from periodontal disease.

Clinically, endodontic testing procedures should reveal a necrotic pulp or, in multirooted teeth, at least an abnormal response, indicating the pulp is degenerating. Because the primary lesion is an endodontic problem that has merely manifested itself through the periodontal ligament, complete resolution is usually anticipated following nonsurgical endodontic therapy without any periodontal treatment.

FIG. 18-2 Primary endodontic lesion. Mandibular molar showing endodontic filling material extending into the furcation and along the lateral root surface because of inadequate canal preparation. Furcation could be probed.

Primary Endodontic Lesions With Secondary Periodontal Involvement

When a lesion of endodontic origin is not treated, usually pathosis will continue, leading to destruction of the periapical alveolar bone and progression into the interradicular area, causing breakdown of surrounding hard and soft tissues (Fig. 18-4). As drainage persists through the gingival sulcus, accumulation of plaque and calculus in the purulent pocket results in periodontal disease and further apical migration of the

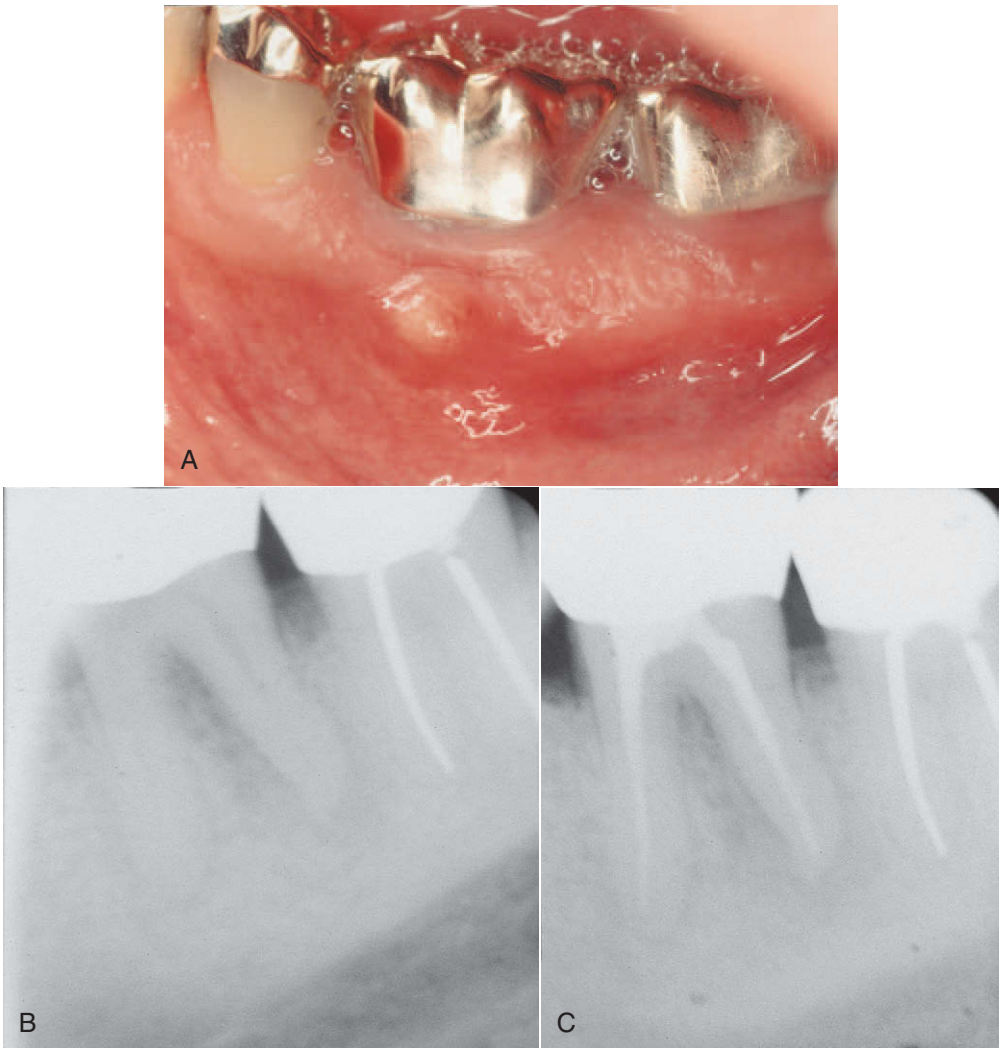

FIG. 18-3 Primary endodontic lesion on mandibular first molar. **A,** Abscess was noted on the buccal surface of the tooth. **B,** Apical radiolucency was evident on the distal root. **C,** Six months after root canal treatment, there is evidence of osseous healing at both the apex and furcation area.

attachment. When this occurs, not only does the diagnosis become more difficult, but the prognosis and treatment may be altered. Diagnostically, these lesions have a necrotic root canal and plaque or calculus accumulation, demonstrable by a probe and radiograph. Radiographs may show generalized periodontal disease with angular defects at the initial site of the endodontic involvement.

Resolution of the primary endodontic and secondary periodontal lesion relies on treatment of both conditions. When only endodontic therapy is provided, only part of the lesion can be expected to heal. If endodontic therapy is adequate, the prognosis depends on the severity of periodontal involvement and efficacy of periodontal therapy.

Primary Periodontal Lesions

Periodontal disease has a progressive nature. It begins in the sulcus and migrates to the apex as deposits of plaque and calculus produce inflammation, causing loss of surrounding alveolar bone and supporting periodontal soft tissues. This leads to a loss of clinical attachment and formation of a periodontal abscess during the acute phase of destruction.[71] The progression of periodontal disease to the formation of osseous defects and subsequent radiographic appearance along lateral aspects of roots and in furcation areas is well known. These defects may or may not be in association with trauma from occlusion, which can often be the cause of an isolated periodontal problem. Osseous lesions of periodontal origin are usually associated with tooth mobility, and the affected teeth respond positively to pulp testing. In addition, careful periodontal examination will usually reveal broad-based pocket formation and an accumulation of plaque and calculus. The bony lesion is usually more widespread and generalized than are lesions of endodontic origin (Fig. 18-5).

The prognosis for those teeth affected by periodontitis worsens as the disease process and periodontal destruction progress. Treatment depends on the extent of the periodontitis and on the patient's ability to comply with potential long-term treatment and maintenance therapy. Because this is purely a periodontal problem, the prognosis depends exclusively on the outcome of periodontal therapy.

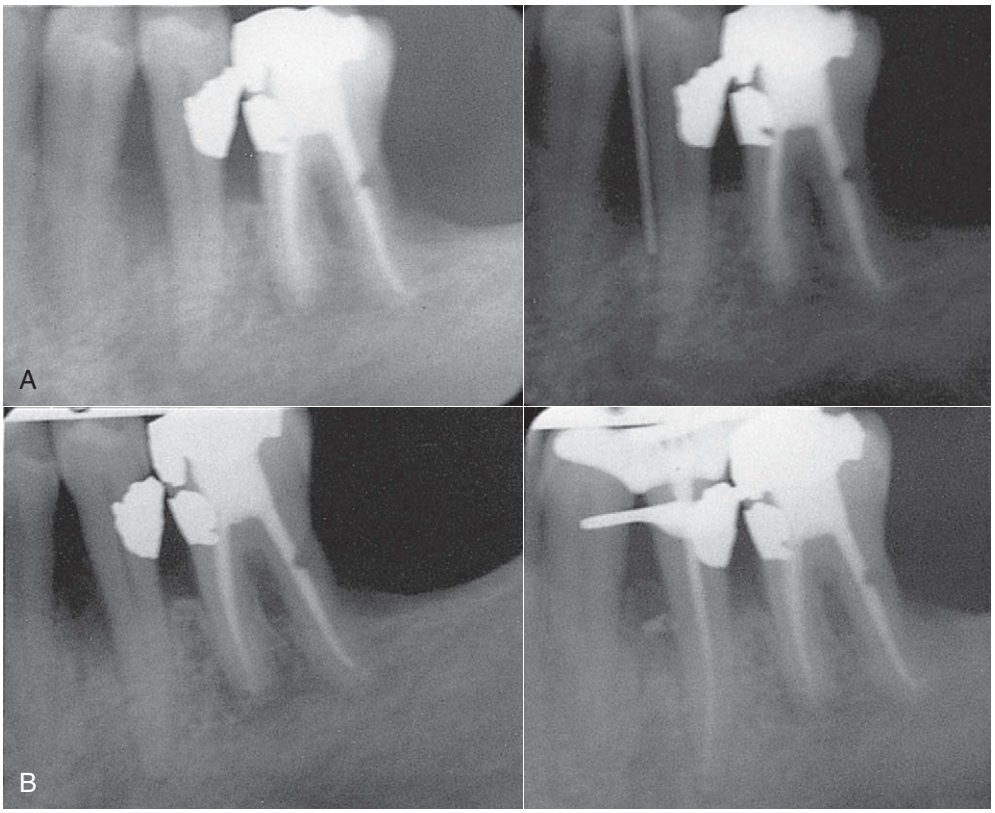

FIG. 18-4 Primary endodontic lesion with secondary periodontal involvement. **A,** Mesial aspect of mandibular second premolar had deep periodontal pocketing (periodontal probe in place demonstrated 6 mm probing depth) even after periodontal therapy. **B,** Pulp tests were performed on the premolar; the tooth was nonresponsive. After endodontic treatment, the periodontal pocket resolved (filling of a lateral accessory canal after obturation is demonstrated).

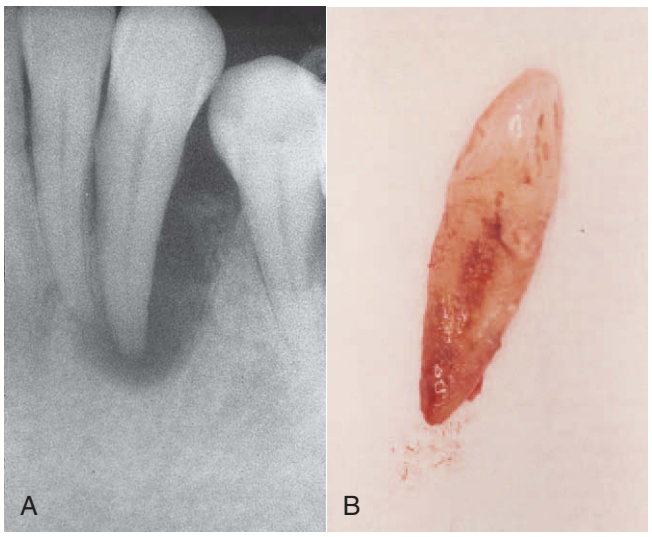

FIG. 18-5 Primary periodontal lesion. **A,** Mandibular cuspid exhibits extensive periodontal destruction; the tooth responded normally to pulp tests. **B,** Extracted tooth depicts extensive calculus accumulation and root concavity.

Primary Periodontal Lesions With Secondary Endodontic Involvement

As stated earlier, periodontal disease can have an effect on the pulp through dentinal tubules, lateral canals, or both. Primary periodontal lesions with secondary endodontic involvement differ from the primary endodontic lesion with secondary periodontal involvement only by the temporal sequence of the disease processes. The tooth with primary periodontal and secondary endodontic disease exhibits deep pocketing, with a history of extensive periodontal disease and, possibly, past treatment. When the pulp becomes involved, the patient often reports accentuated pain and clinical signs of pulpal disease. This situation exists when the apical progression of periodontal disease is sufficient to open and expose the pulp to the oral environment by way of lateral canals or dentinal tubules. On radiographs, these lesions may be indistinguishable from primary endodontic lesions with secondary periodontal involvement. The prognosis depends on continuing periodontal treatment subsequent to endodontic therapy.

True Combined Lesions

Pulpal and periodontal disease may occur independently or concomitantly in and around the same tooth. Once the endodontic and periodontal lesions coalesce, they may be clinically indistinguishable (Fig. 18-6). The prognosis of multi-rooted teeth with combined pulpal and periodontal

FIG. 18-6 True combined pulpal and periodontal lesions on mandibular second premolar and first molar. Periodontal probing depths were to the apices in both teeth.

FIG. 18-7 Concomitant pulpal and periodontal lesion on the maxillary second premolar. An endodontic lesion was noted at the apex, with a noncommunicating periodontal pocket on the distal side.

lesions depends largely on the extent of the destruction caused by the periodontal disease component. A necrotic pulp or a failing endodontic treatment, plaque, calculus, and periodontitis will be present in varying degrees.

Concomitant Pulpal and Periodontal Lesions

An additional classification has been proposed for lesions that may commonly be seen clinically and reflect the presence of two separate and distinct entities.[6] This is referred to as the *concomitant pulpal and periodontal lesion* (Fig. 18-7). In essence, both disease states exist but with different causative factors and with no clinical evidence that either disease state has influenced the other. This situation often goes undiagnosed, and treatment is rendered to only one of the diseased tissues in the hope that the other will respond favorably. In actuality, both disease processes must be treated concomitantly, with the prognosis dependent on the removal of the individual etiologic factors and prevention of any further factors that may affect the respective disease processes.

With the application of research findings and clinical experience, pathways of osseous lesion formation may be theorized. These concepts are intended as a guide for the evaluation and understanding of the clinician's successes and failures in treating teeth with osseous lesions. By understanding the nature of their formation, the clinician can better anticipate the healing potential after treatment.

DIFFERENTIAL DIAGNOSIS

During the course of treatment, clinicians are frequently presented with the dilemma of accurately assessing the contribution of endodontic and periodontal lesions. These lesions may be very separate from each other and present no extraordinary therapeutic consideration. In a few other situations, there is no obvious demarcation between the two lesions, which appear as one, both on radiographs and clinically. In the diagnosis of radiographic osseous lesions, one must resist the temptation to label everything a "combined lesion." Table 18-2 summarizes the differential diagnosis between pulpal and periodontal lesions and highlights a number of common characteristics between these lesions.

Root fractures, especially vertical root fractures, present particular problems in diagnosis (Fig. 18-8). Symptoms and signs associated with vertical root fractures show a varying character and are frequently difficult to distinguish from those associated with periodontal and endodontic lesions. Breakdown can manifest itself on radiographs in a number of different ways. This may be anything from nothing detectable on radiographs to an area of rapid vertical bone loss, given that there is no way to predict when a patient may present for treatment. It is imperative for the clinician to take more than one radiograph at different angles, especially when no clear diagnosis emerges. In these cases, a minor alteration in the angulation may reveal a tooth fracture or periodontal furcation involvement. The diagnosis of vertical root fractures is often difficult because the fracture is usually not detectable by clinical inspection and radiographic examination unless there is a clear separation of the root fragments. Cemental tears or detachment of cementum from a root surface by means of trauma or aging has been reported[14,51]; the lesion often results in periodontal destruction and endodontic involvement.

Sometimes the definitive diagnosis of vertical root fractures has to be confirmed by exploratory surgical exposure of the root for direct visual examination.[82] Vertical root fractures have been associated with root-filled teeth where excessive lateral forces were applied during compaction or possibly with stress induced by a post placement in root-filled teeth.[58] Clinical survey of fractured teeth also reveals that fractures are more common in teeth with extensive restorations, in older patients, and in mandibular posterior teeth.[30] Vertical root fractures that involve the gingival sulcus and periodontal pocket area usually have a hopeless prognosis because of continuous bacterial invasion of the fracture space from the oral environment. Single-rooted teeth are generally extracted. In multirooted teeth, a treatment alternative is hemisection or resection of the fractured root. See Chapter 1 for a further discussion of vertical root fractures.

Developmental grooves, primarily found in maxillary central and lateral incisors, are also capable of initiating localized periodontal destruction along the root surface.[26,41,50] It is

TABLE 18-2

Differential Diagnosis Between Pulpal and Periodontal Disease

	Pulpal	Periodontal
CLINICAL		
Etiology	Pulp infection	Periodontal infection
Vitality	Nonvital	Vital
Restorative	Deep or extensive	Not related
Plaque/calculus	Not related	Primary cause
Inflammation	Acute	Chronic
Pockets	Single, narrow	Multiple, wide coronally
pH value	Often acid	Usually alkaline
Trauma	Primary or secondary	Contributing factor
Microbial	Few	Complex
RADIOGRAPHIC		
Pattern	Localized	Generalized
Bone loss	Wider apically	Wider coronally
Periapical	Radiolucent	Not often related
Vertical bone loss	No	Yes
HISTOPATHOLOGY		
Junctional epithelium	No apical migration	Apical migration
Granulation tissues	Apical (minimal)	Coronal (larger)
Gingival	Normal	Some recession
THERAPY		
Treatment	Root canal therapy	Periodontal treatment

thought they may be a genetic attempt to form an accessory root, but once plaque and calculus invade the epithelial attachment, the groove becomes a pathway for microbes and their noxious allies (toxins), with ample substrate from food debris to create a self-supporting periodontal lesion. Bone demineralization follows the path of the groove. Palatogingival grooves are often associated with poor periodontal health because of patients' inability to keep these areas clean, and a poor prognosis is usually assigned regardless of proper conventional therapy.[30,84] It is easy to identify these grooves if one is aware of their existence. Clinically, these grooves may be asymptomatic, or symptomatic periodontal problems (either acute or chronic) may occur. It is thought that the pulp of these teeth may become secondarily involved and demonstrate symptoms of pulpal disease (Fig. 18-9). These lesions are often confused with the enamel projections in the furcation area of mandibular molars.[55] The prevalence of cervical enamel projections (Fig. 18-10) ranges from 18% to 45%.[36,55] Depending on the apical extent of these cervical grooves, some authors[36,55] also find a high association with pathologic furcation involvement (up to 82.5%[36]).

Lateral Periodontal Cysts

The clinical presentation of a lateral periodontal cyst is often without symptoms (Fig. 18-11). It may be present as a gingival swelling on the facial aspect that may have pain and tenderness on palpation. Radiographic features are a well-circumscribed round or ovoid radiolucent area that usually has a sclerotic margin. Most lateral periodontal cysts are less than 1 cm in diameter and lie somewhere between the apex and cervical margin of a tooth. Three possible etiologies are reported in the literature: (1) reduced enamel epithelium, (2) remnants of dental lamina, or (3) cell rests of Malassez. Histologic evaluation reveals that these cysts are lined by epithelium that closely resembles reduced enamel epithelium lining. The lesion occurs predominantly in the fifth to seventh decades of life, with a predilection for males.[3] The lesion is usually slow growing. Treatment consists of careful excision to help prevent recurrence. The most common location is the mandibular cuspid-bicuspid area, although numerous cases have been reported in the anterior maxilla. Investigators have reported finding unicystic and multicystic (including botryoid) varieties.[3] They found that lateral periodontal cysts were lined predominantly or exclusively by thin, reduced enamel, epithelium-like tissue that contained many clear cells, and epithelial thickenings referred to as *plaques*. Glycogen was present in the epithelium of two thirds of the cases, although not exclusively in the clear cells, many of which were not positive for glycogen. Some of their botryoid variety differed histologically, being lined predominantly by nonkeratinizing stratified squamous epithelium with crowded and pyknotic nuclei and no clear cells. One case contained melanin, and another showed epithelial crypt formation and superficial palisaded low columnar cells, as seen in the glandular odontogenic cyst. This raised the question of whether the latter may form part of the clinicopathologic spectrum of a lateral periodontal cyst. The histogenesis of lateral periodontal cysts is uncertain, but they favor origin from reduced enamel epithelium. There are cases that either do not fit a characteristic endodontic or periodontal lesion or do not respond to treatment as expected. A biopsy and histologic analysis are often recommended. Systemic diseases such as scleroderma, metastatic carcinoma, and osteosarcoma can mimic endodontic and periodontal disease visible on a radiograph. *The conscientious clinician must always be alert for lesions of nonendodontic or nonperiodontal origin and look for other causes.*

TREATMENT ALTERNATIVES

When traditional endodontic and periodontal treatments prove insufficient to stabilize an affected tooth, the clinician must consider treatment alternatives. Generally, a localized periodontal defect associated with an endodontically untreatable tooth or an iatrogenic tooth problem is reason to explore other treatment options. Alternate treatments often consist of resection or regenerative approaches. Resection techniques focus on eliminating the diseased roots or teeth; regenerative efforts are aimed at restoring lost biologic structures. Resection methods involve removal of affected roots or extraction of involved teeth. When a tooth requires extraction, one of the first options for restoring occlusal function should include placement of dental implants with hybrid prostheses. Bone replacement grafts using guided-tissue and bone-regeneration techniques are ways to

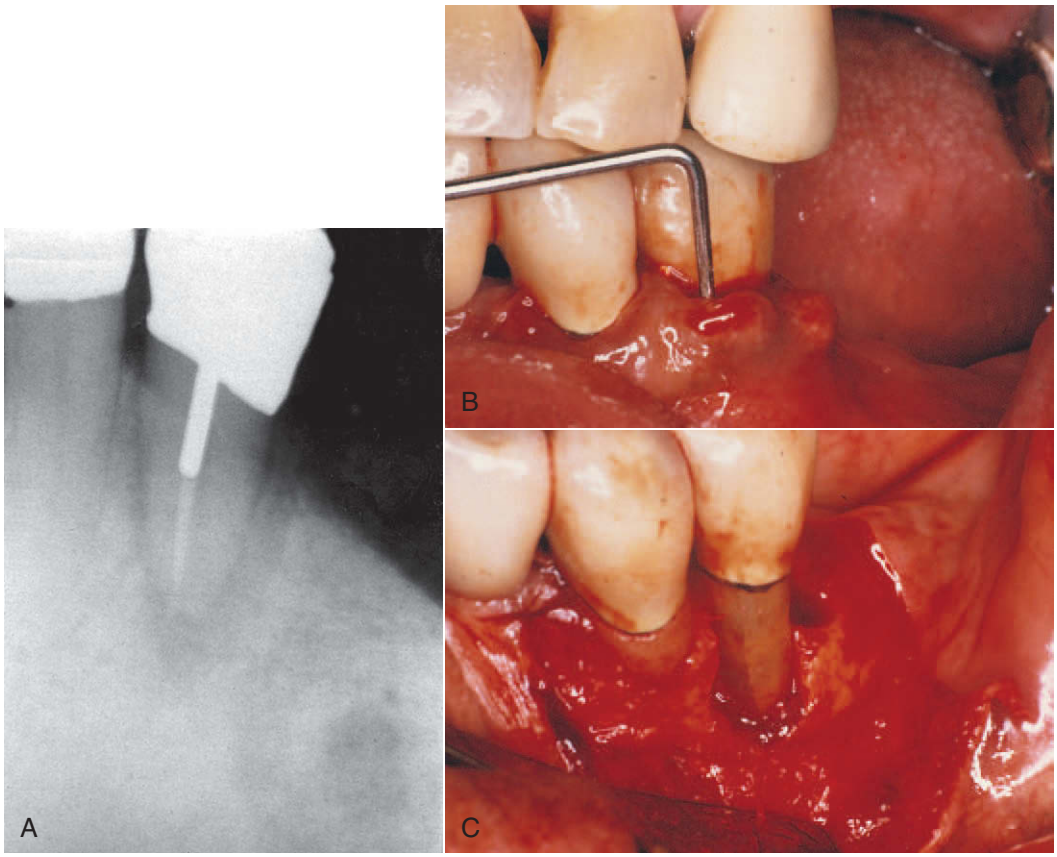

FIG. 18-8 Vertical root fracture. **A,** Radiograph revealed widened periodontal ligament with J-shaped radiolucency around the apex. **B,** Periodontal probe indicated more than 12 mm of probing depth. **C,** Exploratory surgery confirmed vertical root fracture.

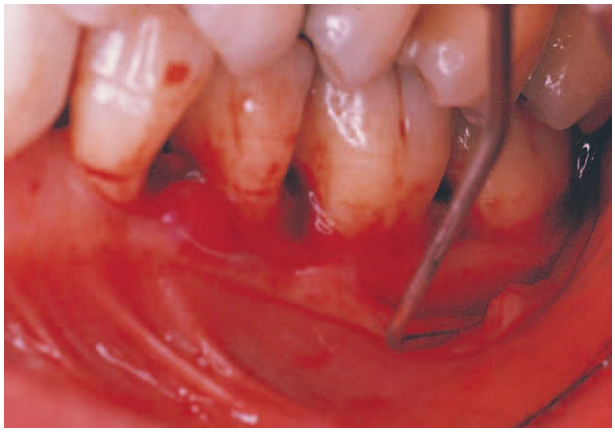

FIG. 18-10 Cervical enamel projection on mandibular molar.

reestablish biologic structures that were lost during this disease process. Fixed partial dentures are still a viable option for some patients and certainly should be considered if abutment teeth already have restorations or endodontic treatment.

Root resection is the removal of a root, with accompanying odontoplasty before or preferably after endodontic treatment.[27] Formerly it was used when root canal therapy was considered too difficult, but now its indications are restricted to multirooted teeth in which one or more roots cannot be saved. The indications for root resection often include (but are not limited to) root fracture, perforation, root caries, dehiscence, fenestration, external root resorption involving one root, incomplete endodontic treatment of a particular root, severe periodontitis affecting only one root, and severe Grade II or III furcation involvement. Root resection is a technique-sensitive procedure (Fig. 18-12) requiring a careful diagnostic process for selection of those teeth that would likely be successful candidates, followed by meticulous interdisciplinary treatment. Factors such as occlusal forces, tooth restorability, and the value of the remaining roots must be examined before treatment. A

Continued

carefully constructed treatment plan is crucial to the success of this resection procedure.[31] Proper reshaping of the occlusal table and restoration of the clinical crown are essential, and the root surface must be recontoured to remove the root stump, thus preventing formation of a potential food trap.[42]

The effectiveness of this approach remains controversial owing to the disparity of results reported in several long-term studies.* Retrospective longitudinal studies have observed the fate of sectioned teeth for time frames ranging from 3 to 12 years and have reported success rates ranging from 62% to 100%, with a low incidence (i.e., 10%) of periodontal breakdown. However, as most long-term studies will point out, the major cause of failure of resection procedures resides in failure of the endodontic and restorative components. Unique anatomic features, such as root length, curvature, shape, size, position of adjacent teeth, and bone density, may influence the end result. For example, root fusion makes resection all but impossible. The removal of roots purely to eliminate a resorptive or traumatic perforation defect, fractured root, or endodontically inoperable root usually results in definitive treatment. If, however, localized or generalized periodontal disease is present, conditions favorable for healing must be created, and concomitant periodontal therapeutic procedures can be implemented to restore the health of the periodontium.[31] The final restoration of root-resected teeth will depend significantly on the nature of the resection, the amount of remaining tooth structure, the periodontal status, and the patient's occlusion. The prosthetic aspects of tooth restoration must be carefully assessed and integrated into the anticipated surgical procedure to ensure proper positioning of tooth margins relative to the osseous crest and also to manage the anticipated changes in occlusal relationships and masticatory forces.[83]

Controversy has also existed regarding the benefits and need for endodontic therapy before root resection. Instances develop in which exploratory surgery is necessary; should the

Endodontic treatment was performed before surgical removal of the mesial root. **B,** Five-year follow-up shows the remaining tooth well maintained.

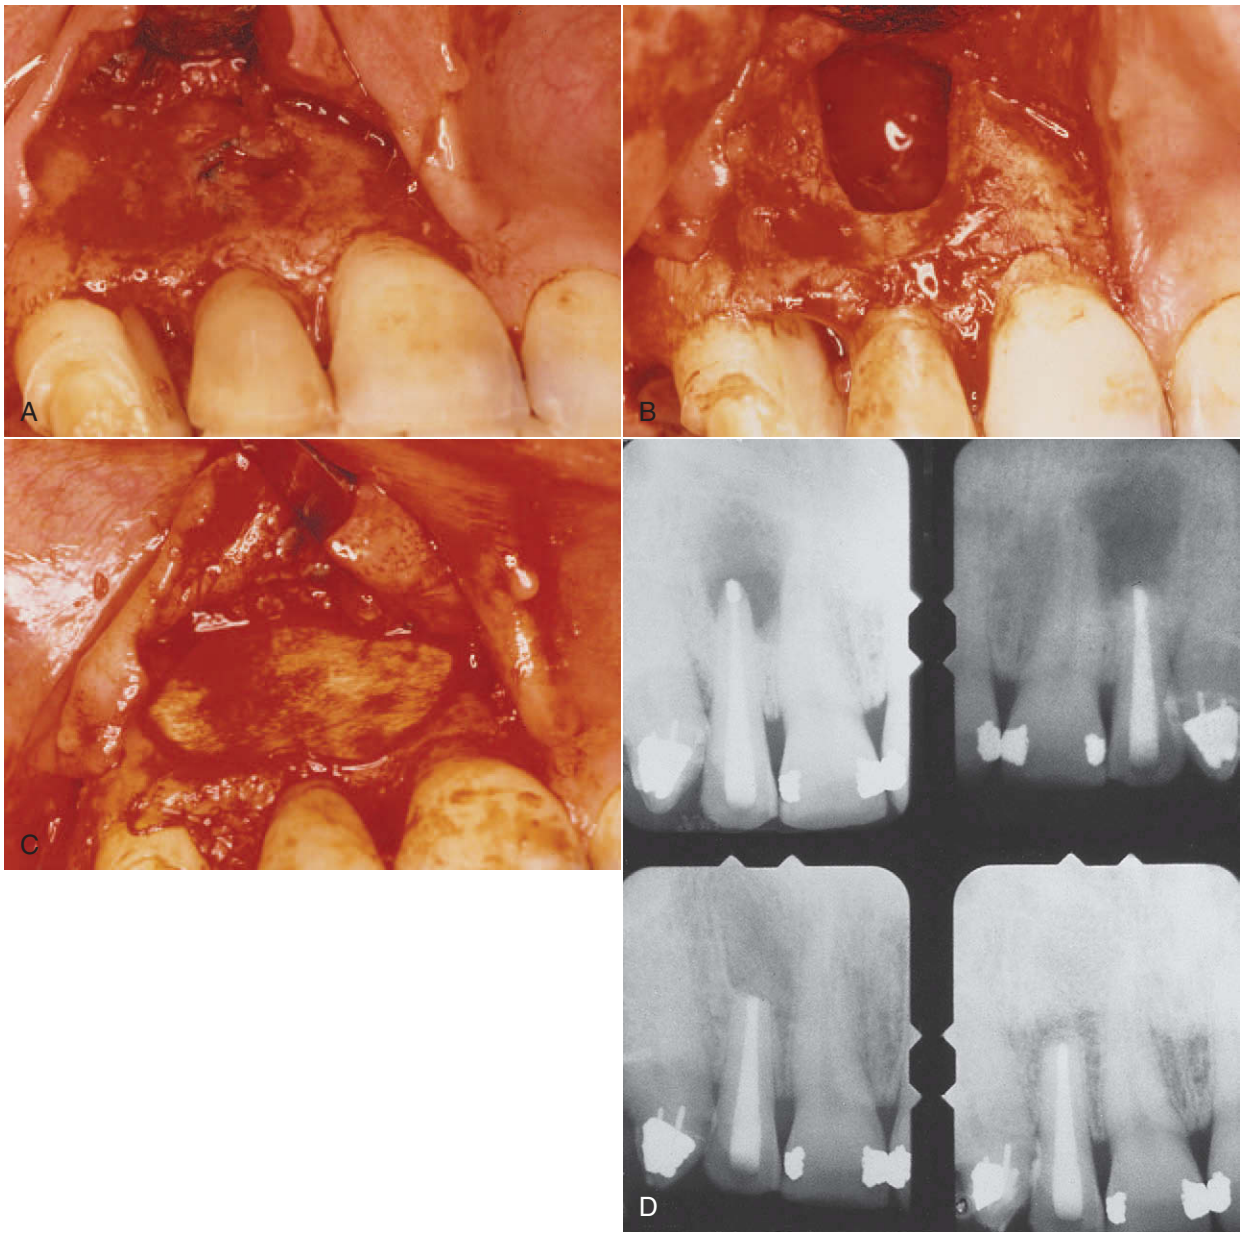

FIG. 18-13 Periradicular endodontic surgery using the combination of bone replacement grafts and collagen GTR (guided tissue regeneration) barrier membranes. **A,** Buccal flap was reflected (note extensive apical lesion). **B,** Osseous window was created with a bur. **C,** The defect was repaired with demineralized freeze-dried bone allograft (DFDBA) and covered with a collagen membrane. **D,** Radiographs show condition before surgery, at the time of surgery, and at 6 months and 2 years after surgery. At 2 years, radiograph reveals complete bone regeneration.

periodontal problem be more extensive than that determined presurgically, the removal of a root should be carried out at that time. In these instances, removal of the involved root without endodontic treatment would be acceptable, but root canal therapy should be performed as soon as possible after root removal.[29,75,78] After resection of a vital root, the pulpal opening in the crown may be sealed and restored with a permanent amalgam restoration or sedative base material (e.g., Dycal) as a temporary solution. Investigators evaluated vital-root resection in maxillary molar teeth for 9 years.[27] Amputated pulps were covered with Dycal base and amalgam. At 1 year, 38% of molar teeth remained vital, but at 5 years only 13% maintained vitality. These findings imply that the long-term prognosis for vital-root resection is poor, so *endodontic therapy should be done before or immediately after resection*. However, one investigator reported that vitality of resected teeth can be maintained even after 16 years.[35] Nonetheless, it is generally agreed that whenever possible, endodontics should be performed in advance (before root resection). If this is not possible, the endodontic treatment should be performed as soon as possible after vital-root amputation. Otherwise, pulpal complications such as internal resorption, pulpal inflammation, and necrosis may occur.[2,77]

The concepts of guided tissue regeneration (GTR) or guided bone regeneration (GBR) have been used to promote bone healing after endodontic surgery.[28,60] Fig. 18-13 illustrates

an endodontic defect successfully treated with the GTR approach. Theoretically, the GTR barrier prevents contact of connective tissue with the osseous walls of the defect, protecting the underlying blood clot and stabilizing the wound.[34] An investigator treated large periradicular lesions with GTR barrier membranes and demonstrated that periradicular healing occurred more rapidly at membrane sites than at control sites.[59,60] The quality and quantity of the regenerated bone were superior with adjunctive use of the membrane than without such use. Similar findings were published in a case report with histologic examination of biopsy material obtained at barrier removal.[62] In addition, during examination of clinical cases, the closer the lesion is to the gingival margin, the greater the fluid and bacterial contamination from the sulcus (and also a greater risk of mechanical trauma). When GTR is considered, the combined endodontic and periodontal lesion probably has the least favorable prognosis compared with cases having only a periodontal lesion.[59]

Many varieties of GTR membranes are available for clinical use, but it is logical to use bioresorbable collagen and polymer membranes in endodontic surgeries because there is often no need for a second surgery to retrieve the membrane. Studies reveal similar results achieved with nonresorbable and resorbable membranes.[17] Long-term studies need to be completed to evaluate the success of this approach.

For more than 40 years, bone grafts have been used to treat osseous defects associated with periodontal disease.[68] Because the "apicoectomy" (i.e., root-end resection) defect has a surrounding bony wall, the need for adjunctive bone grafting during this procedure is questionable (unless it is exceptionally large in diameter). With the introduction of the GTR concept, a combination of bone replacement graft and GTR membrane (Fig. 18-14) has shown promising results.[1,21,40,62,80] Further studies are required to explore the true benefit of this combination treatment approach in root-end resection procedures.

Forced Eruption or Extruson

Teeth that have fractured, undergone extensive decay, or experienced internal or external root resorption or lateral perforation may be candidates for a forced eruption procedure, especially straight, tapering, single-rooted teeth (Fig. 18-15). To obtain good access for endodontic or restorative procedures along with reduced probing depths, it may be necessary to perform extensive resection surgery to gain crown lengthening. Forced eruption may offer a better solution than surgical crown lengthening, which may produce poor aesthetics in some cases. A review of the literature reveals that most successfully treated cases are extrusions of less than 4 mm.[5,9,46] The infrequently used treatment method of forced eruption serves as an alternative to the sacrifice of the natural root system. Forced eruption can preserve the natural root system and related periodontal architecture, resulting in years of additional service for the patient. It also can maintain adjacent tooth structure while retaining the option for future implant reconstruction if needed. Given the reported success of forced eruption, the technique should be employed more often by dentists.[22,25] The increased use of implants in clinical treatments has stimulated clinicians' interest in augmenting bone in patients who have deficient alveolar ridges that might preclude ideal implant placement.

A nonsurgical technique for using the available bone for implant site development and fixture placement is orthodontic extrusion or forced eruption. The concept of extruding a tooth coronally by orthodontic forces and the clinical alterations in the soft-tissue architecture of the periodontium demonstrated during orthodontic extrusive movement of periodontally compromised teeth have demonstrated probing depth reduction in some cases.[54] An investigator reported that tooth movement in the presence of inflammation might cause deepening of osseous defects. Often extrusions are accompanied by an immature-appearing tissue that is red compared with adjacent tissue. This results from the eversion of junctional epithelium, which is nonkeratinized in the sulcus; the vasculature is more readily visible until the newly exposed tissue has a chance to keratinize in about 28 days.[37,38] ost extruded teeth should be retained in place twice as long as it took to force-erupt them in order to minimize relapse before attempting definitive restorative procedures.

SUMMARY

Endodontic and periodontal lesions result from the close interrelationship of pulp tissue and the periodontium. The major pathways of communication between the two types of tissue are the apical foramina, lateral and accessory canals, and dentinal tubules. The differential diagnosis of endodontic and periodontal lesions is not always straightforward and requires clinical data accumulation from a number of diagnostic tests to obtain a correct diagnosis. When examining and treating the combined or individual lesion in endodontics and periodontics, the clinician must bear in mind that successful treatment depends on a correct diagnosis. Lesions with combined causes will require both endodontic and periodontal therapy, and endodontic therapy should usually be completed first. Root resection and regenerative techniques offer alternative approaches, enhancing the clinician's ability to deal with these complex clinical problems.

- Long-Acting Local Anesthetics
- Flexible Plan

FUTURE DIRECTIONS

Even in the 21st century, the terms *root canal* and *pain* often are considered synonymous. Every clinician who provides endodontic therapy has had to deal with this misperception, and the skill of the clinician is often judged primarily by their success or failure of pain control. Achieving successful endodontic pain control in a predictable and efficient manner requires a working knowledge of the underlying biology of the trigeminal pain system and the mechanisms by which available drugs and therapies provide relief. This chapter presents insights into basic science discoveries regarding acute pain and reviews the best evidence available for successful treatment of pain of pulpal and periradicular origins. It will also include a brief overview of the field of pain pharmacogenomics, which promises the possibility of predicting the effects of an analgesic drug depending on the genetic makeup of the patient. A truly inclusive review of the topic of pain control in endodontics would also include the diagnosis of odontogenic pain (see Chapters 1 and 2), the diagnosis of nonodontogenic pain (see Chapter 3), a discussion of the mediators of pulpal and periradicular inflammation (see Chapters 12 to 14), a review of the pharmacology of local anesthetics (see Chapter 20), and behavioral modification (see Chapter 26).

THE TRIGEMINAL PAIN SYSTEM

When activated by a stimulus sufficient to cause tissue damage or release of inflammatory mediators, nerve endings in the pulp and periradicular tissues begin to send bursts of messages to the central nervous system (CNS) that may eventually be perceived as pain. The anatomic pathway for this transmission of information has been fairly well established, and it is tempting to view the perception of pain of orofacial origin as a simple graded response to the intensity of the stimulus. However, researchers have come to realize that the pain system is a complex, multilevel system that begins with the *detection* of tissue-damaging stimuli in the periphery, the *processing* of that input at the level of the medullary spinal cord, and the *perception* of what is felt as pain in higher brain regions such as the cerebral cortex (Fig. 19-1). After a noxious stimulus is detected in the periphery, there is ample opportunity for a great deal of endogenous and possibly exogenous modification of the message prior to its ultimate perception. The clinician deals with all three levels of the pain system in diagnosing and treating odontalgia, and a practitioner with a basic understanding of each level will be able to recognize therapeutic opportunities and apply effective pain control methods.

Detection: The First Step in Pain Perception

Various types of peripheral neurons are found in the trigeminal system, including large-diameter, heavily myelinated Aα, Aβ and Aγ fibers associated with motor, proprioception, touch, pressure, and muscle spindle stretch functions. But it is the smaller, less myelinated Aδ and yet smaller and unmyelinated C fibers that conduct information likely to be perceived as pain. These two classes of pain-sensing nerve fibers, or *nociceptors,* are both found in the tooth pulp, but there are three to eight times more unmyelinated C fibers than Aδ fibers.[22,23,113,227] It should be noted that this classification system is based purely upon the size and myelination of the neurons and does not necessarily indicate function. For example, another class of pulpal C fibers are the postganglionic sympathetic efferents found in association with blood vessels, where they regulate pulpal blood flow[2,127,191,192] and may also influence the activity of peripheral nociceptors (for reviews, see Perl[189] or Hargreaves[91]). Because most pulpal sensory fibers are nociceptive, their terminal branches are free nerve endings, and physiologic

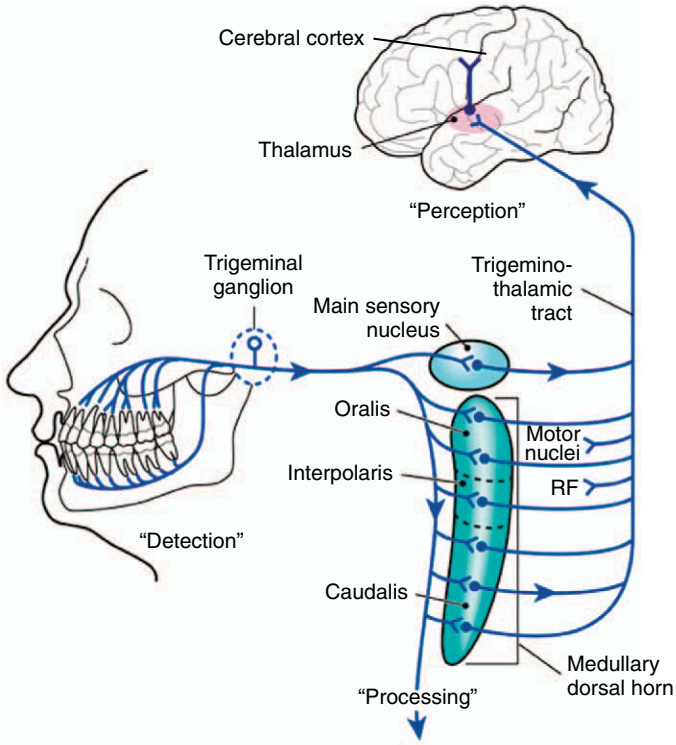

FIG. 19-1 Schematic diagram of the pathway of transmission of nociceptive information from the orofacial region. The trigeminal pain system is a complex multilevel system that begins with the DETECTION of tissue damaging stimuli in the periphery, the PROCESSING of that input at the level of the medullary spinal cord, and the final PERCEPTION of what is felt as pain in the cerebral cortex. There is growing appreciation for the concept that once a noxious stimulus is detected in the periphery, there is the opportunity for a great deal of modification of the message prior to ultimate perception.

stimulation by any modality (temperature, hyperosmotic fluids) results in the perception of pure pain which can be very difficult for patients to localize. Under experimental conditions, electrical stimulation can result in a *prepain* sensation that is also difficult to localize. Once inflammation has extended to the periodontal ligament, which is well endowed with Aβ discriminative touch receptors, localization of pain is more predictable with light mechanical stimuli such as the percussion test.

In the normal uninflamed pulp and periradicular tissues, a noxious stimulus causes depolarization of nociceptors sufficient to generate action potentials by means of the opening of voltage-gated sodium channels (Na_v). Of the nine known voltage-gated sodium channel subtypes ($Na_v1.1$ through $Na_v1.9$), five are believed to exist in the trigeminal system. As will be discussed in Chapter 21, they likely play an important role in the altered sensitivity of pulpal and periradicular nociceptors during inflammation, where even non-noxious stimuli can result in the perception of pain (for review see Henry and Hargreaves[101]).

After generation of an action potential, not only is information sent to the CNS, but in an *antidromic* fashion (i.e., in the reverse direction of the impulse), proinflammatory neuropeptides such as substance P (SP), calcitonin gene-related peptide (CGRP), neurokinins, and the classic neurotransmitter, glutamate, are released from afferent terminals in the inflamed pulp and periradicular tissues.

Peripheral Sensitization

Following repeated noxious stimuli, both A and polymodal C fiber nociceptors undergo a process of sensitization manifested by three obvious changes in response patterns. First, firing thresholds may decrease, so that previously non-noxious stimuli may trigger discharges, contributing to the sensation of pain (*allodynia*). Second, after-discharges may occur, so that noxious stimuli may produce an even greater increase in the perceived intensity of pain (*hyperalgesia*). And third, firing may occur spontaneously, contributing to the development of spontaneous pain. These changes are often seen in endodontic pain patients and may be explained in part by the effects of chemical mediators released into inflamed pulp and periradicular tissues. Such mediators include substances produced from damaged tissues, agents of vascular origin, and peptides released from the nerve fibers themselves (Table 19-1). Other mechanisms of peripheral sensitization are listed in Box 19-1.

Inflammatory Mediators

Among the best characterized of the inflammatory mediators are the prostaglandins (PGs), which are derived from arachidonic acid via the action of the cyclooxygenase (COX) enzyme systems. The human COX enzyme is known to exist in at least two forms, COX-1 and COX-2. COX-1 is constitutively expressed and produces PGs that are involved in basic housekeeping functions such as cytoprotection in the stomach, regulation of blood flow in the kidneys, and the formation of thromboxane A_2. The formation of thromboxane A_2 can ultimately lead to platelet aggregation; therefore, inhibition of thromboxane A_2 should decrease platelet aggregation. COX-2 is inducible, synthesized in inflamed tissues (including dental

BOX 19-1

Peripheral Mechanisms Contributing to Hyperalgesia and Allodynia

Mechanism

- Composition and concentration of inflammatory mediators[90]
- Changes in afferent fiber: activation and sensitization[131,153,201]
- Changes in afferent fiber: sprouting[21]
- Changes in afferent fiber: proteins[21,78,243]
- Tissue pressure[172,173]
- Tissue temperature[159]
- Sympathetic primary afferent fiber interactions[110,136,188]
- Aβ fiber plasticity[176]

pulp),[170] and is important in the production of the proinflammatory PGs as well as the vasodilating prostacyclin (PGI_2). Although they do not produce pain if applied alone, PGs are known to sensitize peripheral nociceptors, which increases the algogenic (pain-producing) properties of serotonin and bradykinin.[50,80] The exact mechanism by which PGs increase neuronal excitability is not clear, but there is a growing body of evidence to suggest that they activate PG receptors EP2 and EP3 in the trigeminal system[184] and exert their effects by regulating the activity of certain ion channels,[234] including voltage-gated sodium channels (for review see England[56]). For example, application of prostaglandin E_2 (PGE_2) to isolated dorsal root ganglion neuronal somata more than doubles the responsiveness of certain sodium channels found predominantly on nociceptors—channels thought to be relatively resistant to lidocaine.[8,79] When administered to rats before an inflammatory insult, ibuprofen, a nonselective COX inhibitor, has been shown to block the increased expression of $Na_v1.7$ and $Na_v1.8$.[84,85] Therefore, if the concentrations of PGs in inflamed pulp and periradicular tissues can be decreased with nonsteroidal antiinflammatory drugs (NSAIDs) or corticosteroids, postoperative pain may be relieved and, in addition, more profound local anesthesia may be achieved in patients with hyperalgesia of pulpal origin.[95,106,160] It is interesting to note that sensory neurons themselves are a source of PGs; during inflammation, the levels of PGE_2 appear to increase in dorsal root ganglia and spinal cord, suggesting that NSAIDs also have a central site of action (discussed later in this chapter).[148,239]

Bradykinin (BK) is a proinflammatory mediator derived from circulating plasma proteins and also causes direct activation of nociceptive neurons, resulting in pain. Increased levels of BK have been demonstrated in the inflamed dental pulp,[135] and the presence of growth factors associated with inflammation (e.g., nerve growth factor) have been reported to cause an increase in the expression of mRNA encoding B1 and B2 receptors in primary cultures of rat trigeminal ganglia,[218] as well as other receptors such as TRPV1 and TRPA1.[41,112] The *transient receptor potential subtype V1* (TRPV1) is the "capsaicin receptor"; it plays a key role in mediating inflammatory pain. TRPA1 is expressed on capsaicin-sensitive neurons[41] and interacts with TRPV1.[200] Bradykinin likely increases the excitability of nociceptive neurons through its action on TRPV1 and TRPA1 (for review, see Tominaga et al.[217]).

Cytokines are a diverse group of regulatory proteins synthesized and secreted by a variety of cell types, such as leukocytes, neurons, and glia. In particular, tumor necrosis factor α (TNF-α), and the interleukins IL-1β, IL-6, and IL-8 are thought to play a role in the neuroplastic changes that occur in nociceptors innervating inflamed tissues, leading to hyperalgesia.[130] Application of TNF-α rapidly sensitizes TRPV1,[124] contributing to activation of the capsaicin-sensitive class of nociceptors. All of the above are thought to exist in the inflamed pulp (for review see Fouad[64]) and are thought to act at least in part by causing increased release of prostanoids.[214]

Changes in Neuronal Phenotypes

Sensory neurons innervating inflamed peripheral tissues undergo striking phenotypic changes, including changes in transduction mechanisms and plasticity of nociceptor organization. In the dental pulp, it is likely that C fibers predominate in the response to inflammation, because the quality of the pain described by patients with pulpal inflammatory disease (e.g., dull, aching, throbbing sensations) is similar to that reported by patients experiencing experimental C fiber activation.[5,169,174] As described previously, certain combinations of inflammatory mediators causes both activation and sensitization of these fibers. Interestingly, when pulpal and periradicular tissues undergo inflammatory changes, C fibers innervating those tissues are found to contain increased amounts of proinflammatory neuropeptides such as SP and CGRP.[19,24,26] It has also been shown that C fiber terminals in inflamed pulpal tissues undergo a process called *sprouting*, whereby those terminals closest to the inflamed tissues actually grow to form additional terminal endings,[22-24] possibly leading to increased participation in detecting and modulating tissue responses to injury.

Another consideration in the neural response to inflammation is the possibility of a change in the distribution and activity of voltage-gated sodium channels. In particular, mice lacking the gene for $Na_v1.7$ show reduced painlike behaviors when treated with a variety of proinflammatory agents.[175] Also implicated in the altered firing characteristics of nociceptors innervating inflamed tissues are the sodium channels that are resistant to tetrodotoxin (TTX), the biotoxin found in the tetraodon pufferfish. The two main TTX-R sodium channels are $Na_v1.8$ and $Na_v1.9$, and both have been shown to be increased two- to fourfold in inflamed dental pulp collected from patients with a diagnosis of irreversible pulpitis.[235,237] When exposed to PGE_2, neurons isolated from dorsal root ganglia cells have been shown to increase TTX-resistant sodium channel currents within minutes,[79] indicating an increased activation of existing channels, rather than de novo protein synthesis. Interestingly, these sodium channels are relatively resistant to lidocaine,[199] and this may explain the difficulty in achieving profound anesthesia in inflamed tissues (see also Chapter 20).[95]

Signs and Symptoms of Pulpalgia and Acute Periradicular Periodontitis

Again, the hallmarks of pain perception due to acute inflammation are allodynia, hyperalgesia, and spontaneous pain. The peripheral mechanisms for these symptoms include a decrease

TABLE 19-2

Signs of Hyperalgesia and Allodynia and Endodontic Diagnostic Tests

Signs of Hyperalgesia	Related Diagnostic Tests or Symptoms
Spontaneous pain	Spontaneous pain
Reduced pain threshold	Percussion test, palpation test, throbbing pain
Increased response to painful stimuli	Increased response to pulp test (EPT or thermal test)

EPT, Electric pulp test.

in firing threshold, an increase in responsiveness to noxious stimuli, and development of spontaneous discharges of nociceptors. All three of these characteristics can be seen in patients experiencing inflammatory pain of pulpal origin (Table 19-2). From this perspective, the histology of the pulp would not be expected to correlate with the patient's symptoms. Simply put, inflammatory pain is the result of molecules interacting with nociceptors, an event that cannot be detected by conventional histologic methods.

Thermal allodynia is the term that best describes a patient whose chief complaint is "I have pain when I drink cold beverages." *Mechanical allodynia* is involved when the chief complaint is "It now hurts when I bite on this tooth." These previously non-noxious stimuli now cause the perception of pain. Hyperalgesia is manifested in endodontic pain patients when noxious stimuli (e.g., refrigerant sprays or carbon dioxide snow used in the cold test) produce much more pain than they would in teeth with normal pulp tissues. Spontaneous pain involves episodes of pain that seem to be unprovoked. All these changes can be partly explained by sensitization of peripheral nerve endings in the pulp and periradicular tissues.

Analgesic Drugs With the Potential to Act in the Periphery

Pain control can be effected by endogenous mechanisms in the periphery. For example, immune cells in inflamed peripheral tissues may release opioids that act on receptors found on sensory neurons.[213] Several drug classes (discussed later in this chapter) also have the potential for reducing the production of agents that serve to cause pain directly or sensitize peripheral nociceptors. These drugs include NSAIDs,[104,105] corticosteroids,[69] and opiates.[47]

Processing: The Second Step in Pain Perception

The Medullary Dorsal Horn

After activation of peripheral nociceptors, nerve impulses in the form of action potentials convey information about the intensity (encoded by firing frequency), quality (encoded by type of neuron activated), and temporal features (encoded by onset, duration, and offset of depolarization) of the peripheral stimuli to the CNS. In the trigeminal pain system, these action potentials arrive at the trigeminal spinal tract nuclear complex located in the medulla.[94,141,204] Three distinct subnuclei can be found in this complex. Named for their anatomic position, they are the *subnuclei oralis, interpolaris,* and *caudalis* (see Fig. 19-1). Although the more rostral subnuclei (oralis and interpolaris) receive some nociceptive input from oral tissues,[39] most such input is received at the level of the subnucleus caudalis.[57,146,206] Because of its organizational similarity to the dorsal horn of the spinal cord (which receives nociceptive input from the somatosensory system), the subnucleus caudalis has been termed the *medullary dorsal horn*.

Components of the Medullary Dorsal Horn

The medullary dorsal horn relays information to higher centers in the brain and serves as the site of much potential processing of the signals from primary afferent sensory nerve fibers. Output from this region can be increased (hyperalgesia), decreased (analgesia), or misinterpreted (referred pain). Understanding the functional components involved in such processing not only helps explain some of these clinical phenomena but also allows evaluation of potential therapeutic modalities currently under investigation. Functional components include the central terminals of primary nociceptors (Aδ and C fiber afferents), the second-order projecting neurons, interneurons, the terminals of descending neurons, and glial[152] cells (for review see Hargreaves[91]).

Primary afferent fibers (whose cell bodies are located in the trigeminal ganglion) transmit signals to projection neurons via the release of transmitters such as the excitatory amino acid, glutamate, and the neuropeptide, substance P. Receptors for these neurotransmitters are found on postsynaptic membranes and include the NMDA and AMPA classes of glutamate receptors and the neurokinin 1 (NK1) class of substance P receptors. Antagonists to these receptors have been shown to reduce hyperalgesia in animal studies.[29] In a human clinical trial using an oral surgery model, the AMPA/kainate antagonist, LY293558, was shown to be antihyperalgesic.[75] NK1 antagonists have shown promising results in animal studies, but in general, they have displayed limited analgesic efficacy in humans.[103]

The cell bodies of the second-order (projection) neurons in the trigeminal pain system are found in the medullary dorsal horn; their processes cross the midline and project rostrally to the thalamus via the trigeminothalamic tract (Fig. 19-2). From the thalamus, third-order neurons relay information to the cerebral cortex via a thalamocortical tract. Once signals have reached the cortex, the input may be perceived as pain. Evidence exists that referred pain is caused by convergence of afferent input from different areas onto the same projection neurons.

Approximately 50% of subnucleus caudalis neurons are estimated to receive convergence of sensory input from cutaneous and deep structures.[206] In one study of a cat, a single nucleus caudalis neuron received input from sensory neurons innervating the cornea, the skin overlying the maxilla, a maxillary premolar tooth, and a mandibular canine and premolar tooth on one side.[208] Subnuclei oralis and interpolaris also receive converging input from orofacial and muscle afferents.[207] This would explain the clinical observation of patients who perceive pain in a particular tooth that actually originates from either a different tooth or structure (see also Chapter 3).

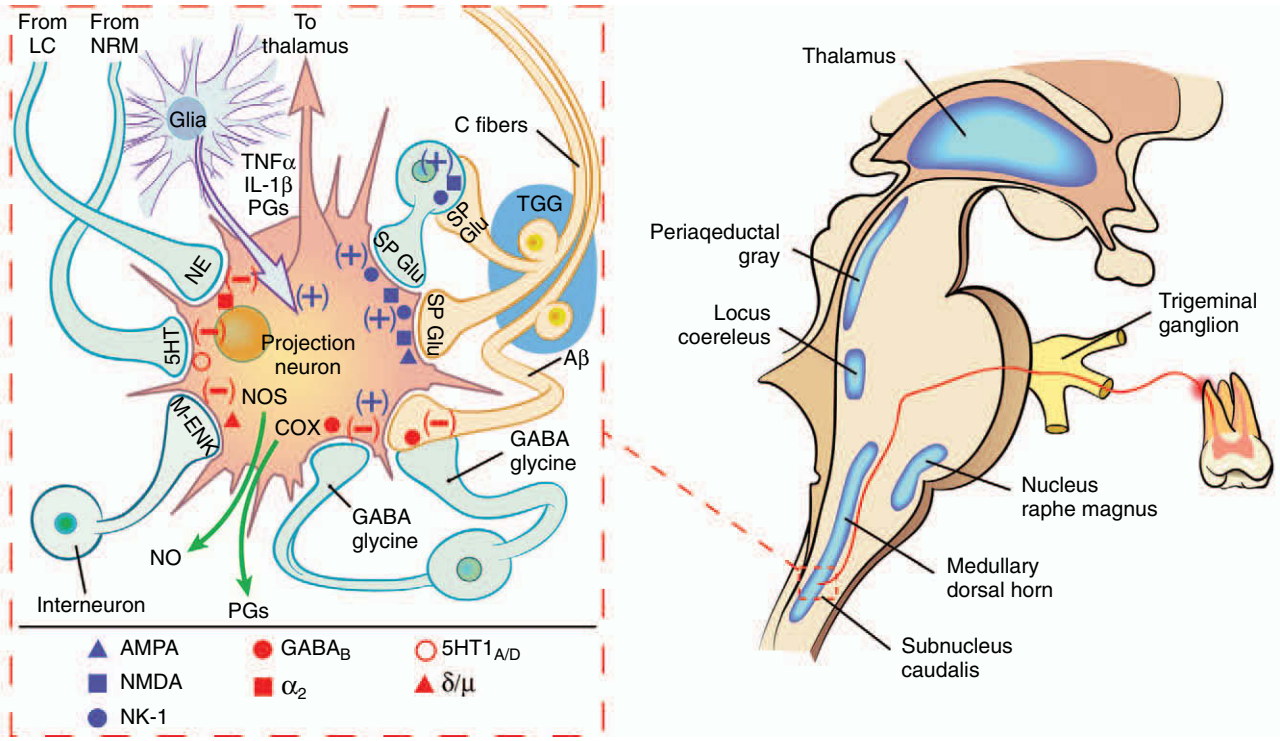

FIG. 19-2 Schematic diagram of the perception and modulation of orofacial pain. Activation of primary afferent fibers (in this example from an inflamed maxillary molar) leads to the entry of a nociceptive signal that is conveyed across a synapse in the subnucleus caudalis of the trigeminal spinal nucleus. The second-order neuron projects to the thalamus; the information is then relayed to the cortex. A great deal of processing of nociceptive input can occur at the level of the medullary dorsal horn (MDH). The *inset* depicts a typical wide dynamic range (WDR) projection neuron and its relationship with other components of the MDH. Primary afferent fibers release the excitatory amino acid, glutamate—which binds and activates either AMPA or NMDA receptors—and substance P—which activates NK-1 receptors on the WDR neuron or excitatory interneurons. Descending fibers from the locus coeruleus (LN) and nucleus raphe magnus (NRM) secrete serotonin (5HT) and norepinephrine (NE), respectively, which inhibit transmission. Release of γ amino butyric acid (GABA), the amino acid, glycine, and endogenous opioid peptides such as metenkephalin (M-ENK) also inhibit transmission of nociceptive information. Projection neurons may have autocrine and/or paracrine effects by the synthesis and release of prostaglandins (PGs) and nitric oxide (NO) via the action of cyclooxygenase (COX) and nitric oxide synthase (NOS), respectively. Glial cells can modulate nociceptive processing by the release of cytokines such as tumor necrosis factor alpha (TNF-α), and interleukin 1 beta (IL-1β). The + sign indicates an excitatory action, whereas the − sign denotes an inhibitory action.

In such cases, anesthetizing the tooth suspected by the patient would afford no relief. However, if an anesthetic is delivered selectively to the suspected primary source of pain, the patient's discomfort should be greatly diminished.[180] Likewise, if the source of a perceived toothache were located in a muscle of mastication, palpation of that muscle should aggravate the pain.[247]

In the medullary dorsal horn, local circuit interneurons have the potential to affect transmission of nociceptive input from primary afferents to projection neurons. Depending on the transmitter released, these neurons have the ability to enhance or diminish the signal. Typically, excitatory interneurons release glutamate and/or substance P, whereas inhibitory interneurons release the amino acid, glycine, and/or gamma amino butyric acid (GABA).[141,205]

The terminals of neurons that descend from brain structures such as the locus coeruleus and nucleus raphe magnus tend to inhibit nociceptive transmission at the level of the medullary dorsal horn.[13] These terminals release a variety of neuroeffective agents, including the endogenous opioid peptides (EOP). The EOPs, similar in three-dimensional structure to many of the exogenous opiates from which their name derives, are released in response to nociceptive input and act to suppress the pain system. The EOPs likely are partly responsible for the placebo effect seen in pain control studies, because this effect can be reversed by administration of the opioid antagonist, naloxone.[92,138]

The final component of the medullary dorsal horn complex to be considered is the glial cell population. Historically considered to be solely supportive in function, they are now recognized to play an important role in the pain processing system.[193,236] Following nociceptive input from primary afferents, glia release cytokines such as TNF-α and IL-1, as well as certain PGs that may facilitate the activity of projection neurons. Glial modulating agents have been shown to be effective in experimental models of neuropathic pain,[216] and NSAIDs potentially could exert part of their analgesic mechanism by acting at this level.

Central Sensitization

Central sensitization can be defined as an increased responsiveness of central nociceptive neurons to peripheral stimulation that occurs in addition to *peripheral sensitization* of the primary afferent nociceptors. Central sensitization is thought to be a

major cause of hyperalgesia and allodynia.[245] Recent clinical trials implicate central sensitization in patients reporting pain due to irreversible pulpitis. In one survey of nearly 1000 patients, 57% of patients with irreversible pulpitis reported mechanical allodynia (pain due to percussion).[182] This appears to be due at least in part to central sensitization, since both the ipsilateral (pulpitis) tooth and a contralateral (normal) tooth demonstrated mechanical allodynia to a force transducer.[125] Thus, central sensitization contributes to endodontic pain, and the clinical application of bite force transducers may provide a novel method for diagnosing pain mechanisms.[125,126]

Different studies shed light on the molecular mechanisms involved in central sensitization (for review, see Cousins and Power[36] and Hargreaves[91]), but the process is generally initiated by a barrage of nociceptive impulses from peripheral C fibers. The level and duration of pain prior to endodontic intervention has been cited in several studies as a predictor of postoperative endodontic pain,[108,219,233] and this may be due to such a prolonged and intense input from C nociceptors. Any reduction of such a barrage should limit the occurrence of central sensitization and the development of pain of longer duration after tissue injury (including surgical and nonsurgical endodontic procedures). The use of long-acting local anesthetics following tonsillectomies and third molar extractions has shown to provide pain relief far beyond the duration of the peripheral tissue anesthesia.[83,111]

A reduction in the chemical mediators of inflammation at the level of the medullary dorsal horn also should serve to reduce sensitization of second-order neurons. Decreasing the synthesis of proinflammatory PGs, cytokines, nitric oxide, and/or the use of drugs that block the receptors of such agents probably will become accepted pharmacotherapy in the future. For example, application of an inflammatory agent to the tooth pulp of rat maxillary molars results in an increased receptive field of Aβ touch receptors on the face. This can be blocked by pretreatment with a glutamate NMDA receptor antagonist, indicating that such centrally acting drugs may offer highly efficacious means of treating odontogenic pain.[29] A similar investigation implicated nitric oxide synthesis at the level of the subnucleus caudalis in the development of tactile hypersensitivity following dental injury.[252] Reduction in nitric oxide synthase levels may also provide protection from central sensitization.[149,157]

Perception: Thalamus to Cortex

The final anatomic step in the trigeminal pain pathway relies on neurons that leave the thalamus and extend to the cerebral cortex (see Fig. 19-1). The patient actually perceives a stimulus as painful at the cortical level. It is interesting to note (but likely of no surprise to the experienced clinician) that a disproportionately large portion of the sensory cortex in humans is devoted to input from orofacial regions.[186]

It is becoming increasingly obvious that higher-order (i.e., cortical) perceptual processes have a profound effect on the ultimate state of pain the patient experiences (for review, see Yaksh[250]). Memories of previous pain experiences provide a framework by which similar new experiences are judged and serve to shape the patient's response to a given stimulus. In the field of dentistry, the anxiety level of the patient at the time of treatment has been shown to affect not only the patient's response to pain experienced during treatment[52,241] but also the tendency of the patient to recall the experience as painful or unpleasant even 18 months posttreatment.[72] The clinician should do everything possible to control a patient's anxiety level prior to endodontic treatment (see also Chapter 26). One simple pretreatment method is to provide patients with positive written information regarding the control of pain during their endodontic treatment. In a placebo-controlled clinical trial, 437 endodontic patients were given one of five informative paragraphs to read prior to treatment. One of the paragraphs contained positive information about pain during treatment. Patients completed questionnaires following treatment that evaluated their dental anxiety and dental fear. Subjects given positive information were shown to be less fearful of pain during endodontic therapy.[228] Along with a positive and caring attitude, pharmacologic intervention may help reduce anxiety. Nitrous oxide has been shown to be effective in a dental setting[44] but may interfere with radiography procedures during endodontic therapy. In a placebo-controlled clinical trial in patients undergoing the extraction of impacted third molars, 0.25 mg of oral triazolam (a benzodiazepine) provided comparable anxiolysis to intravenous diazepam titrated to a typical clinical endpoint.[116] Of course, the patient so medicated must be provided transportation to and from the dental office, and the potential drug-drug interactions with other centrally acting agents such as opioids, barbiturates, and alcohol must be considered. One interaction that should be considered is the capacity of grapefruit juice to prolong the half-life of triazolam.[142] It has been shown that furanocoumarins in grapefruit juice inhibit cytochrome P450 3A4,[183] which is the enzyme responsible for the metabolism of triazolam in the liver. Patients should be told not to take oral triazolam with grapefruit juice.

PREDICTORS OF POSTOPERATIVE ENDODONTIC PAIN

Although current endodontic treatment can be virtually pain free during the procedure itself, certain patients may still experience some pain after the appointment. Early studies investigating postoperative endodontic pain have reported an incidence of moderate to severe pain in the range of 15% to 25%.[30,97,179] In a prospective clinical study, 57% of patients reported no pain after débridement and shaping of the root canal system, although 21% had slight pain, 15% had moderate pain, and 7% had severe pain.[74] Although some patients may experience moderate to severe pain after endodontic treatment, very few experience what is now commonly referred to as a *flare-up* or a postoperative problem requiring an unscheduled visit with unplanned treatment intervention to manage the patient's symptoms.[231] Patients with a flare-up usually describe severe pain, swelling, or the sensation of pressure within their mandible or maxilla within 1 or 2 days of treatment. The incidence of flare-up varies across studies and ranges from about 2% to 20% of patients, with the higher prevalence generally reported in older studies using classical cleaning and shaping techniques.[12,165,224,225]

Numerous studies have evaluated factors related to postoperative endodontic pain and flare-up to better predict when these conditions are more likely to occur. Table 19-3 summarizes the results of clinical endodontic studies evaluating more than 12,000 patients for predictors of postoperative pain.

TABLE 19-3

Factors Related to Postendodontic Pain

Note: A "+" sign indicates that a positive correlation was found between this factor and the presence of pain. AN "=" sign indicates that no correlation was found between this factor and the presence of pain. The absence of either sign indicates that the study did not address this factor. "AP > Pain" indicates that the presence of apical periodontitis was associated with more postoperative pain.

Hx, History; *Tx,* treatment.

Differences in experimental design prevent direct comparison of studies, but interestingly, the presence of *preoperative* pain or mechanical allodynia (reduced mechanical pain threshold or percussion sensitivity) was a positive predictor of postoperative pain in more than 15 studies involving more than 6600 patients.

Other factors were more variable in their predictive value of postoperative pain. In a retrospective study, the dental records of 1000 patients who had received nonsurgical root canal treatment and experienced no flare-ups (i.e., unscheduled return visits) were compared with the records of 1000 patients who experienced flare-ups after the cleansing and shaping of their necrotic root canals.[220] The results showed that factors such as presence of preoperative pain, tooth type, sex, age, history of allergy, and retreatment, were significantly predictive for the incidence of flare-up, although intracanal medicaments, systemic disease, and establishment of patency of the apical foramen had no significant relation to the incidence of flare-ups.[220] Specifically, the highest incidences of flare-ups were associated with mandibular teeth, retreatment procedures, females over the age of 40, and patients with a history of allergies.[220]

In another retrospective study, the flare-up rate was evaluated in patients treated in multiple visits by undergraduate dental students.[163] The incidence in this study was 4.2%, and a positive correlation was found between flare-ups and teeth with necrotic pulp. No correlation was found between the occurrence of a flare-up and the presence or absence of a periradicular radiolucency.

In a prospective study of one-visit nonsurgical root canal treatments, the overall flare-up rate was only 1.8%.[224] However, this same study determined that one-visit endodontic retreatment cases involving teeth with apical periodontitis had almost a 10-fold higher incidence of flare-ups (13.6%), with the recommendation that retreatment of teeth with apical periodontitis should not be completed in one visit. Another prospective clinical study reported an overall flare-up rate of 3.2% of 946 endodontic cases.[233] Patients with severe preoperative pain had a flare-up rate of 19%, although the presence of localized or diffuse swelling related to an incidence of 15%. In this study, pulpal status predicted the flare-up rate, with necrotic teeth having a significantly greater incidence of flare-ups compared with vital teeth (6.5% versus 1.3%). Periradicular status also predicted flare-up rates, with differences noted between chronic apical periodontitis (3.4%), acute apical periodontitis (4.8%), and acute apical abscess (13.1%). No significant difference was seen between single and multiple visits. Finally, no significant increase in flare-ups was seen for teeth undergoing retreatment of a failed root canal, although a subset analysis of retreatment with or without apical periodontitis was not performed.

A recent systematic review of clinical trials evaluating the effectiveness of single versus multiple visits for endodontic therapy concluded that while there was no difference in ultimate outcome of the treatment, those patients treated in one visit were more likely to take analgesic drugs.[132]

In summary, the most consistent factor that predicts postendodontic pain is the presence of preoperative pain or mechanical allodynia. Although no single factor completely predicts the occurrence and magnitude of postoperative pain, an astute clinician should interpret the presence of preoperative pain or mechanical allodynia as a warning sign in selecting the pain control regimen for each patient.

NONNARCOTIC ANALGESICS

Management of endodontic pain is multifactorial and directed at reducing the peripheral and central components of hyperalgesia (see Box 19-1) through combined endodontic procedures and pharmacotherapy. A major class of drugs for managing endodontic pain is nonnarcotic analgesics, which include both NSAIDs and acetaminophen. NSAIDs have been shown to be very effective in managing pain of inflammatory origin and, by virtue of their binding to plasma proteins, actually exhibit increased delivery to inflamed tissue via the extravasation of plasma proteins.[20,48,89,93] Although these drugs classically are thought to produce analgesia through peripheral mechanisms, the CNS now is believed to be an additional site of action.[147,215] Some researchers have proposed that a splice variant of COX1—COX3—is expressed predominantly in the CNS and is the major site of action of acetaminophen.[28,128,202] However, recent studies indicate that the antipyretic and analgesic effects of acetaminophen do not involve inhibition of COX3[102] but are more likely exerted through effects of an active metabolite on CNS cannabinoid receptors.[7]

Numerous NSAIDs are available for management of pain and inflammation (Table 19-4). Unfortunately, comparatively few studies (particularly for endodontic pain) directly compare one NSAID to one another for analgesia and side-effect

TABLE 19-4

Summary of Selected Nonnarcotic Analgesics

Analgesic	Trade Name	Dose Range (mg)	Daily Dose (mg)
Acetaminophen	Tylenol et al.	325-1000	4000
Aspirin	Many	325-1000	4000
Diflunisal	Dolobid	250-1000	1500
Diclofenac potassium	Cataflam	50-100	150-200
Etodolac	Lodine	200-400	1200
Fenoprofen	Nalfon	200	1200
Flurbiprofen	Ansaid	50-100	200-300
Ibuprofen	Motrin et al.	200-800	2400 (Rx)
Ketorolac*	Toradol	30-60 (oral)	60
Naproxen Na	Anaprox et al.	220-550	1650 (Rx)
Naproxen	Naprosyn	250-500	1500
Ketoprofen	Orudis	25-75	300 (Rx)

Note: COX-2 inhibitors are not included (see text).

liability, particularly regarding endodontic pain. The lack of comprehensive comparative studies in endodontic models means that only general recommendations can be made, and clinicians are encouraged to be familiar with several of these drugs. Ibuprofen generally is considered the prototype of contemporary NSAIDs and has a well-documented efficacy and safety profile.[45] Other NSAIDs may offer certain advantages over ibuprofen. For example, etodolac (i.e., Lodine) has minimal gastrointestinal (GI) irritation,[9] and ketoprofen (i.e., Orudis) has been shown in some studies to be somewhat more analgesic than ibuprofen.[34] The advantages of NSAIDs include their well-established analgesic efficacy for inflammatory pain. Many of the NSAIDs listed in Table 19-4 have been shown to be more effective than traditional acetaminophen and opioid combinations such as Tylenol with codeine no. 3.[33,45,226]

A 2002 paper represents the first systematic review comparing all endodontic pain studies evaluating oral NSAIDs.[105] This study also provides a framework for other investigators interested in conducting systematic reviews for endodontic research. The authors concluded that NSAIDs combined with other drugs (e.g., flurbiprofen with tramadol[49]) or pretreatment and posttreatment application of NSAIDs provides effective pain control. Although relatively new to endodontic research, systematic reviews of analgesic drugs in inflammatory pain models have been conducted for several years. Table 19-5 lists the results of a large ongoing systematic review of the relative efficacy of analgesics in inflammatory pain conditions. Importantly, the data are generated based on postoperative patients having moderate to severe pain, and the number needed to treat (NNT) is based on the relative superiority of the analgesic over placebo for producing a 50% relief in pain. These data therefore constitute important, clinically relevant information for clinicians who want to compare the relative efficacy of posttreatment analgesics. Of course, other issues such as the potential adverse effects of drugs and the patient's medical history must be considered when developing a postendodontic pain treatment plan.

The introduction of selective inhibitors of COX-2 offered the potential for both analgesic and antiinflammatory benefits and reduced GI irritation.[43,123] Oral surgery pain studies evaluating COX-2 inhibitors have indicated that rofecoxib (i.e., Vioxx) has significant analgesic efficacy in this model.[53] In one study, a 50-mg dose of rofecoxib produced analgesia equivalent to 400 mg of ibuprofen, with the two drugs displaying similar times for onset of analgesia.[53] Moreover, COX-2 levels are increased in inflamed human dental pulp,[171] and a COX-2 inhibitor (rofecoxib) is analgesic in patients with endodontic pain. Concern has been raised that the COX-2 inhibitors may also display at least some GI irritation in patients with preexisting GI disease.[230]

Another major concern centers on the recognized prothrombic adverse effects of the COX-2 inhibitors. This debate originally started when patients randomized to 50 mg/day of rofecoxib in the VIGOR study had a fivefold increase in thromboembolic cardiovascular (CV) events compared to 1000 mg/day of naproxen.[17] The debate continued until the demonstration of an increased risk for prothrombic events following long-term administration of rofecoxib, which led to the withdrawal of this drug from the market in 2004.[59] Two meta-analyses have examined the CV safety of traditional NSAIDs and COX-2 inhibitors. Kearney et al. conducted a meta-analysis of 138 randomized trials, and McGettigan and Henry conducted a meta-analysis of 23 controlled observational studies.[118,155] Kearney et al. estimated a relative risk for CV events associated with COX-2 to be 1.42 (95% CI, 1.64 to 2.91). Naproxen was found to have no significant adverse effects on the CV system in both meta-analyses. Diclofenac (Voltaren) is a relatively COX-2-selective drug and seems to have a similar degree of COX-2 selectivity as celecoxib. Diclofenac was associated with increased CV events. In the randomized trial analysis, there was an increase in CV risk with high-dose ibuprofen. Based on the available data, the FDA has requested that manufacturers of all prescription products containing nonselective NSAIDs revise their product labeling to include (1) a boxed warning regarding the potential serious adverse CV events and the serious, potentially life-threatening GI adverse events associated with the use of this class of drugs; (2) a contraindication for use in patients who have recently undergone coronary artery bypass surgery; and (3) a medication guide for patients, regarding the potential for CV and GI adverse events associated with the use of this class of drugs. The available data do not suggest an increased risk of serious CV events for the short-term, low-dose use of NSAIDs available over the counter, but the U.S. Food and Drug Administration (FDA) has requested changes to the label to better inform consumers regarding the safe use of these products. Given this situation and reasonable alternative NSAIDs, we recommend not considering COX-2 inhibitors for treating routine endodontic pain patients.

Limitations and Drug Interactions

Clinicians should educate themselves not only on the efficacy of the nonnarcotic analgesics but also on their limitations and interactions with other drugs.[25] For example, NSAIDs exhibit an analgesic ceiling that limits the maximal level of analgesia and induces side effects, including those affecting the GI system (3% to 11% incidence) and the CNS (1% to 9% incidence of dizziness and headache). NSAIDs are contraindicated in patients with ulcers and aspirin hypersensitivity.[31-33,68,248] They also are associated with severe GI complications, and the risk of adverse effects increases with increasing lifetime-accumulated dose of these drugs.[46,240]

The NSAIDs have been reported to interact with a number of other drugs (Table 19-6). Acetaminophen and opioid combination drugs represent alternatives for those patients unable to take NSAIDs.[32] Further information is available on the pharmacology and adverse effects of this important class of drugs.[25,31,46,68,248] Other resources are also available for evaluation of drug interactions, including Internet drug search engines such as rxlist.com, Epocrates.com, and Endodontics. UTHSCSA.edu.

Acetaminophen

Acetaminophen is one of the most commonly used drugs. It is also one of the most common drugs found in combination products for the relief of pain and symptoms of cold or flu. It is considered safe when taken at normal doses, but in higher doses, acetaminophen causes liver toxicity and has become the most common cause of acute liver failure.[134] Most acetaminophen is conjugated in the liver to form inactive metabolites. A small portion is metabolized by the cytochrome P450 system to form *N*-acetyl-*p*-benzoquinone imine (NAPQI),

TABLE 19-5

IM, Intramuscular; *NA,* not applicable; *NNT,* number needed to treat.

*Analgesics are listed in descending order from most to least effective based on the number needed to treat (NNT). The NNT reflects the superiority of an analgesic over a placebo treatment; therefore an analgesic with a lower NNT has greater efficacy than an analgesic with a higher NNT. The NNT is calculated for the proportion of patients with at least 50% pain relief over 4 to 6 hours compared with placebo in randomized, double-blind, and single-dose studies in patients with moderate to severe pain. The 95% confidence interval contains the upper and lower estimates of the NNT with a 95% chance of accuracy.

†Drugs were given orally except where noted.

TABLE 19-6

Summary of Selected NSAID Drug Interactions

Drug	Possible Effect
Anticoagulants	Increase in prothrombin time or bleeding with anticoagulants (e.g., coumarins)
ACE inhibitors	Reduced antihypertensive effectiveness of captopril (especially indomethacin)
Beta-blockers	Reduced antihypertensive effects of beta-blockers (e.g., propranolol, atenolol, pindolol)
Cyclosporine	Increased risk of nephrotoxicity
Digoxin	Increase in serum digoxin levels (especially ibuprofen, indomethacin)
Dipyridamole	Increased water retention (especially indomethacin)
Hydantoins	Increased serum levels of phenytoin
Lithium	Increased serum levels of lithium
Loop diuretics	Reduced effectiveness of loop diuretics (e.g., furosemide, bumetanide)
Methotrexate	Increased risk of toxicity (e.g., stomatitis, bone marrow suppression)
Penillamine	Increased bioavailability (especially indomethacin)
Sympathomimetics	Increased blood pressure (especially indomethacin with phenylpropanolamine)
Thiazide diuretics	Reduced antihypertensive effectiveness

Data from Drug facts and comparisons, ed 54, St Louis, 2000, Facts and Comparisons; Gage T, Pickett F: *Mosby's dental drug reference*, ed 5, St Louis, 2000, Mosby; Wynn R, Meiller T, Crossley H: *Drug information handbook for dentistry*, Hudson, Ohio, 2000, Lexi-Comp.

which is very toxic but is generally detoxified by glutathione and converted into nontoxic compounds. Large doses of acetaminophen saturate the main route of metabolism, causing more acetaminophen to be converted to NAPQI. Liver injury occurs once glutathione becomes depleted and NAPQI is allowed to accumulate. Healthy adults should not take more than 4 g (4000 mg) of acetaminophen in a 24-hour period. However, the FDA convened an Advisory Panel meeting in June 2009, with discussions on limiting the maximal daily dose of acetaminophen and possibly removing certain medications from the market.[58] Although no action was taken by late 2009, the clinician is encouraged to continue to monitor the FDA website for further information (www.FDA.gov). Opioid pain medications may contain up to 650 to 750 mg of acetaminophen per tablet. Care must be taken when prescribing such combinations to keep the maximum acetaminophen dose below 4000 mg. In an effort to address this, manufacturers have made high-dose opioid/low-dose acetaminophen combinations, such as hydrocodone 10 mg and acetaminophen 325 mg.

TABLE 19-7

Selected Opioid Combination Analgesic Drugs

Formulation	Trade Name*	Possible Rx
APAP 300 mg and codeine 30 mg	Tylenol with codeine no. 3	2 tabs q4h
APAP 500 mg and hydrocodone 5 mg	Vicodin, Lortab 5/500	1-2 tabs q6h
APAP 325 mg and oxycodone 5 mg	Percocet	1 tab q6h
APAP 500 mg and oxycodone 5 mg	Tylox	1 tab q6h
ASA 325 mg and codeine 30 mg	Empirin with codeine no. 3	2 tabs q4h
ASA 325 mg and oxycodone 5 mg	Percodan	1 tab q6h

APAP, Acetaminophen; *ASA*, aspirin; *Rx*, prescription.

*Several generics are available for most formulations.

OPIOID ANALGESICS

Opioids are potent analgesics and are often used in dentistry in combination with acetaminophen, aspirin, or ibuprofen. Most clinically available opioids activate mu opioid receptors located at several important sites in the brain (see Fig. 19-2). Activation of this receptor inhibits the transmission of nociceptive signals from the trigeminal nucleus to higher brain regions, and recent studies indicate that opioids also activate peripheral opioid receptors located in dental pulp.[60] Intraligamentary injection of morphine has been shown to significantly reduce pain in endodontic patients and other inflammatory pain states.[47,88] Gender-dependent differences appear to exist in responsiveness to at least the kappa opioid agonists; women have a significantly greater analgesic response to pentazocine compared to men.[71]

Although opioids are effective as analgesics for moderate to severe pain, their use is generally limited by their adverse side effects, which can include nausea, emesis, dizziness, drowsiness, and the potential for respiratory depression and constipation. Chronic use is associated with tolerance and dependence. Because dosage is limited by side effects, these medications are almost always used in combination drugs to manage dental pain. A combination formulation is preferred because it permits a lower dose of the opioid, thereby reducing side effects (Table 19-7).

Codeine is often considered the prototype opioid for orally available combination drugs. Most studies have found that the 60-mg dose of codeine (the amount in two tablets of Tylenol with codeine no. 3) produces significantly more analgesia than placebo, although it often produces less analgesia than either aspirin 650 mg or acetaminophen 600 mg.[32,33,89] In general, patients taking only 30 mg of codeine report about as much analgesia as those taking a placebo.[14,226] Table 19-8 provides comparable doses of other opioids equivalent to 60 mg of codeine.

TABLE 19-8

Analgesic Doses of Representative Opioids

Opioid	Dose Equivalent to Codeine 60 mg
Codeine	60 mg
Oxycodone	5-6 mg
Hydrocodone	10 mg
Dihydrocodeine	60 mg
Propoxyphene HCl	102 mg
Propoxyphene-N	146 mg
Meperidine	90 mg
Tramadol	50 mg

HCl, Hydrochloride; *N,* napsylate.

CORTICOSTEROIDS

Posttreatment pain or flare-up after endodontic treatment can be attributed to inflammation, infection, or both in the periradicular tissues. Establishing patency and subsequently débriding and shaping the root canal system may irritate the periradicular tissues and inadvertently introduce bacteria, bacterial products, necrotic pulp tissue, or caustic irrigating solution through apical foramina.

In response to this irritation, inflammatory mediators (e.g., prostaglandins, leukotrienes, bradykinin, platelet-activating factor, substance P, etc.) are released into the tissues surrounding the apical area of the tooth. As a result, pain fibers are directly stimulated or sensitized, and an increase in vascular dilation and permeability results in edema and increased interstitial tissue pressure.

Glucocorticosteroids are known to reduce the acute inflammatory response by suppressing vasodilation, migration of polymorphonuclear (PMN) leukocytes, and phagocytosis and by inhibiting formation of arachidonic acid from neutrophil and macrophage cell membrane phospholipids, thus blocking the COX and lipoxygenase pathways and respective synthesis of PGs and leukotrienes. It is not surprising that a number of investigations have evaluated the efficacy of corticosteroids (administered via either intracanal or systemic routes) in the prevention or control of postoperative endodontic pain or flare-ups.[150]

Intracanal Administration

Several studies have evaluated intracanal administration of steroids. In 50 consecutive patients requiring nonsurgical root canal treatment of vital teeth, one investigator alternately placed a dexamethasone solution or saline placebo as intracanal medicaments after the root canals had been cleaned and shaped.[167] Pretreatment pain ratings were collected, and at 24, 48, and 72 hours after treatment. Results indicated a significant reduction in pain at 24 hours but no significant difference at 48 and 72 hours. In a similar double-blind clinical trial, intracanal placement of a 2.5% steroid solution or saline placebo on completion of instrumentation resulted in a significant reduction of the incidence of postoperative pain in teeth in which the pulp was vital.[27] When the pulp was necrotic, however, there was no significant difference between the steroid and placebo in reducing postoperative discomfort.

Another study found no significant difference in the flare-up rate when either formocresol, Ledermix (a corticosteroid antibiotic paste), or calcium hydroxide was placed as an intracanal medicament in strict sequence, irrespective of the presence or absence of symptoms or radiographic signs of apical periodontitis.[225] However, a large-scale clinical trial of 223 patients reported significantly less posttreatment pain in patients after intracanal administration of Ledermix compared with either calcium hydroxide or no intracanal dressing.[54] Intracanal steroids appear to have significant effects for reducing postoperative pain.[195]

Systemic Administration

Some studies have evaluated the systemic route of administration of corticosteroids on posttreatment pain or flare-ups. In one double-blind, randomized, placebo-controlled study, dexamethasone (4 mg/ml) or saline was injected intramuscularly at the conclusion of a single-visit endodontic appointment or at the first visit of a multivisit procedure.[151] The results indicated that the steroid significantly reduced the incidence and severity of pain at 4 hours when compared with the placebo. Pain was reduced at 24 hours, but it was not statistically significant, and no difference in incidence or severity was seen at 48 hours.

In a similar study, 106 patients with irreversible pulpitis and acute periradicular periodontitis were given an intraoral intramuscular injection of dexamethasone at different doses, either on completion of a single-visit endodontic treatment or after the first visit of a multivisit procedure.[140] Systemic administration of dexamethasone was shown to significantly reduce the severity of pain at 4 and 8 hours, with an optimum dose between 0.07 and 0.09 mg/kg. However, no significant reduction in the severity of pain was noted at 24, 48, and 72 hours, and no overall effect was seen on the incidence of pain.

Another study compared the effect an intraligamentary injection of methylprednisolone, mepivacaine, or placebo in preventing posttreatment endodontic pain.[117] The results showed that methylprednisolone significantly reduced postoperative pain within a 24-hour follow-up period.

In a double-blind placebo controlled study, patients with irreversible pulpitis were given 4 mg of dexamethasone or placebo by means of a supraperiosteal injection at the apex of the treated tooth following pulpectomy.[156] This is an injection technique that most clinicians would be familiar with (as opposed to intramuscular injection). Posttreatment pain was significantly reduced in the steroid group during the first 24 hours. There was no difference at 48 hours.

Yet another study evaluated the effect of intraosseous injection of methylprednisolone or placebo to patients with irreversible pulpitis. Highly significant pain reduction in the steroid group was maintained for 7 days after a single injection.[70]

Animal studies have histologically evaluated the antiinflammatory effects of corticosteroids on inflamed periradicular tissues. In one study, after an acute inflammatory reaction was

induced in the molar teeth of rats by overextending endodontic instruments, sterile saline or dexamethasone was infiltrated supraperiosteally into the buccal vestibule adjacent to the treated teeth. Dexamethasone significantly reduced the number of neutrophils present and thus had an antiinflammatory effect on the periradicular tissues of the treated teeth.[178]

Other studies of systemic administration have evaluated the efficacy of oral administration of corticosteroids on the incidence and severity of posttreatment endodontic pain. In a double-blind controlled clinical trial, 50 patients randomly received either 0.75 mg dexamethasone or a placebo tablet orally after initial endodontic treatment.[129] Oral dexamethasone significantly reduced posttreatment pain after 8 and 24 hours compared with placebo. A follow-up study evaluated the effect a larger oral dose of dexamethasone (i.e., 12 mg given every 4 hours) on the severity of posttreatment endodontic pain.[76] Results showed that dexamethasone was effective in reducing posttreatment endodontic pain up to 8 hours after the treatment was completed; no affect on the severity of pain was seen at 24 and 48 hours after treatment.

Collectively, these studies on systemic steroid administration indicate that corticosteroids reduce the severity of posttreatment endodontic pain compared with placebo treatment. However, given the relative safety/efficacy relationship between steroids and NSAIDs, most investigators choose an NSAID as the drug of first choice for postoperative pain control.

Antibiotics

Because bacteria are involved in endodontic cases with apical periodontitis, the incidence of a posttreatment infection or flare-up is a concern to clinicians providing endodontic treatment. Prescribing an antibiotic to prevent such an occurrence might make sense, but use of antibiotics is controversial for several reasons.[63] First, overprescribing antibiotics, especially when these drugs are not indicated, has led to increased bacterial resistance and patient sensitization. Second, antibiotics have been mistakenly prescribed for patients with severe pain who have a vital tooth (i.e., when bacteria are unlikely to be a causative factor in periradicular pain).[251] Third, even when bacteria are likely to be present, data from controlled clinical trials provide little or no support for the hypothesis that antibiotics reduce pain.[119]

A series of clinical studies evaluated the efficacy of prophylactically administered systemic antibiotics for preventing posttreatment endodontic flare-ups. Working on the premise that the incidence of infectious flare-ups after endodontic treatment is 15%, Morse et al. randomly prescribed a prophylactic dose of either penicillin or erythromycin to patients after endodontic treatment of teeth with a diagnosis of necrotic pulp and chronic periradicular periodontitis (no placebo was used).[166] The results showed that the overall incidence of flare-ups was 2.2%, with no difference between penicillin or erythromycin. Similar results were obtained in a study in which dental students (instead of private practitioners) provided the endodontic treatment.[3] Outcomes found a 2.6% incidence of flare-up, with no statistically significant differences between penicillin or erythromycin. However, neither the original nor the follow-up study was a randomized, placebo-controlled clinical trial. This observation appears to be highly significant for clinical recommendations, since in general, randomized controlled studies fail to detect any analgesic benefit to antibiotics, whereas open-label or historical control studies often report profound effects.[63]

To determine whether the timing of administration of an antibiotic altered the occurrence of flare-ups and pain unassociated with flare-ups, researchers analyzed components of two separate prospective studies of patients undergoing endodontic treatment for teeth with necrotic pulps and chronic periradicular periodontitis. In the first study, prophylactic penicillin was provided; in the second study, patients were instructed to take penicillin (or erythromycin if they were allergic to penicillin) at the first sign of swelling.[165,166] The authors concluded that prophylactic administration of antibiotics is preferable to having the patient take antibiotics at the first sign of an infection.

Another study of similar design compared the incidence of flare-up when a cephalosporin or erythromycin was given prophylactically.[164] When the data from previous studies were pooled and retrospectively compared, the authors concluded that prophylactically administered antibiotics, including cephalosporins, significantly reduced the incidence of flare-ups in endodontic cases involving necrotic pulp and chronic periradicular periodontitis. However, these studies have been questioned because of the lack of concurrent placebo-treated groups and the use of historical controls.

In a multicenter, two-part clinical study, 588 consecutive patients received one of nine medications or placebos and were monitored for 72 hours after treatment.[221,222] The results showed that ibuprofen, ketoprofen, erythromycin, penicillin, and penicillin plus methylprednisolone significantly reduced the severity of pain within the first 48 hours after treatment.[221] The second part of the study then evaluated the incidence of posttreatment pain after obturation of the same teeth in the first phase of the study.[222] Although only 411 of the original 588 patients participated in this phase, they were randomly given the same medications or placebo after completion of the obturation appointment. The incidence of posttreatment pain was lower after obturation (5.83%) than after cleaning and shaping (21.76%) of the root canal system, and no significant difference was found in the effectiveness of the various medications and placebo in controlling posttreatment pain after obturation.

Walton and Chiappinelli[232] were concerned that previous studies were uncontrolled, retrospective, or carried out on different patient groups at different times and with different treatment modalities. They conducted a randomized, prospective, double-blind clinical trial to test the hypothesis that an antibiotic (e.g., penicillin) can prevent a posttreatment endodontic flare-up.[232] Eighty patients with teeth that had necrotic pulp and chronic periradicular periodontitis were randomly divided into three groups. In the first two groups, either penicillin or a placebo was administered 1 hour before and 6 hours after the individual appointments on a double-blind basis. Upon completion of the individual appointments, which included débridement, shaping, and possibly obturation of the root canal system, the patients completed questionnaires at 4, 8, 12, 24, and 48 hours. No significant difference was found among the three groups in the incidence of flare-ups, pain, or swelling. The authors concluded that the use of prophylactic penicillin offers no benefit for postoperative pain or flare-up, and prophylactic administration of penicillin should not be used routinely in patients undergoing endodontic treatment of necrotic teeth and chronic periradicular periodontitis.

In another randomized, prospective, placebo-controlled clinical study, a group of investigators examined whether supplemental penicillin reduced symptoms or shortened the course of recovery of emergency patients diagnosed with necrotic pulp and acute apical abscess.[65] Patients were randomly given penicillin, a placebo, or no medication. Using a visual analog scale, the subjects then evaluated their postoperative pain and swelling for up to 72 hours. No significant difference was found among the three groups. Recovery occurred as a result of endodontic treatment alone.

It is well recognized that antibiotics may be indicated for the management of infections of endodontic origin. However, a review of the available literature indicates that prophylactic use is contraindicated in immunocompetent patients with no systemic signs of infection and with swelling localized to the vestibule. Controlled clinical studies indicate that antibiotics offer little or no benefit for pain reduction under these circumstances, but they may be indicated for immunocompromised patients and for patients with systemic signs and symptoms of an infection or an infection that has spread into the fascial spaces of the head and neck.

PAIN-MANAGEMENT STRATEGIES

When managing pain in an individual patient, the skilled clinician must customize the treatment plan, balancing the general principles of endodontics, mechanisms of hyperalgesia, and pain-management strategies with the particular factors of the individual patient (e.g., medical history, concurrent medications).[93,120,121,197,209]

Effective management of endodontic pain starts with the "three Ds": *diagnosis*, *definitive* dental treatment, and *drugs* (Box 19-2). Comprehensive reviews on *diagnosis* and *definitive* dental treatment (e.g., incision and drainage, pulpectomy) are provided elsewhere in this text. As described earlier in this chapter, the management of endodontic pain should focus on removal of peripheral mechanisms of hyperalgesia and allodynia (see Box 19-1). This generally requires treatment that removes and reduces causative factors (e.g., bacterial and immunologic factors). For example, both pulpotomy and pulpectomy have been associated with substantial reduction in patient reports of pain compared to pretreatment pain levels.[49,100,154,187] However, pharmacotherapy often is required to reduce continued nociceptor input (e.g., NSAIDs, local anesthetics) and suppress central hyperalgesia (e.g., NSAIDs, opioids).

BOX 19-2

Considerations for Effective "Three-D" Pain Control

1. Diagnosis
2. Definitive dental treatment
3. Drugs
   - Pretreat with NSAIDs or acetaminophen when appropriate.
   - Use long-acting local anesthetics when indicated.
   - Use a flexible prescription plan.
   - Prescribe "by the clock" rather than as needed.

Pretreatment

Treatment with an NSAID before a procedure has been shown to have a significant benefit in many studies[45,109] but not all of them.[177] The rationale for pretreatment is to block the development of hyperalgesia by reducing the input from peripheral nociceptors. For patients who cannot take NSAIDs, pretreatment with acetaminophen also has been shown to reduce postoperative pain.[162] Patients can be pretreated 30 minutes before the procedure with either an NSAID (e.g., ibuprofen 400 mg or flurbiprofen 100 mg) or with acetaminophen 1000 mg.[49,109,162]

Long-Acting Local Anesthetics

A second pharmacologic approach for pain management is the use of long-acting local anesthetics such as bupivacaine and ropivacaine (see Chapter 20 for an extensive review of this topic). Clinical trials indicate that long-acting local anesthetics not only provide anesthesia during the procedure but also significantly delay the onset of posttreatment pain when compared with local anesthetics that contain lidocaine.[38,45,81,82,111] Administration of long-acting local anesthetics by block injection has been shown to reduce posttreatment pain for 2 to 7 days after the oral procedure,[81,82,111] because an afferent barrage of nociceptors can induce central hyperalgesia.[242-244] The analgesic benefit of long-acting local anesthetics is more prominent with block injections than infiltration injections, but the clinician should also be aware of adverse effects attributed to these agents.[10,161]

Flexible Plan

A third pharmacologic approach is the use of a flexible plan for prescribing analgesics (Fig. 19-3).* A flexible prescription plan serves to minimize both postoperative pain and side effects. Given these goals, the clinician's strategy is twofold: (1) to achieve a maximally effective dose of the nonnarcotic analgesic (either an NSAID or acetaminophen for patients who cannot take NSAIDs), and (2) in the rare cases in which the patient still has moderate to severe pain, to consider adding drugs that increase the NSAID's analgesia. Because of its predictive value, the presence of preoperative pain or mechanical allodynia may be an indicator that such NSAID combinations should be considered.

Studies have shown that treatment combining an NSAID with acetaminophen 1000 mg alone (i.e., no opioid) produces nearly twice the analgesic response as just the NSAID.[18,35,158] Administration of ibuprofen 600 mg with acetaminophen 1000 mg produced significant relief of posttreatment endodontic pain, compared to ibuprofen alone or placebo (Fig. 19-4). Studies have also shown that concurrent administration of an NSAID and an acetaminophen-opioid combination drug provided significantly greater analgesia than an NSAID alone.[18,211] The concurrent administration of acetaminophen and NSAIDs appears to be well tolerated, with no detectable increase in side effects or alterations in pharmacokinetics.[18,133,211,246]

In cases of moderate to severe pain, an NSAID may need to be administered with an opioid. Two general methods are used to combine NSAIDs and opioids to achieve the analgesic benefits of both. The first involves an alternating regimen of

*References 1, 33, 87, 89, 93, 120, 122, and 226.

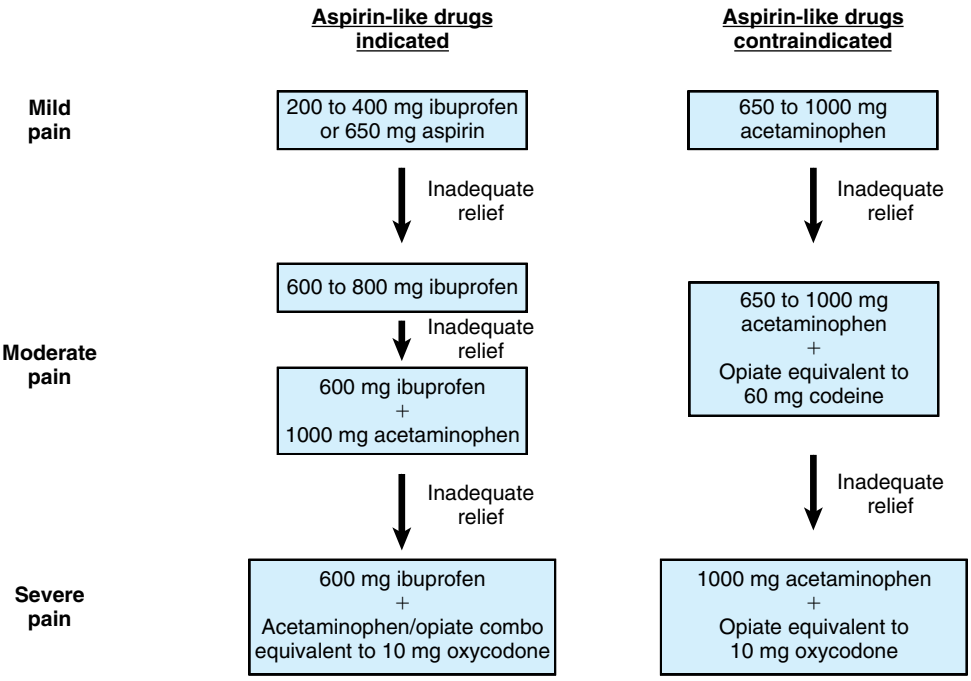

FIG. 19-3 A flexible analgesic strategy.

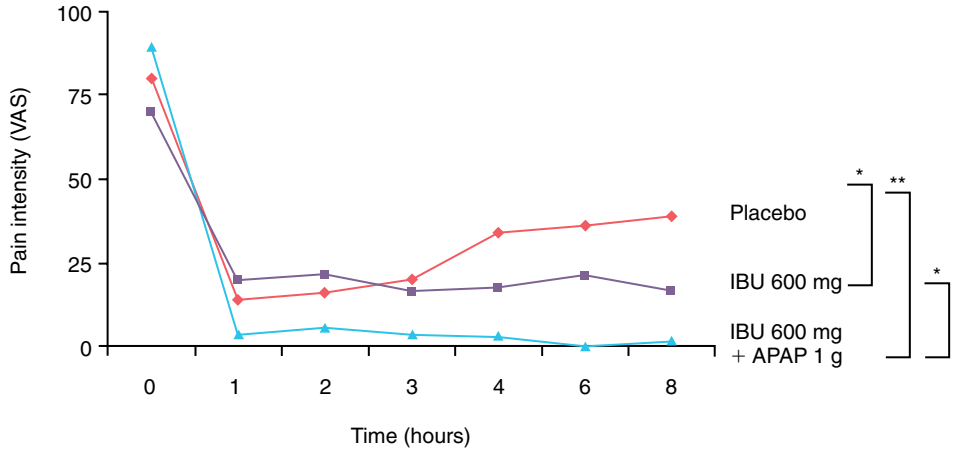

FIG. 19-4 Comparison of ibuprofen 600 mg with acetaminophen 1000 mg to ibuprofen alone or to placebo treatment in postendodontic pain patients. *(From Menhinick KA, Gutmann JL, Regan JD, et al: The efficacy of pain control following nonsurgical root canal treatment using ibuprofen or a combination of ibuprofen and acetaminophen in a randomized, double-blind, placebo-controlled study.* Int Endod J *37:531–541, 2004. Reprinted with permission.)*

an NSAID followed by an acetaminophen-opioid combination.[1,33] Aspirin and opioid combinations are not used in this alternating schedule because of the potential for NSAID/aspirin interactions. The second method involves administration of a single drug consisting of an NSAID-opioid combination. For example, a tablet of Vicoprofen contains both ibuprofen (200 mg) and hydrocodone (7.5 mg). Postoperative pain studies have shown that this combination was about 80% more effective for analgesia than ibuprofen (200 mg) alone, with about the same incidence of side effects.[238] Other opioids can also be added to an NSAID for increased analgesia. Ibuprofen 400 mg with a 10-mg oxycodone tablet produces significantly greater analgesia than ibuprofen alone.[42] A study on posttreatment endodontic pain demonstrated short-term benefits of the combination of flurbiprofen and tramadol.[49] Other NSAID and opioid combinations have also been evaluated.[46] However, the results of clinical trials on the use of NSAIDs alone and combined with acetaminophen (see Fig. 19-4) suggest that opioid combinations may be required only rarely.

Not all patients require concurrent use of NSAIDs with acetaminophen-opioid combinations or combinations of an NSAID and opioid. The basic premise of a flexible prescription plan is that the analgesic prescribed be matched to the patient's need. The major advantage of a flexible plan is that the

clinician is prepared for those rare cases when additional pharmacotherapy is indicated to increase the efficacy of pain control. As mentioned, preoperative hyperalgesia may be an indicator for more comprehensive pharmacotherapy. When considering the combination of various analgesics, the clinician must make sure to use dosing regimens that do not exceed any of the drugs' maximum daily dosage.

FUTURE DIRECTIONS

Current use of analgesics has been driven by clinical trials to arrive at doses that obtain the desired level of pain relief with acceptable side effect profiles. After administration, drugs are absorbed and distributed to their site of action where they interact with functional targets. They then undergo metabolism and eventual excretion. All of the steps along the way are influenced by a variety of environmental and genetic factors. The ability to predict how a patient's genome may affect the efficacy of a given analgesic drug is being discovered in the field of pain pharmacogenomics (for review, see Rollason et al.[196]).

One example relevant to pain control in dentistry is the variable efficacy of codeine in a specific population. Many analgesic drugs are metabolized by the cytochrome P450 (CYP) family of hepatic enzymes, and the genes that encode for their biosynthesis have been identified. Codeine is a prodrug that is demethylated to produce morphine, which is responsible for its analgesic action. This demethylation is catalyzed by the enzyme, cytochrome P402D6. It has been estimated that 6% to 7% of the Caucasian population has a nonfunctional CYP2D6 mutant allele, making them poor metabolizers of codeine to morpine.[41] These patients may be aware that codeine is ineffective in their systems from past experience and may request a different (usually more potent) form of narcotic. The clinician may suspect drug-seeking behavior, when in fact there is a biochemical reason for their request. Given the current state of clinical DNA analysis, it is not incomprehensible to envision a time when rapid (chairside) genomic evaluation will lead to specific recommendations for analgesic prescription.

SUMMARY

The information and recommendations provided in this chapter were selected to aid the clinician in the management of acute endodontic pain. Clinical judgment must also take into account other sources of information—patient history, concurrent medications, the nature of the pain, and the overall treatment plan—when determining the best means of alleviating patient pain. An effective approach to managing endodontic pain demands integration of general principles of pain mechanisms and management with thorough, individualized clinical assessment.

CHAPTER

20

Local Anesthesia in Endodontics

AL W. READER, JOHN M. NUSSTEIN, and KENNETH M. HARGREAVES

CHAPTER OUTLINE

MECHANISMS OF ACTION FOR ANESTHETICS
CLINICALLY AVAILABLE LOCAL ANESTHETICS
SELECTION OF A LOCAL ANESTHETIC: POSSIBLE ADVERSE EFFECTS, MEDICAL HISTORY, PREOPERATIVE ANXIETY
- Possible Adverse Effects

EFFECTS OF SYSTEMIC DISEASES OR CONDITIONS ON LOCAL ANESTHETICS
CLINICAL ANESTHESIA AND ROUTES OF ADMINISTRATION
IMPORTANT CLINICAL FACTORS IN LOCAL ANESTHESIA
- Traditional Methods of Confirming Anesthesia
- Determining Pulpal Anesthesia in Painless Vital Teeth
- Determining Pulpal Anesthesia in Painful Vital Teeth
- Patient Who Has Had Previous Difficulty With Anesthesia
- Failure to Achieve Anesthesia in Patients With Pain
- Use of Topical Anesthetics
- Reversing the Action of Local Anesthesia

MANDIBULAR ANESTHESIA WITH 2% LIDOCAINE AND 1:100,000 EPINEPHRINE
- Anesthetic Success
- Anesthetic Failure
- Noncontinuous Anesthesia
- Slow Onset
- Duration

ALTERNATIVE ANESTHETIC SOLUTIONS FOR THE INFERIOR ALVEOLAR NERVE BLOCK
- Plain Solutions: 3% Mepivacaine (Carbocaine, Polocaine, Scandonest) and 4% Prilocaine (Citanest Plain)
- 4% Prilocaine with 1:200,000 Epinephrine (Citanest Forte) and 2% Mepivacaine with 1:20,000 Levonordefrin (Carbocaine with Neo-Cobefrin)
- Articaine with 1:100,000 Epinephrine (Septocaine)
- Long-Acting Anesthetics

ALTERNATE INJECTION SITES
- Gow-Gates and Vazirani-Akinosi Techniques
- Incisive Nerve Block at the Mental Foramen
- Infiltration Injections of a Lidocaine Solution
- Mandibular First Molar Infiltration Injections of an Articaine Solution
- Mandibular First Molar Infiltration Injections of an Articaine Solution Following an Inferior Alveolar Nerve Block

ATTEMPTS TO INCREASE SUCCESS OF THE INFERIOR ALVEOLAR NERVE BLOCK
- Increasing the Volume of Anesthetic
- Increasing the Epinephrine Concentration
- Addition of Hyaluronidase
- Carbonated Anesthetic Solutions
- Diphenhydramine as a Local Anesthetic Agent
- Addition of Meperidine to Lidocaine

FACTORS IN FAILURE OF THE INFERIOR ALVEOLAR NERVE BLOCK
- Accessory Innervation
- Accuracy of Injection
- Needle Deflection
- Needle Bevel and Success
- Speed of Injection and Success
- Cross-Innervation
- A Theory on Why Failure Occurs With the Inferior Alveolar Nerve Block in Asymptomatic Patients

ENHANCEMENT OF MANDIBULAR ANESTHESIA IN ASYMPTOMATIC PATIENTS
- Supplemental Intraligamentary Injection
- Supplemental Intraosseous Injection
- Use of Mannitol

MAXILLARY ANESTHESIA WITH 2% LIDOCAINE AND 1:100,000 EPINEPHRINE
- Success Rate
- Onset of Anesthesia
- Duration of Anesthesia
- Time Course of Pulpal Anesthesia for the Maxillary First Molar
- Significance of Lip Numbness

ALTERNATIVE ANESTHETIC SOLUTIONS FOR INFILTRATION INJECTIONS
- Plain Solutions: 3% Mepivacaine (Carbocaine, Polocaine, Scandonest) and 4% Prilocaine (Citanest Plain)
- 4% Prilocaine with 1:200,000 Epinephrine (Citanest Forte)
- Articaine with 1:100,000 Epinephrine (Septocaine)
- 0.5% Bupivacaine with 1:200,000 Epinephrine (Marcaine)

EXTENDING THE DURATION OF MAXILLARY INFILTRATIONS
- Increasing the Solution Volume

ALTERNATIVE MAXILLARY INJECTION TECHNIQUES
Posterior Superior Alveolar (PSA) Nerve Block
Infraorbital Nerve Block
Second Division Nerve Block
Palatal–Anterior Superior Alveolar (P-ASA) Nerve Block
Anterior Middle Superior Alveolar (AMSA) Nerve Block
SUPPLEMENTAL ANESTHESIA
Infiltrations of Articaine Following Maxillary or Mandibular Anesthesia in Patients With Irreversible Pulpitis
Supplemental Buccal Infiltration of Articaine After a Failed Inferior Alveolar Nerve Block in Patients With Irreversible Pulpitis
Intraligamentary Anesthesia
Intraosseous Anesthesia
Intrapulpal Injection
MANAGEMENT OF SPECIFIC ENDODONTIC SITUATIONS
Irreversible Pulpitis
Incision and Drainage
Periradicular Surgery
Interim Treatment for Irreversible Pulpitis Using Pulpotomy
Pain Reduction in Irreversible Pulpitis When Endodontic Treatment Is Impossible
Oral Conscious Sedation
SUMMARY AND FUTURE DIRECTIONS

Effective local anesthesia is the bedrock of pain control in endodontics. Regardless of the clinician's skills, endodontic treatment cannot be delivered without effective pain control. This chapter reviews the pharmacology of local anesthetics and the relative advantages and limitations of various anesthetics and routes of administration. Other chapters in this book provide complementary information on the use of local anesthetics in diagnosis (see Chapter 1), the treatment of emergency patients (see Chapter 2), and the development of a comprehensive pain-control plan (see Chapter 19). The authors assume that the reader is familiar with various anesthetic injection techniques; several excellent texts are available for review regarding this point.[116,158]

MECHANISMS OF ACTION FOR ANESTHETICS

Most dental pharmacology courses teach that local anesthetics block sodium channels by partitioning into two types, the uncharged basic form of the molecule (RN), which crosses cell membranes, and the charged acid form of the molecule (RNH^+), which binds to the inner pore of the sodium channel. As a first approximation, this model is reasonably accurate. However, molecular research has demonstrated the existence of at least nine subtypes of voltage-gated sodium channels (VGSCs) that differ in their expression pattern, biophysical properties, and roles in mediating peripheral pain (Table 20-1). These channels have a clear clinical relevance.[18,101,143]

The broad class of VGSCs can be divided into channels that are blocked by a toxin (tetrodotoxin [TTX]) and those that are resistant to the toxin (TTX-R). Most TTX-R channels are found primarily on nociceptors (e.g., Na_v 1.8 and Na_v 1.9).[273] These channels also are relatively resistant to local anesthetics[216] and are sensitized by prostaglandins.[83] As is explained later in the chapter, the presence of TTX-R sodium channels may explain why local anesthetics are less effective when injected into patients with odontalgia. Moreover, the sensitization of these channels by prostaglandins suggests that rapid-acting nonsteroidal antiinflammatory drugs (NSAIDs) may be useful as a pretreatment to enhance the efficacy of local anesthetics in patients with odontogenic pain[112,179] (see Chapter 19). Many of the adverse effects of local anesthetics are attributed to their ability to block other VGSCs expressed in the central nervous system (CNS) or heart (see Table 20-1).

VGSCs consist of an alpha (α) and a beta (β) subunit. The α subunit serves as a voltage sensor, leading to channel activation and sodium ion passage when the channel detects an electrical field. The biologic basis for an electrical pulp tester, therefore, is the generation of a small electrical field across the dental pulp that can activate VGSCs.[101] Interestingly, sensitization of TTX-R channels by prostaglandins lowers the activation threshold and increases the amount of sodium ions that flow through the channel.[83] Put another way, an inflammation-induced elevation in prostaglandin levels sensitizes TTX-R channels, leading to depolarization at lower levels of stimulus strengths. This may explain the increased responsiveness to electrical pulp testing seen in patients with irreversible pulpitis.

Local anesthetics have other mechanisms that may contribute to their pharmacology for treating odontogenic pain. For example, local anesthetics modulate certain G protein–coupled receptors (GPCRs). The GPCRs are a major class of cell membrane receptors, and many classes of dental drugs (e.g., opioids, catecholamines) and endogenous mediators produce their effects by activating specific GPCRs and their related second

TABLE 20-1

Voltage-Gated Sodium Channels and Pain

Channel Subtype	Tissue Expression	Tetrodotoxin Sensitive	Peripheral Role in Pain
Na_v 1.1	Central nervous system (CNS), sensory neurons	Yes	?
Na_v 1.2	CNS	Yes	No
Na_v 1.3	CNS	Yes	No
Na_v 1.4	Muscle	Yes	No
Na_v 1.5	Heart	Somewhat	No
Na_v 1.6	CNS, sensory neurons	Yes	?
Na_v 1.7	CNS, sensory neurons	Yes	?
Na_v 1.8	Sensory neurons	No	Yes
Na_v 1.9	Sensory neurons	No	Yes

messenger pathways. Studies suggest that local anesthetics inhibit the G-alpha-q ($G_{\alpha q}$) class of GPCRs, which includes receptors activated by inflammatory mediators such as bradykinin.[108] Local anesthetics may therefore block the actions of a major hyperalgesic agent.

Other studies have indicated that local anesthetics potentiate the actions of the G-alpha-i ($G_{\alpha i}$) class of GPCRs.[11] This could have a major effect in potentiating the actions of vasoconstrictors, including the newly recognized analgesic role that vasoconstrictors play in inhibiting pulpal nociceptors.[20,100] Prolonged alteration of GPCR function might explain why analgesia obtained with long-acting local anesthetics persists well beyond the period of anesthesia.[40,55,185] More research is needed on this exciting aspect of local anesthetic pharmacology.

CLINICALLY AVAILABLE LOCAL ANESTHETICS

The most common forms of injectable local anesthetics are in the amide class. In 2003, the American Dental Association specified a uniform color code for dental cartridges to prevent confusion among brands (see www.ada.org/prof/resources/topics/color.asp) (Table 20-2). Local anesthetics can be divided roughly into three types: short duration (30 minutes of pulpal anesthesia), intermediate duration (60 minutes of pulpal anesthesia), and long duration (over 90 minutes of pulpal anesthesia). However, clinical anesthesia does not always follow these guidelines, depending on whether the local anesthetic is used as a block or for infiltration. For example, bupivacaine is classified as a long-acting agent, and when it is used in an inferior alveolar nerve (IAN) block, this is true.[58] But when it is used for infiltration for anterior teeth, it has a shorter duration of anesthetic action than 2% lidocaine with 1:100,000 epinephrine[43,90] (discussed in more detail later in the chapter).

SELECTION OF A LOCAL ANESTHETIC: POSSIBLE ADVERSE EFFECTS, MEDICAL HISTORY, PREOPERATIVE ANXIETY

Possible Adverse Effects

Possible adverse reactions to local anesthetics can be divided into six major categories: cardiovascular reactions, systemic effects, methemoglobinemia, peripheral nerve paresthesia, allergic reactions to the anesthetic and/or latex, and reactions to anesthetics containing a sulfite antioxidant. These reactions range from fairly common (e.g., tachycardia after intraosseous injection of 2% lidocaine with 1:100,000 epinephrine) to extremely rare (e.g., allergic reactions to lidocaine).

Cardiovascular Reactions

Although classic research studies have reported that large dosages or intravenous (IV) injections of local anesthetics were required to produce cardiovascular effects,[114,262] it now is well recognized that even comparatively small amounts of epinephrine can induce measurable tachycardia after nerve block or intraosseous injection.[59,85,220] Several authors have reported increases in heart rate with infiltration injections and nerve blocks using 2% lidocaine with 1:100,000 epinephrine[1,102,140,234,261]; others have reported that no significant changes in heart rate occurred or that the changes were clinically insignificant.[173,260,264] When specific information was given on dosing and heart rate increases, several studies found mean heart rate increases.[1,102,139,261] Two studies found increases on average of about 4 beats/min with approximately 20 µg of epinephrine[102,139]; three studies recorded increases of 10 to 15 beats/min with 45 to 80 µg of epinephrine[1,139,234]; and one study found increases of approximately 21 beats/min using 144 µg of epinephrine.[261] Increasing the amount of epinephrine in an

TABLE 20-2

Local Anesthetics Available in the United States

Anesthetic	Vasoconstrictor	Dental Cartridge Color Codes*†	Maximum Allowable Dose*	Typical Maximum Dose†
2% Lidocaine	1:100,000 epinephrine	Red	13	8
2% Lidocaine	1:50,000 epinephrine	Green	13	8
2% Lidocaine	Plain (no vasoconstrictor)	Light Blue	8	8
2% Mepivacaine	1:20,000 levonordefrin	Brown	11	8
3% Mepivacaine	Plain (no vasoconstrictor)	Tan	7	5½
4% Prilocaine	1:200,000 epinephrine	Yellow	5½	5½
4% Prilocaine	Plain (no vasoconstrictor)	Black	5½	5½
0.5% Bupivacaine	1:200,00 epinephrine	Blue	10	10
4% Articaine	1:100,000 epinephrine	Gold	7	7
4% Articaine	1:200,000 epinephrine	Silver	7	7

*NOTE: This table provides the maximum dosage in two formats. The *Maximum Allowable Dose* generally is approached only with complex oral and maxillofacial surgical procedures. The *Typical Maximum Dose* is the usual outer envelope of drug dosage for most endodontic, surgical, and restorative dental procedures. Both columns show the number of cartridges that would be required for an adult weighing 150 pounds (67.5 kg).

†Uniform dental cartridge color codes mandated by the American Dental Association (June 2003).

infiltration or block injection therefore increases the likelihood of an elevated heart rate.

Tachycardia after injection is primarily a pharmacologic effect. The cardiovascular effects are the result of α-adrenoceptor stimulation by systemic distribution of the vasoconstrictor throughout the vascular compartment. The patient may also report heart palpitations associated with anxiety or fear and may experience transient tachycardia and changes in blood pressure. Large doses or inadvertent IV injection may lead to lidocaine toxicity and CNS depression.[61,189] To reduce this risk, the clinician should always aspirate before making the injection, inject slowly, and use dosages within accepted guidelines. The maximal dosages for local anesthetics are listed in Table 20-2.

Systemic Effects

The acute toxicity of an overdose of a local anesthetic often is the result of inadvertent IV administration or of a cumulative large dose (e.g., repeated injections). As shown in Table 20-1, VGSCs are found in the CNS and the myocardium, the two major areas of anesthetic-induced toxicity. Although systemic effects from a local anesthetic are rare, they can include an initial excitatory phase (e.g., muscle twitching, tremors, grand mal convulsions) and a subsequent depressive phase (e.g., sedation, hypotension, and respiratory arrest).[48,61] It should be noted that symptomatic management (possibly including cardiopulmonary resuscitation [CPR], airway support, and supplemental oxygen) is the primary response to this adverse event.[135,137] An acute hypotensive crisis with respiratory failure also has been interpreted as the result of hypersensitivity to local anesthetics[30]; these patients should be evaluated with allergy testing. To reduce the risk of systemic effects from anesthetics, the clinician must always aspirate before giving the injection and must use dosages within accepted guidelines (see Table 20-2). Finder and Moore[61] proposed a "rule of 25" as a simple means of remembering maximal local anesthetic dosages: with currently formulated local anesthetic cartridges, it generally is safe to use one cartridge of local anesthetic for every 25 pounds of patient weight (e.g., six cartridges for a patient weighing 150 pounds [67.5 kg]).

Methemoglobinemia

Metabolism of certain local anesthetics (e.g., prilocaine, benzocaine, articaine, and to a lesser extent lidocaine) can produce a metabolite that causes methemoglobinemia; this effect often occurs several hours after injection of the local anesthetic.[162,276] Typical signs and symptoms include cyanosis, dyspnea, emesis, and headache. In a study on benzocaine-induced methemoglobinemia, 67% of reported adverse effects of benzocaine were associated with methemoglobinemia; of these events, 93% occurred with spray formulations of benzocaine, and only one case involved the gel formulation.[186] To reduce the risk of methemoglobinemia, clinicians should take care to refrain from giving excessive dosages of local anesthetics.

Peripheral Nerve Paresthesia

Postinjection paresthesia is a rare adverse effect of local anesthetics.[96,162,282] A retrospective study reported that articaine is associated with a fivefold higher incidence of paresthesia compared with lidocaine.[96] A recent study evaluated patients referred with a diagnosis of damage to the inferior alveolar and/or lingual nerve which could only have resulted from an IAN block.[212] Thirty-five percent were caused by a lidocaine formulation, and 30% were caused by an articaine formulation. The conclusion was that there was not a disproportionate nerve involvement from articaine. However, with any paresthesia, documentation of the patient's reported area of altered sensation, the type of altered sensation (e.g., anesthesia, paresthesia, dysesthesia), and regular follow-up are important.

Allergic Reactions to Local Anesthetics and Latex

The amide local anesthetics appear to have little immunogenicity and therefore have an extremely low rate of allergic reactions.[239] One study included more than 140 patients specifically referred for allergy testing because of adverse effects after injection of a local anesthetic; none of these patients had hypersensitivity reactions to intradermal local anesthetics,[228] but case reports of hypersensitivity reactions after administration of local anesthetics have been published.[19,30,187,239] Some concern has been raised that the rubber latex stopper in dental anesthetic cartridges might be a source of allergen to patients allergic to latex. In a review of this literature (1966 to 2001), Shojaei and Haas[241] concluded that some evidence for exposure to the latex allergen exists, although no causal study has been published.

Reactions to Anesthetic Formulations Containing a Sulfite Antioxidant

Local anesthetic formulations that contain vasoconstrictors also contain sulfite to prevent oxidation of this agent. Sulfite-induced reactions came to prominence with the report of six deaths after exposure to salad bars or homemade wine.[6] Common reported signs and symptoms include allergic-like reactions such as urticaria, bronchospasm, and anaphylaxis. Risk factors include an active history of asthma (perhaps 5% of asthmatics are at risk) and atopic allergy. The use of local anesthetics without vasoconstrictors is a possible alternative with these patients. No sulfite reaction in dental practice has ever been documented, possibly because the amount of sulfite in local anesthetic cartridges is relatively small.

EFFECTS OF SYSTEMIC DISEASES OR CONDITIONS ON LOCAL ANESTHETICS

Several systemic diseases or disorders may require modification of the dosage of local anesthetic. Cardiac patients (e.g., those with unstable angina pectoris, history of myocardial infarction or stroke within the past 6 months, severe hypertension, uncontrolled congestive heart failure, or heart transplant) should not receive a local anesthetic containing a vasoconstrictor and should consult their physicians before undergoing endodontic treatment.[189] A review suggests that patients with Hodgkin's disease or breast cancer who have received radiation treatment to the chest are at risk for radiation-induced coronary artery disease, and this condition also may require medical consultation regarding a reduced dosage of local anesthetic containing a vasoconstrictor.[65]

Alcoholics have been found to be more sensitive to painful stimulation.[254] Alcoholics with a history of depression/unhappiness may also have shallower pulpal anesthesia.[62] In contrast, alcoholics in recovery may not be at increased risk for inadequate pain control with local anesthesia.[62]

Any of the commonly available local anesthetics are safe for use in pregnant or lactating women.[97] The most important aspect of care with pregnant patients is to eliminate the source of pain by performing the indicated endodontic treatment; this reduces the need for systemic medications.[97]

Local anesthetics may interact with a patient's medications, so a thorough review of the medical history is an absolute requirement. Potential drug-drug interactions occur primarily with the vasoconstrictors in local anesthetic formulations (Table 20-3). Judicious use of local anesthetic solutions without vasoconstrictors (e.g., 3% mepivacaine) is a reasonable alternative for adult patients.

Authors have found that women try to avoid pain more than men, accept it less, and fear it more.[51,60,147,188] A study found women find postsurgical pain more intense than males, but men are more disturbed than women by low levels of pain that lasts several days.[188] Another study found gender differences in analgesia for postoperative endodontic pain.[233] Anxiety may also modulate differences in pain responses between males and females. We should be aware that women might react differently to pain than men.[60]

CLINICAL ANESTHESIA AND ROUTES OF ADMINISTRATION

Recognition is growing that evidence-based therapeutics offers an excellent source of information that should become an aspect of treatment in conjunction with the practitioner's clinical skills and the patient's particular needs. In many areas of dentistry, this is a limited concept because few randomized, placebo-controlled, double-blind clinical trials have been conducted. However, this is not the case with dental pharmacology. The astute clinician can make informed decisions on various local anesthetics and routes of injection based on a large collection of well-designed clinical trials. The following discussion focuses on the clinical aspects of local anesthesia, with special emphasis on endodontics.

IMPORTANT CLINICAL FACTORS IN LOCAL ANESTHESIA

Traditional Methods of Confirming Anesthesia

Traditional methods of confirming anesthesia usually involve questioning the patient ("Is your lip numb?"), soft-tissue testing (e.g., lack of mucosal responsiveness to a sharp explorer), or simply beginning treatment. However, these approaches may not be effective for determining pulpal anesthesia.[28,106,169,266] Moreover, from a research perspective, they provide only bimodal responses (e.g., yes or no) and therefore are of little use for detecting parametric differences between anesthetics or routes of injection.

Determining Pulpal Anesthesia in Painless Vital Teeth

Anesthesia in painless vital teeth can be measured more objectively by applying a cold refrigerant (Fig. 20-1) or by using an electric pulp tester (EPT; Fig. 20-2). Application of cold or the electric pulp tester can be used to test the tooth under treatment for pulpal anesthesia before a clinical procedure is started.[26,52,120,154]

TABLE 20-3

Possible Drug Interactions With Vasoconstrictors

Drugs	Possible Adverse Effects	Recommendations
TRICYCLIC ANTIDEPRESSANTS		
Amitriptyline, doxepin	Increased cardiovascular responses	Reduce or eliminate vasoconstrictors
NONSELECTIVE β-BLOCKERS		
Nadolol, propranolol	Hypertension, bradycardia	Reduce or eliminate vasoconstrictors
RECREATIONAL DRUGS		
Cocaine	Hypertension, myocardial infarction, dysrhythmias	Instruct patient to abstain from drug use for 48 hours before procedure; do not use vasoconstrictors
COMT INHIBITORS		
Entacapone, tolcapone	Increased cardiovascular responses	Reduce or eliminate vasoconstrictors
ANTIADRENERGIC DRUGS		
Guanadrel, guanethidine	Increased cardiovascular responses	Reduce or eliminate vasoconstrictors
NONSELECTIVE α-ADRENERGIC BLOCKERS		
Chlorpromazine, clozapine, haloperidol	Increased cardiovascular responses	Reduce or eliminate vasoconstrictors
DIGITALIS		
Digoxin	Dysrhythmias (especially with large dosage of vasoconstrictor)	Reduce or eliminate vasoconstrictor
THYROID HORMONES		
Levothyroxine	Dysrhythmias (especially with large dosage of vasoconstrictor)	*Euthyroid:* No precaution *Hyperthyroid:* Reduce or eliminate vasoconstrictors
MONOAMINE OXIDASE[35] INHIBITORS		
Furazolidone, linezolid, selegiline, tranylcypromine	No interaction	None

Modified from Naftalin L, Yagiela JA: Vasoconstrictors: indications and precautions. *Dent Clin North Am* 46:733, 2002.

Determining Pulpal Anesthesia in Painful Vital Teeth

In painful vital teeth and after administration of local anesthesia, the cold test or electric pulp tester can be used to test for

FIG. 20-1 A cold refrigerant may be used to test for pulpal anesthesia before the start of a clinical procedure. *(Courtesy Coltene Whaledent, Mahwah, NJ.)*

FIG. 20-2 An electric pulp tester also may be used to test for pulpal anesthesia before a clinical procedure is started. *(Courtesy SybronEndo, Orange, CA.)*

pulpal anesthesia before an endodontic procedure is started.[36,52,200,217] If the patient responds to the stimulus, pulpal anesthesia has not been obtained, and supplemental anesthesia should be administered. However, in painful vital teeth (e.g., irreversible pulpitis), the lack of a response to pulp testing may not guarantee pulpal anesthesia.[52,200,217] Therefore, if a patient experiences pain when the endodontic procedure is started, supplemental anesthesia is indicated regardless of the responsiveness to pulpal testing. If the chamber is necrotic and the canals are vital, no objective test can predict the level of clinical anesthesia.

Patient Who Has Had Previous Difficulty With Anesthesia

Anesthesia is more likely to be unsuccessful in patients who report a history of previous difficulty with anesthesia.[129] These patients generally make comments such as "Novocaine doesn't work on me" or "It takes a lot of shots to get my teeth numb." A good clinical practice is to ask the patient if dentists previously have had difficulty obtaining anesthesia in the individual's mouth. If the answer is yes, supplemental injections should be considered.

Failure to Achieve Anesthesia in Patients With Pain

Obtaining anesthesia often is difficult in patients with endodontic pain who have pulpal pathosis. A number of explanations have been proposed for this.[101] One is that conventional anesthetic techniques do not always provide profound pulpal anesthesia, and patients with preexisting hyperalgesia may be unable to tolerate any noxious input. Another explanation relates to the theory that inflamed tissue has a lower pH, which reduces the amount of the base form of anesthetic that penetrates the nerve membrane. Consequently, less of the ionized form is available in the nerve to achieve anesthesia. This explanation does not account for the mandibular molar with pulpitis that is not readily blocked by an inferior alveolar injection administered at some distance from the area of inflammation. Correlating localized inflammatory changes with failure of the IAN block is difficult.

Another explanation for failure is that nerves arising from inflamed tissue have altered resting potentials and decreased excitability thresholds.[24,268] Two studies demonstrated that local anesthetics were unable to prevent impulse transmission because of these lowered excitability thresholds.[180,268] Another factor might be the TTX-R sodium channels, which are resistant to the action of local anesthetics[232] and are increased in inflamed dental pulp.[271,273] A related factor is the increased expression of sodium channels in pulps diagnosed with irreversible pulpitis.[250,271,273]

Finally, patients in pain often are apprehensive, which lowers the pain threshold. Therefore practitioners should consider supplemental techniques (e.g., intraosseous injections[197,200,206,217] or periodontal ligament injections[36]) if an IAN block fails to provide pulpal anesthesia for patients with irreversible pulpitis.

Use of Topical Anesthetics

Fear of needle insertion is a major cause of apprehension in dental patients.[138,177,178] Although some studies have demonstrated the effectiveness of topical anesthetics,[102,108,192,215] others have shown no significant pain reduction.[82,131,163] Interestingly, one study showed that patients who thought they were receiving a topical anesthetic anticipated less pain regardless of whether they actually received the anesthetic.[163] The most important aspect of a topical anesthetic may not be its clinical effectiveness but rather its psychologic effect on the patient who believes the practitioner is doing everything possible to prevent pain.

Reversing the Action of Local Anesthesia

Phentolamine mesylate (0.4 mg in a 1.7 ml cartridge, OraVerse, Novalar Pharmaceuticals, San Diego, CA) is a recently developed agent that shortens the duration of soft-tissue anesthesia. The duration of soft-tissue anesthesia is longer than pulpal anesthesia and is often associated with difficulty eating, drinking, and speaking.[104,144] The greatest value of using OraVerse is in the majority of dental procedures where postoperative pain is not of concern. However, some endodontic patients may benefit from the use of a reversal agent when they have speaking engagements, important meetings, or perform in musical or theatrical events. OraVerse may be used to shorten the duration of soft-tissue anesthesia if the patient presents with an asymptomatic tooth and little postoperative pain is anticipated.

MANDIBULAR ANESTHESIA WITH 2% LIDOCAINE AND 1:100,000 EPINEPHRINE

Because failure occurs most often with the IAN block,[129] factors that modify mandibular anesthesia must be carefully reviewed. The technique for administering an IAN block can be reviewed in available textbooks.[116,158] This discussion reviews the expected outcomes after administration of a conventional IAN block to asymptomatic patients using 1.8 ml of 2% lidocaine with 1:100,000 epinephrine (Xylocaine, Lignospan, Octocaine). Although anesthesia requirements vary among dental procedures, the following discussion concentrates on *pulpal* anesthesia.

Anesthetic Success

One way to define anesthetic success is the percentage of subjects who achieve two consecutive 80 readings on electric pulp testing within 15 minutes and continuously sustain this lack of responsiveness for 60 minutes. In other words, the objective is to achieve anesthesia within 15 minutes and to have it last 1 hour. This endpoint is as important for restorative dentistry as it is for endodontic treatment, so it is used as a benchmark for clinically significant information from research on local anesthetics. Using this criterion, the percentage of cases in which anesthesia was obtained after IAN block injections ranged from 35% (lateral incisor) to 60% (first premolar and first molar).* It is important to note that all patients from these studies reported a positive lip sign (e.g., profound lip numbness); therefore profound lip numbness does *not* predict pulpal anesthesia. However, lack of soft-tissue anesthesia is a useful indicator that the block injection was not administered accurately for that patient. Missed blocks occur in about 5% of cases, and the clinician should readminister the nerve block before continuing with treatment.

Anesthetic Failure

Anesthetic failure can be defined as the percentage of subjects who never achieved two consecutive 80 EPT readings at any time during a 60-minute period. Using this criterion, anesthetic failure ranged from 11% (first premolar) to 32% (lateral incisor).†

*References 28, 58, 99, 106, 169, 199, and 266.

†References 28, 58, 99, 106, 169, 199, 243, 266, 267.

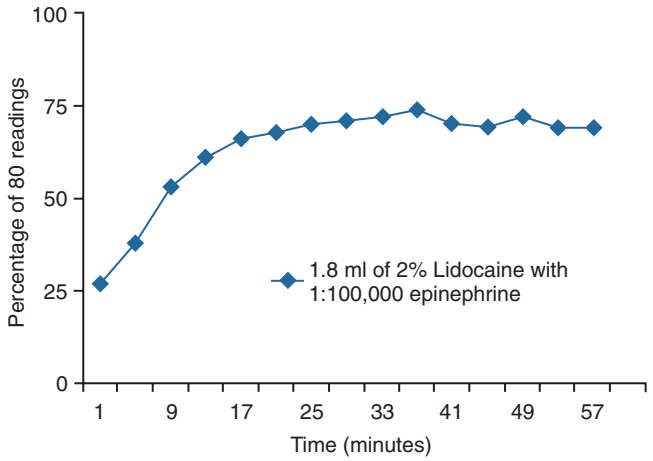

FIG. 20-3 Incidence of first mandibular molar anesthesia as determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes.

Noncontinuous Anesthesia

Another measure of mandibular anesthesia is noncontinuous anesthesia, which may be related to the action of the anesthetic solution on the nerve membrane (blocking and unblocking the sodium channels). This occurs in about 12% to 20% of cases in mandibular teeth.*

Slow Onset

After a conventional IAN block injection, the onset of pulpal anesthesia occurs within 10 to 15 minutes in most cases (Fig. 20-3).† *Slow onset* can be defined as the percentage of subjects who achieved an 80 EPT reading after 15 minutes. In mandibular teeth, slow onset occurs in 19% to 27% of patients.

Duration

The duration of action for pulpal anesthesia in the mandible is very good.‡ If patients are anesthetized initially, anesthesia usually persists for approximately 2½ hours.[58] Fig. 20-3 depicts the time course for complete pulpal anesthesia for an asymptomatic first molar, as defined by the percentage of patients who did not respond to an 80 stimulus (EPT) across time for 60 minutes. Most patients achieved pulpal anesthesia within 15 minutes and had a duration of anesthesia of at least 1 hour, but the success rate was not 100% for the population.

ALTERNATIVE ANESTHETIC SOLUTIONS FOR THE INFERIOR ALVEOLAR NERVE BLOCK

Plain Solutions: 3% Mepivacaine (Carbocaine, Polocaine, Scandonest) and 4% Prilocaine (Citanest Plain)

In a study of volunteers without dental pathosis, anesthesia from IAN injection of 3% mepivacaine plain and 4% prilocaine plain were as effective as 2% lidocaine with 1:100,000

*References 28, 92, 99, 106, 142, 169, 199, 266, and 290.

†References 28, 58, 99, 106, 169, 199, 243, 266, and 267.

‡References 28, 58, 99, 106, 169, 199, 243, 266, and 267.

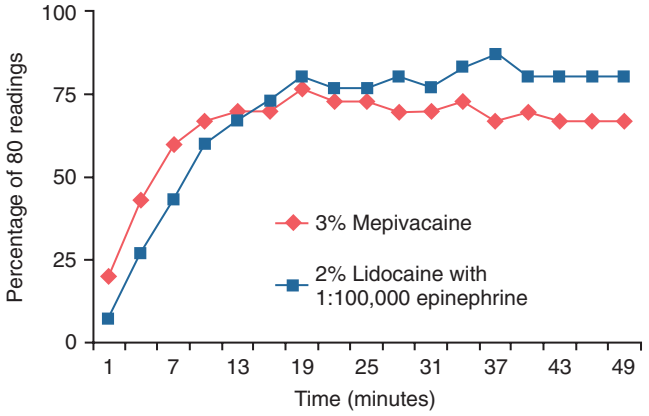

FIG. 20-4 Incidence of first mandibular molar anesthesia: comparison of 3% mepivacaine to 2% lidocaine with 1:100,000 epinephrine. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 50 minutes. No significant difference between the two solutions was noted.

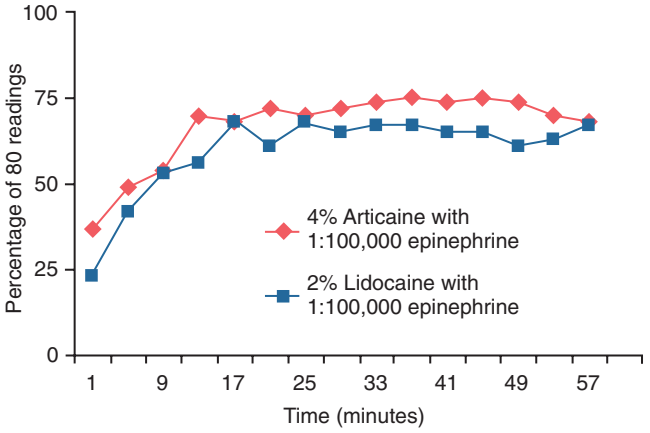

FIG. 20-5 Incidence of first mandibular molar anesthesia: comparison of 4% articaine with 1:100,000 epinephrine to 2% lidocaine with 1:100,000 epinephrine. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. No significant difference between the two solutions was noted.

(Fig. 20-4).[169] A clinical study of patients with irreversible pulpitis also found that 3% mepivacaine and 2% lidocaine with 1:100,000 epinephrine were equivalent for IAN blocks.[36] These findings support the selection of 3% mepivacaine as a local anesthetic when medical conditions or drug therapies suggest caution in the administration of solutions containing epinephrine.

4% Prilocaine With 1:200,000 Epinephrine (Citanest Forte) and 2% Mepivacaine With 1:20,000 Levonordefrin (Carbocaine With Neo-Cobefrin)

In a study of volunteers without dental pathosis, IAN injection of 4% prilocaine with 1:200,000 epinephrine or 2% mepivacaine with 1:20,000 levonordefrin worked as well as 2% lidocaine with 1:100,000 in achieving pulpal anesthesia.[106]

Levonordefrin has 75% α activity and only 25% β activity, making it seemly more attractive than epinephrine (50% α activity and 50% β activity).[158] However, levonordefrin is marketed as a 1:20,000 concentration in dental cartridges.[158] Clinically, the higher concentration of levonordefrin makes it equipotent to epinephrine in clinical and systemic effects,[92,106] so 1:20,000 levonordefrin offers no clinical advantage over 1:100,000 epinephrine.

Articaine With 1:100,000 Epinephrine (Septocaine)

Articaine has been reported to provide very effective local anesthesia.[236] It was approved for use in the United States in April 2000 and is marketed as Septocaine (Septodont, New Castle, DE) and as a 4% solution with either 1:100,000 or 1:50,000 epinephrine.[162,184] Articaine is classified as an amide. It has a thiophene ring (instead of a benzene ring, as do the other amide local anesthetics) and an extra ester linkage, which results in hydrolysis of articaine by plasma esterases.[162] A number of studies have evaluated articaine and concluded that it is safe when used in appropriate doses.* Lidocaine and articaine have the same maximal dose of 500 mg for adult patients (recommended dose: 6.6 to 7 mg/kg), but the maximum number of cartridges is different because of the differences in drug concentration (see Table 20-2).[158]

Clinical Effectiveness of Articaine for Inferior Alveolar Nerve Blocks

The available literature indicates that articaine is equally effective when statistically compared to other local anesthetics.† When comparing the anesthetic efficacy of 4% articaine with 1:100,000 epinephrine to 2% lidocaine with 1:100,000 epinephrine for IAN blocks, one study found that the two solutions were not significantly different (Fig. 20-5).[176] Two studies found no difference in efficacy between 4% articaine with 1:100,000 and 1:200,000 epinephrine.[184,259] Another study compared the anesthetic efficacy of 4% articaine with 1:100,000 epinephrine to 2% lidocaine with 1:100,000 epinephrine for IAN blocks in patients experiencing irreversible pulpitis, in mandibular posterior teeth.[32] The success rate (none or mild pain upon endodontic access or initial instrumentation) for the IAN block using the articaine solution was 24% and for the lidocaine solution success was 23%. There was no significant difference between the articaine and lidocaine solutions. Neither solution resulted in an acceptable rate of anesthetic success in mandibular posterior teeth. In summary, repeated clinical trials have failed to demonstrate any statistical superiority of articaine over lidocaine for nerve blocks.

Articaine and Uncorroborated Insurance Carrier Warning

A letter was sent to thousands of U.S. dentists in 2006 by insurer Emery and Webb/Ace USA stating, "…we have noticed an increase in reversible and, in some cases, nonreversible paresthesias (with Septocaine) … We are writing you to alert you to these events in hopes that you will not fall victim to one of these incidents."[156] Knowledgeable dentists and educa-

*References 44, 105, 115, 160, 162, 181, 203, 244, and 280.

†References 32, 50, 94, 95, 160, 161, 176, 263, and 281.

tors communicated their concerns, and a Notice of Retraction was issued:

> *Unfortunately, we at Emery & Webb discovered upon further review, and subsequent to the mailings, that both documents contained inaccuracies and an alarmist tone, which was not warranted … Emery and Webb has not noted an increase in malpractice claims or lawsuits in connection with articaine … It should be made clear that Emery and Webb has not conducted any scientific investigation, sampling, testing, or other investigation of the articaine anesthetic, and has no independent knowledge or data which would restrict the use of the product.*[156]

Astute clinicians should be very careful of Web chat sites and colleagues' clinical endorsements, because they may not accurately reflect the correct information regarding articaine.

Long-Acting Anesthetics

Clinical trials with bupivacaine (Marcaine) and etidocaine (Duranest) have been done in patients undergoing oral surgery,[46,230] endodontic treatment,[55,185] and periodontic treatment.[40,151] Etidocaine was recently withdrawn from the market by DENTSPLY Pharmaceuticals (York, PA). Bupivacaine provides prolonged analgesia and is indicated when postoperative pain is anticipated, but not all patients want lip numbness for an extended period.[230] Patients should be questioned about their preference. Bupivacaine has a somewhat slower onset than lidocaine, but its duration of pulpal anesthesia in the mandible is almost twice as long (approximately 4 hours; Fig. 20-6).[58]

Ropivacaine (Naropin), a relatively new long-acting local anesthetic, is a structural homolog of bupivacaine.[132] A number of studies have shown that ropivacaine has a lower potential for toxic CNS and cardiovascular effects than bupivacaine but produces equivalent pharmacologic effects.[132] Ropivacaine and levobupivacaine are being developed as potentially new local anesthetics based on their stereochemistry. Both are S-isomers and are thought to cause less toxicity than the racemic mixture of bupivacaine currently marketed.[245] A clinical trial has indicated that levobupivacaine showed significantly better postoperative pain control at 4 and 24 hours after infiltration injection than ropivacaine.[205] Because of their decreased potential for cardiac and CNS toxicity, ropivacaine and levobupivacaine may replace bupivacaine with epinephrine in clinical dental practice.

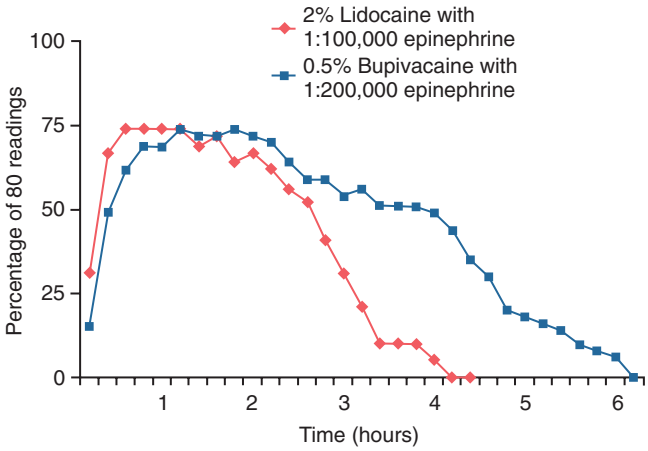

FIG. 20-6 Incidence of first mandibular molar anesthesia: comparison of 0.5% bupivacaine with 1:200,000 epinephrine to 2% lidocaine with 1:100,000 epinephrine. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 6 hours. The bupivacaine solution showed a longer duration of anesthesia than the lidocaine solution.

ALTERNATIVE INJECTION SITES

Gow-Gates and Vazirani-Akinosi Techniques

Some clinicians have reported that the Gow-Gates technique[88] has a higher success rate than the conventional IAN block injection,[157,158] but controlled experimental studies have failed to show superiority of the Gow-Gates technique.[2,84,182,258] Neither has the Vazirani-Akinosi technique[3,84,158] been found superior to the standard inferior alveolar injection.[84,164,246,258,288] In a small study of 21 patients, no difference was found between lidocaine (11 patients) and articaine (10 patients) formulations for the Gow-Gates injection in patients with irreversible pulpitis.[240] These techniques do not replace the conventional IAN block. The Vazirani-Akinosi technique is indicated for cases involving a limited mandibular opening.

Incisive Nerve Block at the Mental Foramen

The incisive nerve block alone is successful for anesthetizing the premolar teeth,[121,193,275] but it does not anesthetize the central and lateral incisors.[193] A slow injection (60 seconds) did not increase success over a fast injection (15 seconds).[275] The combination of an incisive nerve block and an IAN block increases success of anesthetization of mandibular first molars, but an intraosseous or PDL injection is a better choice for supplemental anesthesia of the first molar if the IAN block fails.[193]

Infiltration Injections of a Lidocaine Solution

Labial or lingual infiltration injections alone are not very effective for obtaining pulpal anesthesia in mandibular teeth.[94,95,286] A combination of labial and lingual infiltration significantly increases success in anterior teeth over either labial or lingual infiltration alone.[172] Adding a labial infiltration (1.8 ml of 2% lidocaine with 1:100,000 epinephrine) to a conventional IAN injection increases the success of pulpal anesthesia in mandibular anterior teeth but not in the mandibular first molar.[33,64]

Mandibular First Molar Infiltration Injections of an Articaine Solution

Four studies showed articaine was significantly better than lidocaine for a primary buccal infiltration of the mandibular first molar.[38,122,124,225] Success rates (two consecutive 80 readings with the electric pulp tester) of 64%, 54%, 64% to 70%, and 87% were recorded for an articaine formulation in these studies. However, the duration of pulpal anesthesia declined over 60 minutes.

Mandibular First Molar Infiltration Injections of an Articaine Solution Following an Inferior Alveolar Nerve Block

A recent study found 4% articaine with 1:100,000 epinephrine resulted in a higher success rate (88%) than 2% lidocaine

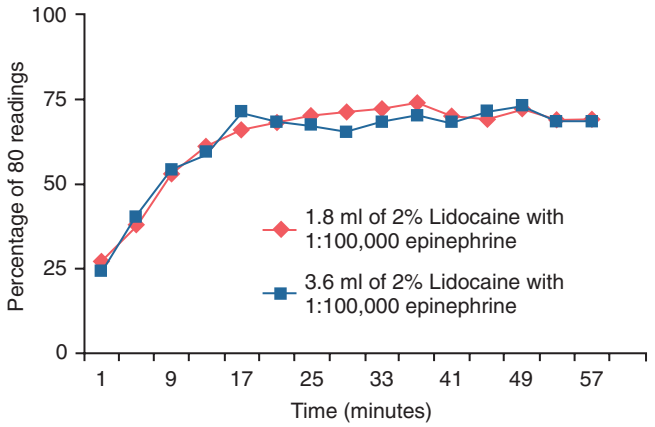

FIG. 20-7 Incidence of first mandibular molar anesthesia: comparison of 3.6 ml and 1.8 ml of 2% lidocaine with 1:100,000 epinephrine. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. No significant difference between the two volumes was noted.

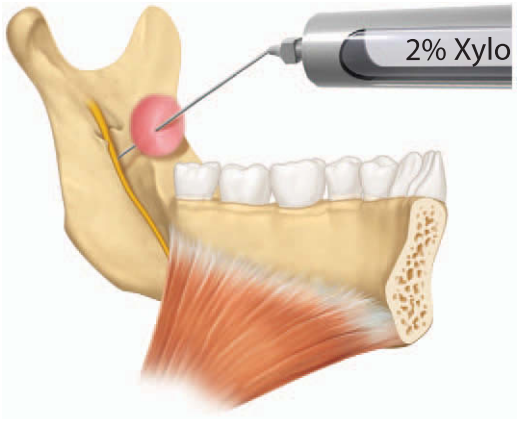

FIG. 20-8 Injection site for the mylohyoid nerve block.

with 1:100,000 epinephrine (71% success rate) for mandibular first molar buccal infiltrations following an IAN block.[98] Success was defined as achieving two consecutive 80 readings within 10 minutes following the IAN block plus infiltration injections, and the 80 reading was continuously sustained through the 60th minute. The finding is important to dentists and patients because we now have a way to help anesthetize the mandibular first molar when the IAN block fails in asymptomatic patients.

ATTEMPTS TO INCREASE SUCCESS OF THE INFERIOR ALVEOLAR NERVE BLOCK

Increasing the Volume of Anesthetic

A possible method for increasing anesthetic success is to double the injection volume of local anesthetic solution. However, increasing the volume of 2% lidocaine with epinephrine to 3.6 ml (two cartridges) does not increase the incidence of pulpal anesthesia with the IAN block (Fig. 20-7).

Increasing the Epinephrine Concentration

A second approach for increasing the success of the IAN block is to increase the concentration of epinephrine. However, when this technique was evaluated in clinically normal teeth, no advantage was seen in using a higher concentration (1:50,000) of epinephrine.[42,267]

Addition of Hyaluronidase

Hyaluronidase reduces the viscosity of the injected tissue, permitting a wider spread of injected fluids.[7] Early studies in dentistry found that an IAN block was more easily attained and was more complete when hyaluronidase was added to an anesthetic solution.[136,155] However, a controlled clinical trial found that adding hyaluronidase to a lidocaine solution with epinephrine did not statistically increase the incidence of pulpal anesthesia in IAN blocks.[222] In addition, hyaluronidase increased the occurrence of adverse effects (i.e., increased pain and trismus).[222]

Carbonated Anesthetic Solutions

Experimentally, carbonated anesthetic solutions are more effective because the anesthetic is trapped in the nerve.[28] In addition, carbon dioxide (CO_2) has a synergistic relationship with local anesthetics and a direct depressant action on nerves.[28] However, a controlled clinical study was unable to demonstrate a superior effect of lidocaine hydrocarbonate in IAN blocks.[28]

Diphenhydramine as a Local Anesthetic Agent

Diphenhydramine (Benadryl) has been advocated for patients who are allergic to commonly used local anesthetics. Two studies found diphenhydramine was less effective than lidocaine for extractions.[174,272] Another study found the combination of lidocaine/diphenhydramine with epinephrine and diphenhydramine with epinephrine were significantly less effective for pulpal anesthesia than lidocaine with epinephrine for IAN blocks.[277] They also found that the diphenhydramine solutions were more painful upon injection and had a high incidence of moderate postoperative pain.

Addition of Meperidine to Lidocaine

Two studies found the addition of meperidine (Demerol) to a lidocaine formulation did not increase the success of the IAN block.[16,87]

FACTORS IN FAILURE OF THE INFERIOR ALVEOLAR NERVE BLOCK

Accessory Innervation

The mylohyoid nerve is the accessory nerve most often cited as a cause of failure of mandibular anesthesia.[70,278] A controlled clinical trial compared the IAN block alone to a combination of the IAN block and mylohyoid nerve block using 2% lidocaine with 1:100,000 epinephrine (Fig. 20-8), which was aided by the use of a peripheral nerve stimulator.[34] The investigators found that the mylohyoid injection did not significantly enhance pulpal anesthesia of the IAN block (Fig. 20-9), so the study does not support the hypothesis that the mylohyoid nerve is a major factor in failure of the IAN block.

*References 34, 84, 199, 266, 283, and 287.

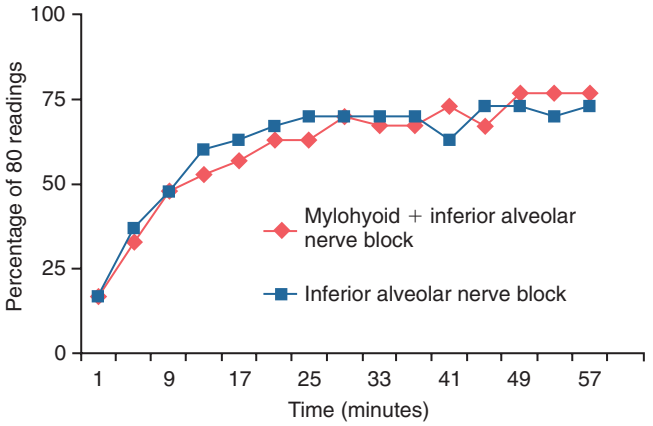

FIG. 20-9 Incidence of first mandibular molar anesthesia: comparison of the combination mylohyoid infiltration plus the inferior alveolar nerve block to the inferior alveolar nerve block alone. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. No significant difference between the two techniques was noted.

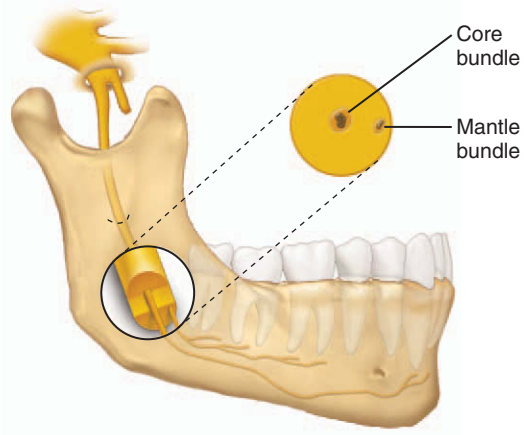

FIG. 20-10 Central core theory. The axons in the mantle bundle supply the molar teeth, and those in the core bundle supply the anterior teeth. The extraneural local anesthetic solution diffuses from the mantle to the core. (*Modified from De Jong RH: Local anesthetics, St Louis, 1994, Mosby.*)

Accuracy of Injection

It has been theorized that an inaccurate injection contributes to inadequate mandibular anesthesia, but a number of studies determined that use of a medical ultrasound unit or radiographs to guide needle placement for IAN blocks did not result in more successful pulpal anesthesia.[14,74,99] The authors of these studies speculated that the anesthetic solution migrated along the path of least resistance, which was determined by fascial planes and structures encountered in the pterygomandibular space. These studies highlight an important clinical point: Lack of pulpal anesthesia is not necessarily the result of an inaccurate injection.

Needle Deflection

Needle deflection has been proposed as a cause of failure with the IAN block.[37,45,107a] Several in vitro studies have shown that beveled needles tend to deflect toward the nonbeveled side (i.e., away from the bevel).* To compensate for this, a bidirectional needle rotation technique using the computer-assisted Wand (CompuDent, Milestone Scientific, Deerfield, IL) has been proposed in which the Wand handpiece assembly and needle are rotated in a fashion similar to the rotation of an endodontic hand file.[107a] The technique was found to reduce deflection during insertion of the needle. A controlled clinical trial compared the anesthetic success of the conventional IAN block using two needle insertion methods.[133] No significant difference in anesthetic success was seen when the needle bevel was oriented away from the mandibular ramus (so that the needle would deflect toward the mandibular foramen [50% success]) and when the bidirectional Wand needle rotation technique was used (56% success).[133] Neither technique resulted in an acceptable rate of anesthetic success in patients with irreversible pulpitis.

*References 4, 37, 45, 107a, 118, and 226.

Needle Bevel and Success

In asymptomatic subjects, the orientation of the needle bevel away or toward the mandibular ramus for an IAN block did not affect anesthetic success or failure.[252] Therefore, the use of commercial needles with markers to indicate needle bevel is not necessary.

Speed of Injection and Success

A slow IAN block injection (60 seconds) resulted in higher success rates (electric pulp testing) than a rapid injection (15 seconds).[123]

Cross-Innervation

Cross-innervation from the contralateral inferior alveolar nerve has been implicated in failure to achieve anesthesia in anterior teeth after an IAN injection. Experimentally, cross-innervation occurs in incisors[227,286] but plays a very small role in failure with IAN block.

A Theory on Why Failure Occurs With the Inferior Alveolar Nerve Block in Asymptomatic Patients

The central core theory may be the best explanation of why failure occurs with the IAN block.[47,255] According to this theory, nerves on the outside of the nerve bundle supply molar teeth, and nerves on the inside of the nerve bundle supply anterior teeth (Fig. 20-10). Even if deposited at the correct site, the anesthetic solution may not diffuse into the nerve trunk and reach all nerves to produce an adequate block. Although this theory may explain the higher experimental failure rates with the IAN block in anterior teeth compared with posterior teeth*, it does not explain the increased failure rate observed in painful teeth.

*References 28, 58, 99, 106, 169, 199, 243, 266, and 267.

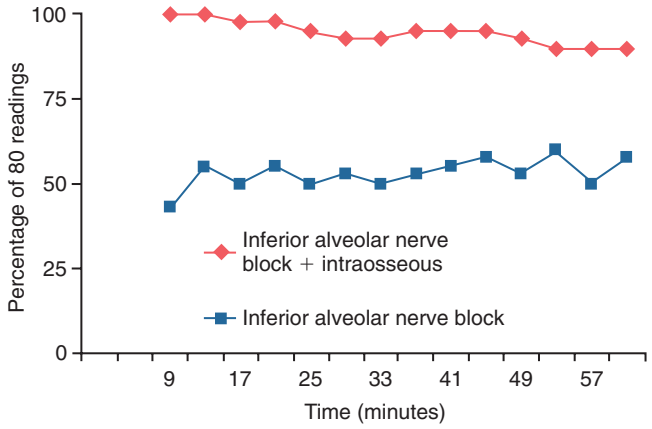

FIG. 20-11 Incidence of first mandibular molar anesthesia: comparison of the combination intraosseous injection of 2% lidocaine with 1:100,000 epinephrine plus the inferior alveolar nerve block to the inferior alveolar nerve block alone. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. The combination technique was significantly better at all postinjection times.

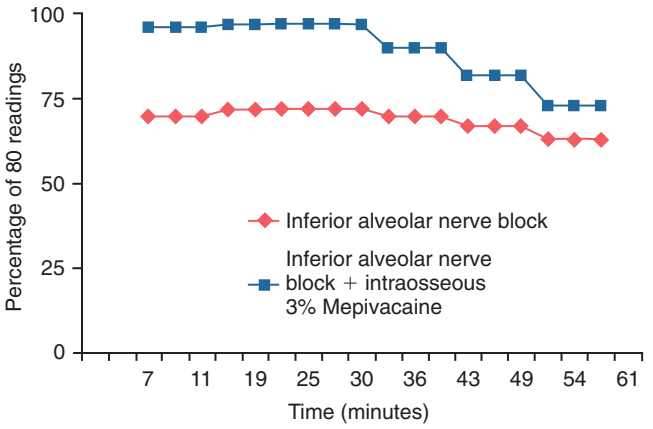

FIG. 20-12 Incidence of first mandibular molar anesthesia: comparison of the combination intraosseous injection with 3% mepivacaine plus the inferior alveolar nerve block to the inferior alveolar nerve block alone. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. The combination technique proved significantly better for approximately 30 minutes.

ENHANCEMENT OF MANDIBULAR ANESTHESIA IN ASYMPTOMATIC PATIENTS

Supplemental Intraligamentary Injection

Experimental studies in volunteers without dental pathosis have shown that the addition of an intraligamentary injection of 2% lidocaine with 1:100,000 epinephrine (delivered with a high-pressure syringe) to an IAN block significantly increased the success of pulpal anesthesia for 23 minutes.[29] The short incidence of anesthesia was related to the small amount of anesthetic solution administered.

Supplemental Intraosseous Injection

Several studies have shown that supplemental Stabident intraosseous injection, when added to an IAN block and using local anesthetics with vasoconstrictors, significantly increased the success of pulpal anesthesia for 60 minutes in the first molar (Fig. 20-11).[54,92,251] The intraosseous injection was more successful than the periodontal ligament injection because more anesthetic solution was delivered with the intraosseous injection. The addition of a supplemental intraosseous injection reduced the incidence of slow onset of pulpal anesthesia to zero compared with the IAN block alone (18% incidence).[54]

Another clinical study has shown that the use of 3% mepivacaine as a supplemental intraosseous injection after an IAN block significantly increased the success of pulpal anesthesia for 30 minutes (Fig. 20-12).[77] The shorter duration of the 3% mepivacaine, compared with 2% lidocaine with 1:100,000 epinephrine, was related to the lack of a vasoconstrictor.

Use of Mannitol

An Ohio State University research group studied the use of mannitol to increase the efficacy of nerve blocks. Mannitol, a hyperosmotic sugar solution, is thought to temporarily disrupt the protective covering (perineurium) of sensory nerves, allowing the local anesthetic to gain entry to the innermost part of the nerve.[8] These researchers found that the use of mannitol in combination with lidocaine increased anesthetic success in IAN blocks about 15% to 20%. The drug combination may be introduced sometime in the future.

MAXILLARY ANESTHESIA WITH 2% LIDOCAINE AND 1:100,000 EPINEPHRINE

Descriptions of conventional techniques for maxillary anesthesia are available for review in numerous articles and textbooks.[116,158]

Clinically, maxillary anesthesia is more easily obtained than mandibular anesthesia.[129] As a frame of reference, the most commonly used injection for anesthetization of maxillary teeth is infiltration with 1.8 ml of 2% lidocaine (1:100,000 epinephrine).

Success Rate

In anterior and posterior teeth, infiltration anesthesia results in a high incidence (90% to 95%) of successful pulpal anesthesia (obtaining an 80 reading on an EPT that ranges from 0 to 80 in intensity).* Failure (never achieving an 80 reading) occurs about 5% to 10% of the time.† Maxillary infiltration anesthesia, therefore, is more successful than an IAN block. The technique does not achieve 100% pulpal anesthesia because of individual variations in response to the drug used and variations in anatomy and tooth position.

Onset of Anesthesia

The onset of pulpal anesthesia usually occurs within 5 to 7 minutes,[90,126,166,175] but slow onset of anesthesia (defined in these cases as achieving an 80 EPT reading after 7 minutes) occurs about 20% of the time in first molars.[90,126,166,175]

*References 31, 90, 95, 126, 166, 175, 210, 213, 263.

†References 31, 90, 126, 166, 175, 210, and 213.

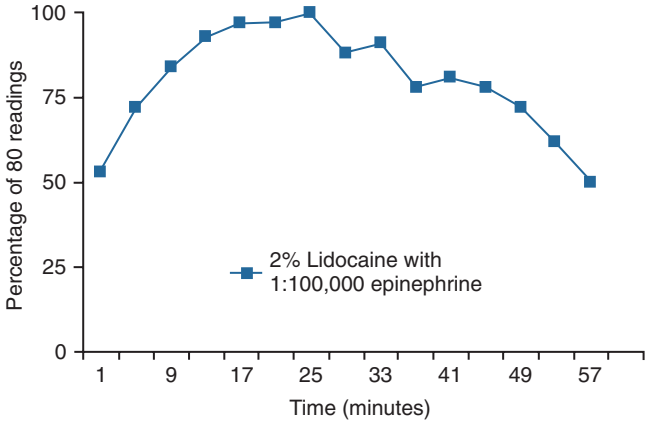

FIG. 20-13 Incidence of first maxillary molar anesthesia, as determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes.

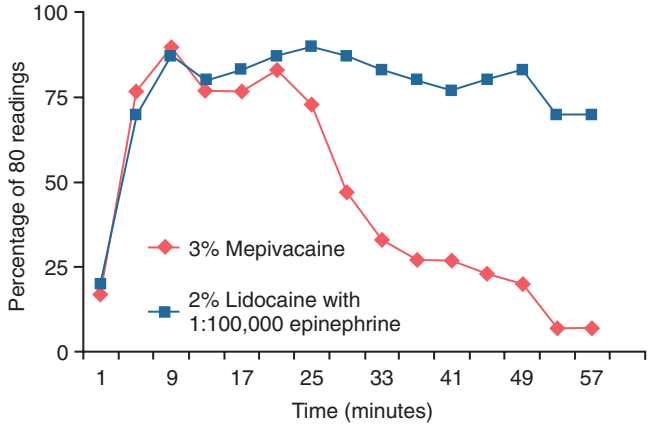

FIG. 20-14 Incidence of first maxillary molar anesthesia: comparison of 3% mepivacaine to 2% lidocaine with 1:100,000 epinephrine. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. The 3% mepivacaine showed a shorter duration of anesthesia than the lidocaine solution.

Duration of Anesthesia

The potential problem with infiltration anesthesia in the maxilla is duration. The incidence of short duration of anesthesia (achieving an 80 reading and then losing this reading) ranges from about 60% in lateral incisors to 38% in first molars.[90,126,166,175] Pulpal anesthesia in anterior teeth starts to decline after about 20 to 30 minutes; in molar teeth, anesthesia declines after about 30 to 45 minutes. These time courses have clinical implications. In an emergency endodontic procedure on a first molar, the pulp usually can be removed within 20 to 30 minutes, so the duration of anesthesia is of little consequence. However, if the practitioner is preparing to obturate the tooth and this procedure takes an hour, the patient might experience pain. Therefore additional local anesthetic should be administered.

Time Course of Pulpal Anesthesia for the Maxillary First Molar

Fig. 20-13 shows the time course for complete pulpal anesthesia for an asymptomatic first molar, as defined by the percentage of patients who do not respond to an 80 EPT stimulus across time. Some patients (20%) had a slow onset of anesthesia until around 11 minutes. The overall success rate (no response at the 80 reading) is 95% to 100%, with peak effects observed at around 30 minutes after injection.

Significance of Lip Numbness

Soft-tissue anesthesia (lip or cheek numbness) is not necessarily related to the duration of pulpal anesthesia. Pulpal anesthesia does not last as long as soft-tissue anesthesia[90,166,175]

ALTERNATIVE ANESTHETIC SOLUTIONS FOR INFILTRATION INJECTIONS

Plain Solutions: 3% Mepivacaine (Carbocaine, Polocaine, Scandonest) and 4% Prilocaine (Citanest Plain)

Solutions of 3% mepivacaine plain and 4% prilocaine plain provide a short duration of pulpal anesthesia, averaging about 15 to 20 minutes (Fig. 20-14),[126,166] and are indicated for procedures of short duration. These agents are generally not as safe as solutions with vasoconstrictors if *large* volumes are administered, because they are rapidly absorbed systemically, resulting in excessive plasma concentrations and possible toxic reactions.[158]

4% Prilocaine With 1:200,000 Epinephrine (Citanest Forte)

The effect of 4% prilocaine (1:200,000 epinephrine) is similar to that of an infiltration injection with 2% lidocaine (1:100,000 epinephrine).[126]

Articaine With 1:100,000 Epinephrine (Septocaine)

Several studies have shown that articaine with epinephrine was similar in action to prilocaine with epinephrine and lidocaine with epinephrine for maxillary infiltration injections.[50,94,95,263] A recent study found maxillary infiltration of 4% articaine with 1:100,000 epinephrine statistically improved anesthetic success, when compared to 2% lidocaine with 1:100,000 epinephrine, in the lateral incisor but not in the first molar. [57]

0.5% Bupivacaine With 1:200,000 Epinephrine (Marcaine)

Success rates (no response to EPT) with bupivacaine range from 80% to 95% in the maxillary lateral incisor, compared with 50% in the maxillary second premolars.[43,90,132,257] Although bupivacaine provides long-term anesthesia in the mandible, it *does not* provide prolonged pulpal anesthesia with maxillary infiltration injection.[43,90,132] In the lateral incisor, bupivacaine has a shorter duration of pulpal anesthesia than lidocaine.[43,90] In the first molar, bupivacaine's duration of pulpal anesthesia is equivalent to that of lidocaine.[90]

EXTENDING THE DURATION OF MAXILLARY INFILTRATIONS

Increasing the Solution Volume

For maxillary infiltrations, increasing the volume of 2% lidocaine with 1:100,000 epinephrine from 1.8 ml to 3.6 ml

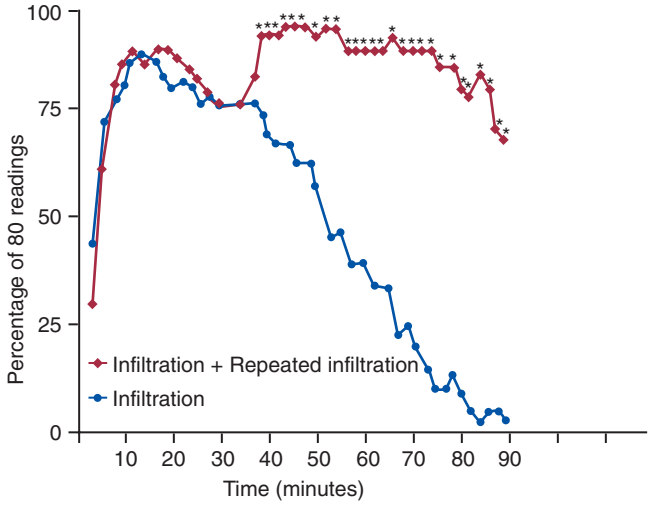

FIG. 20-15 Incidence of maxillary lateral incisor pulpal anesthesia using an initial infiltration and a repeated infiltration 30 minutes later (both infiltrations used 1.8 ml of 2% lidocaine with 1:100,000 epinephrine). Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings). The repeated infiltration injection significantly prolonged the duration of pulpal anesthesia.

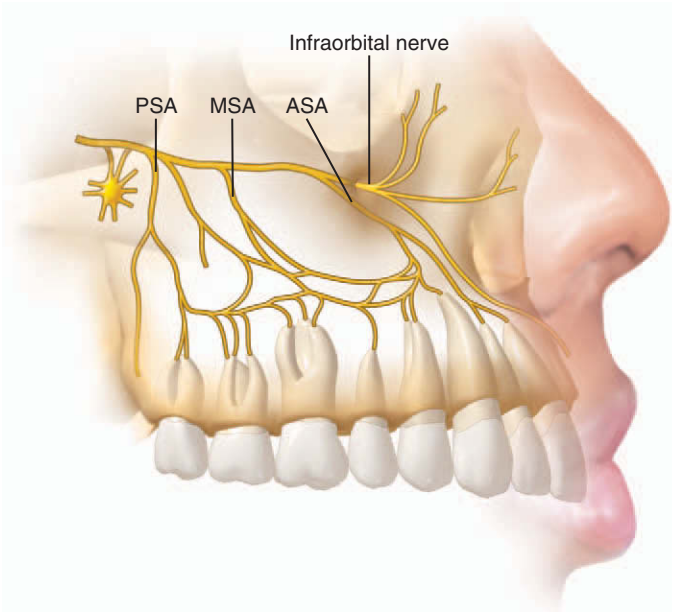

FIG. 20-16 Distribution of the maxillary division of the trigeminal nerve, showing the anterior superior alveolar (ASA) nerve, the middle superior alveolar (MSA) nerve, and the posterior superior alveolar (PSA) nerve.

provided a statistically longer duration of pulpal anesthesia.[175] A repeated infiltration of 1.8 ml of 2% lidocaine with 1:100,000 epinephrine given 30 minutes following an initial infiltration of 1.8 ml of 2% lidocaine with 1:100,000 epinephrine significantly improved the duration of pulpal anesthesia (from 37 minutes through 90 minutes) in the maxillary lateral incisor[238] (Fig. 20-15).

ALTERNATIVE MAXILLARY INJECTION TECHNIQUES

Posterior Superior Alveolar (PSA) Nerve Block

The PSA nerve block provides pulpal anesthesia for the second and third molars and in some first molars.[154] Generally, with the first molar, an additional buccal infiltration injection may be needed after the PSA block to ensure patient comfort. The PSA injection often is indicated when all the molar teeth require anesthesia. If the procedure involves the first molar, an infiltration injection is a better choice because it is more predictable for pulpal anesthesia than the PSA injection.

Infraorbital Nerve Block

The infraorbital nerve block produces profound lip numbness.[12,125] It successfully anesthetizes the first and second premolars, but the duration of pulpal anesthesia is less than 60 minutes.[12,125] The infraorbital block does not successfully anesthetize the pulps of the central or lateral incisors.[12,125] Essentially, this injection technique is the same as an infiltration injection over the premolar teeth for pulpal anesthesia.

Second Division Nerve Block

The second division nerve block successfully anesthetizes the pulps of molar teeth and about 50% of the second premolars.[22,165] It does not routinely anesthetize the pulps of anterior teeth.[22,165] The high tuberosity approach is preferred over the greater palatine technique because the success rate is similar and the procedure is less painful.[22]

Palatal–Anterior Superior Alveolar (P-ASA) Nerve Block

Traditionally, maxillary anterior teeth have been anesthetized with an infiltration injection near the apex of the target tooth. In the late 90s the P-ASA injection, a site-specific injection for maxillary anterior teeth, was introduced.[68,69] The P-ASA injection involves a palatal injection into the incisive canal and derives its name from the injection's supposed ability to anesthetize both the right and left anterior superior alveolar nerves (Fig. 20-16). A P-ASA injection of 0.9 to 1.4 ml of anesthetic solution has been reported to produce anesthesia of the maxillary incisors and usually the canines, with an expected duration of approximately 60 minutes.[68] One study compared the anesthetic efficacy of 2% lidocaine with 1:100,000 epinephrine and 3% mepivacaine using the computer-assisted Wand Plus injection system and the P-ASA injection route.[23] Neither anesthetic produced greater than 58% successful pulpal anesthesia and therefore would not clinically ensure predictable pulpal anesthesia for the four maxillary incisors and canines.

Moreover, 30% to 43% of patients report moderate to severe pain from the needle insertion for the P-ASA injection.[195] For needle placement into the incisive canal, 54% to 58% of subjects reported moderate to severe pain. For deposition of the anesthetic solution, 8% to 12% of subjects reported moderate pain. Postoperatively, approximately 12% to 18% of the subjects experienced temporary numbness or paresthesia of the incisive papilla, and 20% to 28% had swelling or soreness of the incisive papilla. The P-ASA injection, therefore, can be a painful injection, and it has a low to modest success rate.

FIG. 20-17 Palatal injection site for the anterior middle superior alveolar (AMSA) injection.

Anterior Middle Superior Alveolar (AMSA) Nerve Block

The AMSA injection is another new technique for anesthetizing maxillary teeth.[66,67,69] The AMSA injection site is located palatally at a point that bisects the premolars and is approximately halfway between the midpalatine raphe and the crest of the free gingival margin (Fig. 20-17). The AMSA injection supposedly can anesthetize both the anterior and middle superior alveolar nerves[66,67,69] (see Fig. 20-16). Injection of 0.6 to 1.4 ml of anesthetic solution has been reported to produce pulpal anesthesia of the maxillary central and lateral incisors, canines, and first and second premolars, with an expected duration of 45 to 60 minutes.[66,67,69] A bilateral AMSA injection supposedly anesthetizes 10 maxillary teeth, extending from the second premolar on one side to the second premolar on the opposite side.[67]

Two studies of the AMSA technique found rather modest to low success rates, slow onset, and declining duration of pulpal anesthesia over 60 minutes.[73,146] The AMSA injection would not ensure predictable pulpal anesthesia from the second premolar to the central incisor.[73,146] Moreover, the AMSA injection, whether made with a computer-assisted injection system or a conventional syringe, produced moderate pain on needle insertion in 32% to 38% of study subjects and moderate pain upon solution deposition in 25% to 40% of subjects.[198]

When the Wand Plus was used for the AMSA injection, statistically lower pain ratings were recorded for deposition of the anesthetic solution. However, regardless of whether the Wand Plus or a conventional syringe is used, the AMSA injection can be a painful injection, and it has a low to modest success rate.

SUPPLEMENTAL ANESTHESIA

Supplemental injections are essential when, as frequently occurs, anesthesia from conventional injections is inadequate and the pain is too severe for the practitioner to proceed. Three such supplemental techniques can be used: the intraligamentary injection, the intraosseous injection, or the intrapulpal injection.

If the patient has *profound lip numbness and experiences pain upon endodontic access,* repeating the IAN block does not help the problem. Clinicians may think another injection is helpful because the patient sometimes achieves pulpal anesthesia after the second injection, but the patient may simply be experiencing slow onset of pulpal anesthesia from the first injection.

Infiltrations of Articaine Following Maxillary or Mandibular Anesthesia in Patients With Irreversible Pulpitis

Using a visual analog scale to evaluate success, no significant differences were found between an articaine solution and a lidocaine solution when used as a supplemental infiltration after IAN blocks or maxillary infiltrations in patients with irreversible pulpitis.[229] In a small study of 19 patients, no difference was found between lidocaine (9 patients) and articaine (10 patients) formulations in maxillary infiltrations for patients with irreversible pulpitis.[240]

Supplemental Buccal Infiltration of Articaine After a Failed Inferior Alveolar Nerve Block in Patients With Irreversible Pulpitis

A recent study found that when IAN block failed, there was only a 58% success rate for a supplemental buccal infiltration of 1.8 ml of 4% articaine with 1:100,000 epinephrine in mandibular posterior teeth in patients with irreversible pulpitis.[167] This success rate was much lower than a supplemental intraosseous injection.

Intraligamentary Anesthesia

The technique for intraligamentary injection of anesthesia is reviewed in a number of published papers and textbooks.

Success of Intraligamentary Injection

The success of supplemental intraligamentary injections in achieving pulpal anesthesia for endodontic procedures has been reported to be 50% to 96%.[36,159,249,269] Intraligamentary injection produced a 50% to 79% success rate in endodontic treatment when used as a primary anesthetic technique.[127,159] If the first intraligamentary injection failed, reinjection was successful in 71% of patients, for an overall success rate of 92%.[269] Similar results have been reported by other investigators.[36,249] Intraligamentary injection is not successful in mandibular anterior teeth.[172,274]

Mechanism of Action

An intraligamentary injection forces anesthetic solutions through the cribriform plate into the marrow spaces around the tooth.[53,72,215,248,270] The primary route is *not* via the periodontal ligament, and unlike the intrapulpal injection,[17,265] the mechanism of action is not a pressure anesthesia.[56,183] The intraligamentary injection should be considered an intraosseous injection.

Back-Pressure

Studies have shown that the most important factor for anesthetic success with an intraligamentary injection is injection under *strong back-pressure*.[248,269] Pressure is necessary to force the solution into the marrow spaces.

Anesthetic Solutions

A vasoconstrictor significantly increases the efficacy of an intraligamentary injection.[89,128,134,170,237] Injection of a vasoconstrictor alone (1:100,000 epinephrine) does not produce pulpal anesthesia.[237] Anesthetic solutions with reduced vasoconstrictor concentrations (bupivacaine or etidocaine with 1:200,000 epinephrine) are not very effective with this technique.[89,119,128]

Amount of Solution Delivered

Usually about 0.2 ml of solution is deposited with each mesial and distal injection, using a traditional or pressure syringe. The exact amount is not always known because some of the anesthetic solution may escape from the sulcus during the injection.

Injection Discomfort

When an intraligamentary injection is given as a primary injection, needle insertion and injection of the anesthetic solution are only mildly discomforting in posterior teeth[41,159,237,274]; however, in maxillary lateral incisors, an intraligamentary injection can be painful.[274]

When the intraligamentary injection is given as a supplemental injection to anesthetize symptomatic vital teeth (i.e., in irreversible pulpitis), the patient may have moderate pain.[52] Patients should be informed of this possibility.

Onset of Anesthesia

The onset of anesthesia is immediate with an intraligamentary injection,* which means no waiting period is required for the anesthesia to take effect.

Duration

Experimental studies with the EPT have shown that when the intraligamentary injection is given as a primary injection, the duration of profound pulpal anesthesia is approximately 10 to 20 minutes.[183,237,274] When the injection is used as a supplemental technique in asymptomatic teeth after an IAN block, the duration of pulpal anesthesia is approximately 23 minutes.[29] Therefore, when the intraligamentary injection is used as a supplemental technique in endodontic therapy, the clinician must work fairly quickly and be prepared to reinject if profound anesthesia dissipates.

Postoperative Discomfort

Most patients have postoperative discomfort (mostly mild pain) when an intraligamentary injection is used as a primary technique.[41,237,274] Most of this discomfort occurs the first day after injection, and the duration of discomfort averages 14 hours to 3 days.[41,237,274] Postinjection discomfort is related to damage from insertion of the needle and not from the pressure of solution deposition.[41] About 40% of patients report that the tooth feels high in occlusion.[237,274]

When an intraligamentary injection is used as a supplemental technique for endodontic therapy, pain from the intraligamentary injection probably occurs in addition to any postoperative pain from the endodontic treatment.

*References 41, 183, 237, 249, 269, and 274.

Avulsion

In a letter to the editor of the *Journal of the American Dental Association*, Nelson[191] reported on the avulsion of a tooth following intraligamentary injections. However, *no* clinical or experimental study has reported avulsion or loosening of teeth with this technique.[183,237,274] Avulsion should not be a concern with intraligamentary injections.

Selective Anesthesia

Although some have reported that the intraligamentary injection can be used in the differential diagnosis of pulpally involved teeth,[153,242] experimental studies have shown that adjacent teeth may also become anesthetized with intraligamentary injection for a single tooth.[183,237,274] Therefore the intraligamentary injection should *not* be used for differential diagnosis.

Systemic Effects

When a high-pressure syringe was used in dogs, intraligamentary injection of solutions containing epinephrine caused cardiovascular responses similar to those seen with IV injections.[247] Clinical studies using a high-pressure syringe in human beings found that intraligamentary injections of such solutions did not significantly change the heart rate, rhythm, amplitude, or the blood pressure.[25,194] These studies support the conclusion that intraligamentary injections do not cause significant changes in heart rate in human beings.

Needle Gauge

Different needle gauges (25, 27, or 30) have been shown to be equally effective.[159,269]

Ligamental Syringes

Special ligamental syringes have not proved any more effective than a standard syringe.[41,249,269]

Safety to the Periodontium

Clinical and animal studies have demonstrated the relative safety of the intraligamentary injection technique.* Minor transient damage occurs only at the site of needle penetration, and the tissue subsequently undergoes repair. In very rare cases, periodontal abscesses and deep pocket formation have occurred after intraligamentary injections.[29,274] A very small clinical risk of periodontal abscess formation and bone loss exists with this technique, and although these effects are rare, the clinician should be aware of them. Localized areas of root resorption after intraligamentary periodontal ligament injections have also been reported.[207,223]

Safety to the Pulp

Clinical and animal studies have shown that intraligamentary injections have no permanent effect on the pulp.† However, intraligamentary injection of a solution with epinephrine produces a rapid, prolonged decrease in blood flow.[134] Some have suggested that using this injection technique during restorative procedures could result in accumulation of inflammatory mediators that would not be effectively removed because of the

*References 21, 71, 72, 75, 152, 183, 208, 237, 269, and 274.

†References 149, 183, 209, 223, 237, and 274.

reduced blood flow.[134] This hypothesis was directly tested, and intraligamentary injection of an anesthetic solution containing a vasoconstrictor in conjunction with a deep cavity preparation did *not* produce a more severe reaction than in controls (cavity preparation only).[211] Rather, the depth of the cavity preparation was the most important factor dictating pulpal responses. Intraligamentary injections are therefore unlikely to cause pulpal necrosis.

Safety in Primary Teeth

One study has shown that intraligamentary injection of primary teeth may cause enamel hypoplasia of the developing permanent teeth.[21] The effect noted was not caused by the injection technique but by the anesthetics used—that is, the cytotoxic anesthetic agents bound to the enamel matrix in the developing tooth germ. The same effect seemingly would be produced by an infiltration injection next to the developing tooth, so the recommendation that intraligamentary injections be used with great care on primary teeth close to developing permanent teeth[21] may not be correct.

Safety in Periodontally Involved Sites

Intraligamentary injections have been shown to be safe in cases of mild to moderate gingival inflammation or incipient periodontitis.[39]

Precautions

No research as yet has shown how painful an intraligamentary injection would be or if it would result in anesthesia in teeth with cellulitis or abscess formation (symptomatic necrotic teeth with periradicular radiolucencies).

New Technology for Intraligamentary Injections: The Wand

A computer-assisted local anesthetic delivery system was introduced by Milestone Scientific (Livingstone, NJ) that can be used to administer an intraligamentary injection. The Wand (also called *CompuDent* or *CCLAD*) accommodates a standard local anesthetic cartridge that is linked by sterile microtubing to a disposable, penlike handpiece with a Luer-Lok needle (Fig. 20-18). The device is activated by a foot control, which automates the infusion of local anesthetic solution at a controlled rate. Two flow rates, slow or fast, may be initiated and maintained by a foot pedal control. The fast rate delivers 1.4 ml of solution in 1 minute. The slow rate delivers 1.4 ml of solution in approximately 4 minutes, 45 seconds. The slow rate is used for the intraligamentary injection.

Anesthetic Success of the Intraligamentary Injection, Using the Wand in Asymptomatic Vital Teeth

An experimental study recently compared the anesthetic efficacy of primary intraligamentary injection of 1.4 ml of 4% articaine with 1:100,000 epinephrine and 1.4 ml of 2% lidocaine with 1:100,000 epinephrine administered with a computer-controlled local anesthetic delivery system in the mandibular first molar.[13]Successful pulpal anesthesia (two consecutive 80 EPT readings) was obtained 86% of the time with the articaine solution and 74% of the time with the lidocaine solution. No significant difference was seen between the articaine and lidocaine solutions. The duration of pulpal anesthesia ranged from 31 to 34 minutes, longer than the 10 minutes recorded in a similar study using a pressure syringe and 0.4 ml of a lidocaine solution.[274] Therefore the computer-controlled local anesthetic delivery system offers the advantage of increasing the duration of pulpal anesthesia; however, the anesthesia slowly decreases over 60 minutes.

FIG. 20-18 Wand computer-assisted local anesthetic delivery unit. The handpiece assembly and microtubing are also shown. *(Courtesy CompuDent/Milestone Scientific, Livingston, NJ.)*

Anesthetic Success of the Intraligamentary Injection Using the Wand in Symptomatic Vital Teeth

Supplemental intraligamentary injection, administered with a computer-controlled anesthetic delivery system in mandibular posterior teeth diagnosed with irreversible pulpitis after failure of an IAN injection, produced a 56% anesthesia success rate.[196] These results were somewhat disappointing because the computer-controlled anesthetic delivery system should have been capable of delivering approximately 1.4 ml of anesthetic solution with the intraligamentary injection by consistent maintenance of a precise flow rate.

Intraosseous Anesthesia

Stabident and X-Tip Systems

The intraosseous route delivers a local anesthetic solution directly into the cancellous bone adjacent to the tooth to be anesthetized. Infiltration injections of lidocaine formulations are not effective for anesthesia of the mandibular molar teeth because of the thickness of the cortical plate; therefore dentists do not attempt infiltration anesthesia in the posterior mandible. The intraosseous injection overcomes this problem by allowing direct access to the cancellous bone. One clinical study directly compared the infiltration and intraosseous injection techniques, using 1.8 ml of 2% lidocaine with 1:100,000 epinephrine in the maxillary lateral incisor.[201] The two techniques produced similar results, except that the intraosseous technique had a quicker onset and a shorter duration of anesthesia (Fig. 20-19).

Two intraosseous systems have been studied clinically: the Stabident system (Fairfax Dental Inc, Miami, FL) and the X-tip

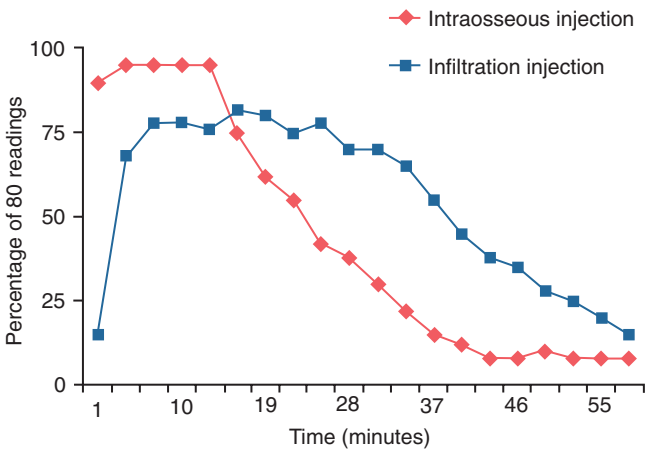

FIG. 20-19 Incidence of anesthesia for intraosseous and infiltration injections. Results were determined by lack of response to electrical pulp testing at the maximum setting (percentage of 80 readings) across time for 60 minutes. The intraosseous injection showed a quicker onset and a shorter duration of anesthesia.

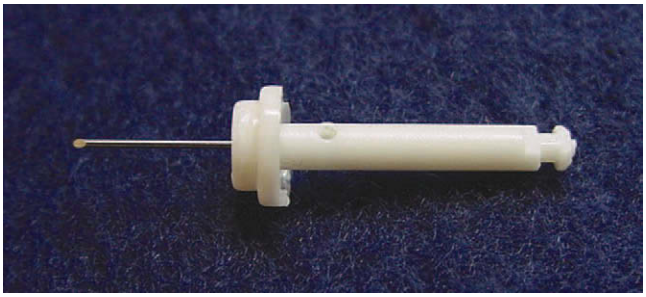

FIG. 20-20 Stabident perforator, a solid 27-gauge wire with a beveled end that is placed in a slow-speed handpiece.

FIG. 20-21 The anesthetic solution is delivered to the cancellous bone through the needle placed into the hole made by the perforator.

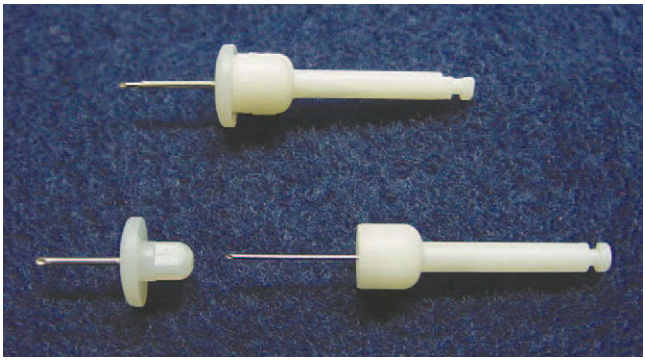

FIG. 20-22 The X-tip anesthesia delivery system consists of an X-tip (*top*) that separates into two parts: the drill (a special hollow needle) and the guide sleeve component (*bottom*).

system (DENTSPLY, Tulsa, OK). Two other anesthetic systems have been introduced: the IntraFlow (Pro-Dex Inc, Irvine, CA) and the Comfort Control Syringe (DENTSPLY International, York, PA). The IntraFlow system combines a slow-speed handpiece with an anesthetic cartridge dispenser system and a rotating needle/drill. The anesthetic solution is delivered after the cortical bone is perforated. When the IntraFlow system was used as a primary technique in a small group of 15 patients with irreversible pulpitis, an 87% success rate was reported (two consecutive 80 readings with a pulp tester).[216] While encouraging, more research on the IntraFlow system is needed. The Comfort Control Syringe is an electronic delivery system and has five preprogrammed injection rates. No published controlled studies have evaluated the Comfort Control Syringe system in clinical dentistry.

The Stabident system is composed of a slow-speed, handpiece-driven perforator, a solid 27-gauge wire with a beveled end that drills a small hole through the cortical plate (Fig. 20-20). The anesthetic solution is delivered to cancellous bone through the 27-gauge, ultrashort injector needle placed into the hole made by the perforator (Fig. 20-21).

The X-tip anesthesia delivery system consists of an X-tip that separates into two parts, the drill and the guide sleeve (Fig. 20-22). The drill, a special hollow needle, leads the guide sleeve through the cortical plate, whereupon it is separated and withdrawn. The remaining guide sleeve is designed to accept a 27-gauge needle for injection of the anesthetic solution (Fig. 20-23). The guide sleeve is removed after the intraosseous injection is complete.

The technique for intraosseous injection of anesthesia using the Stabident or X-tip system can be reviewed in the systems' instruction manuals or in published papers.[35,78,218-220]

PERFORATION PAIN AND SOLUTION DEPOSITION WITH IRREVERSIBLE PULPITIS

Generally the Stabident system produces a very low incidence of moderate pain from perforation and solution deposition in asymptomatic patients.[35,78,218-220] A higher incidence was reported when the system was used to make intraosseous injections in mandibular posterior teeth with irreversible pulpitis. Up to 9% of patients reported moderate to severe pain after perforation, and 5% to 31% reported moderate to severe pain during deposition of the anesthetic solution.[200,217]

With the X-tip system, 48% of patients with irreversible pulpitis had moderate to severe pain with perforation, and 27% had moderate pain with solution deposition.[197] Patients with

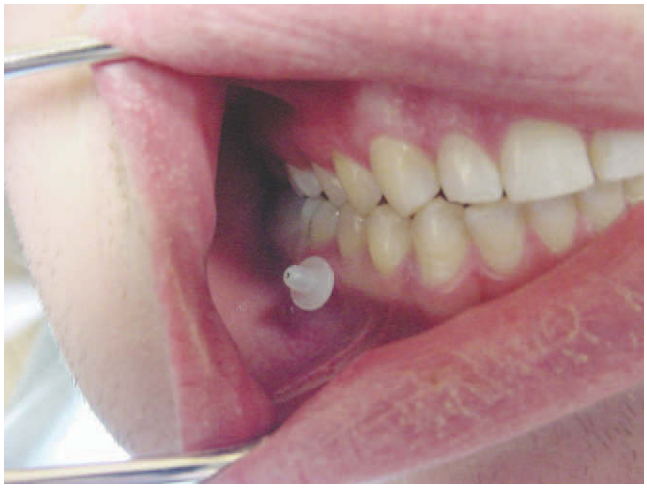

FIG. 20-23 Anesthetic solution is injected through the X-tip guide sleeve.

irreversible pulpitis may experience a transient but moderate to severe pain on perforation and solution deposition when either the Stabident or X-tip system is used. The higher pain ratings, compared with those for asymptomatic teeth, are probably related to preexisting hyperalgesia, which leads to increased pain responsiveness and preoperative anxiety.

PERFORATOR BREAKAGE

In about 1% of cases, the metal perforator separates from the plastic shank during use.[35,54,79,197,218-220] The metal wire is easily removed with a hemostat. This separation usually occurs during a difficult perforation (e.g., dense cortical bone); the wire probably is heated excessively, causing the plastic hub to melt. No perforator breakage (metal perforator breaking into parts) has been reported in numerous studies.[35,54,79,197,218-220]

Optimal Location for Injection Site

Injection at a site distal to the tooth to be anesthetized produces the best anesthesia.* Maxillary and mandibular second molars are an exception to this rule. A mesial site should be selected for these teeth because of the increased thickness of the cortical plate in the mandible and the difficulty with perforation and needle placement at a distal site.

Onset of Anesthesia

The onset of anesthesia is immediate,* which eliminates the waiting period.

Site Selection: Attached Gingiva or Alveolar Mucosa

Both the Stabident and X-tip intraosseous systems instruct the user to locate the perforation site in attached gingiva. The gingival site allows the perforation to be made through a minimal thickness of cortical bone and generally is equidistant between adjacent root structures. However, because the guide sleeve remains in place with the X-tip system, two studies have successfully used it in alveolar mucosa at a more apical location.[79,197] The X-tip system has a definite clinical advantage over the Stabident system, because the X-tip perforation may be made at an apical location in unattached gingiva. If the Stabident system is used apically in alveolar mucosa, the hole for delivering the anesthetic solution is almost impossible to find. The clinician may want to consider using the X-tip in an apical location in specific clinical situations. For example, when periodontal pocketing does not allow perforation into cancellous bone through the more coronal attached gingiva or when interproximal space is lacking (i.e., roots are too close together), the X-tip system can be used to achieve pulpal anesthesia. If the Stabident system fails, the clinician may want to consider using the X-tip apically to achieve pulpal anesthesia.

Success of the Inferior Alveolar Nerve Block in Patients With Irreversible Pulpitis

Clinical studies of endodontics in patients with irreversible pulpitis have found that success (mild or no pain upon endodontic access or initial instrumentation) with the IAN block occurred between 19% and 56% of the time.* These studies would indicate that anesthesia is often difficult to achieve in irreversible pulpitis with only the IAN block.

Success of Intraosseous Anesthesia With Irreversible Pulpitis

STABIDENT SYSTEM

In a clinical trial on patients with posterior teeth with irreversible pulpitis, a supplemental mandibular intraosseous Stabident injection (1.8 ml of 2% lidocaine with 1:100,000 epinephrine) was 91% successful in achieving total pulpal anesthesia.[200] A second clinical trial evaluated the Stabident intraosseous injection in patients with irreversible pulpitis when conventional local anesthetic techniques failed. These researchers found that an initial supplemental intraosseous injection (0.45 to 0.9 ml of 2% lidocaine with 1:100,000 epinephrine) was successful in 79% of posterior mandibular teeth.[206] A second intraosseous injection of the remaining cartridge increased the success rate to 91%. Therefore, initially giving a quarter to a half cartridge of 2% lidocaine with 1:100,000 epinephrine was less successful than initially giving a full cartridge. A third clinical trial in patients with mandibular teeth with irreversible pulpitis showed that supplemental intraosseous injection of 1.8 ml of 3% mepivacaine increased the success rate to 80% compared with the IAN block alone (25% success).[217] A repeat intraosseous injection of 1.8 ml of 3% mepivacaine increased the success rate to 98%. Therefore one cartridge of 3% mepivacaine plain is not as effective as one cartridge of 2% lidocaine with 1:100,000 epinephrine. However, injection of 3% mepivacaine does not produce the tachycardia observed with solutions that contain epinephrine.

X-TIP SYSTEM

One clinical trial evaluated a supplemental X-tip intraosseous injection (1.8 ml of 2% lidocaine with 1:100,000 epinephrine) in patients with irreversible pulpitis when a conventional IAN block failed.[197] The X-tip injection site was 3 to 7 mm apical to the mucogingival junction of the mandibular molar or premolar tooth. The results showed an 82% success rate for

*References 15, 32, 36, 197, 200, and 217.

anesthesia; it also showed an 18% failure rate caused by backflow of the anesthetic solution into the oral cavity. These researchers concluded that when an IAN block fails to provide profound pulpal anesthesia, the X-tip system, when used in an apical location without backflow of the anesthetic solution into the oral cavity, successfully achieves pulpal anesthesia in mandibular posterior teeth with irreversible pulpitis.

Intraosseous Success With an Articaine Solution in Patients With Irreversible Pulpitis

For posterior teeth diagnosed with irreversible pulpitis, the supplemental intraosseous injection of 1.8 ml of 4% articaine with 1:100,000 epinephrine was 86% successful when the IAN block failed.[15] Therefore, the success rate of the articaine solution was similar to a solution of lidocaine.

Repeating the Intraosseous Injection

Repeating the intraosseous injection, using 1.4 ml of 2% lidocaine with 1:100,000 epinephrine 30 minutes after the initial intraosseous injection, provided an additional 15 to 20 minutes of pulpal anesthesia—similar to the duration of the initial intraosseous injection.[117]

Key to Successful Intraosseous Injection

The key to a successful intraosseous injection is flow of the anesthetic into the cancellous space. If anesthetic solution leaks out of the perforation site into the oral cavity, no anesthetic effect is achieved. Reperforation or use of another perforation site is a practical way to gain access to the cancellous bone in such cases. In fewer than 10% of cases, constricted cancellous spaces may limit the distribution of the anesthetic solution around the apices of the teeth.* In such cases, failure may result even if the anesthetic solution is delivered intraosseously.

Duration

In patients with irreversible pulpitis, supplemental intraosseous injection using either the Stabident or X-tip system provided anesthesia for the entire débridement appointment.[197,200,217]

Timing of Intraosseous Injection

Considering the high failure rate of the IAN block in patients in pain, prudent practice would be to give all patients with irreversible pulpitis a supplemental intraosseous injection after an IAN block—that is, once the signs of lip numbness have developed, an intraosseous injection should be given. This technique significantly reduces pain and allows treatment to start sooner.

Many practitioners do not use this regimen because clinicians essentially do what they were taught in their initial clinical training, and sometimes change can be difficult. For example, a 1998 study in the *Journal of the American Medical Association* urged the use of anesthesia during circumcision[5]; nevertheless, up to 96% of baby boys currently don't receive anesthesia. Because many physicians were taught during their residencies not to administer anesthesia, changing their practice philosophy probably will be a slow process. This is a common problem in many health care disciplines, and it emphasizes the need for practitioners to stay current with recent advances.

Anesthetic Success in Painful Teeth With Totally Necrotic Pulps and Radiolucent Areas

No study has investigated the use of intraosseous anesthesia in patients with painful teeth, totally necrotic pulps, and radiolucent areas. In a preliminary study performed at Ohio State, anesthetic solution deposition was very painful in these teeth, and the study had to be terminated.

Anesthetic Success in Partially Vital Teeth

The intraosseous injection should work in teeth in which the chamber is necrotic, the canals are vital or partially vital, and widening of the periodontal ligament can be seen radiographically. A recent history of hot and cold sensitivity should differentiate this condition from that of a necrotic tooth experiencing an acute exacerbation (Phoenix abscess).

Systemic Effects of Intraosseous Injection

CARDIOVASCULAR EFFECTS

A transient increase in heart rate has been reported in 46% to 93% of cases involving Stabident and X-tip intraosseous injection of solutions containing epinephrine or levonordefrin.* Four clinical trials using techniques such as objective electrocardiographic recordings and pulse oximetry have shown that subjects experienced a transient tachycardia (mean increase of 12 to 32 beats/min) after Stabident intraosseous injection of 1.8 ml of 2% lidocaine with 1:100,000 epinephrine, 2% mepivacaine with 1:20,000 levonordefrin, or 1.8 ml of 1.5% etidocaine with 1:200,000 epinephrine.[27,92,221,251] Another clinical trial reported transient tachycardia after intraosseous injection, but not with infiltration injection, of 1.8 ml of 2% lidocaine with 1:100,000 epinephrine in the maxillary anterior region.[279] Generally, all these studies showed that the heart rate returned to baseline readings within 4 minutes in most patients. Therefore injection of anesthetic solutions containing vasoconstrictors, using either the Stabident or X-tip systems, results in a transient tachycardia. No significant change in diastolic, systolic, or mean arterial blood pressure has been observed with intraosseous injection of 2% lidocaine with 1:100,000 epinephrine.[27,221]

An intraosseous injection of 1.4 ml of 2% lidocaine with 1:100,000 epinephrine with the Wand (CompuDent, CCLAD, Milestone Scientific, Livingston, NJ) at a fast rate resulted in a significantly higher heart rate when compared to a slow solution deposition using either the Wand or traditional syringe.[256]

Clinical Significance of Increased Heart Rate. Although the patient is likely to notice the transient tachycardia that occurs after Stabident or X-tip intraosseous injection of 2% lidocaine with 1:100,000 epinephrine, it generally is not clinically significant in healthy patients.[221] The clinical significance, cardiovascular effects, and contraindications to the use of vasoconstrictors in intraosseous injections have been reviewed.[221]

*References 35, 54, 79, 92, 197, 200, 217-220, and 251.

*References 35, 54, 79, 92, 197, 200, 218-220, and 251.

Lack of Heart Rate Effect Of 3% Mepivacaine in Intraosseous Anesthesia. No significant tachycardia occurs when 3% mepivacaine is used for intraosseous anesthesia.[77,221] Clinicians should keep in mind that this anesthetic is an alternative for intraosseous injection in patients whose medical condition or drug therapy suggests caution in the use of solutions containing epinephrine or levonordefrin.[77,221]

CAUTIOUS USE OF LONG-ACTING ANESTHETICS FOR INTRAOSSEOUS ANESTHESIA

In an attempt to increase the duration of pulpal anesthesia with intraosseous injections, some clinicians may consider using long-acting anesthetics. Bupivacaine (Marcaine) and etidocaine (Duranest) are long-acting anesthetics but only for IAN blocks. Long-acting anesthetics do not show an extended duration of anesthesia when injected by the intraosseous or maxillary infiltration routes.[43,90,109,251] Bupivacaine and etidocaine have cardiotoxic effects[10] and for intraosseous anesthesia basically are equivalent to 2% lidocaine with epinephrine in terms of efficacy, duration, and heart rate effects. Therefore bupivacaine and etidocaine offer no advantage clinically and should not be used for intraosseous anesthesia.

Plasma Levels of Lidocaine After Intraosseous Injection

Some authors have cautioned that administration of an overly large volume of local anesthetic with an intraosseous injection could lead to overdose reactions.[113] One experimental study using volunteers found that injection of 1.8 ml of 2% lidocaine with 1:100,000 epinephrine produced venous plasma levels of lidocaine that were the same for maxillary anterior intraosseous and infiltration injections (Fig. 20-24).[279]Although systemic concentrations of vasoconstrictors have a short-lived effect on the heart rate, the plasma concentration of lidocaine delivered with intraosseous injection is no more than that delivered with infiltration, so the intraosseous technique should not be considered an intravascular injection with regard to lidocaine. Also, if it were an intravascular injection, little or no anesthetic effect would be demonstrated—that is, all the local anesthetic solution would be carried into the vascular system, with none left for pulpal anesthesia. Obviously, clinical and experimental studies have demonstrated clinical anesthesia with intraosseous techniques.* Therefore the precautions for the maximum amount of lidocaine for an infiltration injection would seem to apply to an intraosseous injection.

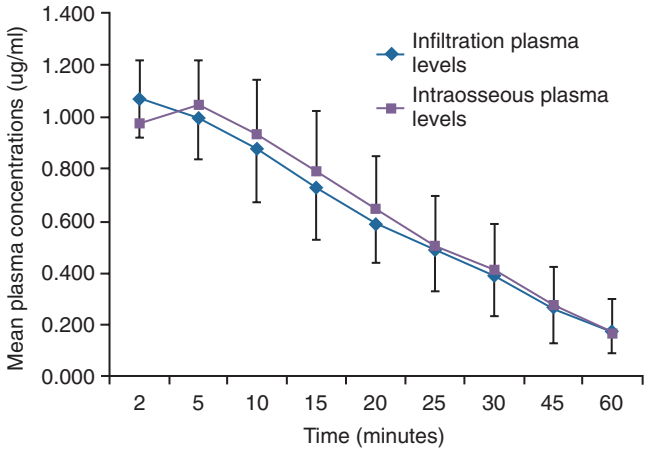

FIG. 20-24 Mean plasma concentrations of lidocaine for the intraosseous and infiltration injection techniques. No statistical differences were seen between the two techniques at any time period.

Postoperative Discomfort

When intraosseous injections are given with the Stabident system, either as a primary or a supplemental technique, most patients report no or only mild pain; approximately 2% to 15% report moderate pain.[35,92,218-220] Less postoperative discomfort is reported for the Stabident intraosseous injection than for periodontal ligament injection.[237]

One study found that significantly more men experienced postoperative pain with the X-tip system than with the Stabident system.[78] The authors interpreted these results as being due to the denser, more mineralized bone in the posterior mandible in men and to the fact that the diameter of the X-tip perforating system is larger than that of the Stabident perforator, meaning that the X-tip system generates more frictional heat during perforation. In patients with irreversible pulpitis, the postoperative pain of the endodontic procedure likely adds to any postoperative pain from the intraosseous injection.

Postoperative Problems

With the Stabident system, fewer than 5% of patients develop swelling or exudate at the site of perforation.[35,92,218-220] The X-tip system may show a higher incidence of postoperative swelling clinically.[78] With both systems, swelling or exudate (or both) may persist for weeks after the injection, but this resolves with time.[35,78,92,218-220] Slow healing of perforation sites may be the result of overheating of the bone caused by pressure during perforation.

With both the Stabident and X-tip systems, approximately 4% to 15% of patients report that for a few days, the tooth "feels high" during chewing.[35,78,92,218-220] This feeling most likely is an increased awareness to biting that results from soreness in the area caused by damage from perforation or inflammation of the bone. The incidence for the intraosseous injection is lower than that reported for the periodontal ligament injection (36% to 49%).[41,237]

INTRAPULPAL INJECTION

In about 5% to 10% of mandibular posterior teeth with irreversible pulpitis, supplemental injections, even when repeated, do not produce profound anesthesia; pain persists when the pulp is entered. This is an indication for an intrapulpal injection.

The major drawback of the intrapulpal injection technique is that the needle is placed and the injection is made directly into a vital and very sensitive pulp; this injection is often moderately to severely painful.[200] Because endodontics currently offers more successful methods of supplemental anesthesia, the intrapulpal injection should be given only after all other supplemental techniques have failed. Another disadvantage of the technique is the possible duration of pulpal anesthesia (15 to 20 minutes). The bulk of the pulpal tissue must be removed quickly, at the correct working length, to prevent reoccurrence of pain during instrumentation. Yet another disadvantage is that the pulp obviously must be exposed to allow direct

*References 35, 54, 79, 92, 197, 200, 217, and 218-220.

injection. Anesthetic problems frequently occur before exposure while the clinician is still working in dentin.[196,197,200,217]

The advantage of the intrapulpal injection is that it produces profound anesthesia if given under back-pressure.[17,265] The onset of anesthesia is immediate, and no special syringes or needles are required. The methods for this technique can be found in many excellent endodontic textbooks. As mentioned previously, strong back-pressure is a major factor in achieving successful intrapulpal anesthesia.[17,265] Depositing the anesthetic solution passively into the chamber is insufficient because the solution will not diffuse throughout the pulp.

MANAGEMENT OF SPECIFIC ENDODONTIC SITUATIONS

Irreversible Pulpitis

When irreversible pulpitis is a factor, the teeth that are most difficult to anesthetize are the mandibular molars, followed by the mandibular premolars, the maxillary molars and premolars, and the mandibular anterior teeth. The fewest problems arise in the maxillary anterior teeth.

In some teeth, irreversible pulpitis is the condition in the apical portion of the canals; the tissue in the chamber is necrotic and does not respond to pulp testing. The pulp chamber can be entered easily, but when attempts are made to place a file to length, severe pain results. Intraosseous injections are helpful in these cases, and an intrapulpal injection may be used. However, irreversible pulpitis must be differentiated from a symptomatic necrotic tooth with apical pathosis. In the latter condition, it is unknown whether intraosseous injections are effective, and bacteria may be forced into the periradicular tissues by an intrapulpal injection.

Mandibular Teeth

Up until the 1980s, before supplemental intraligamentary and intraosseous injections became popular, clinicians would administer conventional anesthesia. After signs of soft-tissue anesthesia became evident, the pain abated and the patient relaxed. Local anesthesia produced the classic soft-tissue signs and relieved the painful symptoms, but pain frequently resulted when the access opening was begun or the pulp was entered. Currently, this pain has been significantly reduced with supplemental techniques.

Integration of the results of many recent clinical trials has changed the paradigm for anesthesia in these cases. Now, after administering conventional anesthesia and observing signs of soft-tissue anesthesia (which is required for a successful supplemental injection), the clinician administers an intraosseous injection. The patient should be informed that the tooth is not as numb as desired and that a little extra anesthetic will ensure his or her comfort. The clinician then explains that this extra anesthetic is placed next to the tooth and that the patient may feel some discomfort during the injection. For mandibular teeth with irreversible pulpitis, the supplemental intraosseous injection has evolved into a routine second injection, which is made before the clinician places a rubber dam and begins the access opening preparation.

The authors recommend using 1.8 ml of 3% mepivacaine plain (e.g., 3% Carbocaine) for the intraosseous injection. The basis for this recommendation is not the cardiovascular risks associated with anesthetic solutions containing a vasoconstrictor but rather the results of clinical research, which indicate that 3% mepivacaine is reasonably effective and has no clinical side effect of increased heart rate.[77,221] A few patients may overreact to the heart rate increase produced by solutions containing epinephrine, making treatment difficult or time consuming because the patient must be calmed before treatment can begin. However, many clinicians also use 2% lidocaine with 1:100,000 epinephrine for intraosseous anesthesia. Individual clinicians may want to experiment to determine which anesthetic solution (3% mepivacaine or 2% lidocaine with epinephrine) works best for them.

After anesthesia has been given, the rubber dam is placed, and the access preparation is slowly begun. The patient should be assured that the procedure will be stopped if he or she feels pain.

If the initial pain occurs in dentin, the rubber dam is removed and another cartridge of 3% mepivacaine administered, which should be successful.[217] Again, the clinician should make sure that lip numbness has developed from the IAN block and that the anesthetic solution is deposited into medullary bone.

If the initial pain occurs when the pulp is entered, the rubber dam is removed, and another cartridge of 3% mepivacaine is administered. If the patient still has pain, an intrapulpal injection is given. Prudent practitioners often modify the access preparation under these conditions by creating a straight-line shaft that directly opens the pulp tissue with little lateral access preparation (i.e., creating an entry hole the size of a #2 round bur). This provides quick access to the pulp, and the small size of the access facilitates intrapulpal injection with high back-pressure if this technique is indicated.

Maxillary Molar and Premolar Teeth

The initial anesthetic dose of 2% lidocaine with 1:100,000 epinephrine is doubled (to 3.6 ml) for the buccal infiltration.[175] A small amount of anesthetic solution usually is administered palatally for the rubber dam retainer. Although fewer anesthetic problems develop with the maxillary molars and premolars than with the mandibular posterior teeth, the clinician should be aware that they can occur.[200] Administration of an intraosseous injection before proceeding with access may prove helpful in anesthetizing these teeth. As an alternative, the clinician can administer the anesthetic and then test the pulp with an EPT or cold refrigerant. If the response is negative, access preparation may proceed. If the response is positive, an intraosseous injection should be given. The clinician must keep in mind that pulp testing may not guarantee pulpal anesthesia in teeth with irreversible pulpitis.[52,200,217] Therefore, if a patient experiences pain despite a negative result on pulp testing, an intraosseous injection should be given.

Infiltration anesthesia does not last as long in maxillary teeth as in mandibular teeth. If the patient experiences pain during the later stages of instrumentation, an additional infiltration injection is necessary. Occasionally, pain is experienced in the palatal canal of molars. Infiltration over the palatal apex with 0.5 ml of anesthetic solution enhances pulpal anesthesia and may prove helpful.[91]

Maxillary Anterior Teeth

Anesthetic can be administered initially as a labial infiltration. Articaine with 1:100,000 epinephrine may be used.[57] Palatal

anesthesia may be necessary for the rubber dam clamp. Although supplemental anesthesia is not often necessary, the intraosseous injection should be successful when given. The duration of anesthesia may be less than 1 hour. An additional infiltration injection may be necessary if the patient experiences pain during the later stages of instrumentation.

Symptomatic Teeth With Total Pulp Necrosis and Periradicular Radiolucencies

Symptomatic teeth with total pulp necrosis and periradicular radiolucencies are an indicator of pain in the periradicular tissue. These teeth may be painful to manipulation and movement during treatment and require extra care.

For mandibular teeth, the IAN block (and long buccal injection) are given in all situations. For maxillary teeth with no swelling, anesthesia is administered with conventional infiltration or a block. If soft-tissue swelling is present (i.e., cellulitis or abscess), infiltration should be done on either side of the swelling, or a block should be administered (second division nerve block, PSA nerve block or infraorbital nerve block). These provide some degree of bone and soft-tissue anesthesia. After signs of anesthesia are observed, the rubber dam is placed, and the access is begun *slowly*. The pulp chamber usually can be entered without causing the patient discomfort if the tooth is not torqued excessively. Hand and rotary file shaping can be performed without causing much pain if instruments are used with gentleness and care.

Occasionally, the conventional injections do not provide profound anesthesia, particularly in the maxillary teeth. Although results from clinical trials are lacking for treating this region, anecdotal experience suggests that careful consideration of a supplemental injection consisting of an additional palatal infiltration injection may be helpful.

Asymptomatic Teeth With Total Pulp Necrosis and Periradicular Radiolucencies

Asymptomatic teeth with pulp necrosis are the easiest to anesthetize; patient comfort usually is attained without difficulty. Although it may be tempting to proceed without anesthesia, the patient may have pain during instrumentation.

The conventional injections are administered: IAN block and long buccal injection for mandibular teeth, infiltration injections for maxillary teeth. The clinician then proceeds with access and file placement. The patient usually is comfortable in such cases. Rarely, some discomfort may be felt during canal preparation, requiring an intraosseous injection. An intrapulpal injection should not be given, because bacteria and debris may be forced from the canal into the periradicular tissue. Additional infiltration may be necessary in the maxilla if anesthesia begins to wear off.

Incision and Drainage

Clinicians should always attempt to achieve some degree of anesthesia before performing an incision and drainage procedure, because patients tolerate such procedures better. In the mandible, a conventional IAN injection and long buccal injection are given. In the maxilla, 1.8 ml of 2% lidocaine with 1:100,000 epinephrine is infiltrated on both sides of the facial swelling. As an alternative, because we are mostly concerned with soft-tissue anesthesia, a PSA or second division nerve block can be used for premolar and molar teeth and an infraorbital injection given for anterior teeth. For palatal swelling, 0.5 ml of 2% lidocaine with 1:100,000 epinephrine is infiltrated over the greater palatine foramen (molar and premolar teeth) or nasopalatine foramen (anterior teeth). These injections should not be used if swelling is present over the foramen; infiltration should be done on either side of the swelling. The Wand system reduces the pain of palatal injections. Except in a few studies,[9,86,235] the computer-assisted injection system caused less pain than the conventional syringe technique for AMSA, palatal injections, and IAN block injections.*

Profound anesthesia usually is difficult to achieve in these cases, and this must be explained to the patient. The swelling is not injected, because traditionally it has been believed that injection directly into a swelling is contraindicated. Reasons for this included the possible spread of infection and the contention that the inflamed tissue's lower pH would make the anesthetic solution less effective. These ideas may have some merit, but swellings are not injected basically because it is *very* painful and relatively ineffective. An area of cellulitis has an increased blood supply, and an anesthetic injected into this area is largely carried away into the systemic circulation, which diminishes the anesthetic's local effectiveness. (See Chapters 2 and 15 for additional information on incision and drainage procedures.)

Periradicular Surgery

In the mandible, the inferior alveolar and long buccal injections are reasonably effective. Additional buccal infiltration injections in the vestibule may be useful to achieve vasoconstriction, particularly in the mandibular anterior region. In the maxilla, infiltration injections are generally effective; usually larger volumes are necessary to provide anesthesia over the surgical field.

If the area of operation is inflamed, anesthesia may not be totally successful. After the flap is reflected, if anesthesia is inadequate, attempts to enhance or regain anesthesia (through additional infiltrations or injecting the sensitive area) are not particularly effective. The effectiveness of surgical anesthesia is decreased by half when compared to anesthesia for nonsurgical procedures, because when reflecting a flap and opening into bone, the anesthetic solution is diluted by bleeding and removed by irrigation.[284]

As a prophylactic measure, an intraosseous injection using an anesthetic agent with 1:100,000 epinephrine may be administered at the site—after the above injections and before the surgery. This seems to enhance depth of anesthesia and may provide better hemostasis.

Use of a long-acting anesthetic has been advocated for surgery.[46,230] In the mandible, this is reasonably effective. In the maxilla, long-acting agents have a shorter duration of anesthesia and decreased epinephrine concentrations, which result in more bleeding during surgery.[40,284]

After periradicular surgery, administration of a long-acting anesthetic has been suggested.[158] However, postsurgical pain is usually not severe and can be managed by analgesics.[171]

Interim Treatment for Irreversible Pulpitis Using Pulpotomy

Patients often have to decide between extraction and endodontic treatment for irreversible pulpitis. Because of financial circumstances, patients may choose extraction if they are only presented with two choices. One study performed pulpotomies in patients with irreversible pulpitis and restored the teeth with IRM or IRM base/glass ionomer core.[161] They found pain was present in 10% of patients at 6 months and in 22% at 12 months. While not ideal, the third option of pulpotomy and temporary restoration may allow the patient time to find the means to finance complete endodontic treatment.[49,130,168]

Pain Reduction in Irreversible Pulpitis When Endodontic Treatment Is Impossible

Endodontic débridement (pulpectomy or pulpotomy) most predictably relieves the pain of irreversible pulpitis.[204] When débridement is not possible, clinicians may prescribe strong analgesics and penicillin in an attempt to relieve the pain. Unfortunately, the pain persists, and penicillin has no effect on the pain of untreated irreversible pulpitis.[190] One clinical trial evaluated pain reduction in untreated irreversible pulpitis by giving an intraosseous injection of Depo-Medrol (a long-acting methylprednisolone).[76] Clinically, the authors found that Depo-Medrol reduced the pain to manageable levels for up to 7 days before the patient received endodontic treatment, supporting this as a method for controlling a patient's pain until definitive endodontic treatment can be performed.

Oral Conscious Sedation

Oral conscious sedation is beneficial in reducing patient's anxiety, but it is not a way to reduce pain during dental treatment.[150] Profound local anesthesia is still required to control the patient's pain.

SUMMARY AND FUTURE DIRECTIONS

The emergence of evidence-based dentistry has rapidly drawn interest across all fields of dentistry. Fortunately, the large number of high-quality, randomized, controlled studies in anesthesia and analgesia provide a wealth of information supporting evidence-based recommendations. The practitioner must focus on high-quality research when making clinical decisions. In contrast, little evidence is available when decisions are based on clinical anecdotes or advertisements. This chapter adopted the evidence-based approach in providing a comprehensive summary of local anesthetic clinical trials for the treatment of patients with endodontic pain.

The prudent practitioner knows that there is no "magic bullet" in pain control. Rather, the clinician must be knowledgeable about the advantages and disadvantages of several anesthetic-vasoconstrictor combinations and the various routes of injection. Clearly, judicious selection of the combination local anesthetics, possibly delivered through multiple sites of injection, is likely to provide predictable anesthesia with minimal exposure to side effects.

Research continues in the development of new or improved anesthetics. Investigations on extended-duration anesthetic formulations suggest that local anesthetics may prove useful for treating postprocedural pain.[80,289] In the future, clinicians may be able to provide anesthesia of a specific area for a day or maybe a number of days using liposomal-encapsulated anesthetic agents. The timing of anesthesia would be tailored by how the liposome is formulated to dissolve and the amount of drug in the liposome.

The use of adjuvants to shorten the onset or increase the duration of local anesthetics also has been evaluated. The addition of hyaluronic acid significantly increases bupivacaine anesthesia in rats.[253] Tramadol has both a unique central mechanism of action and peripheral anesthetic properties. For patients in pain, 30 to 200 mg of tramadol significantly enhanced postoperative analgesia when combined with 1.5% mepivacaine.[224] Other studies have shown that the addition of 1 mg of morphine to a local anesthetic solution significantly increases postoperative analgesia in human beings and animals.[63,148] Clonidine directly inhibits pulpal pain neurons[99] and enhances anesthesia when combined with a local anesthetic.[111,141] Also, it does not increase the risk of cardiotoxicity seen with local anesthetics.[93] In a clinical model of postsurgical pain, the combination of lidocaine with bupivacaine produced better long-term pain control than lidocaine alone.[145]

Considerable ongoing research is directed at the development of new local anesthetic formulations that allow clinicians to better treat patients in pain.

CHAPTER 21

Periradicular Surgery

BRADFORD R. JOHNSON, MOHAMED I. FAYAD, and DAVID E. WITHERSPOON

CHAPTER OUTLINE

INDICATIONS FOR PERIRADICULAR SURGERY
- Etiology of Persistent Periradicular Disease
- Rationale for Surgical Treatment
- Clinical Decision Making

GENERAL BIOLOGIC PRINCIPLES OF WOUND HEALING

SOFT-TISSUE WOUND HEALING
- Inflammatory Phase
- Proliferative Phase
- Maturation Phase

HARD-TISSUE HEALING: EXCISIONAL DENTOALVEOLAR WOUND
- Osteoblasts: Osteogenesis
- Cementoblasts: Cementogenesis

SYSTEMIC MEDICATIONS AND WOUND HEALING
- Bisphosphonates
- Glucocorticoids
- Nonsteroidal Antiinflammatory Drugs
- Cyclooxygenase-2 Inhibitors

PREOPERATIVE EVALUATION OF MEDICALLY COMPLEX PATIENTS

ANATOMIC CONSIDERATIONS
- Posterior Mandible
- Posterior Maxilla
- Anterior Maxilla and Mandible

CONE-BEAM VOLUMETRIC TOMOGRAPHY
- Differences Between CT and CBVT Imaging
- Potential Applications of CBVT in the Management of Endodontic Posttreatment Disease

PATIENT PREPARATION FOR SURGERY
- Informed Consent Issues Specific to Surgery
- Premedication: NSAIDs, Antibiotics, Chlorhexidine, and Conscious Sedation

INSTRUMENTS AND OPERATORY SETUP

LOCAL ANESTHESIA FOR SURGERY

SURGICAL ACCESS
- Soft-Tissue Access
- Vertical Incision
- Horizontal Incision
- Flap Design
- Tissue Reflection
- Tissue Retraction
- Hard-Tissue Access

PERIRADICULAR CURETTAGE AND BIOPSY

LOCALIZED HEMOSTASIS
- Preoperative Considerations
- Local Hemostatic Agents
- Cautery/Electrosurgery

MANAGEMENT OF THE ROOT END
- Determining Need for Root-End Resection and Filling
- Root-End Resection
- Angle of Resection
- Root-End Surface Preparation
- Resected Root-End Surface Topography
- Root-End Conditioning

ROOT-END CAVITY PREPARATION
- Ultrasonic Root-End Preparation and Apical Fractures
- Significance of Ultrasonic Tip Design
- Temperature Changes Induced by Ultrasonic Instruments
- Bonded Root-End Fillings

ROOT-END FILLING MATERIALS
- Zinc Oxide Eugenol Cements
- Glass Ionomer Cements
- Diaket
- Composite Resins and Resin-Ionomer Hybrids
- Mineral Trioxide Aggregate
- Overview of Root-End Filling Materials

CLOSURE AND SUTURING
- Closure of the Surgical Site
- Selection of Suture Material

GUIDED TISSUE REGENERATION AND ENDODONTIC SURGERY
- Ridge Preservation

INTENTIONAL REPLANTATION

POSTOPERATIVE CARE

MANAGEMENT OF SURGICAL COMPLICATIONS

Nonsurgical endodontic treatment is a highly predictable treatment option in most cases, but surgery may be indicated for teeth with persistent periradicular pathosis unresponsive to nonsurgical approaches. Surgical root canal therapy, including root-end resection, has been practiced since at least the mid-1800s.[199] In 1906, Schamberg[455] described using radiographs to assist diagnosis and using surgical burs to perform a rapid osteotomy and root-end "ablation."

Perhaps the single most important development in dental practice in the early 20th century was the introduction of safe, effective local anesthesia, which allowed for more meticulous and comfortable surgical treatment. Formal recognition of

endodontics as a specialty in 1963 ushered in a new era of basic and clinical research focused on the prevention and treatment of pulpal and periradicular pathosis.

Over the past 2 decades, periradicular surgery has continued to evolve into a precise, biologically based adjunct to nonsurgical root canal therapy. The parallel development of new instruments and materials, along with a better understanding of the biology of wound healing, has made surgical treatment a viable alternative to extraction and tooth replacement rather than a treatment of last resort.

Periradicular surgery, when indicated, should be considered an extension of nonsurgical treatment, because the underlying etiology of the disease process and the objectives of treatment are the same: prevention or elimination of apical periodontitis. Surgical root canal treatment should not be considered as somehow separate from nonsurgical treatment, although the instruments and techniques are obviously quite different. Surgical treatment accounts for about 3% to 10% of the typical endodontic specialty practice.[2,72,355] A recent study found that endodontists perform almost 78% of surgical root canal treatments; general dentists and other specialists perform 15.5% and 6.6%, respectively.[229] Although appropriately trained general dentists and other dental specialists may perform periradicular surgery, individuals with advanced training in endodontics have developed most of the current periradicular surgery techniques and science presented in this chapter. We feel that endodontists must continue to include periradicular surgery as a routine part of clinical endodontic practice and not abrogate this treatment option to others who may not possess the same background, skills, or values.[325,405,420] When patient preferences and quality-of-life measures are considered, patients can be expected to place high value on endodontic treatment and the retention of a natural tooth.[146,171]

INDICATIONS FOR PERIRADICULAR SURGERY

Etiology of Persistent Periradicular Disease

The first and arguably most important step in treatment decision making is attempting to determine the cause of persistent periradicular disease. Treatment then is directed at eliminating the etiology, which most often is the presence of bacteria and other microbial irritants in the root canal space.[471] Nonsurgical retreatment, when possible, often is the first choice for attempting to correct obvious deficiencies in the previous treatment. However, microorganisms can survive even in apparently well-treated teeth in dentinal tubules, canal irregularities, deltas, and isthmus areas.[261,290,537] If residual microorganisms remain completely entombed in the root canal system, periradicular healing should occur. Sealing off all potential routes of microbial escape from the root canal system is the goal of both nonsurgical and surgical treatment. When microorganisms of sufficient pathogenicity and number gain access to the periradicular tissues, pathosis develops.

Enterococcus faecalis is commonly isolated from failing root canal–treated teeth and is known to be especially difficult to eliminate with standard instrumentation and irrigation techniques.[485] Unlike primary endodontic infections, which predominately are associated with mixed anaerobic microbiota, it has been commonly accepted that treatment failures are more frequently associated with one or two microorganisms (see also Chapter 15).[471] However, recent research using more sophisticated techniques (16S ribosomal RNA gene clone library analysis) has determined that multiple previously uncultivated phylotypes can be identified in the majority of teeth with persistent apical periodontitis.[446] Fungi and viruses recently have also emerged as potential causes of root canal failure and may play either a primary or secondary role in persistent periradicular pathosis.[350,380,444,545]

Established extraradicular colonies of microorganisms also may be a reason for failure of some teeth to respond to nonsurgical treatment. When microorganisms are able to arrange in an extraradicular biofilm, they may be particularly resistant to elimination by host defense mechanisms and antimicrobial agents.[469] Persistent extraradicular root surface colonization cannot be diagnosed by noninvasive methods but may be suspected in well-treated cases that are refractory to nonsurgical treatment.[157,206,447,474,486] Although the presence of extraradicular microbial colonies has been somewhat controversial, recent studies using DNA-DNA hybridization techniques have confirmed the persistence of microorganisms in the periradicular tissues of some root canal–treated teeth.[178,484]

Overextended filling materials may contribute to treatment failure, presumably as a result of a chronic inflammatory response.[350] Although this is possible and even likely with certain toxic materials (e.g., pastes containing formaldehyde[357]), the role of relatively inert materials such as gutta-percha and set sealer is less clear, and these materials probably become a significant contributing factor only if microorganisms are present. If the root apex is close to the buccal cortical plate, apical fenestration may occur, leading to persistent symptoms, especially tenderness to palpation over the root apex.[69] Some have suggested that overextension of filling materials may contribute to endodontic failure because certain dental materials may induce periodontal ligament (PDL) cell apoptosis.[449] This specific interaction between filling materials and periradicular tissues is not fully understood and deserves further research. The poorer prognosis often reported with overextended root canal fillings also may be related simply to lack of an adequate apical seal and subsequent egress of microorganisms from the root canal space. Regardless, minor overextension of filling material is rarely a sole indication for surgery except when symptoms or periradicular pathosis develops. Significant overextension of filling material, especially when important anatomic areas and possibly toxic materials are involved, is an indication for referral to an endodontist or oral surgeon for evaluation and possibly treatment.

The presence of periradicular cholesterol crystals may interfere with healing after nonsurgical root canal treatment.[345] Although relatively uncommon, true periradicular cysts (completely enclosed, epithelium-lined cavities) may not be expected to resolve after nonsurgical treatment.[346] As with other extraradicular causes of failure, surgery is indicated, because definitive diagnosis and treatment require an excisional biopsy and removal of the periradicular tissue.

Vertical root fractures are a significant cause of failure and may be difficult to diagnose in the early stages.[86] Exploratory surgery often is required to confirm a root fracture. Cone-beam computed tomography (CBCT) is a promising tool for noninvasive diagnosis of root fractures and is discussed in greater detail later in this chapter. Although several promising approaches to the management of vertical root fractures have been proposed,[214,254,481] the prognosis generally is believed to

be poor. Extraction usually is the treatment of choice, especially if appropriate tooth replacement options are available. Root amputation or hemisection may be considered in a multirooted tooth if the remaining tooth structure is uninvolved and sufficient periodontal support is present.

The relationship between systemic disease and periradicular healing is not completely understood. The possible influence of certain systemic medications on wound healing is discussed later in the chapter. Compromised host healing capacity may be a contributing factor in delayed healing and failure of some root canal–treated teeth. For example, complete healing after nonsurgical root canal treatment is less likely in diabetic patients with preoperative periradicular pathosis.[75,166] Patients undergoing immunosuppressive therapy may be at greater risk for delayed healing, treatment failure, or acute exacerbation of a subclinical infection, although two studies involving subgroups of immunocompromised patients (bone marrow transplant and acquired immunodeficiency syndrome [AIDS]) did not find these patients to be at higher risk for complications related to endodontic treatment.[187,387]

Rationale for Surgical Treatment

Although nonsurgical retreatment generally is believed to be the preferred first approach in the management of persistent apical periodontitis,[74,471,485] periradicular surgery is indicated when nonsurgical retreatment is impractical or unlikely to improve on the previous result (see Chapter 25). In particular, a surgical approach may be the first choice for managing teeth with long posts or irretrievable separated instruments, nonnegotiable ledges and canal blockages or transportation, hard cement filling materials, failure of previous nonsurgical retreatment, suspected vertical root fracture, or when a biopsy is indicated (Figs. 21-1 to 21-4). Even when surgical treatment is the likely definitive approach, nonsurgical therapy before the procedure may be recommended to help reduce the number of microorganisms in the root canal system and ensure a more favorable long-term prognosis.[217] Surgery may be the first choice even if a tooth can be treated nonsurgically, if the risks and costs of retreatment are considered excessive. For example, disassembling a recently restored bridge abutment tooth to allow endodontic retreatment may be technically possible but not economically feasible. Case-specific variables and clinical judgment are key elements in the decision-making process; current evidence supports the contention that the prognosis for surgical treatment is approximately the same as that for nonsurgical retreatment.*

Clinical Decision Making

Clinical decision making is a process that combines the best available evidence, clinical judgment, and patient preferences. Treatment choices are always made under conditions of at least some uncertainty. Surgical root canal treatment rarely is the only possible choice. Clinicians and patients must weigh the relative benefits, risks, and costs of two or more acceptable alternatives. Patients and clinicians can be expected to hold different attitudes about the value of potential treatment outcomes.[255] In a prognosis study of single-tooth dental implants, investigators[183] reported that factors considered significant by health care professionals may not be important to patients.

FIG. 21-1 Previously treated maxillary lateral incisor with persistent periradicular disease. Nonsurgical retreatment is possible but would involve disassembly of an otherwise adequate coronal restoration. Periradicular surgery is a reasonable option.

Even among groups of dentists and dental specialists, the threshold for treatment varies widely, and treatment recommendations may depend more on personal values and experience than objective analysis of treatment costs, prognosis, risks, and alternatives.[55,325,420]

Shared decision making, in which the patient and clinician consider outcome probabilities and patient preferences and agree on the appropriate treatment, is preferable to a clinician-directed treatment decision (see also Chapter 11).[46,170] Such a two-way exchange allows the clinician to provide the best available current evidence and case-specific clinical judgment while encouraging a decision that considers the patient's personal values and preferences. This decision-making model has been shown to increase patient knowledge about and satisfaction with the treatment choice.[249,367,368] In general, most patients prefer to be actively involved in the decision-making process but want to leave the specifics of the treatment to the clinician.[170] That is, the risks, benefits, and costs of treatment alternatives are important to patients, but the details of the procedure usually are not. Shared decision making is particularly relevant in light of the current trend in some areas to recommend implants as an alternative to root canal treatment.

Comparative probabilities for a successful outcome after surgical root canal treatment, nonsurgical retreatment, or extraction and replacement with a fixed prosthesis or implant are difficult to project. Many treatment variables are complex and not easily quantified, such as the affected location in the mouth, bone quality, clinician's skill, possible influence of systemic disease on healing, periodontal support, bulk of the remaining tooth structure and resistance to fracture, quality of the coronal restoration, patient susceptibility to recurrent caries, materials used, and other factors. In addition, the defini-

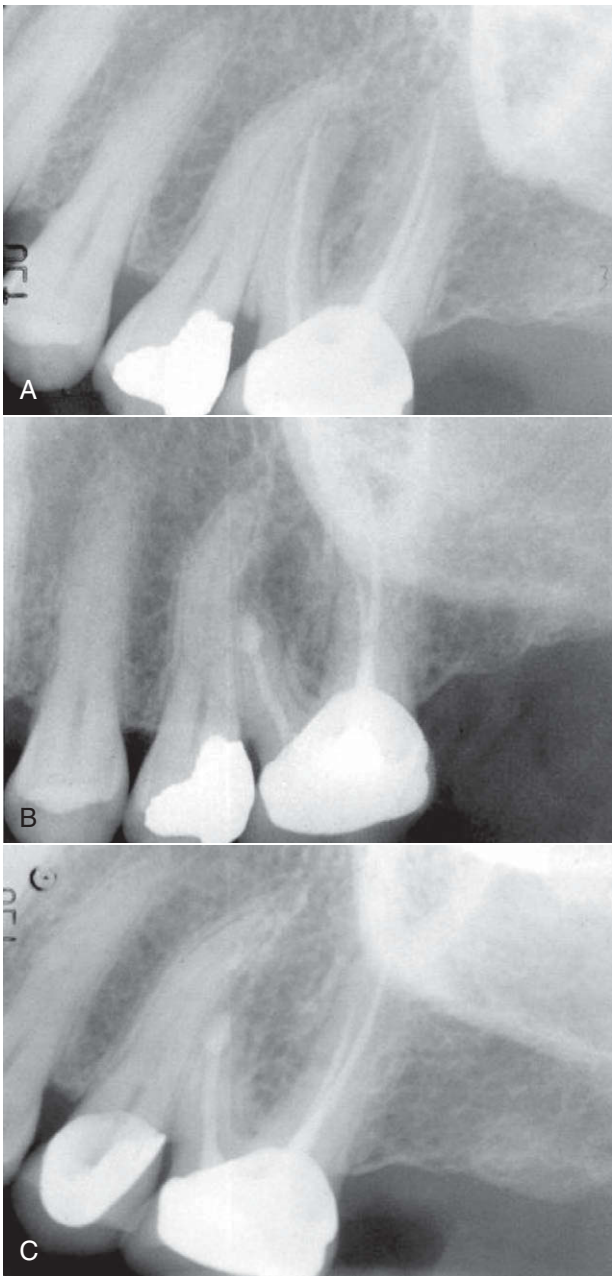

FIG. 21-2 A, Previously treated maxillary first molar with persistent periradicular disease and obvious transportation of the main mesiobuccal (MB-1) canal. Nonsurgical retreatment is unlikely to correct this iatrogenic condition; surgery is the preferred choice. **B,** Immediate postsurgery radiograph. The root-end preparation and fill was extended from the MB-1 canal in a palatal direction to include the isthmus area and the second (MB-2) canal. **C,** One-year follow-up examination: the tooth is asymptomatic, and periradicular healing is apparent radiographically. Although surgery was the first-choice treatment in this case and the outcome was favorable, a good argument could be made for nonsurgical retreatment before surgery to ensure disinfection of the canal and attempt to locate an MB-2 canal.

tion of success varies considerably and is inconsistent from study to study.

One study[65] performed a meta-analysis of implant studies and reported a 93% survival rate at 5 years. The 5- to 10-year success rate for implant retention routinely is reported to be 90% to 97%, depending on the location in the mouth and other variables.[285,292] Surgical root canal treatment often is reported to have a much lower success rate than implant placement.[217,521] However, most of these studies would be considered weak by today's evidence-based standards and, more importantly, do not reflect the use of many of the newer surgical materials and techniques. With careful case selection, surgical skill, and the use of materials and techniques described later in this chapter, many authors have reported success rates over 90% for surgical root canal treatment.[308,430,521,578]

In broad terms and under ideal conditions, the prognoses for nonsurgical retreatment, surgical treatment, and implant placement would be roughly equal. The choice of treatment should be based on the best available evidence, case-specific clinical judgment, and the patient's preferences. As a stronger evidence base continues to develop, we predict that algorithms encompassing multiple patient and treatment variables will be devised to assist clinical decision making.

GENERAL BIOLOGIC PRINCIPLES OF WOUND HEALING

Wound healing varies from region to region in the body and depends on several factors, including the type of tissue, the type of wound, and the type of healing. In periradicular surgery, the tissues include free and attached gingiva, the alveolar mucosa, periosteum, bone, the periodontal ligament, and cementum. The wound may be intentional surgical trauma, which includes incision, blunt dissection, and excision (surgical), or pathologic or traumatic wounds. Healing occurs by primary or secondary intention.[201]

An incisional blunt dissectional wound, for example, can be considered to heal typically by primary intention, whereas a dissectional wound involving the resected root surface and osseous crypt heals by secondary intention. An important concept of the wound healing process in general is the difference between regeneration and repair. The goal of all surgical procedures should be *regeneration,* which returns the tissues to their normal microarchitecture and function, rather than *repair,* a healing outcome in which tissues do not return to normal architecture and function. Repair typically results in the formation of scar tissue.

The wounding process varies depending on the types of tissue and injury, but all wounds progress through three broad, overlapping phases in the process of healing: the inflammatory phase, the proliferative phase, and the maturation phase.[227,539] Although these phases can be identified in healing tissue, none of them has a clear beginning or end. In a wound such as an endodontic surgical site that involves more than one tissue type, these phases progress at different rates in each type of tissue.

SOFT-TISSUE WOUND HEALING

Inflammatory Phase

Broadly speaking, the inflammatory phase of healing is very similar for all tissues.[517] This phase can be broken down further into clot formation, early inflammation, and late inflammation.

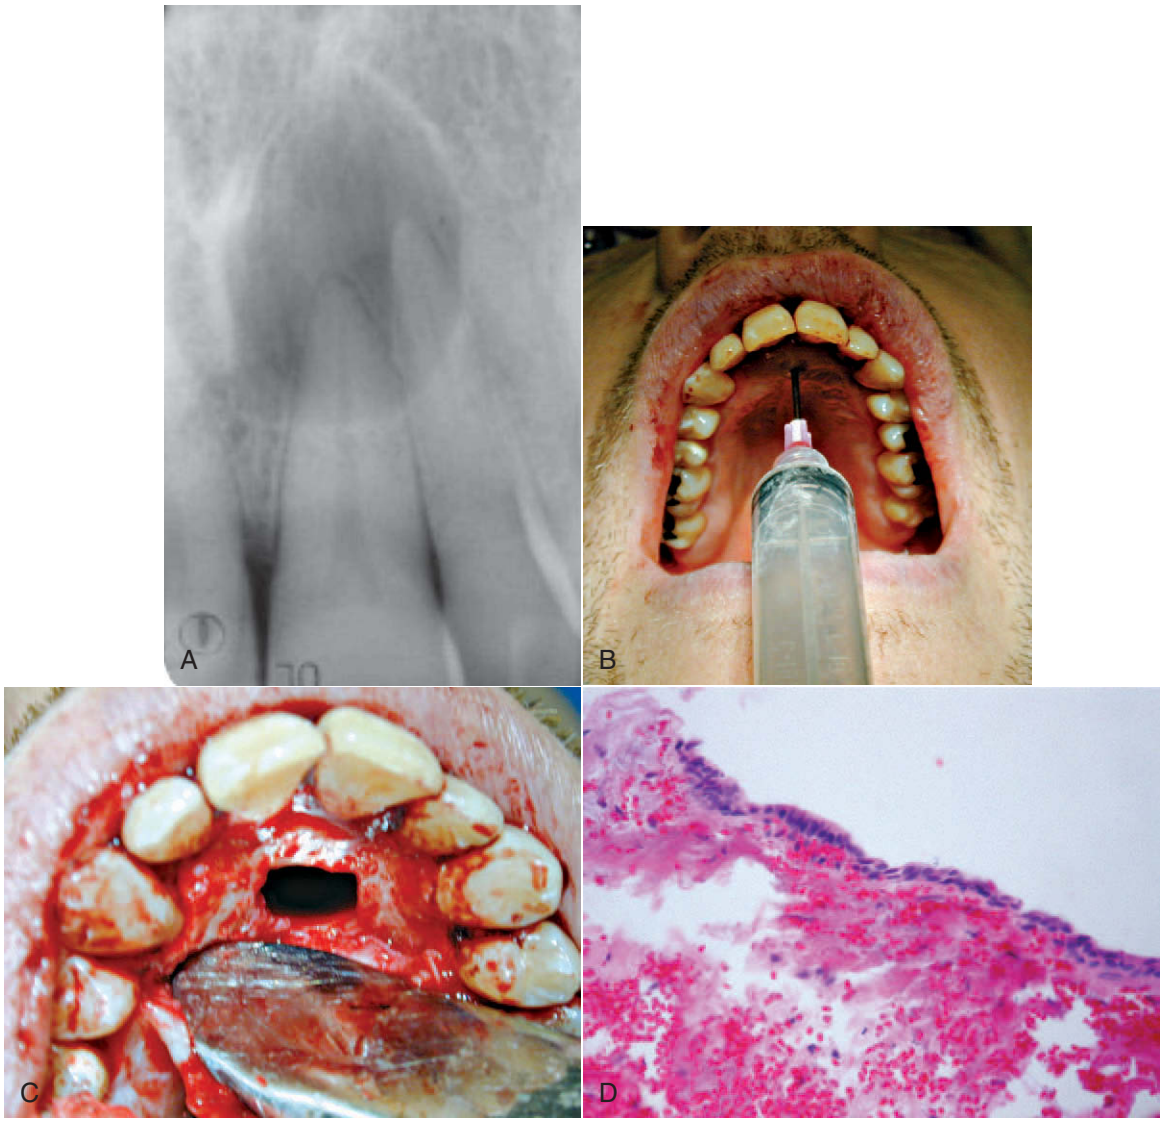

FIG. 21-3 A, Indication for surgery (biopsy): large radiolucent lesion in the area of the maxillary left central and lateral incisors was detected on routine radiographic examination. All anterior teeth responded within normal limits to pulp vitality testing. **B,** After administration of a local anesthetic but before surgery, the lesion was aspirated with a large-gauge needle to rule out a vascular lesion. **C,** Buccal and palatal flaps were reflected. The lesion was directly accessible from the palate. An excisional biopsy was performed, and the sample was submitted for evaluation. **D,** Light microscopic section of the biopsy specimen (×400); the lesion was diagnosed as a nasopalatine duct cyst. *(Courtesy Dr. Vince Penesis.)*

Clot Formation

Clot formation begins with three events:

1. Blood vessel contraction is initiated by platelet degranulation of serotonin, which acts on the endothelial cell and increases the permeability of the vessel, allowing a protein-rich exudate to enter the wound site.
2. A plug composed of platelets forms, primarily through intravascular platelet aggregation.
3. Both the extrinsic and intrinsic clotting mechanisms are activated.

Several other events occur simultaneously, including activation of the kinin, complement, and fibrinolytic systems and the generation of plasmin.[34,234,495] These events stabilize hemostasis, begin the production of a number of mitogens and chemoattractants, and initiate the process of wound decontamination. The result is a coagulum consisting of widely spaced, haphazardly arranged fibrin strands with serum exudate, erythrocytes, tissue debris, and inflammatory cells. Compression of the surgical flap with sterile iced gauze immediately after surgery is designed to minimize the thickness of the fibrin clot and thereby accelerate optimal wound healing.

Early Inflammation: Polymorphonuclear Neutrophil Organization

As a result of production of chemoattractants by the various components of the clot, polymorphonuclear neutrophils (PMNs) begin to enter the wound site within 6 hours of clot stabilization. The number of PMNs increases steadily, peaking at about 24 to 48 hours after the injury. Three key steps mark PMN migration into the wound site: *pavementing,* in which red

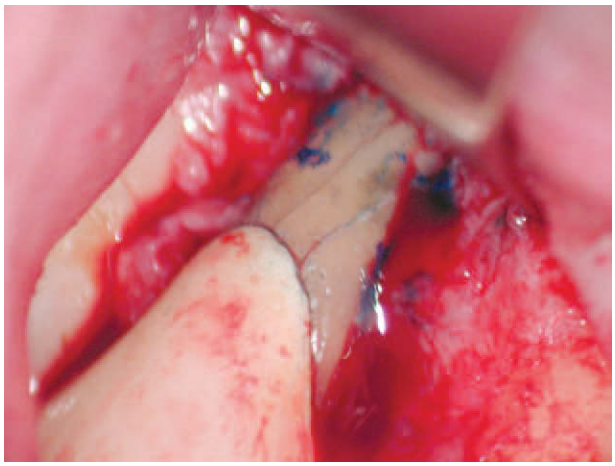

FIG. 21-4 Exploratory surgery was indicated to rule out or confirm a root fracture. Magnification and staining with methylene blue dye confirmed the presence of multiple root fractures. The tooth was subsequently extracted. *(Courtesy Dr. Martin Rogers.)*

blood cells undertake intravascular agglutination, allowing PMNs to adhere to the endothelial cells; *emigration*, in which PMNs actively pass through the vascular wall; and *migration*, in which PMNs use amoeboid motion, under the influence of various chemotactic mediators, to move into the injured tissues.[201]

The principal role of PMNs is wound decontamination by means of phagocytosis of bacteria. The high number of PMNs in the wound site is relatively short lived, dropping rapidly after the third day.

Late Inflammation: Macrophage Organization

About the time the PMN population is declining (48 to 96 hours after injury), macrophages begin to enter the wound site. They reach a peak concentration by approximately the third or fourth day. These cells, which are derived from circulating monocytes, leave the bloodstream under the influence of chemoattractants in the wound site. Monocytes subsequently evolve into macrophages. Macrophages have a much longer lifespan than PMNs; they remain in the wound until healing is complete. Similar to PMNs, macrophages play a major role in wound decontamination through phagocytosis and digestion of microorganisms and tissue debris.

Macrophages are considerably more bioactive than PMNs and can secrete a vast array of cytokines. A key action of many of these bioactive substances is initiation of the proliferative phase of wound healing, which is accomplished by prompting the formation of granulation tissue. Two other major functions of macrophages are ingestion and processing of antigens for presentation to T lymphocytes, which enter the wound after the macrophages. Unlike PMNs, macrophages play an essential role in the regulation of wound healing.[105,212] Reduction in the number of macrophages in the wound site delays healing, because the wound does not progress to the next phase. For example, age-related reduction in healing potential appears to be partly due to loss of estrogen regulation of macrophages in healing tissues.[33]

Proliferative Phase

The proliferative phase is characterized by the formation of granulation tissue in the wound, and two key cell types, fibroblasts and endothelial cells, have a primary role. Granulation tissue is a fragile structure composed of an extracellular matrix of fibrin, fibronectin, glycosaminoglycans, proliferating endothelial cells, new capillaries, and fibroblasts mixed with inflammatory macrophages and lymphocytes. Epithelial cells also are active during this phase of soft-tissue healing and are responsible for initial wound closure. Guided tissue regeneration (GTR) procedures are based on control of the epithelial cell growth rate during this phase.

Fibroblasts: Fibroplasia

Undifferentiated ectomesenchymal cells in the perivascular tissue and fibroblasts in the adjacent connective tissue migrate into the wound site on the third day after injury and achieve their peak numbers by approximately the seventh day. This action is stimulated by a combination of cytokines (e.g., fibroblast growth factor [FGF], insulin-like growth factor 1 [IGF-1], and 2-15 platelet-derived growth factor [PDGF]) produced initially by platelets and subsequently by macrophages and lymphocytes. As the number of macrophages declines and the fibroblast population increases, the tissue in the wound transforms from a *granulomatous* tissue to a *granulation* tissue.

Fibroblasts are the crucial reconstructive cell in the progression of wound healing, because they produce most of the structural proteins (e.g., collagen). Collagen is first detected in the wound about the third day after injury. The fibroblasts produce type III collagen initially and then, as the wound matures, type I collagen. As this network of collagen fibers is laid down, endothelial and smooth muscle cells begin to migrate into the wound. Subsequently, as wound healing progresses, the collagen fibers become organized by cross-linking. Regularly aligned bundles of collagen begin to orient so as to resist stress in the healing wound.[104,269,394,490]

A focused type of fibroblast known as a *myofibroblast* plays a significant role in wound contraction, particularly in incisional-type wounds.[299,498] Myofibroblasts align themselves parallel with the wound surface and then contract, drawing the wound edges together. These cells are eliminated by apoptosis after wound closure.[130,131]

Endothelial Cells: Angiogenesis

Capillary buds originate from the vessels at the periphery of the wound and extend into the wound proper. This occurs concurrently with fibroblast proliferation and can begin as early as 48 to 72 hours after injury. Without angiogenesis, the wound would not have the blood supply needed for further active healing. The capillary sprouts eventually join to form a network of capillary loops *(capillary plexuses)* throughout the wound.

In addition to a low oxygen concentration in the wound proper,[188,272] several factors have been identified as potent stimulators of angiogenesis, including vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), acidic FGF (aFGF), transforming growth factors alpha and beta (TGF-α, TGF-β), epidermal growth factor (EGF), interleukin 1 (IL-1), tumor necrosis factor alpha (TNF-α),[138] and

lactic acid.[235,245,479] All of these have been shown to stimulate new vessel development.

Epithelium

The first step in epithelial healing is formation of an epithelial seal on the surface of the fibrin clot. This process begins at the edge of the wound, where the basal and suprabasal prickle cells rapidly undergo mitosis. The cells then migrate across the fibrin clot at a remarkable rate (0.5 to 1 mm per day). This monolayer of epithelial cells continues to migrate by contact guidance along the fibrin scaffold of the clot below. Migration stops as a result of contact inhibition of the epithelial cells from the opposing wound edge. Once the epithelium from both sides of the wound is in contact, an epithelial seal is achieved. In wounds healing by primary intention, formation of an epithelial seal typically takes 21 to 28 hours after reapproximation of the wound margins.[211]

Maturation Phase

Under ideal conditions, maturation of the wound begins 5 to 7 days after injury. A reduction in fibroblasts, vascular channels, and extracellular fluids marks the transition to this phase of healing. During the early stages of wound maturation, the wound matrix is chiefly composed of fibronectin and hyaluronic acid. As the tensile strength of the wound increases, significant upregulation of collagen fibrogenesis occurs. Collagen remodeling ensues, with the formation of larger collagen bundles and alteration of intermolecular cross-linking. The result is a conversion of granulation tissue to fibrous connective tissue and a decreased parallelism of collagen to the plane of the wound. Aggregated collagen fibril bundles increase the tensile strength of the wound. As healing progresses in the wound, the collagen gradually reorganizes; this requires degradation and reaggregation of the collagen. Degradation of collagen is controlled by a variety of collagenase enzymes, and remodeling results in a gradual reduction in cellularity and vascularity of reparative tissue. The degree to which this occurs determines the extent of scar-tissue formation. Active remodeling of scar tissue can continue very slowly for life.[131,234]

Maturation of the epithelial layer quickly follows formation of the epithelial seal. The monolayer of cells forming the epithelial seal differentiates and undergoes mitosis and maturation to form a definitive layer of stratified squamous epithelium. In this way an epithelial barrier is formed that protects the underlying wound from further invasion by oral microbes. The epithelial barrier typically forms by 36 to 42 hours after suturing of the wound and is characterized by a significant increase in wound strength.[211]

HARD-TISSUE HEALING: EXCISIONAL DENTOALVEOLAR WOUND

The inflammatory and proliferative phases of hard-tissue healing are similar to those for soft tissue. A clot forms in the bony crypt, and an inflammatory process ensues that involves PMNs initially and macrophages subsequently. This is followed by the formation of granulation tissue with an angiogenic component. However, the maturation phase of hard-tissue healing differs markedly from that for soft tissues, primarily because of the tissues involved: cortical bone, cancellous bone, alveolar bone proper, endosteum, periodontal ligament, cementum, dentin, and inner mucoperiosteal tissue.

Osteoblasts: Osteogenesis

The healing of an excisional osseous wound approximately 1 cm in diameter is similar to that of a fractured long bone. It progresses from hematoma to inflammation, eradication of nonvital debris, proliferation of granulation tissue, callus formation, conversion of woven bone to lamellar bone, and finally remodeling of the united bone ends. The coagulum that initially forms delays healing and must be removed to allow wound healing to progress.

A major difference between soft- and hard-tissue wound healing is found in the role of the osteoclast. Functionally, osteoclasts act as an organizational unit to debride necrotic bone from the wound margin, much as macrophages remove tissue debris from the clot. Granulation tissue begins to proliferate from the severed periodontal ligament by 2 to 4 days after root-end resection.[210] This tissue rapidly encapsulates the root end. Simultaneously, endosteal proliferation into the coagulum occurs from the deep surface of the bony wound edge. The coagulum in the bony crypt is quickly converted into a mass of granulation tissue. In addition to those already discussed, several different cell types migrate into the coagulum, including osteoprogenitor cells, preosteoblasts, and osteoblasts. These cells begin the formation of woven bone within the mass of granulation tissue. New bone formation is apparent about 6 days after surgery.[210]

Bone formation can be categorized into two types, each having several phases. The phases differ, depending on which type of formation is involved. One type of bone formation is a matrix vesicle–based process, and the other type is based on osteoid secretion. In both processes, osteoblasts produce the bone matrix. They secrete a collagen-rich ground substance essential for mineralization. Osteoblasts also cause calcium and phosphorus to precipitate from the blood.

In the formation of woven bone, which occurs by the matrix vesicle–based process, osteoblasts produce matrix vesicles through exocytosis (the release of substances contained in a vesicle within a cell by a process in which the membrane surrounding the vesicle unites with the membrane forming the outer wall of the cell) of their plasma membranes. As hydroxyapatite crystals accrue in the vesicles, they become enlarged and eventually rupture. This process begins with the deposition and growth of hydroxyapatite crystals in the pore regions. The crystals then amalgamate to form structures known as *spherulites*. Union of the separate spherulites results in mineralization.

Formation of lamellar bone does not require the production of matrix vesicles; rather, it proceeds by the osteoblast secretion process. Osteoblasts secrete an organic matrix composed of longitudinally arranged collagen matrix fibrils (mainly type I collagen). Mineralization occurs by mineral deposition directly along the collagen fibrils.[226,227] This stage has been associated with a rise in pH, most likely because of the enzyme, alkaline phosphatase, which is secreted by osteoblasts and other cells and plays an important role in mineralization. The exact role of alkaline phosphatase during mineralization is unclear. The balance of evidence favors a positive catalytic role.[20,21] Some hypothesize[67,68,526,527] that alkaline phosphatase promotes mineralization through a combination

of mechanisms involving various cells, extracellular matrix proteins, and elements. The interaction of alkaline phosphatase and phosphoproteins in both bone and dentin appears to be especially critical to the mineralization process.[67,68,526,527]

Inhibitor molecules such as pyrophosphate and acidic noncollagenous bone proteins regulate mineralization. Several growth factors also have been identified as key components in the production of osseous tissue: TGF-β, bone morphogenetic protein (BMP), PDGF, FGF, and IGF.[94,181,458,488]

About 3 to 4 weeks after surgery, an excisional osseous wound is 75% to 80% filled with trabeculae surrounded by intensely active osteoid and osteoblastic cells. A reforming periosteum can be seen on the outer surface of the wound. It is highly cellular and has more fibrous connective tissue oriented parallel to the plane of the former cortical plate. At 8 weeks after surgery, the trabeculae are larger and denser and the osteoblasts less active; these cells occupy about 80% of the original wound. Also, fewer osteoid cells are associated with the maturing trabeculae. The overlying periosteum has reformed and is in contact with the newly developed bone. The osseous defect typically is filled with bone tissue by 16 weeks after surgery, but the cortical plate has not yet totally reformed. Maturation and remodeling of the osseous tissue continues for several more months.[210]

Local healing is also influenced systemically by the endocrine system and its three general categories of hormones: polypeptide regulators (parathyroid hormone, calcitonin, insulin, and growth hormone); steroid hormones (vitamin D_3, glucocorticoids, and the sex hormones), and thyroid hormones.[207]

Cementoblasts: Cementogenesis

During regeneration of the periradicular tissues, cementum forms over the surface of surgically resected root ends.[110] The exact spatial and temporal sequences of events leading to this formation of new cementum remain undefined; however, cementogenesis is important because cementum is relatively resistant to resorption (osteoclasts have little affinity for attaching to cementum).

Cementogenesis begins 10 to 12 days after root-end resection. Cementoblasts develop at the root periphery and proceed centrally toward the root canal.[25] Considerable evidence indicates that the cells that regulate cementogenesis are derived from ectomesenchymal cells in the tooth germ proper rather than from bone or other surrounding tissues. The migration and attachment of precementoblasts to the root surface dentin is monitored by mediators from within the dentin itself.[133,198] Cementum covers the resected root end in approximately 28 days. Newly formed PDL fibers show a functional realignment that involves reorientation of fibers perpendicular to the plane of the resected root end, extending from the newly formed cementum to the woven bone trabeculae. This occurs about 8 weeks after surgery.[201,301,302]

SYSTEMIC MEDICATIONS AND WOUND HEALING

Bisphosphonates

Bisphosphonates are commonly used for the treatment of osteopenia; osteoporosis; Paget's disease of bone; multiple myeloma; and metastatic bone, breast, and prostate cancer. The potential association between bisphosphonate use and osteonecrosis of the jaw was first reported in 2003.[314,333] The current preferred term for this condition is *bisphosphonate-associated osteonecrosis* (BON).[8] BON can occur spontaneously but is more commonly associated with dental procedures that involve bone trauma. Patient variables that increase the risk for BON include age (older than 65 years), chronic use of corticosteroids, use of bisphosphonates for more than 2 years, smoking, diabetes, and obesity.[264,316,322,552] The risk for BON with commonly prescribed oral bisphosphonates appears to be very low, whereas the overall benefits of this drug class for reducing morbidity and mortality related to hip, vertebral, and other bone fractures are significant.[8] The estimated incidence of BON in patients taking oral bisphosphonates ranges from 0 to 1 in 2260 cases, although dental extractions may quadruple the risk of developing BON.[8,322] The majority of cases have been reported in patients taking IV bisphosphonates (e.g., zoledronic acid and pamidronate). Approximately 20% of patients taking IV bisphosphonates may develop BON.[8,322]

Conservative and timely management of apical periodontitis is essential to reduce the risk of BON in patients taking bisphosphonates. Since periapical pathosis may exacerbate or increase risk,[8] the no-treatment option is not a viable choice. Treatment options and the potential risk for BON should be thoroughly discussed with all patients who are taking bisphosphonates. Nonsurgical retreatment should usually be considered the first choice, especially for patients with a history of IV bisphosphonate use or other risk factors. Even so, surgical treatment may be indicated to manage chronic or acute apical periodontitis. When the only viable treatment options for managing persistent periradicular inflammation are surgical root canal therapy or extraction, the question of which option is more or less likely to lead to BON in at-risk patients remains unanswered. In general, the procedure that could most predictably eliminate the periradicular inflammation with the least amount of surgical trauma would be preferred. Conservative surgical technique, primary tissue closure, and use of chlorhexidine mouth rinses preoperatively and during the healing stage, are recommended.[8] Prophylactic antibiotics are generally not indicated unless the patient is at risk for developing an infection independent of bisphosphonate use.[8] Since bisphosphonates have a substantial half-life when incorporated into bone, their discontinuation prior to dental treatment is unlikely to provide any measurable benefit and may place the patient at greater risk for complications the drug is intended to prevent.

Clinical observations[315] have suggested the possibility of predicting which patients may be at greater risk for BON, based on serum levels of C-terminal cross-linking telopeptide of type I collagen (CTX). This observation may provide a valuable tool for future risk assessment but requires additional validation prior to widespread acceptance.[8] The most current treatment recommendations for patients taking bisphosphonates can be accessed online at various dental and medical specialty websites, including: www.ada.org/prof/resources/topics/osteonecrosis.asp.

Glucocorticoids

Glucocorticoid therapy has been shown to induce rapid bone loss within the first 3 months of treatment. Even inhaled steroids have been implicated as a cause of bone loss. Bone formation

is inhibited partly through a decrease in osteoblast lifespan and function, a reduction in the mineral apposition rate, and a prolonged mineralization lag time. Biochemical markers of bone formation (i.e., osteocalcin and bone-specific alkaline phosphatase) are suppressed. In addition to this primary suppressive effect, glucocorticoids cause accelerated bone resorption. The number and activity of osteoclasts increase during early glucocorticoid exposure. With continued use of glucocorticoids, the rapid rate of osteoclast-mediated bone resorption slows, but suppression of bone formation continues as the overriding skeletal activity.[258] Bone loss therefore is progressive because bone resorption chronically exceeds bone formation.

The adverse effects of glucocorticoids on bone are mediated by sex steroid deficiency and expression of locally produced growth factors and related proteins, such as reduced production of IGF-1 and alterations in IGF-binding proteins in osteoblasts. The direct effect on calcium metabolism through alteration of vitamin D metabolism leads to a state of secondary hyperparathyroidism.[428,550,551]

Nonsteroidal Antiinflammatory Drugs

Bone homeostasis is regulated by many factors, including prostaglandins (PGs).[253] PGs are important to both normal and pathologic bone turnover and modulate osteoblast proliferation and differentiated functions.[407,408] The levels of prostaglandins E (PGE) and F (PGF) are elevated in the early phase of fracture healing, and administration of PGE_2 has increased the rate of osseous repair in several animal studies.[258] Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit the enzyme, cyclooxygenase (COX), which is involved in the synthesis of PGs. This is the same mechanism by which NSAIDs control pain. By inhibiting the COX enzymes and the subsequent production of prostaglandins, NSAIDs accomplish the desired antiinflammatory effects but also prevent the increased production of PGs required for bone healing. In vitro studies using animal models have shown that NSAIDs inhibit osteoblast proliferation and stimulate protein synthesis.[222] These drugs also have been shown to delay fracture healing and adversely affect bone formation in animals and humans.[16,182] In one study, the use of NSAIDs reduced the amount of bony ingrowth into an orthopedic implant.[208]

In other studies, NSAIDs reduced bone resorption associated with experimentally induced periapical lesions,[19,370] and systemic NSAIDs may play a positive role in maintaining bone height around endosseous titanium dental implants.[244] Additional research is needed to clarify the specific influence of NSAIDs on healing after periradicular surgery.

Cyclooxygenase-2 Inhibitors

Although both COX-1 and COX-2 have been identified in osteoblasts, the different roles of the two cyclooxygenases in bone formation remain unclear. A study using COX-1 and COX-2 knockout mice compared the roles of the two enzymes in fracture healing. COX-2 was shown to have an essential role in both endochondral and intramembranous bone formation during wound healing. COX-2 knockout mice showed a persistent delay in cartilage tissue ossification. No difference in fracture healing was observed between the COX-1 knockout mice and the wild-type control used in this study.[572] Additional studies have shown a persistent delay in healing with COX-2 NSAIDs[192,193]; however, this difference in effect was not apparent clinically in a study examining the healing of spinal fusion wounds.[173]

PREOPERATIVE EVALUATION OF MEDICALLY COMPLEX PATIENTS

The preoperative assessment must take into account both the type of procedure planned and the type of patient (i.e., physical health and psychological status). Healthy patients clearly can be expected to tolerate surgical procedures better than medically complex patients (see Chapters 4 and 25). Clinicians should anticipate and prepare for the inevitability of treating more medically complex patients as the population ages. It is beyond the scope of this brief section to cover all possible medical considerations; rather, the most common issues that may require modification of an endodontic surgical treatment plan are presented. Relatively few absolute contraindications to periradicular surgery exist for patients well enough to seek care in an ambulatory dental office. Nonetheless, if any question arises about a patient's ability to tolerate a surgical procedure, medical consultation is advised. A thorough medical history and assessment of vital signs are required parts of the presurgical evaluation.

The American Society of Anesthesiologists (ASA) has developed a widely used system for establishing surgical risk. Patients categorized as ASA 1 are healthy and usually require no modification of the surgical treatment plan. Patients classified as ASA 4 or ASA 5 are not treated in a dental office; these individuals have significant medical problems that take priority over dental considerations. Patients considered ASA 2 or ASA 3 are commonly seen on an outpatient basis but may require medical consultation and modification of the surgical treatment plan. Patients in the ASA 2 and ASA 3 categories have mild to moderate systemic disease and often are undergoing treatment with one or more prescription medications. The ASA classification system alone is not a reliable predictor of operative risk and should only be used as a general guide.[191] Even experienced anesthesiologists exhibit differences of opinion when using the ASA system to classify patients.[215,376] The patient's psychologic status and anticipated procedural stress should be considered in addition to ASA classification of physical health. A stress-reduction protocol may be helpful for patients who report moderate dental anxiety with concurrent mild to moderate systemic disease.

Surgical procedures typically require a larger amount of local anesthetic with a vasoconstrictor than nonsurgical root canal treatment. An essential part of the presurgical evaluation is an assessment of the patient's cardiovascular status and tolerance for local anesthetics that contain epinephrine. In particular, patients with advanced cardiovascular disease, geriatric patients, and patients taking certain medications may have a reduced tolerance for local anesthetics containing a vasoconstrictor (see Chapters 19 and 20). The use of local anesthetics with vasoconstrictors was addressed in the recently revised seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7).[218] Most experts feel that 0.036 to 0.054 mg of epinephrine (approximately two to three cartridges of local anesthetic with 1:100,000 epinephrine) should be safe for all patients except those with severe cardiovascular disease or other specific risk factors.[38,218,563] Local anesthetics

with vasoconstrictors should be avoided or used with extreme caution in patients with the following cardiovascular conditions: severe or poorly controlled hypertension, arrhythmias that are refractory to treatment, myocardial infarction within the past month, stroke within the past 6 months, coronary artery bypass graft within the past 3 months, and uncontrolled congestive heart failure.[294] Patients unable to tolerate vasoconstrictors may not be good candidates for periradicular surgery, because a local anesthetic with a vasoconstrictor is essential for obtaining adequate hemostasis and visibility during this type of procedure. Surgery can be performed using only local anesthetics without vasoconstrictors, but this is not recommended.

The potential for multiple drug interactions is increasing because of the aging population and the introduction of many new drugs. Many elderly patients have diminished liver and kidney function and therefore cannot metabolize and excrete drugs as efficiently as younger, healthy patients. The potential for drug interactions and decreased metabolism and excretion of drugs should be considered even for commonly used agents such as local anesthetics and analgesics.

A transient bacteremia is a virtual certainty with periradicular surgery; therefore patients at high risk for bacterial endocarditis should receive appropriate antibiotic prophylaxis as recommended by the American Heart Association. New guidelines for prevention of infective endocarditis were published in 2007 and represent a significant change from previous American Heart Association guidelines.[557] Antibiotic prophylaxis is no longer recommended for patients with a history of mitral valve prolapse (with or without regurgitation), rheumatic heart disease, bicuspid valve disease, aortic stenosis, and certain congenital heart conditions. Antibiotic prophylaxis is now only recommended for patients with valvular disease associated with the highest risk of adverse outcomes from infective endocarditis. For patients in the highest risk category, antibiotic prophylaxis is recommended for dental procedures that involve manipulation of gingival tissues or the periapical region of teeth or perforation of the oral mucosa. For all other patients with valvular disease, the risks associated with routine antibiotic prophylaxis are greater than potential benefits.[557] Patients with prosthetic joints may also be at increased risk for developing a hematogenous joint infection after oral surgery. Although the need for prophylactic antibiotics in this group of patients is somewhat controversial, consultation with the patient's orthopedic surgeon is advised; current recommendations include antibiotic coverage for many of these patients.[1] Selection and dosage of the antibiotic may be different from the commonly accepted regimen for preventing bacterial endocarditis, since different microorganisms are more commonly associated with late joint infections.

Management of patients undergoing anticoagulant therapy depends on the type of anticoagulant, the reason for anticoagulant therapy, and the type of oral surgery planned. Warfarin (Coumadin), a commonly prescribed anticoagulant used to treat or prevent thromboembolisms, blocks the formation of prothrombin and other clotting factors. The international normalized ratio (INR) value is the accepted standard for measuring prothrombin time (PT). The desired therapeutic range for the INR usually is 2 to 3.5, depending on the underlying medical indication for anticoagulant therapy. Limited oral surgery procedures, such as simple forceps extraction of one to three teeth, may be performed safely on patients with INR values within the normal therapeutic range.[9,85,242,460] Periradicular surgery, however, may present a greater challenge for hemostasis, even for patients well maintained within the therapeutic range. The clear field visibility normally required for proper surgical management of the root end may not be possible in patients undergoing anticoagulant therapy. The patient's physician must be consulted for assistance in developing an appropriate treatment plan. Some patients may be able to tolerate discontinuation of warfarin therapy 2 days before a planned surgical procedure, which allows the INR to drift downward. In a prospective cohort study, investigators[443] reported that suspension of warfarin 2 days before a surgical procedure resulted in no bleeding problems and no thromboembolic events. They found that the average time spent at an INR below 2 (critical value) was 28 hours, and 90% of the patients returned to the desired therapeutic INR value within 7 days. However, this strategy may place certain patients at greater risk for a thromboembolic event, so discontinuation of anticoagulant therapy would not be recommended.

In general, patients undergoing anticoagulant therapy should present minimal risk for significant bleeding during or after oral surgery, and local measures to control bleeding should be adequate.[84,538] In a review prepared for the American Dental Association Council on Scientific Affairs and Division of Science, Jeske and Suchko[247] recommended against routine discontinuation of anticoagulant therapy before dental procedures, including surgical procedures. Regardless of the management approach selected, consultation with the patient's physician and an INR test on the day of surgery are strongly recommended. Hospitalization and conversion to heparin therapy may be considered in special cases, but the patient, physician, and surgeon must carefully weigh the potential risks against the expected outcome and benefits. A new category of heparin anticoagulant, low-molecular-weight heparins (LMWHs), allows patient self-administration and may be an alternative for patients who need to maintain a high level of anticoagulation but want to reduce the cost and time required for traditional heparin conversion therapy.

Low-dose aspirin therapy is known to increase bleeding time by irreversibly inhibiting platelet aggregation. A common practice has been to advise patients to discontinue aspirin therapy for 7 to 10 days before oral surgery.[29] At low-dose therapeutic levels (less than 100 mg per day), aspirin may increase bleeding time and complicate surgical procedures. However, one study[29] concluded that low-dose aspirin therapy (less than 100 mg per day) should *not* be discontinued before surgical procedures and that bleeding could be controlled by local measures. Higher-dose therapy may create a greater risk of bleeding during or after surgery.

Although a patient undergoing aspirin therapy may not be at high risk for significant bleeding during or after surgery, a concern in periradicular surgery is the visibility problems created by oozing blood. The clinician should consult the patient's physician about the medical reason for aspirin therapy and should weigh the risks and benefits of discontinuing aspirin before the proposed surgery. It should be possible to perform periradicular surgery without discontinuing aspirin therapy if necessary, but visibility during the procedure may be compromised, which may adversely affect the prognosis.

Herbs, dietary supplements, and vitamins can contribute to bleeding problems during surgery, and patients often fail to report use of these substances in the preoperative evaluation.[366] In a recent survey of surgical patients, approximately a third reported using a nonprescription medication that might inhibit coagulation or interact with anesthetics.[365] In particular, ginkgo biloba, ginger, garlic, ginseng, feverfew, and vitamin E inhibit platelet aggregation and can increase the risk of bleeding.[93] Ingredients in over-the-counter (OTC) weight loss products can potentiate the effect of epinephrine and increase cardiac stress, although the most obvious example of this phenomenon, ephedra, has been removed from the U.S. market by U.S. Food and Drug Administration (FDA) order.

Patients with inherited or acquired bleeding disorders are also at risk for excessive bleeding during and after periradicular surgery. Impaired liver function associated with past or current alcohol or drug abuse may also predispose a patient to excessive bleeding during surgery. A thorough medical history and patient interview should help identify these patients and, in consultation with the patient's physician, allow for any necessary treatment modifications.

Many other medical conditions, such as recent myocardial infarction, stroke, cardiac arrhythmias, diabetes, radiation therapy for head and neck cancer, immunocompromising conditions, seizure disorders, adrenal suppression, liver or kidney disease, and pregnancy may require modification of the treatment plan. However, these conditions usually present more general problems that are not unique to a surgical procedure. The value of a thorough medical history and patient interview cannot be overemphasized.

ANATOMIC CONSIDERATIONS

Evaluating the access to the surgical site is one of the most important steps in case selection for periradicular surgery. Anatomic studies can provide some guidance, but individual variation is great, and there is no substitute for a complete clinical examination. A small oral opening, active facial muscles, shallow vestibule, and thick buccal alveolar bone all can significantly increase the difficulty of the procedure, even in cases that appear straightforward on radiographic examination.

Posterior Mandible

The primary anatomic structure of concern for periradicular surgery in the posterior mandible is the neurovascular bundle that courses through the mandibular canal and exits through the mental foramen. The relationship between the mandibular canal, the mental foramen, and the root apices of mandibular teeth has been well studied, but anthropometric averages have limited value in the treatment of individual patients. An understanding of the typical anatomic relationships is important, but even more important is an evaluation of the individual patient to develop a case-specific risk assessment.

The depth of the vestibular fornix generally is a good predictor of the possible difficulty involved in obtaining surgical access to the mandibular posterior teeth.[288] A shallow vestibule usually portends thicker alveolar bone and more difficult access to the root end.

The mental foramen, another key anatomic structure, usually is located between and apical to the mandibular first and second premolars[113,337]; however, this varies considerably, and the practitioner must examine each patient carefully to determine its location (Figs. 21-5 and 21-6). Vertical location of the mental foramen may vary even more than horizontal location. One investigator[337] found that the average location was 16 mm inferior to the cementoenamel junction (CEJ) of the second premolar, although the range was 8 to 21 mm, which would place approximately 20% of the foramina at or coronal to the root apex. Fortunately, the mental foramen usually is easily visualized with standard periapical and panoramic radiographs. A vertically positioned periapical radiograph often may be more useful than a horizontally positioned one, especially in individuals with longer roots. Also, the mental foramen usually can be palpated.

When a vertical releasing incision is indicated, it typically is made at the mesial line angle of the mandibular canine. This location is always mesial to the mental foramen, because the

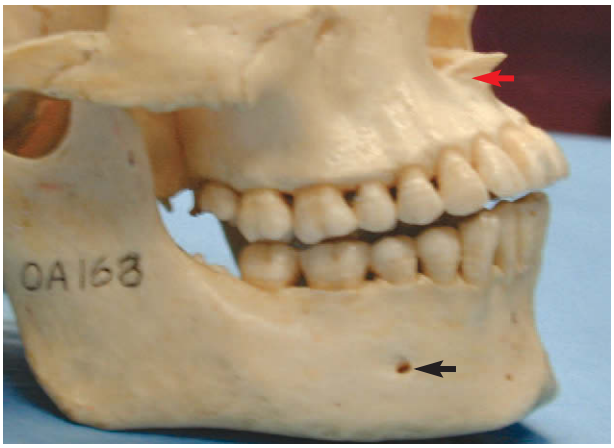

FIG. 21-5 Lateral view of the skull showing anterior nasal spine and proximity of the maxillary anterior root apices to the floor of the nose *(red arrow)*, as well as the typical location of the mental foramen *(black arrow)*.

FIG. 21-6 Preoperative evaluation of a mandibular left second premolar included a panoramic radiograph to help locate the mental foramen *(white arrow)*, which was not visible on a standard periapical radiograph.

foramen is located in the area ranging from the apex of the mandibular first premolar to slightly distal to the second premolar. The nerve bundle exits from the foramen in a distal direction. An alternative technique for gaining access to mandibular posterior teeth involves a distal releasing incision between the mandibular first and second molars.[336] This approach may be especially useful for access to the mandibular second premolar and first molar. Care must be taken to avoid the facial artery as it crosses the level of the inferior vestibular fornix near the mandibular first molar. Inadvertent contact with the facial artery is unlikely if the incision is not extended beyond the depth of the vestibule.

Regardless of the approach selected, it obviously is important to avoid making an incision in the immediate vicinity of the mental foramen. The mental nerve is encased in a relatively tough sheath, and permanent damage can be avoided if careful blunt dissection is used in the area. A misguided vertical releasing incision, however, may sever the nerve, causing permanent injury. Trauma to the nerve from blunt dissection in this area or from pressure from a misplaced retractor may cause temporary paresthesia but is much less likely to do permanent injury. (Documentation and management of nerve injuries are discussed later in the chapter.)

The borders of the mandibular canal often are more difficult to visualize with conventional radiographic techniques. A parallel periapical radiograph, either horizontally or vertically positioned, usually can provide a reasonably accurate image of the relationship between the superior border of the mandibular canal and the root apices. However, the mandibular canal sometimes cannot be readily visualized. Such cases should be approached with extreme caution because an increased risk of paresthesia secondary to nerve injury may be an unacceptable risk for many patients.

Periapical radiographs taken from two vertical angulations, 0 degrees (parallel technique) and −20 degrees, may help determine the buccolingual position of the canal in the same way horizontally angled radiographs may differentiate between buccal and lingual roots.[295] That is, if the apparent distance between the root apices and the mandibular canal is greater on the radiograph taken at the −20-degree angulation, the mandibular canal is positioned in the lingual half of the mandible. This is a useful rule to understand but may have limited practical application because visualizing the mandibular canal is difficult in angled radiographs. Cone-beam computed tomography (CBCT) imaging can be very useful for identifying the location of the mandibular canal and determining its relationship to the root apices.[528]

In the buccolingual dimension, the mandibular canal commonly follows a curving pathway from the buccal half of the mandible near the distal root of the second molar to the lingual half of the mandible near the first molar, then curving back to the buccal near the second premolar as it exits the mental foramen.[129] The average vertical distance from the superior border of the mandibular canal to the distal root apex of the mandibular second molar is approximately 3.5 mm. This increases gradually to approximately 6.2 mm for the mesial root of the mandibular first molar and to 4.7 mm for the second premolar.[129,295] This relationship typically provides a greater margin of safety for surgery on the mandibular first molar compared with the second premolar and especially the second molar. Surgery on the mandibular second molar may be further complicated by relatively thick overlying buccal bone, lingual inclination of the roots, and a more buccal location of the mandibular canal. This is not to say that periradicular surgery should not be performed on mandibular second molars; rather, it points out that the relative risks and benefits must be carefully considered. Often the most prudent choice for a mandibular second molar is an intentional replantation procedure or extraction and placement of an implant.

Posterior Maxilla

The primary anatomic structure of concern in the posterior maxilla is the maxillary sinus. Perforation of the sinus during surgery is fairly common, with a reported incidence of about 10% to 50% of cases.[149,168,438] Even without periradicular pathosis, the distance between the root apices of the maxillary posterior teeth and the maxillary sinus sometimes is less than 1 mm.[213] An inflammatory periradicular lesion often increases the likelihood of sinus exposure during surgery. Fortunately, perforation of the maxillary sinus rarely results in long-term postoperative problems.[213] In a report of 146 cases of sinus exposure during periradicular surgery, researchers[548] found no difference in healing compared with similar surgical procedures without sinus exposure. The sinus membrane usually regenerates, and a thin layer of new bone often forms over the root end, although osseous regeneration is less predictable.[50,149,548] The general rule of placing a vertical releasing incision at least one tooth mesial and distal to the surgical site is especially important when sinus perforation is possible, because the exposure site should be completely covered with the mucoperiosteal flap to provide primary closure.

If the maxillary sinus is entered during surgery, special care must be taken to prevent infected root fragments and debris from entering the sinus. The most commonly used root resection technique involves grinding the root apex with a high-speed drill for approximately 3 mm in an apical to coronal direction, and an opening could allow infected debris into the sinus. A sinus opening can be temporarily occluded with a material such as Telfa gauze, although the gauze should be secured to prevent inadvertent displacement into the sinus. A suture can be placed through the packing material to prevent displacement and aid retrieval. Researchers[246] suggest securing the apical root segment by drilling a small hole in the root tip and threading a piece of suture material through the hole. The root is then resected at the appropriate level, and the root-end fragment is removed in one piece. If a root fragment or other foreign object is displaced into the sinus, it should be removed. An orascope or endoscope may be useful for visualizing the foreign object, but referral for evaluation and surgical removal may be indicated if the fragment cannot be located and removed.

The palatal roots of maxillary molars present a special challenge for surgical access. Palatal roots may be reached from either a buccal (transantral) or palatal approach. One surgeon[541] described a transantral approach in which a buccal flap is reflected, the buccal roots are resected, the osteotomy access into the sinus is enlarged to approximately 1 × 1.5 cm, and the palatal root tip is resected, ultrasonically prepared, and filled. The sinus may be packed with moist gauze to catch debris, and it should be irrigated with sterile saline upon completion of the surgery. In some cases, careful reflection and retraction of the sinus membrane may be possible, allowing access to the

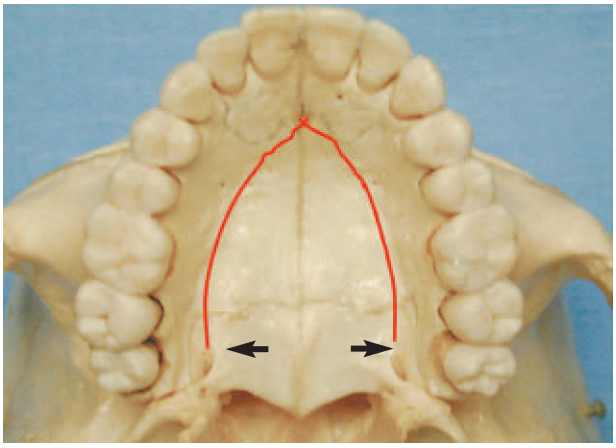

FIG. 21-7 Palatal view showing the position of the greater palatine foramen *(arrows)*. The approximate location of the anterior palatine artery is marked in red.

palatal root end without direct invasion of the sinus.[17] Many who have tried this approach find it more challenging than it might initially seem. The enhanced illumination and magnification provided by a dental operating microscope, endoscope, or orascope are essential aids in this type of surgery.

A palatal approach to the palatal root of maxillary molars may seem more direct than a transantral approach, but it can present certain difficulties. Visibility in the surgical field is reduced, and manipulation of instruments is more difficult than with most routine buccal approaches. Patients with a deep, vertical palatal vault are better candidates for this approach than individuals with a wide, shallow palate. A sinus tract or a large lesion on the palatal root may allow easier access and better visualization of the palatal root, because only limited bone removal would be required. The position of the anterior palatine artery must be carefully considered when the incision is made and the flap reflected. This artery emerges from the greater palatine foramen distal to the maxillary second molar at the junction of the vertical section of the alveolar process, and the flat portion of the palate and continues anteriorly (Fig. 21-7). A vertical releasing incision can be placed between the maxillary first premolar and canine, where the artery is relatively narrow and branches off into smaller arteries. If needed, a short distal vertical releasing incision may be made distal to the second molar, but it should not approach the junction of the alveolar process and roof of the palate. If the anterior palatine artery is severed, local clamping and pressure may not stop the hemorrhage, and ligation of the external carotid artery may be necessary. Because of the palatal vault's concave shape, repositioning the flap may be challenging. An acrylic surgical stent may be fabricated before surgery to assist repositioning of the flap and help prevent pooling of blood under the flap.

Anterior Maxilla and Mandible

Periradicular surgery on anterior teeth generally involves fewer anatomic hazards and potential complications than in posterior teeth. Nonetheless, access to the root apex in some patients may be unexpectedly difficult because of long roots, a shallow vestibule, or lingual inclination of the roots. As shown in Fig. 21-5, the root apices of maxillary central and lateral incisors can be quite close to the floor of the nose and the bony anterior nasal spine. The average maxillary canine is about 26 mm long and usually presents no difficulty for surgical access, but the combination of a shallow vestibule and a longer-than-average root length could complicate access to the root apex area. In such cases, the creation of an osteotomy apical to the root end may be impossible. An alternative approach for long-rooted teeth and root tips in the vicinity of critical anatomic structures is to enter the bone and resect the root at a level approximately 3 mm coronal to the apex. After the root tip is removed, the area apical to the root can be inspected and curetted as needed.

Periradicular surgery on mandibular incisors often is more challenging than expected. The combination of lingual root inclination, a shallow vestibule, and a prominent mental protuberance all can increase the degree of difficulty, as can proximity to adjacent roots and the need for perpendicular root-end resection and preparation to include a possible missed lingual canal.

CONE-BEAM VOLUMETRIC TOMOGRAPHY

Radiographic examination is an essential component in all aspects of endodontic treatment, from diagnosis and treatment planning to assessing outcome. Information gained from conventional films and digital periapical radiographs is limited by the fact that the three-dimensional (3D) anatomy of the area is compressed into a two-dimensional (2D) image. As a result of superimposition, periapical radiographs reveal limited aspects of the 3D anatomy. In addition, there may also be geometric distortion of the anatomic structures imaged. These problems may be overcome using small-volume cone-beam volumetric tomography (CBVT) imaging techniques that can produce 3D images of individual teeth and the surrounding tissues. CBVT may be particularly useful in diagnosis and treatment planning for periradicular surgery[108,155,236,300] (Fig. 21-8). The term *cone-beam computed tomography* (CBCT) is often used interchangeably with CBVT.

Differences Between CT and CBVT Imaging

The benefits of 3D medical computed tomography (CT) imaging are already well established in certain dental specialties. Current CT scanners have a linear array of multiple detectors, allowing multiple slices to be taken simultaneously, resulting in faster scan times and often less radiation exposure to the patient.[482] The slices of data are then "stacked" and can be reformatted to obtain 3D images. The high radiation dose, cost, availability, poor resolution, and difficulty in interpretation have resulted in limited use of CT imaging in endodontics. These issues may be addressed by recent cone-beam innovations in CBVT technology.

In 2000, the FDA approved the first CBVT unit for dental use in the United States. Cone-beam technology uses a cone-shaped beam of radiation to acquire a volume in a single 360-degree rotation, similar to panoramic radiography. The volume of acquired images by a CBVT is composed of voxels. Essentially, a voxel is a 3D pixel. Because the data are captured in a volume as opposed to slices, all the voxels are isotropic, enabling objects within the volume to be accurately measured in different directions. Unlike the CBVT voxel, a medical CT voxel is not a perfect cube, and measurements made in multiple planes are not accurate. In addition to increased accuracy

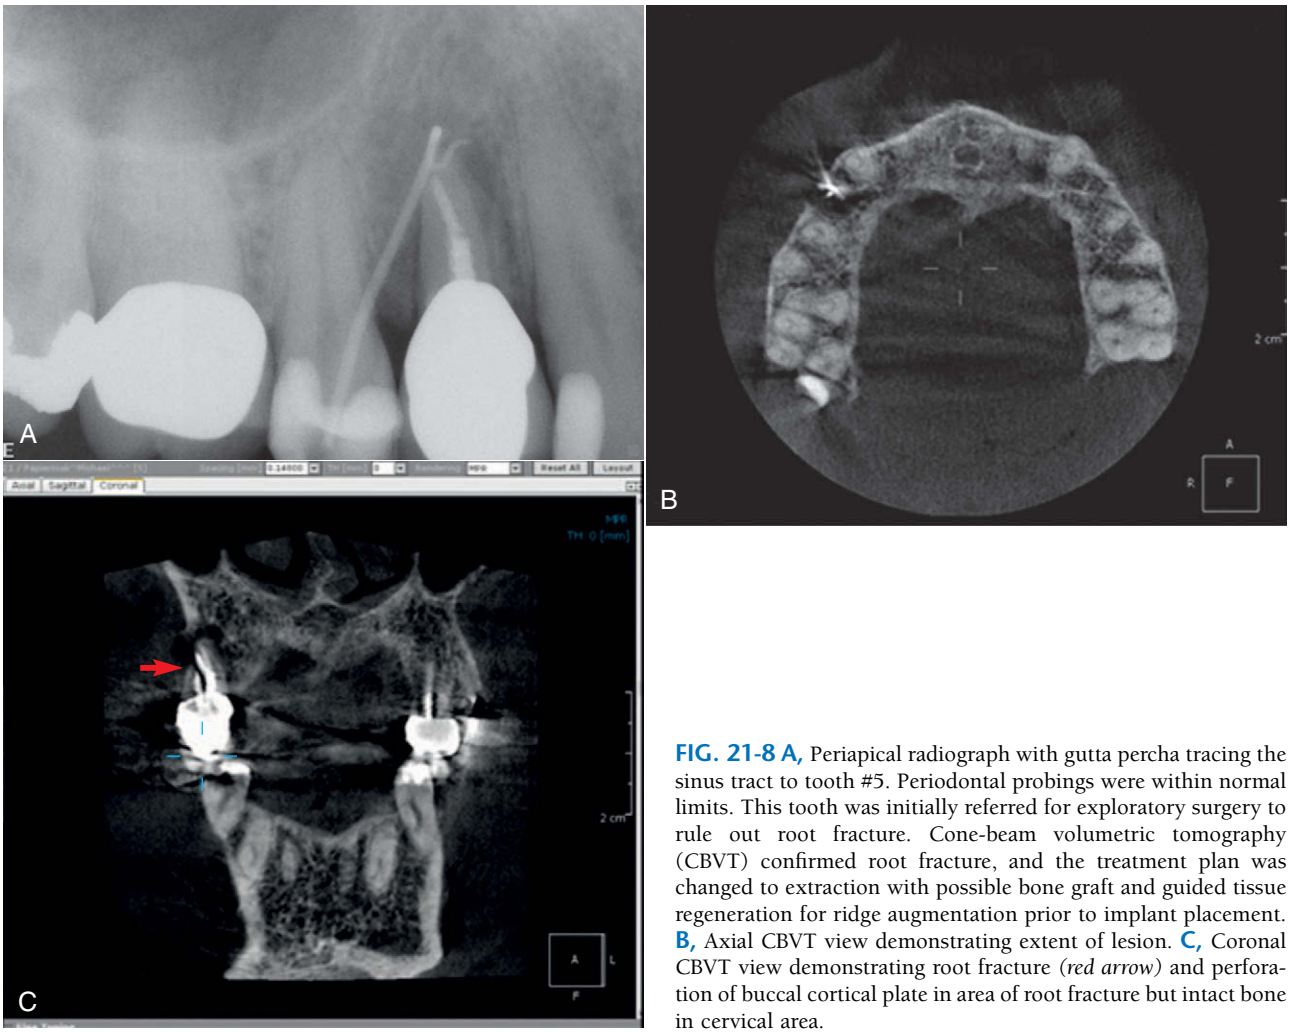

FIG. 21-8 A, Periapical radiograph with gutta percha tracing the sinus tract to tooth #5. Periodontal probings were within normal limits. This tooth was initially referred for exploratory surgery to rule out root fracture. Cone-beam volumetric tomography (CBVT) confirmed root fracture, and the treatment plan was changed to extraction with possible bone graft and guided tissue regeneration for ridge augmentation prior to implant placement. **B,** Axial CBVT view demonstrating extent of lesion. **C,** Coronal CBVT view demonstrating root fracture *(red arrow)* and perforation of buccal cortical plate in area of root fracture but intact bone in cervical area.

and higher resolution, CBVT offers significant scan-time reduction, radiation dose reduction, and reduced cost for the patient.[454,564,575] CBVT systems can be classified into two categories: limited (dental or regional) CBVT or full (ortho or facial) CBVT. The field of view (FOV) of limited CBVT ranges in diameter from 40 to 100 mm, whereas the FOV of full CBVT ranges from 100 to 200 mm.[108] Another difference between limited and full CBVT is that a voxel is generally smaller for the limited version (0.1 to 0.2 mm versus 0.3 to 0.4 mm), so limited CBVT systems offer higher resolution and are better suited for endodontic applications. Limited volume CBVT scanners capture small volumes of data that can include just two or three individual teeth. For example, the 3D Accuitomo (J. Morita Corporation, Osaka, Japan) captures a 30 mm high × 40 mm diameter cylindrical volume of data, similar in overall height and width to a periapical radiograph. Recently, the Planmeca Promax 3D (Planmeca, Helsinki, Finland) has been introduced to the dental market. This CBVT scanner, like the 3D Accuitomo, can also produce images of small specific areas of interest, with the smallest FOV being a 50 mm high × 30 mm diameter cylinder.

The most important and clinically useful feature of CBVT technology is the highly sophisticated software that allows the huge volume of data collected to be reconstructed. Tomographic slices as thin as one voxel thick may be displayed in a number of different ways. One option, for example, is for the images to be displayed in the three orthogonal planes—axial, sagittal, and coronal—simultaneously. The axial and proximal (sagittal in the anterior, coronal in the posterior) views are of particular value because they are generally not seen with conventional periapical radiography. The ability to reduce or eliminate superimposition of the surrounding structures makes CBVT superior to conventional periapical radiography.[297]

Scan times are typically 10 to 40 seconds, although the actual exposure time is significantly less (2 to 5 seconds) because scans involve a number (up to 360) of separate small, individual exposures rather than one continuous exposure. With medical CT scanners, scanning and exposure times for the skull can be significantly longer. Most CBVT scanners are much smaller than medical CT scanners, taking up about the same space as a dental panoramic machine. They are also significantly less expensive than medical CT scanners. With the help of viewer software, the clinician is able to scroll through the entire volume and simultaneously view axial, coronal, and sagittal 2D sections that range from 0.125 to 2.0 mm thick. Comparing the radiation dose of different CBVT scanners with

medical CT scanners may be confusing because different units of radiation dose are often used. There are three basic measurement units in radiation dosimetry: the radiation absorbed dose (D), the equivalent dose (H), and the effective dose (E). The *radiation absorbed dose* is defined as the measure of the amount of energy absorbed from the radiation beam per unit mass of tissue and is measured in joules per kilogram. The *equivalent dose* is defined as a measure that indicates the radiobiologic effectiveness of different types of radiation and thus provides a common unit. The *effective dose* is calculated by multiplying the equivalent dose by different tissue-weighting factors, which converts all doses to an equivalent whole-body dose and allows doses from different investigations of different parts of the body to be compared. The unit remains as the sievert (Sv) and can be used to estimate the damage from radiation to an exposed population. The reported effective doses from CBVT scanners vary but can be almost as low as those from panoramic dental x-ray units and considerably less than that from medical CT scanners.[379] The higher effective dose from particular models of CBVT scanners is in part due to the larger size of the FOV used and the type of image receptor employed. The small volume scanners, such as the 3D Accuitomo and Planmeca Promax 3D, capture information from a small region of the jaw, approximately the same area as a periapical radiograph. The effective dose of the 3D Accuitomo has been reported to be in the same range as two to three standard periapical radiograph exposures, whereas the effective dose for a full mouth series of periapical radiographs has been reported to be similar to the effective dose of a large-volume CBCT scan.[118,184] If multiple teeth in different quadrants require endodontic evaluation or treatment, a large-volume CBVT scan with a large FOV may be more appropriate. If endodontic information is required from multiple teeth in one jaw, a large-volume CBVT scan with the FOV limited to the jaw of interest could be the investigation of choice. This has the advantage of reducing the effective dosage from the full large-volume CBVT scan by up to 65%.[303]

Potential Applications of CBVT in the Management of Endodontic Posttreatment Disease

Clinical radiographic examinations are usually limited to 2D views captured using radiographic film or digital sensors. Crucial information related to the true 3D anatomy of teeth and adjacent structures is obscured. Even with paralleling techniques, distortion and superimposition of dental structures in periapical views is unavoidable. A major reported advantage of CBVT is the accuracy of measurements in all dimensions.[313] The ability to view thin sagittal, coronal, and axial slices effectively eliminates the problem of superimposition of anatomic structures. For example, roots of maxillary posterior teeth and surrounding tissues can be viewed without superimposition of the zygomatic buttress, alveolar bone, maxillary sinus, and other roots (Fig. 21-9). When compared to conventional periapical radiographs, CBVT enables clinicians to detect changes in apical bone density at an earlier stage and therefore has the potential to detect previously undiagnosed periradicular pathoses.[155,297,352] CBVT may also prove to be a useful tool for noninvasive differentiation of periapical cysts and granulomas,[468] a previously unattainable goal using conventional radiographic imaging.

Three-dimensional imaging allows for clear identification of the anatomic relationship of the root apices to important neighboring anatomic structures such as the mandibular canal, mental foramen, and maxillary sinus (Fig. 21-10). Investigators reported that the relationship of the inferior alveolar canal to the root apices could be determined in every case when utilizing medical CT but in less than 40% of cases when using conventional radiography.[528] It is likely that similar results could be achieved with CBCT using considerably less radiation. Researchers concluded that CBVT may play an important role in periapical microsurgery of palatal roots of maxillary first molars.[423] The distance between the cortical plate and the palatal root apex could be measured using CBVT, and the presence of the maxillary sinus between the roots could be assessed. Additional information such as the thickness of the cortical plate, cancellous bone pattern, fenestrations, and inclination of the roots can be obtained prior to surgical entry.[352] Root morphology (shape, size, curvature, number of canals) can be visualized in three dimensions. Unidentified (and untreated) canals in root-filled teeth can be routinely visualized in axial slices. Recently CBVT has been used to determine the location and extent of invasive external root resorptive defects.[379]

One of the most useful potential applications of CBVT may be the assessment of endodontic treatment outcomes, both nonsurgical and surgical. When compared to 2D film and digital images, CBVT is dimensionally precise and can detect smaller changes in bone density.[313]

It is worth remembering that CBVT still uses ionizing radiation and is not without risk. It is essential that patient exposure is kept as low as reasonably practical and that justifiable selection criteria for CBVT use are developed. CBVT may be indicated when it is determined that the additional information obtained is likely to result in a more accurate diagnosis and enhanced patient safety.

PATIENT PREPARATION FOR SURGERY

Informed Consent Issues Specific to Surgery

The general principles of informed consent discussed in Chapter 11 form the basis for informed consent for periradicular surgery. The patient must be thoroughly advised of the benefits, risks, and other treatment options and must be given an opportunity to ask questions. The main consent issues specific to surgical procedures are closely related to the anatomic considerations discussed in the previous section. That is, major neurovascular bundles may be traumatized, and a sinus exposure may occur. Paresthesia after mandibular posterior surgery is uncommon but should be discussed with the patient, since this potential complication is a risk some patients may be unwilling to assume. Postoperative swelling, bruising, bleeding, and infections are possible complications that typically are self-limiting or readily manageable. Although the incidence of serious complications related to surgical procedures is very low, patients should be advised of any risks unique to their situation. Prompt attention to any surgical complications and thorough follow-up are essential from a medicolegal standpoint.

Premedication: NSAIDs, Antibiotics, Chlorhexidine, and Conscious Sedation

Administration of an NSAID, either before or up to 30 minutes after surgery, enhances postoperative analgesia.[473] NSAIDs

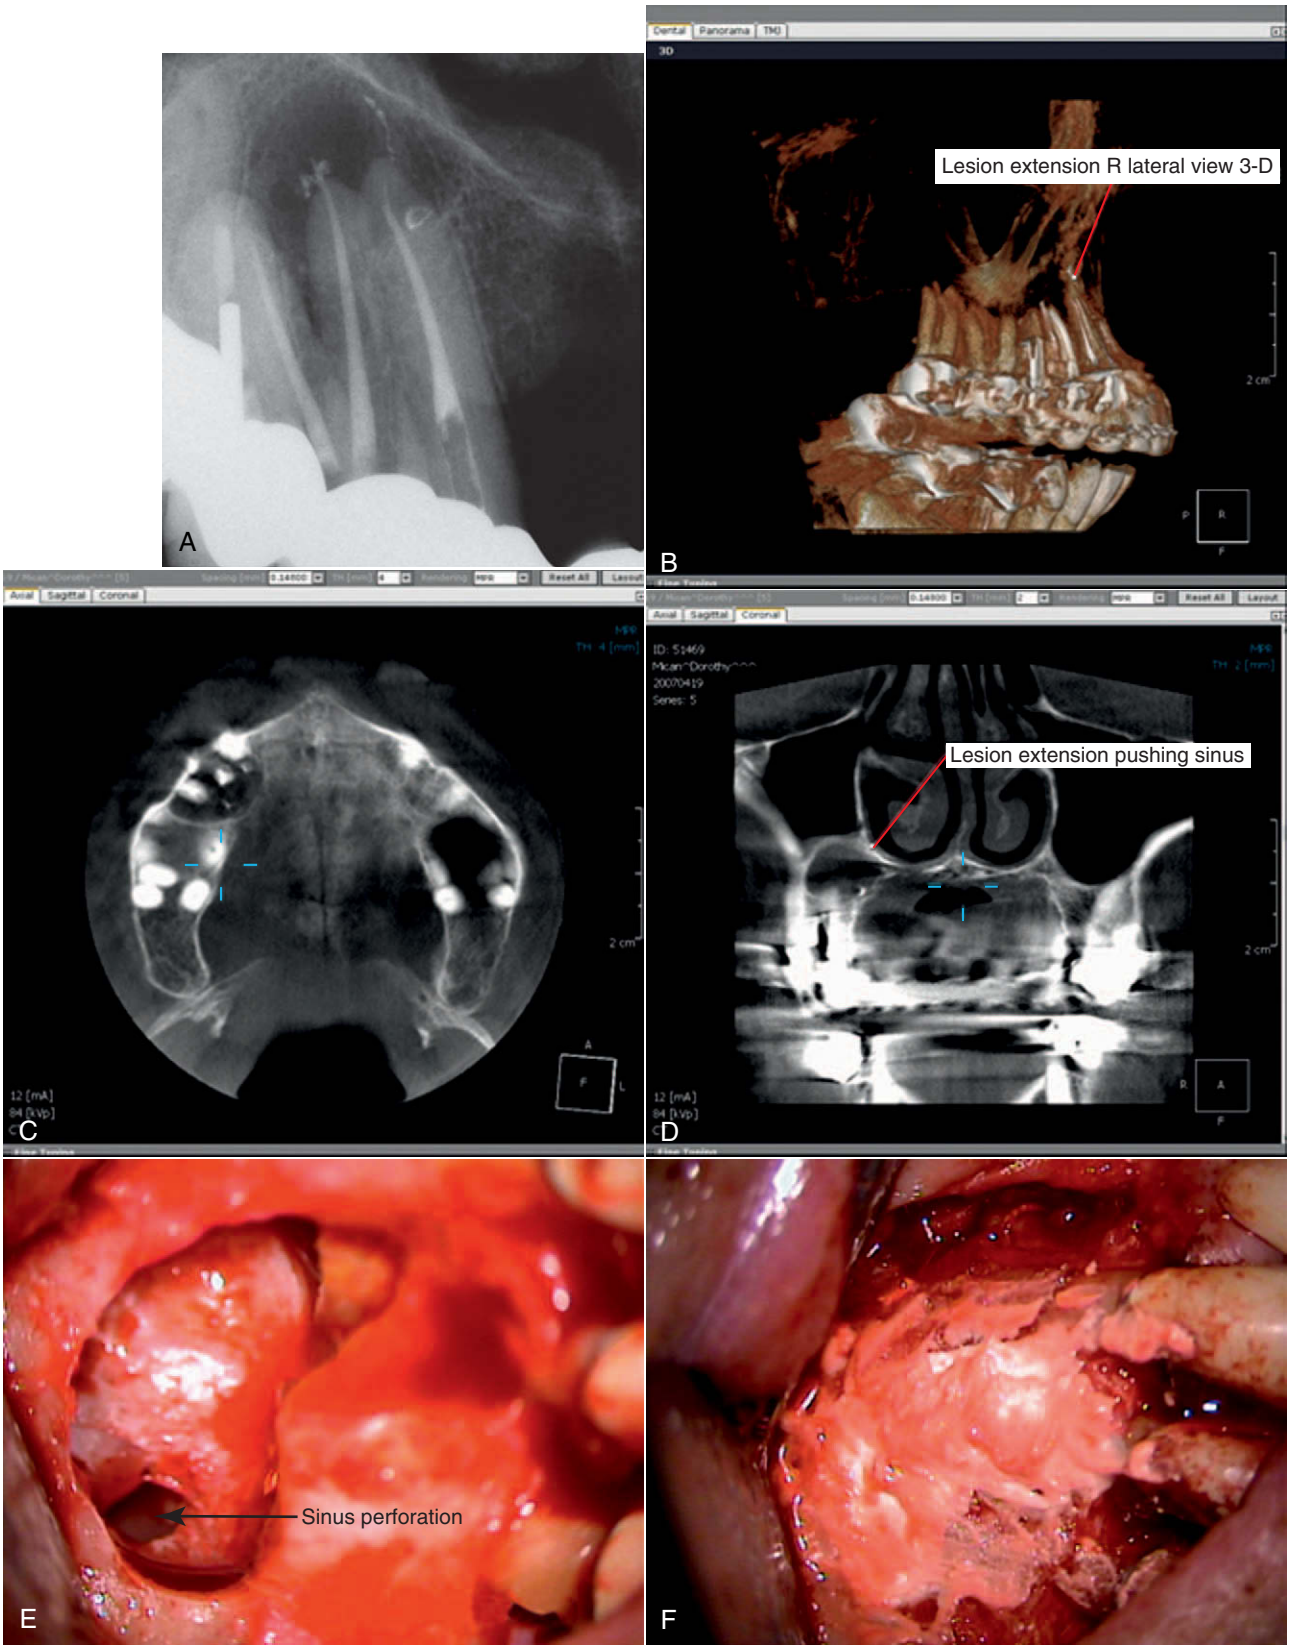

FIG. 21-9 A, Preoperative periapical radiograph showing large radiolucency associated with teeth #4, #5, and #6. **B,** Cone-beam volumetric tomography (CBVT) reconstruction (lateral view). Rotation of the 3D volume on a computer monitor demonstrated that intact bone was present around the apex of tooth #6, and the lesion was associated only with #4 and #5 (could not be detected with multiple-angled periapical radiographs). **C,** Axial CBVT view demonstrating facial-palatal extent of the lesion. **D,** Coronal CBVT view showing displacement of the sinus membrane (suggests a sinus membrane perforation will be detected during surgery). **E,** Clinical image after surgical access removal of granulation tissue and root-end resection; note sinus perforation (*arrow*). **F,** Placement of bone graft and Capset.

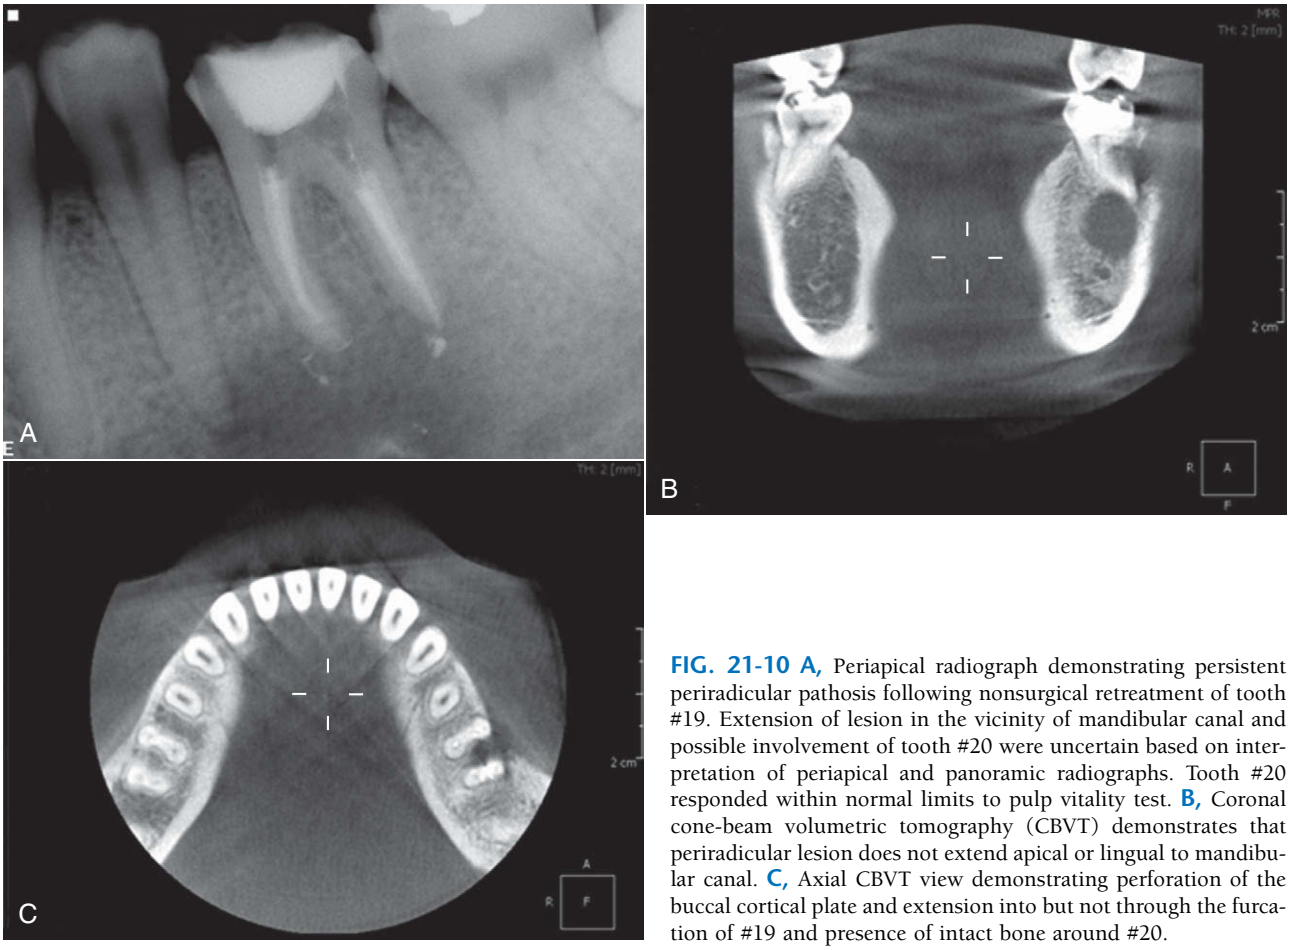

FIG. 21-10 A, Periapical radiograph demonstrating persistent periradicular pathosis following nonsurgical retreatment of tooth #19. Extension of lesion in the vicinity of mandibular canal and possible involvement of tooth #20 were uncertain based on interpretation of periapical and panoramic radiographs. Tooth #20 responded within normal limits to pulp vitality test. **B,** Coronal cone-beam volumetric tomography (CBVT) demonstrates that periradicular lesion does not extend apical or lingual to mandibular canal. **C,** Axial CBVT view demonstrating perforation of the buccal cortical plate and extension into but not through the furcation of #19 and presence of intact bone around #20.

generally have proved more effective in the management of postoperative oral surgery pain than placebo or acetaminophen and codeine combinations.[10,41,136] The combination of preoperative administration of an NSAID and use of a long-acting local anesthetic may be particularly helpful for reducing postoperative pain.[137] Many types of NSAIDs are available, but ibuprofen remains the usual standard for comparison. Ibuprofen 400 mg provides analgesia approximately equal to that obtained with morphine 10 mg and significantly greater than that from codeine 60 mg, tramadol 100 mg, or acetaminophen 1000 mg.[328] The analgesic effectiveness of ibuprofen tends to level off at about the 400 mg level *(ceiling effect)*, although a slight increase in analgesic potential may be expected in doses up to 800 mg. (See Chapter 19 for further discussion of analgesics.)

The value of antibiotic prophylaxis before or after oral surgery is controversial, and the current best available evidence does not support the routine use of prophylactic antibiotics for periradicular surgery.[12] For most patients, the risks of indiscriminate antibiotic therapy are believed to be greater than the potential benefits.[500] The incidence of infection after oral surgery in healthy patients is very low. One investigator[358] reported that only 1% of patients developed infections after third molar extractions. A systematic review of the use of antibiotics to prevent complications after placement of dental implants found that evidence was lacking either to recommend or discourage the use of antibiotics for this purpose.[154] However, the use of prophylactic antibiotics for more invasive procedures, such as orthognathic surgery, has significantly reduced the risk of postoperative infection and complications.[139] Although routine use of prophylactic antibiotics for periradicular surgery is not currently recommended, clinical judgment is important in determining exceptions to the general rule. For example, immunocompromised patients may be good candidates for prophylactic antibiotic coverage. Certain categories of medically complex patients also may benefit from antibiotic coverage. Diabetic patients have shown impaired healing capacity after nonsurgical root canal treatment,[75,166] and a like pattern of delayed or impaired healing may emerge in studies of surgical outcomes. The global problems associated with overprescription of antibiotics are significant and should prompt due caution in the decision whether to use these drugs prophylactically.

Chlorhexidine gluconate (0.12%) often is recommended as a mouth rinse to reduce the number of surface microorganisms in the surgical field, and its use may be continued during the postoperative healing stage.[8,265,520] Although no solid evidence supports this practice in periradicular surgery, the use of chlorhexidine follows from the general surgical principle of surface disinfection before incision and opening into a body cavity. In addition, chlorhexidine has proved to be a safe, effective adjunct in the treatment of periodontitis, and short-term use (i.e., several days) poses little or no risk. Chlorhexidine may be useful for reducing the risk of postoperative infection after oral surgery,[66,567] although the evidence in this area is conflicting. Postoperative use of chlorhexidine mouth rinse can reduce bacterial growth on sutures and wound margins[374] but may interfere with fibroblast reattachment to the root surface.[15] A useful empirical regimen is to have the patient rinse for 30 seconds twice a day beginning 1 or 2 days before surgery and continuing until the sutures are removed.

Conscious sedation, either by an orally administered sedative or by nitrous oxide/oxygen inhalation analgesia, may be useful for patients who are anxious about the surgical procedure or dental treatment in general. Benzodiazepines with a short half-life are particularly useful because they generally have a wide margin of safety, good absorption after oral administration, and limited residual sedative effects. When these drugs are used in sedative-hypnotic doses, the blood pressure, pulse, and respiration must be monitored, and states differ in their requirement for additional training or certification of staff members who do this monitoring. With oral conscious sedation, pulse oximetry should be used to monitor the pulse and blood oxygen saturation during the surgery.[80] As with all orally administered drugs, the dosage cannot be closely titrated, so the effect of the agent varies somewhat. A typical protocol is a single dose at bedtime the evening before the procedure and a second dose 1 hour before the start of surgery. The patient should not drive to or from the office and should have a responsible adult for assistance as needed. In appropriate doses, benzodiazepines and similar drugs may allow for a more relaxed patient and thus a less stressful surgical experience for both patient and surgeon.

INSTRUMENTS AND OPERATORY SETUP

The development of microsurgical techniques and new materials has changed the typical surgical instrument tray dramatically over the past 15 years. Instruments have been designed to take full advantage of the increased visibility obtained with dental operating microscopes, endoscopes, and orascopes. Better visualization of the surgical site would have limited value without microsurgical instruments such as ultrasonic tips for root-end preparation and micromirrors for inspecting the root end. Fig. 21-11 shows a typical basic surgery tray arrangement. This setup is not a definitive guide to the surgical armamentarium but rather an adequate, efficient starting point for most periradicular surgical procedures. Although the number of instruments can easily be doubled or even tripled, the ease of locating a specific instrument is inversely proportional to the number of instruments on a tray. Specialized instruments can be kept readily available in separate sterilized bags or trays and opened as needed. A skilled surgeon can use a wide variety of instruments (Figs. 21-12 to 21-23) to achieve excellent results.

Periradicular surgery can be performed without the benefit of enhanced magnification and illumination, but those who use microscopes, endoscopes, and orascopes report dramatically improved visualization and control of the surgical site.[39,89,266,332] The authors are unaware of any randomized controlled clinical trials comparing surgical outcomes with and without the use of magnification and illumination. However, current studies reporting the highest surgical success rates and those cited previously in this chapter all involved some form of enhanced magnification and illumination as part of the standard operating protocol. Surgeons accustomed to using microscopes, endoscopes, orascopes, and microsurgical instruments find it extremely difficult to go back to "dark field" surgery.

LOCAL ANESTHESIA FOR SURGERY

Local anesthesia for surgical root canal procedures differs from that for nonsurgical root canal treatment, primarily in the need

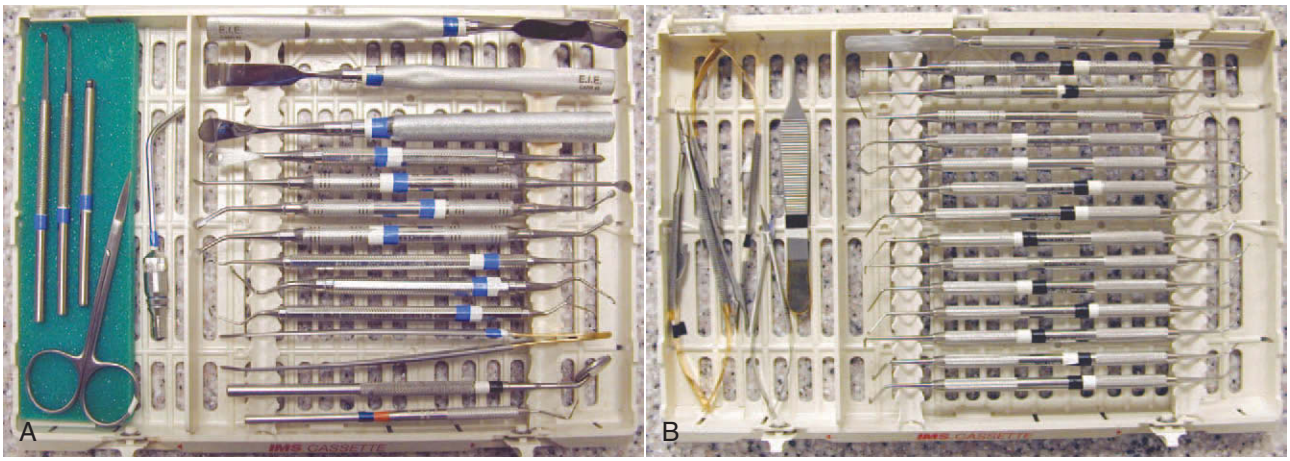

FIG. 21-11 A, Basic tray setup for initial surgical access. Surgical instruments shown are distributed by Hu-Friedy ([HF] Chicago), CK Dental Specialties ([CKDS] Orange, CA), EIE ([EIE]), and G. Hartzell & Son ([GHS]). *Left to right (left section of tray):* Small round micromirror (CKDS); medium oval micromirror (CKDS); handle for microscalpel (CKDS); scissors (S18 [HF]); surgical suction tip (GHS). *Top to bottom (main section of tray):* Carr #1 retractor (EIE); Carr #2 retractor (EIE); TRH-1 retractor (HF); periosteal elevator (HF); Ruddle R elevator (EIE); Ruddle L elevator (EIE); Jacquette curette (SJ 34/35 [HF]); spoon curette (CL 84 [HF]); scaler (7/8 [HF]); surgical forceps (TP 5061 [HF]); mouth mirror (HF); periodontal probe (HF). **B,** Instrument tray for root-end filling and suturing. *Left to right (left section of tray):* Two Castroviejo needle holders (Roydent Dental Products, Rochester Hills, MI); Castroviejo scissors (S31 [HF]); micro tissue forceps (TP 5042 [HF]). *Top to bottom (main section of tray):* Cement spatula (HF); Feinstein super plugger (F1L); microexplorer (CX-1 [EIE]); endoexplorer (DG-16 [EIE]); right SuperEBA Placing & Plugging instrument (MRFR [HF]); left SuperEBA Placing & Plugging instrument (MRFL [HF]); small anterior microburnisher and plugger (HF); small left microburnisher and plugger (HF); small right microburnisher and plugger (HF); medium anterior microburnisher and plugger (HF); medium left microburnisher and plugger (HF); medium right microburnisher and plugger (HF); large anterior microburnisher and plugger (HF); large left microburnisher and plugger (HF); large right microburnisher and plugger (HF).

for localized hemostasis in addition to profound local anesthesia. In fact, use of a local anesthetic with a vasoconstrictor may be the single most important local measure to help control hemorrhage and provide a clear surgical field. Otherwise, the same regional block and local infiltration techniques used for nonsurgical treatment (see Chapter 25) are used for surgical root canal procedures. Infiltration of the surgical site with a local anesthetic containing 1:50,000 epinephrine is the technique of choice to obtain vasoconstriction and hemostasis.[266] The local anesthetic is first slowly deposited in the buccal root apex area of the alveolar mucosa at the surgical site and extended two or three teeth on either side of the site. Usually palatal or lingual infiltration is also required, although this requires a much smaller amount of local anesthetic than the primary buccal infiltration. After the injections for anesthesia, the surgeon should wait at least 10 minutes before making the first incision.

Long-acting local anesthetics (e.g., 0.5% bupivacaine with 1:200,000 epinephrine) have been shown to reduce postoperative pain and analgesic use after surgical removal of impacted third molars,[119,194] but use of a local anesthetic with 1:200,000 epinephrine may result in greater blood loss during surgery.[221,472] To maximize postoperative analgesia and minimize intraoperative bleeding, a local anesthetic can be used with higher epinephrine concentrations (1:100,000 or 1:50,000) for the primary surgical anesthesia and supplemented with one cartridge of long-acting local anesthetic immediately after surgery. Long-lasting local anesthetics are particularly beneficial in mandibular surgery but much less so for surgery in the maxillary arch.

Every effort must be made to ensure profound local anesthesia before surgery begins. Usually a minimum of 10 to 20 minutes is required from the time of injection to the start of surgery to ensure both profound local anesthesia and adequate vasoconstriction for hemostasis. The patient should be asked about the usual signs of soft-tissue anesthesia, and a sharp explorer can be used to test the surgical area for sensation. Even when the surgeon pays careful attention to local anesthetic technique, a patient sometimes has inadequate

anesthesia or loss of anesthesia during the surgical procedure. Providing supplemental infiltration anesthesia is difficult after a full-thickness flap has been reflected. A supplemental block injection may be useful for mandibular teeth and maxillary posterior teeth. In the maxillary anterior area, a palatal approach to the anterior middle superior nerve may be helpful. The key to this approach is slow injection of approximately 1 ml of local anesthetic in the area of the first and second

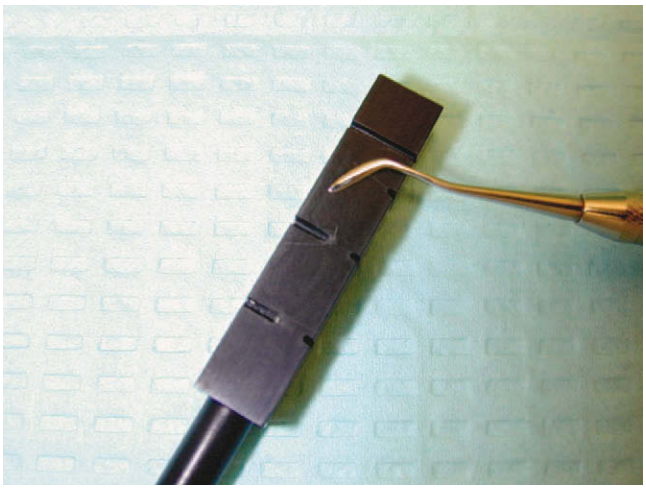

FIG. 21-21 Hard plastic block with notches of varying shapes and sizes (G. Hartzell & Son). MTA is mixed on a glass slab to the consistency of wet sand and then packed into a notch. The applicator instrument is used to transfer the preformed plug of MTA from the block to the root end.

maxillary premolars, midway between the gingival crest and the palatal midline. An intraosseous injection also may be used to regain lost anesthesia, but even when it is effective, the area of local anesthesia often is smaller than desired for a surgical procedure. As a last resort, the procedure can be terminated short of completion, and the patient can be rescheduled for surgery under sedation or general anesthesia.

SURGICAL ACCESS

The goals of periradicular surgery are to access the affected area, remove the diseased tissue, evaluate the root circumference and root canal system, and place a biocompatible seal in the form of a root-end filling that can stimulate regeneration of the periodontium. The formation of new cementum on the surgically exposed root surface and on the root-end filling material is essential to regeneration of the periodontium.

Successful endodontic surgery requires the surgeon to use several conceptual elements in planning the procedure. A vision of the immediate postoperative surgical endpoint (i.e., replacement of the reflected tissues) is essential for designing each phase of the surgery. Visualization of a 3D image of the surgical procedure allows the surgeon to anticipate and prepare for unusual circumstances. In surgical root canal treatment, once a procedure is started, it must be completed uninterrupted within a limited time; this is the paramount difference between nonsurgical and surgical root canal treatment. For this reason, it is absolutely essential that the surgeon plan the procedure thoroughly and include alternative plans of action that anticipate unusual findings during the process of discovery.

Several general principles are important for designing the access to a diseased region:

1. The surgeon must have a thorough knowledge of the anatomic structures in relation to each other, including tooth anatomy.
2. The surgeon must be able to visualize the 3D nature of the structures in the soft and hard tissue (this reduces unnecessary tissue damage).
3. The trauma of the surgical procedure itself must be minimized, which includes the preservation of tooth and supporting structures.
4. The tissue and instruments must be manipulated within a limited space, with the aim of removing diseased tissues and retaining healthy tissues.

Soft-Tissue Access

In designing the soft-tissue access window to the diseased tissue, the surgeon must take into consideration various anatomic features, such as frenum-muscle attachments, the width of attached gingiva, papillary height and width, bone eminence, and crown margins. The supraperiosteal blood vessels of the attached gingiva extend from the alveolar mucosa and run parallel to the long axis of the teeth, lying in the reticular layer superficial to the periosteum.[163] A vertical (rather than an angled) releasing incision severs fewer vessels,[306] reducing the possibility of hemorrhage. Also, the blood supply to the tissue coronal to the incision is not compromised,[459] which prevents localized ischemia and sloughing of these tissues. Ultimately, the result is less bleeding during the procedure and enhanced healing. For these reasons, an angled releasing incision is contraindicated in periradicular surgery.

FIG. 21-24 Intrasulcular incision with two vertical releasing incisions (rectangular flap).

Vertical Incision

The general principles for placement of a vertical relieving incision are:

1. The incision should be made parallel to the supraperiosteal vessels in the attached gingiva and submucosa (Fig. 21-24).
2. No cuts should be made across frenum and muscle attachments.
3. Frenum and muscle attachments should not be located in the reflected tissue if possible.
4. The incision should be placed directly over healthy bone.
5. The incision should not be placed superior to a bony eminence.
6. The dental papilla should be included or excluded but not dissected.
7. The incision should extend from the depth of the vestibular sulcus to the midpoint between the dental papilla and the horizontal aspect of the buccal gingival sulcus.

Horizontal Incision

Three types of horizontal incisions can be used to gain access to a surgical site in hard tissue:

- An intrasulcular incision that includes the dental papilla. This incision extends from the gingival sulcus through the PDL fibers and terminates at the crestal bone of the alveolar bone proper. The incision then passes in a buccolingual direction adjacent to each tooth of the dental papilla and includes the midcol region of each dental papilla. The entire dental papilla is completely mobilized.
- An intrasulcular incision that excludes the dental papilla (papillary-based incision, Fig. 21-25). This technique consists of a shallow first incision at the base of the papilla and a second incision directed to the crestal bone.
- An incision made in the attached gingiva (a submarginal or Ochsenbein-Luebke flap).[304] With this technique, at least 2 mm of attached gingiva must be retained to prevent mucogingival degeneration.[279] Consequently, the incision must be placed at least 2 mm from the depth of the gingival sulcus. Extensive periodontal probing should be done to establish the depth of the gingival sulcus before the incision is made. The average width of the attached gingiva is 2.1 to 5.1 mm in the maxilla and 1.8 to 3.8 mm in the mandible.[11,189,323,534] It is widest over the central and lateral incisors, narrows over the canine and the first premolar,

FIG. 21-25 Papillary-based incision with one vertical releasing incision.

FIG. 21-26 Intrasulcular incision with one vertical releasing incision (triangular flap).

and then widens over the second premolar and the first molar. These variances were similar for both the maxilla and mandible.[491] Overall, this incision technique has a narrow margin of safety. It generally is recommended for use in the maxilla, especially where the esthetics of existing crown margins are a concern.

Studies have compared the incision techniques that include and exclude the dental papilla in patients with healthy marginal periodontal conditions.[494,495] These researchers found that the papillary-based incision resulted in rapid recession-free healing. In contrast, complete mobilization of the papilla led to a marked loss of papillary height. The authors suggested that use of the papillary-based incision in aesthetically sensitive regions could help prevent papillary recession and surgical cleft, or double papilla.

Flap Design

Combinations of vertical and horizontal incisions are used to achieve various flap designs. The full mucoperiosteal and limited mucoperiosteal are the two major categories of flap design used during periradicular surgery, the main differentiating feature being the position of the horizontal incision. In each case the entire body of soft tissue is reflected as one unit and includes the alveolar mucosa, the gingival tissues, and periosteum. The number and position of the vertical relaxing incisions therefore governs the major variation in design.

1. Full mucoperiosteal (intrasulcular incision including the dental papilla or papillary based) (Figs. 21-26 and 21-27)
   - a. Triangular: one vertical relieving incision
   - b. Rectangular: two vertical relieving incisions
   - c. Trapezoidal: two angled vertical relieving incisions
   - d. Horizontal: no vertical relieving incision
2. Limited mucoperiosteal (Figs. 21-28 and 21-29)
   - a. Curve submarginal (semilunar)
   - b. Freeform rectilinear submarginal (Ochsenbein-Luebke)

Tissue Reflection

Elevation and reflection of the entire mucoperiosteal complex, maintaining the microvasculature in the body of the tissue flap, increases hemostatic control during surgery. Tissue reflection should begin from the vertical releasing incision at the junction of the submucosa and the attached gingiva (Figs. 21-30 and 21-31). By initiating the reflection process at this point, damage to the delicate supracrestal root-attached fibers is avoided. Using a flap reflection technique that reduces reflective tissue forces in the intrasulcular incisional wound and avoids curettage of the root surface conserves the root-attached tissues and helps prevent apical downgrowth of epithelium and loss of soft-tissue attachment.[211] Force should be applied such that the periosteum and superficial tissues are reflected as a complete unit. Using a gentle rocking motion, the surgeon initially should reflect the tissue in a horizontal direction.[200]

FIG. 21-27 Reflection of the triangular flap to expose the root-end area.

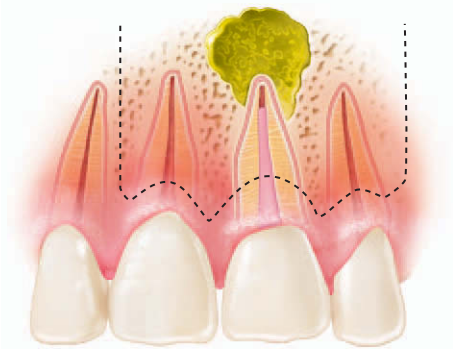

FIG. 21-28 Submarginal (Ochsenbein-Luebke) flap.

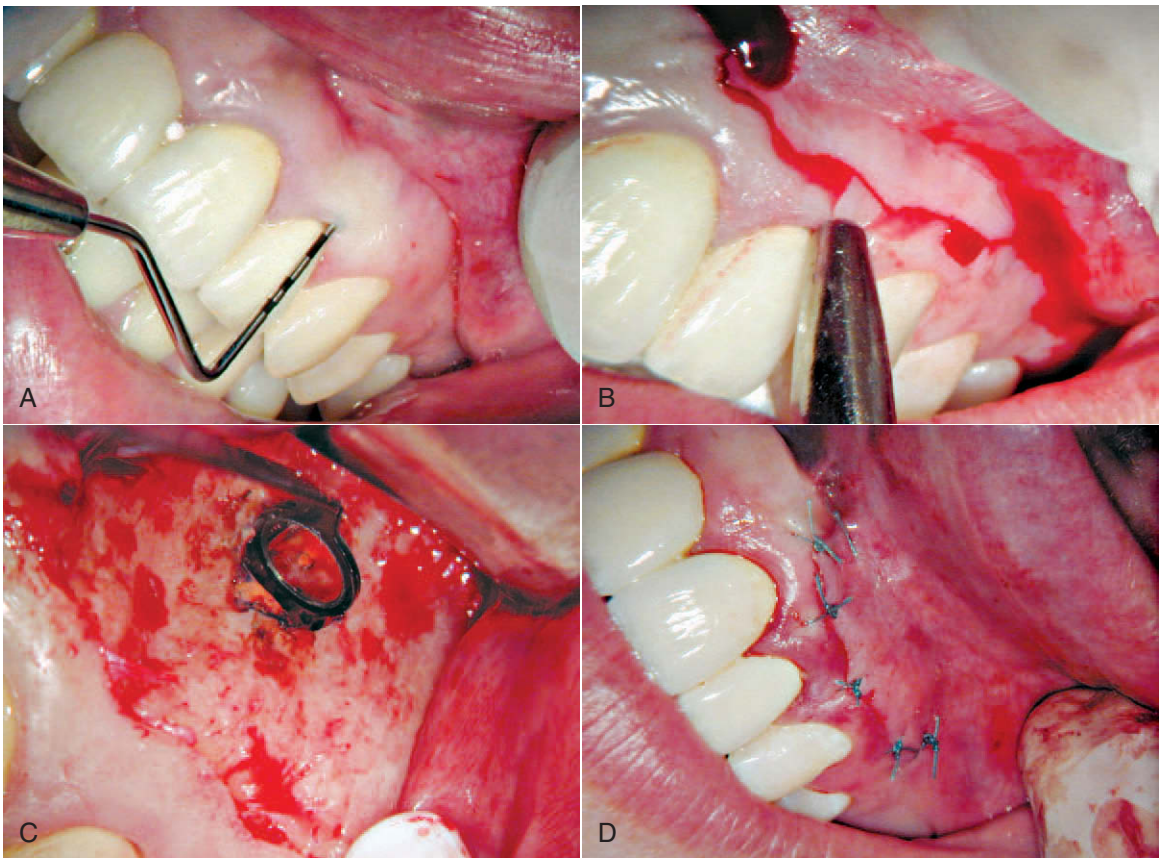

FIG. 21-29 Clinical case involving a submarginal incision and flap. **A,** Periodontal probing of entire area was performed before this type of flap was selected and incision started. A submarginal incision often is used in esthetic anterior areas of the mouth where postoperative gingival recession might expose crown margins. **B,** Incision should be at least 2 mm apical to depth of sulcus. **C,** With flap reflected, osteotomy and root-end resection were performed. Methylene blue dye was placed to mark outline of root end and help identify cracks or fractures before root-end cavity preparation and filling. **D,** The flap was repositioned and sutured with 5-0 Tevdek. *(Courtesy Dr. Martin Rogers.)*

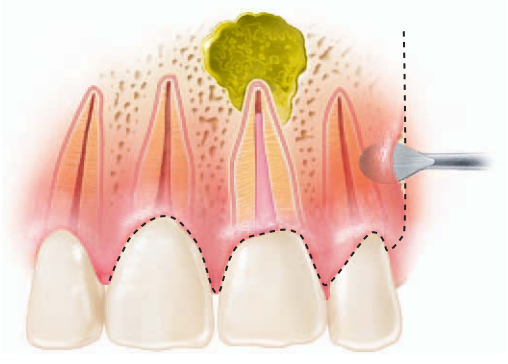

FIG. 21-30 Elevator placed in the vertical incision for the first step in undermining flap reflection.

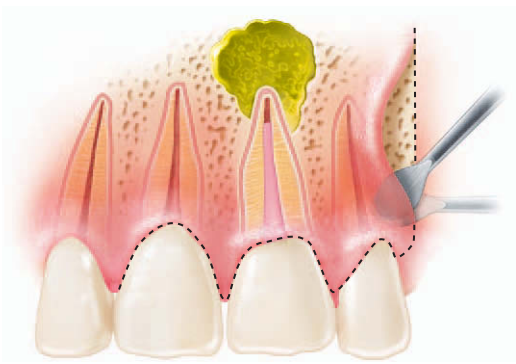

FIG. 21-31 Continuation of reflection of full-thickness flap.

The underlying bone of the cortical plate is irregular, and it is critical to avoid damaging the fragile tissues during elevation.

The clinician should take great care not to slip during the tissue reflection process; this can be done by using an appropriate instrument stabilized with adequate finger support. Slipping can result not only in puncture of the immediate overlying tissue but also damage to the surrounding structures.

As space permits, the elevator should be directed coronally, undermining the attached gingiva. As the interdental papilla is approached, a narrower instrument may be required to undermine and gently elevate the tissue in this region to avoid crushing the delicate free gingival tissues. This process should be continued gradually until the osseous tissues overlying the diseased tooth structure have been adequately exposed. Generally, elevation of the flap 0.75 cm apical to the estimated apex

of the root should allow adequate space to perform the surgical procedure.

No single instrument is essential for the flap elevation procedure, because every instrument has both advantages and disadvantages. Surgeons should familiarize themselves with the various instruments available.

Tissue Retraction

After the tissue is reflected, it must be retracted to provide adequate access for bone removal and root-end procedures. The main goals of tissue retraction are to provide a clear view of the bony surgical site and to prevent further soft-tissue trauma. Accidental crushing of the soft tissues leads to more postoperative swelling and ecchymoses.[210,211]

The general principles of retraction are (1) retractors should rest on solid cortical bone; (2) firm but light pressure should be used; (3) tearing, puncturing, and crushing of the soft tissue should be avoided; (4) sterile physiologic saline should be used periodically to maintain hydration of the reflected tissue; and (5) the retractor should be large enough to protect the retracted soft tissue during surgical treatment (e.g., prevent it from becoming entangled in the bone bur). No one retractor suffices for all surgical procedures; the surgeon should have a selection of retractors available for the various situations that arise during surgery. If difficulty is encountered in stabilizing the retractor, a small groove can be cut into the cortical plate to support it.

Hard-Tissue Access

Two biologic principles govern the removal of bone for hard-tissue access to diseased root ends: healthy hard tissue must be preserved, and heat generation during the process must be minimized.

Temperature increases above normal body temperature in osseous tissues are detrimental. Heating osseous tissue to 117° F to 122° F (47° C to 50° C) for 1 minute significantly reduces bone formation and is associated with irreversible cellular damage and fatty cell infiltration.[153,320] Two critical factors determine the degree of injury: how high the temperature is increased and how long it remains elevated. As the temperature rises above 104° F (40° C), blood flow initially increases. It stagnates at 198° F (46° C) applied for 2 minutes. Heating osseous tissue to 133° F (56° C) deactivates alkaline phosphatase.[403,404] Studies using animal bone have shown that at temperatures above 109° F (42.5° C), for every 1° C elevation in temperature, the exposure time for the same biologic effect decreases by a factor of approximately 2.[150-153] Temperatures above 117° F (47° C) maintained for 1 minute produce effects similar to those at 118° F (48° C) applied for 30 seconds. This correlation means that the decisive exposure time declines quickly as the temperature increases. Temperatures above 127° F (53° C) applied for less than 1 second can adversely affect osteogenesis.[150-153]

Several factors determine the amount of heat generated during bone removal, including the shape and composition of the bur, the rotational speed, the use of coolant, and the pressure applied during cutting.

The round bur has the best shape for removing osseous tissue, and it should be used with a gentle brushstroke action.[493] This type of bur also readily allows access of coolant to the actual cutting surfaces. Studies comparing the heat generated with round and fissure burs found more favorable results with the round burs.[81,107,204,320,341] Cutting with round burs produced a wound site with less inflammation, which is more favorable for rapid wound healing. Although fissure-type burs cut efficiently on the sides, the tip of the bur is very inefficient because it allows no coolant access. The net result is increased inflammation and a reduced healing response.

FIG. 21-32 Surgical handpiece with 45-degree angle head and rear air exhaust (Impact Air 45).

Use of a diamond bur to remove osseous tissue is inefficient and retards ultimate wound healing. Because of its larger surface area, more of a diamond bur is in contact with the bone tissue. As a result, less coolant reaches the cutting surface, and the bur has a greater tendency to become clogged with residual bone fragments. The net effect is greater heat generation, increased inflammation, and reduced healing.[81,555]

Use of a coolant during bone cutting is essential. If an appropriate irrigant is not used, temperatures can exceed those known to impair bone healing[260]; histologically, healing can be delayed up to 3 weeks.[160] It also is critical that the coolant reach the cutting surface. Temperatures can rise above 212° F (100° C) when excess pressure is applied during cutting. This burrows the bur into the bone, where little or no irrigant can reach the cutting tip[493]; hence the recommendation for a gentle brushstroke technique.[200] Favorable results are obtained with these, provided the surgeon follows the basic tenet of minimizing heat generation: using a round, fluted bur with coolant and a brushstroke technique. A high-speed handpiece that exhausts air from the base rather than the cutting end is recommended to reduce the risk of air embolism (Fig. 21-32).

PERIRADICULAR CURETTAGE AND BIOPSY

Most periradicular lesions originate in the pulp and can be classified histopathologically as granulomas or cysts.* Histologically, such lesions consist mainly of granulation tissue associated with angiogenesis, fibroblasts, connective tissue fibers, and inflammatory cells. Foreign material, cholesterol clefts,[345,351] and stimulated strands of epithelium also may be present. The stimulated epithelium can form into a stratified, squamous epithelium–lined cystic cavity.[347] These periradicular lesions (granulomas and cysts) are inflammatory lesions that develop in response to irritation caused by intraradicular

*References 52, 57, 275, 278, 280, 340, 348, 363, and 467.

and extraradicular microorganisms associated with the root canal system[344,349] or by foreign materials forced into the periradicular tissues.[569]

An important aspect of periradicular surgery is the removal of diseased tissue associated with the root apex. Because a large portion of this tissue is reactionary, the focus of surgical root canal treatment is removal of the irritant or diseased tissues. Histologically, an inflammatory periradicular lesion is similar to healing granulation tissue. If the irritant can be readily identified and successfully eliminated, it is not always necessary to completely curette all the inflamed periradicular tissues during surgery.[289] This is especially true when complete removal might result in injury to neural or vascular tissues. In addition to removing diseased tissue, periradicular curettage provides visibility and accessibility to facilitate treatment of the apical root canal system or removal of foreign materials in the periradicular tissues.

The need for histopathologic assessment of all tissues removed from the body cannot be understated. Although only a small percentage of periradicular lesions are associated with pathoses other than a periradicular cyst or granuloma, all lesions must be diagnosed definitively because of the potential gravity of the few rare diseases associated with periradicular lesions.[13,116,176,364,390]

The technical aspect of removing soft tissue from the bony crypt varies among surgeons and clinical settings. A large array of bone and periodontal curettes is available for this purpose, and no one instrument suffices for all cases. Regardless of the instrument selected, the basic principles are the same. A sharp instrument is always preferable to a blunt instrument. The soft-tissue lesion first should be peeled away from the osseous crypt, starting at the lateral borders. This can be accomplished efficiently by using the curette with the concave surface facing the internal wall of the osseous crypt. Once the soft-tissue lesion has been separated from the osseous crypt to the point where the crypt changes its convexity, the curette can be used in a scraping manner to remove the remainder of the lesion from the medial wall of the osseous defect.

LOCALIZED HEMOSTASIS

Localized hemostasis during periradicular surgery is essential to successful management of the resected root end. Appropriate hemostasis during surgery minimizes surgical time, surgical blood loss, and postoperative hemorrhage and swelling.[200] The hemostatic agents used during endodontic surgery are intended to control bleeding from small blood vessels or capillaries. Localized hemorrhage control not only enhances visibility and assessment of the root structure, it also ensures the appropriate environment for placement of the current root-end filling materials and minimizes root-end filling contamination.

Many hemostatic agents have been advocated for use during surgery, and the action of these agents, their ability to control bleeding, and their effect on healing vary considerably. They generally aid coagulation by inducing rapid development of an occlusive clot, either by exerting a physical tamponade action or by enhancing the clotting mechanism and vasoconstriction (or both). No one local hemostatic agent is ideal; each has disadvantages. Further investigation is warranted to find the ideal local hemostatic agent.

Preoperative Considerations

A thorough review of the patient's body systems and medical history increases the likelihood of detecting an undiagnosed condition that might affect hemostasis during periradicular surgery. Review of the patient's medications, both prescribed and over-the-counter (OTC) drugs, is essential. Many OTC drugs can affect the clotting mechanism. The patient's vital signs (i.e., blood pressure, heart rate, and respiratory rate) should be assessed. Vital signs also can be used to monitor anxious patients. An increase in blood pressure and heart rate above a patient's known normal values indicates increased stress or poorly controlled hypertension. Easing the patient's anxiety before surgery reduces the possible hemostatic-potentiating effect of elevated cardiac output during surgery.[148] Anxiety and stress can be alleviated with planning, sedation, and profound local anesthesia.

Local Hemostatic Agents

Collagen-Based Materials

A wide variety of collagen-based hemostatic agents are available for use as local hemostatic agents. The principal differences are in the microstructure and density of the collagen. Collagen can act as a mild allergen, but the problem of allergenization and unwanted tissue reaction does not occur when highly purified animal collagen is used.[49] The mechanisms by which collagen products help achieve hemostasis involves stimulation of platelet adhesion, platelet aggregation and release reaction,[256,257] activation of factor XII (Hageman factor),[317,318] and mechanical tamponade by the structure that forms at the collagen-blood/wound interface. Collagen shows minimal interference in the wound healing process, with a limited foreign body reaction.[203] It does not increase the incidence of infection and only slightly delays early bone repair.[233] Osseous regeneration in the presence of collagen typically proceeds uneventfully, without a foreign body reaction.[159]

Collagen-based materials can be difficult to apply to the bony crypt because they adhere to wet surfaces, particularly instruments and gloves.[448] Several collagen-based products are commercially available. They include CollaCote (Integra Life Sciences, Plainsboro, NJ) (Fig. 21-33, *A*), CollaStat (American Medical Products Corp, Freehold, NJ), Hemocollagene (Septodont, Kent, UK), and Instat (Ethicon, Piscataway, NJ). These materials act in essentially similar ways, and the surgical area undergoes a similar healing pattern.[464,480] Overall, studies of wound healing with collagen-based hemostatic agents have shown favorable results.

Surgicel

Surgicel (Ethicon, Somerville, NJ) is a chemically sterilized material prepared through oxidation of regenerated alpha cellulose (oxycellulose). The basic element of Surgicel is polyanhydroglucuronic acid, which is spun into threads and then woven into gauze. Surgicel has a pH of 3. If the material is maintained in the wound for up to 120 days, a pH this low could retard healing.[389] It is primarily a physical hemostatic agent which acts as a barrier to blood and then becomes a sticky mass that serves as an artificial coagulum. It does not enhance the clotting cascade through adhesion or aggregation of platelets. Surgicel is retained in the surgical wound,[354] and

FIG. 21-33 A, Absorbable collagen (CollaCote) is a convenient, biocompatible packing material for localized hemostasis. **B,** Cotton pellets impregnated with racemic epinephrine (Racellet) also may be used for localized hemostasis.

healing is retarded, with little evidence of resorption of the material at 120 days.[56] Use of Surgicel in extraction sockets resulted in greater postoperative pain compared with a control in a split mouth–designed study.[389]

Gelfoam

Gelfoam (Pharmacia, Peapack, NJ) is a gelatin-based sponge that is water insoluble and biologically resorbable. It stimulates the intrinsic clotting pathway by promoting platelet disintegration and the subsequent release of thromboplastin and thrombin.[156] The initial reaction to Gelfoam in the surgical site is a decrease in the rate of healing. Extraction sockets containing Gelfoam showed a greater inflammatory cell infiltrate, marked reduction in bone ingrowth, and a foreign-body reaction at 8 days.[71] However, these effects were transitory and did not impair long-term bone healing.[372]

Bone Wax

Historically, bone wax has been advocated for controlling both hemostasis and debris in the bony crypt during periradicular surgery.[461] It is a nonabsorbable product composed of 88% beeswax and 12% isopropyl palmitate. Healing with bone wax is best described as poor. The bony crypt typically contains fibrous connective tissue and has no bony or hematopoietic tissue. Bone wax retards bone healing and predisposes the surgical site to infection[112,359] by producing a chronic inflammatory foreign-body reaction[35] and impairing the clearance of bacteria.[250] The use of bone wax can no longer be recommended, because it impairs healing and several good alternatives are available.[559]

Ferric Sulfate

Ferric sulfate (Cut-Trol, Ichthys Enterprises, Mobile, AL), a necrotizing agent with an extremely low pH, is one of the few products investigated for use in periradicular surgery. Two studies using a rabbit model[243,284] reported hemostatic control for 5 minutes, near-normal healing, and only a mild foreign-body reaction, provided the surgical wound was adequately curetted and irrigated with saline. Failure to remove ferric sulfate from the surgical wound site resulted in severely impaired healing, a foreign body–type reaction, and in some cases, abscess formation. The possibility of acute inflammation and necrosis of the surrounding soft tissue with careless use of this solution should not be underestimated.[281] A similar product, Monsel's solution (ferric subsulfate), has been used to control local hemostasis in dermatologic procedures. However, the popularity of this solution has declined because application to wound sites has resulted in tissue necrosis for up to 2 weeks,[124] differences in the degree of epidermal maturation, and tattoo formation.[510]

Calcium Sulfate

Calcium sulfate has been used as a substitute bone graft material to fill bone defects since the late 1800s. The presence of calcium sulfate in an osseous wound does not inhibit bone formation.[544] It is gradually removed from the site of implantation regardless of whether new bone has formed.[106] Use of calcium sulfate during periradicular surgery does not significantly affect healing, and deposition of cementum and osseous healing proceed normally.[28] As a hemostatic agent, calcium sulfate acts as a physical barrier. The material is placed in the bony crypt, allowed to set, and then partly carved away to allow access to the root end.[268] The remaining material lines the crypt walls, preventing bleeding. When the root-end filling has been placed and all extraneous root-end filling material removed, the residual calcium sulfate can be removed or left in situ.

Epinephrine Pellets

Epinephrine, a sympathomimetic-amine vasoconstrictor, is frequently used to control hemorrhage during oral surgery.[79,268] All granulation tissue should be removed from the root apex area prior to placement of the epinephrine pellet to assure direct contact with bone.[267] Vasoconstrictive amines exert their effects by binding to and interacting with adrenergic receptors in various body tissues. When epinephrine is bound to α_1- and α_2-adrenergic receptors, a powerful vasoconstricting effect results. Racemic epinephrine cotton pellets (Racellet #3; Pascal Co, Bellevue, WA) contain an average of 0.55 mg of racemic epinephrine hydrochloride per pellet, half of which is the pharmacologically active L-form. Racellets (see Fig. 21-30, *B*) provide very good localized hemostasis in periradicular surgery.[529]

Two concerns arise with the use of Racellets in the surgical site: the cardiovascular impact of the additional epinephrine and the retention of cotton fibers in the wound, resulting in impaired wound healing.[200,252] A recent study[529] examined the cardiovascular effects of epinephrine pellets and concluded that no evidence existed of cardiovascular changes (blood pressure and pulse) compared with saline-saturated pellet controls. These authors hypothesized that the vasoconstrictive effect on the capillaries is localized and immediate and that little or no systemic uptake of epinephrine occurred.

Although the cardiovascular effect appears to be of little concern, retention of cotton fibers in the surgical site could result in inflammation and impaired wound healing, so due diligence on the part of the surgeon is paramount when epinephrine pellets are used. Each pellet applied during surgery must be accounted for, and the bony crypt should be lightly curetted to remove any embedded cotton fibers before the wound is closed. The retention of cotton fibers in the crypt can

be eliminated by substituting CollaCote saturated with 10 drops of 2.25% racepinephrine inhalation solution.[536] As previously noted, CollaCote is biocompatible and does not interfere with wound healing.

Cautery/Electrosurgery

Cautery stops the flow of blood through coagulation of blood and tissue protein, leaving an eschar that the body attempts to slough.[511] The effect of cautery in the bony crypt during periradicular surgery has not been studied to date. However, the effect of electrosurgery on alveolar bone has been studied in periodontal surgery. Tissue destruction was greater in areas exposed to electrosurgery, and healing was delayed compared with surgical sites not exposed to electrosurgery. Twelve hours after surgery, a more extensive inflammatory reaction and greater destruction of periosteum were noted with electrosurgery.[36] At 24 hours, many empty lacunae were observed in the bone associated with electrosurgery, and this necrosis was even more extensive by 48 hours. At 96 hours, the electrosurgical connective tissue wounds were still lined by coagulum, whereas the scalpel wound was beginning to repair.[362] The detrimental effect of applying heat to bone is proportional to both temperature and the duration of application.

MANAGEMENT OF THE ROOT END

Management of the resected root end during periradicular surgery is critical to the overall success of a case. The aim of surgery should be to create an environment conducive to regeneration of the periodontium—that is, healing and regeneration of the alveolar bone, periodontal ligament, and cementum overlying the root end and root-end filling material. The key to regeneration is the presence of appropriate inducible cell types, growth factors, and specific substances necessary for mineralization. Failure to create an environment conducive to this process results in tissue repair rather than regeneration and healing that may be less than ideal.

Determining Need for Root-End Resection and Filling

The basis for periradicular surgery is twofold. The first objective is to remove the etiologic factor; the second is to prevent recontamination of the periradicular tissues once the etiologic agent has been removed.

Etiologic factors typically can be categorized as intraradicular or extraradicular bacteria,* intraradicular or extraradicular chemical substances, or extraradicular physical factors,[351,473,476] but etiology cannot always be determined with complete certainty. Frequently a number of factors are involved.[95] Most cases involve some form of bacterial participation (e.g., bacteria within apical ramifications), and the only definitive means of eradicating such an irritant is physical removal through root-end resection. The rationale for root-end resection in such cases is to establish access to and remove the diseased tissues. This ensures that the optimum environment for wound healing is established.

As mentioned, the second objective of periradicular surgery is to prevent recontamination of the tissues after removal of the etiologic agent. It follows that if the remainder of the canal system cannot be verified to be irritant free, a root-end filling should be placed to seal any remaining irritants within the canal system, thus preventing recontamination of the periradicular tissues.

*References 241, 270, 348, 470, 514, 515, 530, and 549.

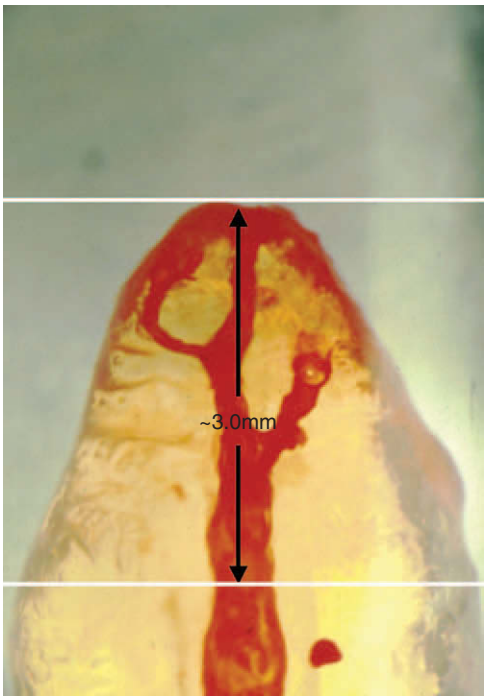

FIG. 21-34 Cleared section of a typical single-canal root that was injected with dye to demonstrate apical accessory canals. Most of the apical ramifications can be eliminated with a 3 mm resection.

Root-End Resection

Two main principles dictate the extent of the root-end resection. First and foremost, the cause (or causes) of an ongoing disease process must be removed; this includes removal of the diseased tissue and, when indicated, reduction of an apically fenestrated root. Second, adequate room must be provided for inspection and management of the root end.

The anatomy of each tooth root is complex (see Chapter 7). The surgeon must understand the anatomy of the apical third of the root to determine the extent of a root-end resection. Approximately 75% of teeth have canal irregularities (e.g., accessory or lateral canals) in the apical 3 mm of the tooth.[125,462] An apical resection of approximately 3 mm should include most accessory and lateral canals and thus eliminate most residual microorganisms and irritants (Fig. 21-34). When roots with more than one main canal are resected, isthmus tissue may be present, and the preparation should be modified to include the isthmus area (Fig. 21-35).

If the root apex is close to the buccal cortical plate, apical fenestration can occur, leading to persistent symptoms, especially tenderness to palpation over the root apex.[69] Reduction of an apically fenestrated root apex below the level of the surrounding cortical bone allows remodeling of the bone over the tooth structure. The buccal root of the maxillary first premolar often is closet to the buccal cortical plate.

The surgeon's convenience as a rationale for root-end resection depends on the individual case and the surgeon's

abilities. The basic principle of the dental surgeon's convenience should be modified by the desire to minimize the trauma of the surgical procedure itself, including the preservation of tooth and supporting structures. Access to and visibility of the periradicular root structures historically has determined the extent of root-end resection. The surgeon must be able to inspect the resected root end, prepare a root-end cavity, and place a root-end filling. Enhanced visualization equipment (e.g., microscopes, endoscopes, and orascopes) have reduced the need to resect large amounts of the root to gain adequate visualization and access.* In some cases, part of the root must be resected to gain access to the entire soft-tissue lesion, an additional palatally positioned root (e.g., maxillary premolars), or foreign material in the periradicular tissues.

A major consideration in determining the extent of root-end resection is the presence of anatomic structures such as the mental foramen or mandibular canal.[336,391-393] The surgeon should position the resection of the root to avoid possible damage to these structures.

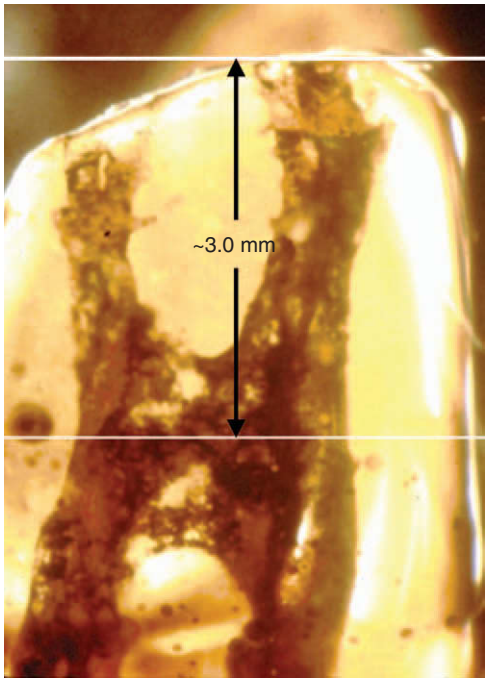

FIG. 21-35 Cleared section of a mesiobuccal (MB) root in a maxillary first molar. Root resection at the recommended 3 mm level exposes isthmus tissue connecting the MB-1 and MB-2 canals.

Angle of Resection

Enhanced magnification and illumination techniques have eliminated the need to create a beveled root surface in most cases.[91,422] From a biologic perspective, the most appropriate angle of root-end resection is perpendicular to the long axis of the tooth (Figs. 21-36 and 21-37). The rationale for a perpendicular root-end resection is based on several anatomic parameters. First, a perpendicular resection approximately 3 mm from the anatomic apex is more likely to include all the apical ramifications in that region of the tooth.[321] Second, as the angle of resection increases, the number of dentinal tubules that communicate with the periradicular region and the root canal system increases significantly. The probability that irritants from within the canal system will gain access to the healing tissues also rises as the resection angle increases.[172,497] Third, extending the root-end cavity preparation beyond the coronal extent of the root surface is simpler if the root-end resection is perpendicular to the long axis of the tooth.[185] Finally, with a perpendicular root-end resection, the stress forces exerted in the apical region are more evenly distributed; this may reduce the propagation of apical fractures and provide a better environment for apical healing.[452]

Root-End Surface Preparation

As with all phases of endodontic surgery, the goal is to produce a resected root end with optimum conditions for the growth

*References 40, 87, 90, 216, 266, 422, 429, and 465.

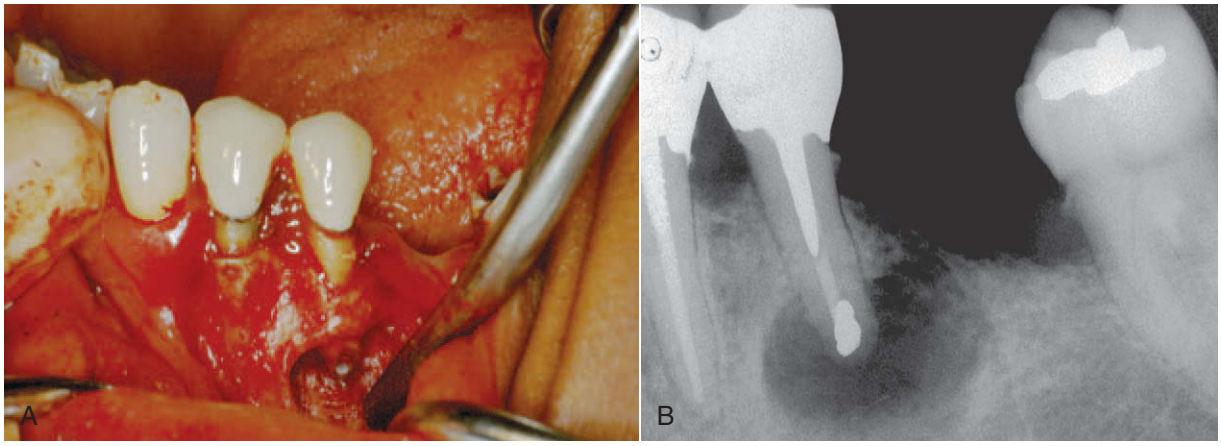

FIG. 21-36 Periradicular surgery circa 1990. **A,** The root end was prepared with a 45-degree bevel and rotary bur microhandpiece. Amalgam was a commonly used root-end filling material at this time. **B,** Immediate postoperative radiograph of a mandibular second premolar with amalgam root-end filling. Although many teeth treated this way healed successfully, newer materials and techniques described in this chapter are currently recommended.

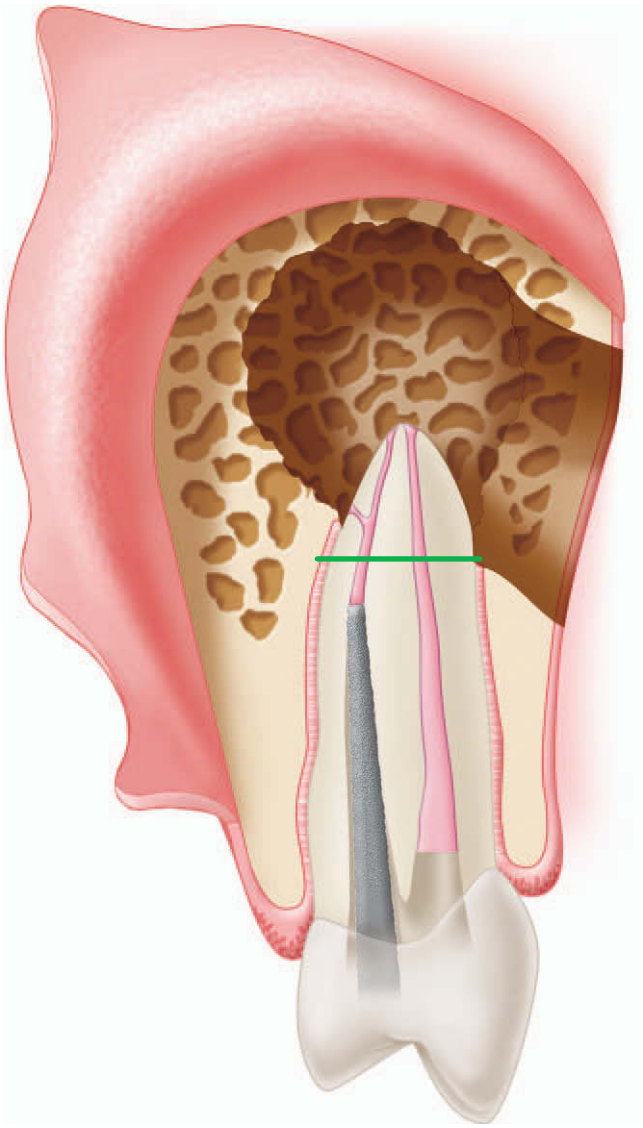

FIG. 21-37 Perpendicular or near-perpendicular root-end resection *(green line)* can be achieved with the use of microsurgical instruments and enhanced magnification and illumination.

of cementum and subsequent regeneration of the PDL across the resected root end. Two important aspects of this process are the surface topography and chemical treatment of the resected root end. Healthy cementum on the root end is required for successful regeneration of periodontal tissues.[23] A number of substances found in cementum stimulate the migration, growth, and attachment of periodontal fibroblasts. Cementum extracts also activate fibroblast, protein, and collagen synthesis, which is necessary to reestablish a functional periodontal ligament.[51,453,533]

Resected Root-End Surface Topography

The conventional axiom for surface preparation of the resected root end has been to produce a smooth, flat root surface without sharp edges or spurs of root structure that might serve as irritants during the healing process. However, little information exists on whether smooth root ends heal differently or more quickly than rough root ends after root-end resection. A study investigating the effect of the surface topography of resected root ends on human PDL fibroblast attachment found no significant difference in fibroblast attachment to the root ends prepared with various instruments.[553] However, with a smooth resected root-end surface, the surgeon is better able to detect surface cracks and anatomic variations.[339] Given that human PDL fibroblast attachment to a smooth surface was not impaired, it would seem appropriate to produce as smooth a surface as possible to facilitate inspection of the resected root end. A smooth root end therefore should be considered advantageous.

Different types of burs tend to produce different patterns on the resected root surface.[201] Several studies have compared the root-end surface after resection.[339,358,554] Generally, crosscut fissure burs in both high-speed and low-speed handpieces produced the roughest and most irregular surfaces. Researchers[339] compared the surface topography of root-end resection with a #57 straight fissure bur (Midwest Dental Products, Des Plains, IL), a Lindeman bone bur (Brasseler, Savannah, GA), and the Multi-Purpose bur (DENTSPLY Maillefer, Milford, DE), then finished with either a multifluted carbide finishing bur (Brasseler) or an ultrafine diamond finishing bur (Brasseler). The Multi-Purpose bur produced the smoothest, most uniplanar resected root-end surface, with the least amount of shattering. Regardless of the type of bur used, smearing and shredding of the gutta-percha across the root face occurred only when the handpiece was moved across the root face in reverse direction in relation to the bur's direction of rotation.[554] Burs that produce a smooth surface also tend to cut with less vibration and chatter, resulting in greater patient comfort.

Root-End Conditioning

Root surface conditioning removes the smear layer and provides a surface conducive to mechanical adhesion and cellular mechanisms for growth and attachment. It exposes the collagenous matrix of dentin and retains biologically active substances, such as growth factors, in the dentin proper. Experimental studies have shown that demineralized dentin can induce the development of bonelike mineralized tissue.[42,43,228,524,566] Some contend that root surface conditioning produces a biocompatible surface conducive to periodontal cell colonization without compromising the vitality of the adjacent periodontium.

Three solutions have been advocated for root surface modification: citric acid, tetracycline, and ethylenediamine tetraacetic acid (EDTA). All three solutions have enhanced fibroblast attachment to the root surface in vitro. However, citric acid is the only solution tested in an endodontic surgical application.

Citric acid traditionally has been the solution of choice. Periodontists have used an aqueous solution of citric acid (pH 1) for 2 to 3 minutes to etch diseased root surfaces to facilitate formation, new attachment, and cementogenesis.[415-419] One study[110] examined the effect of citric acid demineralization of resected root ends on periradicular healing. A 1- or 2-minute application of 50% citric acid (pH 1) resulted in demineralized root ends and earlier complete healing than in the nondemineralized root ends. However, the periodontal literature recently has questioned the benefit of etching dentin surfaces with low pH agents. At a low pH, adjacent vital periodontal tissues may

be compromised. Also, extended application (3 minutes) has been shown to discourage alveolar bone growth.[59,61]

EDTA, a solution with a neutral pH that endodontists have used as a canal irrigant, has been shown to be equally effective at exposing collagen fibers on dentin surfaces.[63] Unlike the lower-pH solution, EDTA does not adversely affect the surrounding tissues.[62]

A series of studies that examined the effect of EDTA and citric and phosphoric acids in a periodontal application showed that application of 15% to 24% EDTA for approximately 2 minutes produces the optimum root surface.[58,60,63] These researchers concluded that EDTA at neutral pH was able to selectively remove mineral from a dentin surface, exposing a collagenous matrix. Citric and phosphoric acids, which have a low pH, appeared not only to remove the mineral component but also to denature the collagenous matrix.

Tetracycline has been shown to remove the dentin smear layer, leaving clean, open tubules with application times as short as 30 seconds.[309] A histologic evaluation of new attachment in periodontally diseased human roots treated with tetracycline hydrochloride showed a trend for greater connective tissue attachment after tetracycline treatment of roots.[14] Studies comparing the effect of a 3-minute application of either EDTA (pH 7.3) or tetracycline HCl (pH 1.8) showed no significant difference in the treated tooth surfaces,[37] but EDTA has been shown to be more favorable to human PDL cell attachment.[570]

Although the root-surface conditioning effects of citric acid, EDTA, and tetracycline are well documented in the periodontal literature, this treatment has not translated into significant gains in periodontal attachment in periodontally diseased teeth.[312] Currently, only citric acid has been assessed as a root-end conditioning agent. In an animal model, citric acid was shown to enhance periradicular healing. Nonetheless, its effect and the effect of other root-end conditioning agents on the outcome of human periradicular surgery have not been established. Based on periodontal research, it would appear that if a root surface conditioning agent were to be used during periradicular surgery, EDTA might be the most appropriate solution. However, the manufacturer {personal communication, Dr. Torabinejad} has advised against the use of EDTA when mineral trioxide aggregate (MTA) is used as a root-end filling material, because it may interfere with the hard tissue–producing effect of MTA.

ROOT-END CAVITY PREPARATION

Root-end cavity preparation is a crucial step in establishing an apical seal. The goal is to make a cavity in the resected root end that is dimensionally sufficient for placement of a root-end filling material and at the same time avoid unnecessary damage to the root-end structures. The ideal preparation is a class I cavity prepared along the long axis of the tooth to a depth of at least 3 mm (Figs. 21-38 and 21-39). The surgical procedure is most likely to be successful if the remaining canal system has been thoroughly cleaned and shaped to eliminate microorganisms and irritants.[169,431] Traditionally, a microhandpiece with a rotating bur has been used, but with the advent of ultrasonic tips designed specifically for this purpose (Fig. 21-40), root-end preparations now are most often performed with the ultrasonic technique.[87] Clinical evidence is emerging

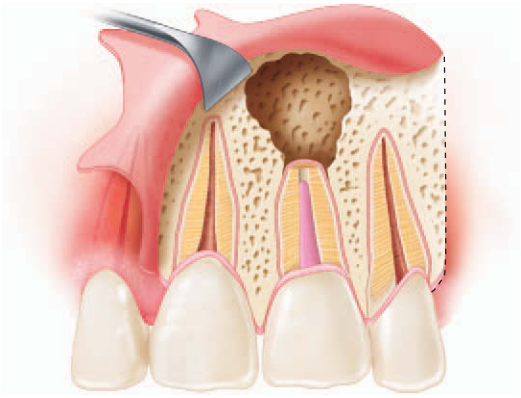

FIG. 21-38 Diagram of a perpendicular root-end preparation and 3-mm-deep cavity preparation along the long axis of the root.

FIG. 21-39 Error in root-end cavity preparation: ultrasonic preparation did not follow the long axis of the mesial root and therefore did not allow for proper sealing of this root. Healing is unlikely.

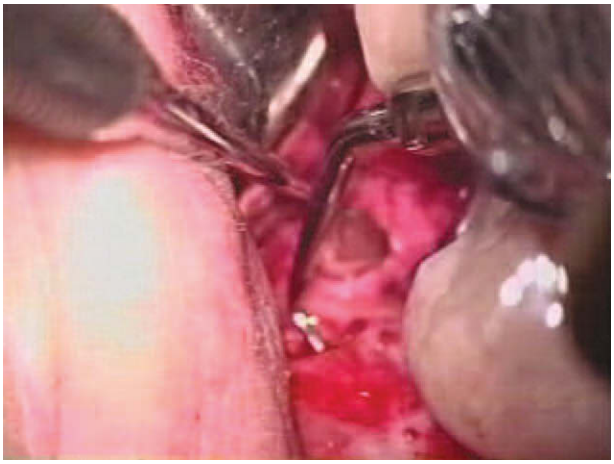

FIG. 21-40 Ultrasonic tip in use. Preparation along the long axis of the root is possible using tips designed for each area of the mouth. In this case, the tip is properly positioned for root-end cavity preparation of a maxillary first premolar but is dangerously close to the lip because of improper retraction. Heat generated by an ultrasonic tip can cause a thermal burn, which may result in scar-tissue formation.

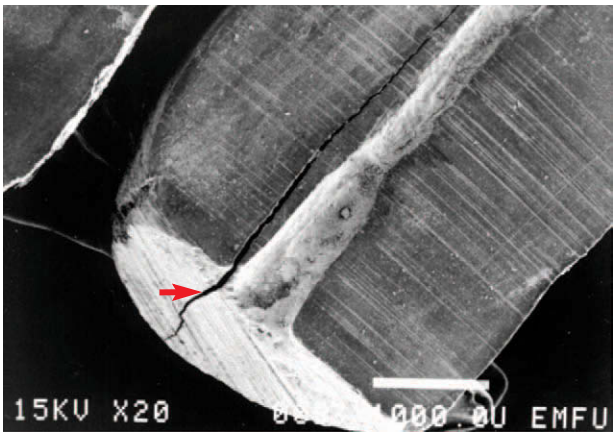

FIG. 21-41 Scanning electron microscope (SEM) image of a root end prepared in vitro with an ultrasonic device at high-power setting. A distinct fracture line can be seen *(red arrow)*. Root-end preparation with ultrasonic devices should be done at low power and with water coolant.

FIG. 21-42 Ultrasonic tips (Obtura Spartan) are available in a wide variety of configurations for use in different areas of the mouth. Most new tips have a special coating (zirconium nitride or diamond) that improves cutting efficiency.

to support the benefit of ultrasonic root-end preparation when compared to traditional bur preparation, especially in molar surgery.[126]

Ultrasonic root-end preparation techniques have several advantages over the microhandpiece method. Less osseous tissue must be removed to gain proper access to the resected root end. Also, the surgeon is better able to produce a more conservative preparation that follows the long axis of the tooth and remains centered in the canal. The risk of root-end perforation is reduced, partly because of enhanced manipulation of the instrument. In addition, ultrasonic root-end techniques produce a more consistent, deeper cavity preparation that requires less beveling of the root.[92,287,329,561] Ultrasonic apical preparation generates significantly less smear layer compared with burs alone[195]; root-end preparation with a bur produces a heavy smear layer at all levels of preparation.[202]

The major concern with ultrasonic root-end preparation is the potential for creating root fractures as a result of the ultrasonic vibration (Fig. 21-41).

Ultrasonic Root-End Preparation and Apical Fractures

Several studies have investigated the fracture-inducing potential of ultrasonic root-end preparation techniques. This is possibly the most controversial question that arises in relation to the use of ultrasonic root-end preparation tips. Three types of root-end fractures have been described: intracanal fractures (originating from the root canal system and extending into the dentin), extracanal fractures (originating on the root surface and extending into the dentin), and communicating fractures (extending from the root surface to the root canal system).[406] This classification system is not universally used in studies of root-end cavity preparation, so it is difficult to establish the significance, if any, of one type of fracture over another. When a strain gauge was used to measure root deformation, ultrasonic root-end preparation was shown to produce significantly greater strain on average than that generated by a microhandpiece. However, this did not translate into an increase in cracks observed on the resected surface of roots after root-end cavity preparation.[48,286,356,406] Several other in vitro studies that used different models to assess root-end fractures conversely concluded that ultrasonic root-end preparation does induce apical fractures.[3,175,282,335,451] Thus the degree to which apical fractures are induced during ultrasonic root-end cavity preparation is difficult to determine from in vitro studies.

On the other hand, in an in vivo study[338] and cadaver-based studies[82,196] designed to replicate the clinical scenario, root fractures were not attributed to ultrasonic use. In these studies, ultrasonic root-end preparation did not induce a significant number of root-end fractures. Several reasons may account for the differences observed. The surrounding tissues in cadaver and clinical subjects may disperse the ultrasonic energy away from the root tip. Thermal energy produced during ultrasonic preparation may have been controlled more adequately in some studies than in others. The power setting used on the ultrasonic unit may have been in the low range; a low power setting has been shown to produce fewer fractures in an in vitro setting[167,282] and therefore is recommended for clinical use.

Significance of Ultrasonic Tip Design

Several different types of ultrasonic tips are available for root-end preparation (Figs. 21-42 and 21-43), including tips of varying lengths and diameters constructed of stainless steel. These tips are left uncoated or are coated with diamond or zirconium nitride. Tips with a curvature of 70 degrees or greater are more susceptible to fracture under continuous loading, and fracture typically occurs at the bend.[543] Coating of ultrasonic tips undoubtedly improves the cutting efficiency compared with uncoated stainless steel tips; this translates into significantly less time required to prepare a root-end cavity.[190,386] In the coated tips, the diamond coating appears to be the most aggressive and requires the least amount of time to produce a root-end cavity preparation.[240] Furthermore, the type of tip (i.e., stainless steel, diamond coated, or zirconium nitride coated) appears to have little effect on the number or types of fractures that can be induced in the root end during preparation.[73,190,240,356,406] The cavity wall of root-end preparations

formed by stainless steel tips typically have cleaner canal walls than those formed by coated root-end preparation tips. Stainless steel tips appear to produce less superficial debris and smear layer. Coated root-end preparation instruments typically produce a heavily abraded, debris-covered cavity wall surface.[73,579] Overall, the quality of coated-tip preparation has been suggested to be superior.[386]

Temperature Changes Induced by Ultrasonic Instruments

The importance of heat generation and temperature changes has already been discussed. All ultrasonic surgical tips should have an irrigation port. Use of an ultrasonic instrument in the periradicular tissues without adequate irrigation results in an extreme temperature increase in the tissues, although this specific effect has not been demonstrated during root-end preparation. Scaling without irrigation can increase the temperature in dentin as much as 95° F (35° C) above the baseline temperature[273]; such an increase can injure pulpal and periodontal tissues.[361]

FIG. 21-43 Ultrasonic tip with diamond coating and irrigation port (DENTSPLY Tulsa Dental).

Bonded Root-End Fillings

Root-end cavity preparation for bonded root-end filling materials requires a change in the standard root-end cavity preparation technique. A shallow, scalloped preparation of the entire root surface should be made using a round or oval bur; the preparation should be at least 1 mm at the deepest concavity.[27,435] An ultrasonic preparation can be made into the root canal system, but this may not be necessary. The root-end filling material is placed in a dome fashion and bonded to the entirety of the resected root end (Fig. 21-44).

ROOT-END FILLING MATERIALS

The ideal root-end filling material seals the contents of the root canal system within the canal, preventing egress of any bacteria, bacterial byproducts, or toxic material into the surrounding periradicular tissues. The material should be nonresorbable, biocompatible, and dimensionally stable over time. It should be able to induce regeneration of the PDL complex, specifically cementogenesis over the root-end filling itself. Finally, the handling properties and working time should be such that the endodontic surgeon can place a root-end filling with sufficient ease.

Many materials have been used as root-end fillings, including gutta-percha, polycarboxylate cements, silver cones, amalgam, Cavit (3M ESPE St. Paul, MN), zinc phosphate cement, gold foil, and titanium screws. However, this section

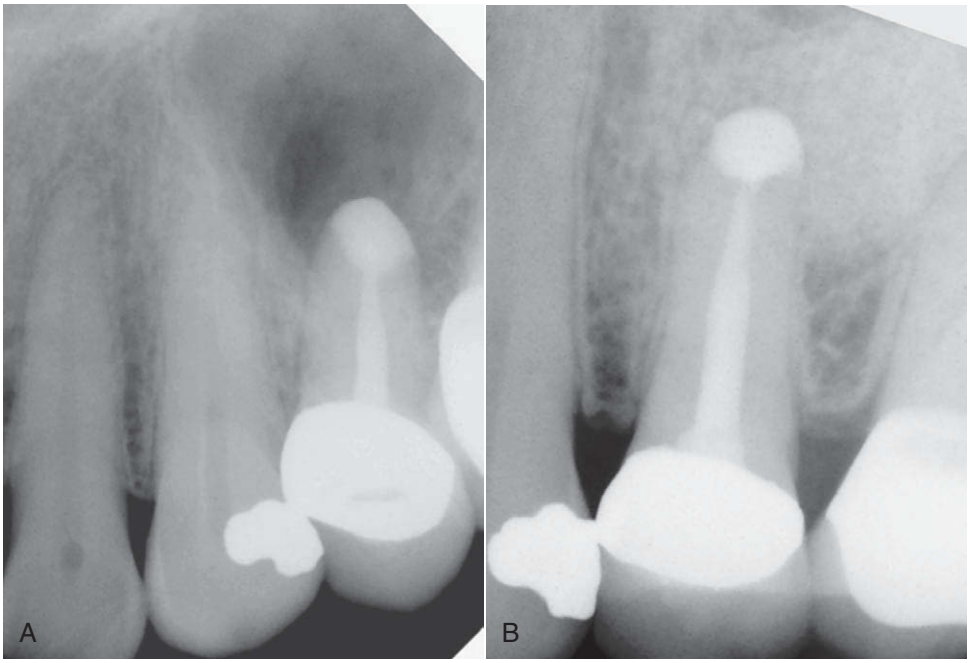

FIG. 21-44 A, Immediate postoperative radiograph of a bonded root-end filling in a maxillary first premolar. **B,** Follow-up radiograph at 20 months showing good periradicular healing.

focuses on root-end filling materials discussed in the literature within the past 10 years that are in common clinical use. These materials are zinc oxide eugenol cements (IRM and SuperEBA), glass ionomer cement, Diaket, composite resins (Retroplast), resin–glass ionomer hybrids (Geristore), and mineral trioxide aggregate (ProRoot-MTA).

Zinc Oxide Eugenol Cements

Zinc oxide powder and eugenol liquid (ZOE) can be mixed to form a paste that is compacted into a cavity preparation. Use of this material dates back to the 1870s. Eugenol is released from ZOE mixtures, although this declines exponentially with time and is directly proportional to the liquid/powder ratio.[230] When ZOE comes in contact with water, it undergoes surface hydrolysis, producing zinc hydroxide and eugenol. This reaction continues until all the ZOE in contact with the free water is converted to zinc hydroxide.[230-232] Eugenol can have a number of effects on mammalian cells, depending on the concentration and length of exposure. These effects include cell respiration depression, macrophage and fibroblast cytotoxicity, depressed vasoconstrictor response, inhibition of prostaglandin, and suppressing or enhancing effects on the immune response.[132,331,532] Other materials have been added to the basic ZOE mixture in an effort to increase the strength and radiopacity and reduce the solubility of the final material. Commercially available ZOE materials include intermediate restorative material (DENTSPLY/Caulk, Milford, DE) and SuperEBA (Bosworth Company, Skokie, IL).

Intermediate Restorative Material

Intermediate restorative material (IRM) consists of a powder containing greater than 75% zinc oxide and approximately 20% polymethacrylate mixed in equal parts with a liquid that contains greater than 99% eugenol and less than 1% acetic acid. IRM seals better than amalgam and is not affected by the liquid/powder ratio or root-end conditioning agents.[111,388] IRM appears to be tolerated in the periradicular tissue, but it has no dental hard-tissue regenerative capacity. The response is similar to that seen with other ZOE-based materials.[209,311,398-401] In vitro, IRM prevents adherence of enamel matrix proteins.[445]

SuperEBA

SuperEBA consists of a powder containing 60% zinc oxide, 34% aluminum oxide, and 6% natural resins. It is mixed in equal parts with a liquid that contains 37.5% eugenol and 62.5% *o*-ethoxybenzoic acid. SuperEBA is available in two forms, fast set and regular set. Other than the setting time, the properties of the two forms appear to be the same.[562] SuperEBA has radiopacity[463] and sealing effects similar to those of IRM and is less leaky than amalgam.[219,369] The leakage pattern of SuperEBA does not appear to be affected by root-end conditioning or finishing techniques.[165,451] When SuperEBA and IRM were finished with a carbide finishing bur in a high-speed handpiece, marginal adaptation was better than with ball burnishing, which was equal to burnishing with a moistened cotton pellet.[161] The environment of the periradicular wound may affect the long-term stability of SuperEBA, which has been shown to disintegrate over time in an acid pH environment.[31]

Biologically, SuperEBA is well tolerated in the periradicular tissues when used as a root-end filling, but it has no capacity to regenerate cementum. Bone healing has been demonstrated at 12 weeks, with some fibrous tissue persisting. SuperEBA root-end fillings show a basophilic-stained line adjacent to the filling material, which may indicate hard-tissue formation.[385,399,401,516] Collagen fibers appear to grow into the cracks of the material,[377] but the significance of this is unknown. SuperEBA has limited antibacterial effect.[98] The cytotoxicity of SuperEBA is similar to that of amalgam and IRM.[99,574] The incidence of persistent disease after endodontic surgery in which SuperEBA was used as a root-end filling material ranges from 4% to 20%. In comparative studies in which amalgam was also used as a root-end filling material, use of SuperEBA always resulted in less persistent disease. The follow-up period for these studies ranged from 0.5 to 4.6 years.*

Glass Ionomer Cements

Glass ionomer cement (GIC) consists of aqueous polymeric acids, such as polyacrylic acid, plus basic glass powders, such as calcium aluminosilicate. GIC sets by a neutralization reaction of aluminosilicate, which is chelated with carboxylate groups to cross-link the polyacids; a substantial amount of the glass remains unreacted and acts as reinforcing filler. Glass ionomer cements can be either light or chemically cured. Silver has been incorporated into GIC to improve the physical properties, including compressive and tensile strength and creep resistance. Both forms of GIC have been suggested as an alternative root-end filling material.[44,396,397]

The seal and marginal adaptation of light-cured GIC are superior to those with chemical-cured GIC. The seal achieved with GIC generally is better than that with amalgam and similar to that with IRM.† Long-term surface changes can occur in silver-GIC that may affect its stability in the periradicular tissues.[54] Glass ionomer cements are susceptible to attack by moisture during the initial setting period, resulting in increased solubility and decreased bond strength.[179,483,565] Contamination with moisture and blood adversely affected the outcome when GIC was used as a root-end filling material; this occurred significantly more often in unsuccessful cases.[571] The cytotoxicity of chemical- and light-cured GIC does not differ significantly from that of SuperEBA or amalgam.[99,375] The tissue response to GIC is considerably more favorable than to amalgam and similar to that with ZOE-based materials.[97,101,127,397] In a comparative clinical study using amalgam or GIC for root-end filling, healing was evaluated clinically and radiographically after 1 and 5 years.[248,571] No difference was seen in healing capacity between the two materials. The overall success rate in both groups was 90% at 1 year and 85% at 5 years. This study showed that the 5-year follow-up result can be predicted in more than 95% of the cases at the 1-year follow-up. These authors concluded that GIC is a valid alternative to amalgam for use as an apical sealant after root-end resection and that it provides equally good long-term clinical results.[248,571]

Diaket

Diaket (ESPE GmbH, Seefeld, Germany) a polyvinyl resin initially intended for use as a root canal sealer, has been advocated for use as a root-end filling material.[556] It is a powder consisting of approximately 98% zinc oxide and 2% bismuth phosphate

*References 140, 307, 378, 429, 492, and 535.

†References 102, 103, 239, 425, 494, and 560.

mixed with a liquid consisting of 2.2-dihydroxy-5.5 dichlorodiphenyl methane, propionylacetophenone, triethanolamine, caproic acid copolymers of vinyl acetate, and vinyl chloride vinyl isobutyl ether. Leakage studies comparing Diaket to other commonly used root-end filling materials have shown it to have superior sealing ability,[180,251,296,540] but its sealing ability has not been directly compared to that of MTA. When Diaket was used as a root canal sealer, biocompatibility studies showed that it was cytotoxic in cell culture[262] and generated long-term chronic inflammation in osseous[478] and subcutaneous tissues.[373] However, when mixed at the thicker consistency advocated for use as a root-end filling material, Diaket has shown good biocompatibility with osseous tissues.[360,556] Histologically, a unique tissue barrier has been observed to form across the Diaket at the resected root end, the nature of which is unknown. This tissue resembles an osteoid or cementoid type of matrix with a close approximation of periodontal tissue fibers, suggesting a regenerative response to the root-end filling material.[556] In animal studies, Diaket has shown a better healing response than resected gutta-percha in uninfected teeth[558] and a healing response similar to that with MTA, but no cementum formation was evident.[414] This material is no longer available in the United States.

Composite Resins and Resin-Ionomer Hybrids

Composite resin materials have some desirable properties and may be considered for use as root-end filling materials. Generally, when assessed for sealability, composite resins perform well in in vitro studies. Composite resins also tend to leak less than amalgam, SuperEBA, IRM, and GICs.[120,326,327,494] However, blood contamination during the bonding process reduces bond strength and increases leakage.[334,531] Marginal adaptation varies, depending on conditions and bonding agents.[18] Certain components of composite resins and dentin-bonding agents can have a cytotoxic effect on cells; this effect varies, depending on the agent and its concentration.[77,205,409,410,489] Studies have shown that once the composite resin sets, cells can grow on its surface.[310,343,383,573] The healing response of the periradicular tissues to composite resins in general appears to be very diverse, ranging from poor to good[26,516]; this may depend on the type of material used. Two composite resin–based materials, Retroplast (Retroplast Trading, Rørvig, Denmark) and Geristore, (Den-Mat, Santa Maria, CA) have been advocated for use as root-end filling materials.

Retroplast

Retroplast is a dentin-bonding composite resin system developed in 1984 specifically for use as a root-end filling material. The formulation was changed in 1990, when the silver was replaced with ytterbium trifluoride and ferric oxide. Retroplast is a two-paste system that forms a dual-cure composite resin when mixed. Paste A is composed of bis-GMA/TEGDMA 1:1, benzoyl peroxide *N*,*N*-di-(2-hydroxyethyl)-*p*-toluidine, and BHT. This is mixed in equal parts with paste B, which is composed of resin ytterbium trifluoride aerosil ferric oxide. A Gluma-based dentin bonding agent is used to adhere the material to the root-end surface. The working time is 1½ to 2 minutes, and the radiopacity (due to the ytterbium trifluoride content) is equivalent to 6 mm of aluminum.

Only limited information is available on the physical and chemical properties of Retroplast, although a number of human clinical studies have been published.* In all cases, the material appeared to be well tolerated and promoted a good healing response. There is evidence that Retroplast promotes hard-tissue formation at the root apex, and some have suggested that this is a form of cementum. In a limited number of case reports, Retroplast root-end fillings have demonstrated regeneration of the periodontium, with a cementum layer over the root-end restoration.[23,435,436] The healing response in these cases showed deposition of minimal cementum and the insertion of new Sharpey's fibers. The PDL fibers also entered the newly formed adjacent alveolar bone, indicating that tissue regeneration, including cementogenesis, may occur on composite material, consequently forming a biologic closure of the root canal.[26] In an investigation of 388 cases comparing root-end fillings of Retroplast or amalgam, radiographic healing after 1 year was as follows: with Retroplast, 74% showed complete healing, 4% showed fibrous healing, 15% were uncertain, and 7% were failures; with amalgam, 59% showed complete healing, 3% showed fibrous healing, 30% were uncertain, and 8% were failures.[435] Complete healing occurred significantly more often after root-end filling with Retroplast. The number of immediate postoperative complications did not differ significantly between the composite and the amalgam groups. A more recent clinical study of 351 cases reported a complete healing rate of 80% to 89%.[442] A 10-year follow-up of 34 of these cases showed complete healing in 33 of the cases.[440]

Resin-Ionomer Suspension (Geristore) and Compomer (Dyract)

The resin-ionomer suspension and compomer group of materials attempts to combine the various properties of composite resins and glass ionomers. Geristore and Dyract (DENTSPLY, Tulsa, OK) have been investigated for use as root-end filling materials, although the available published literature on both is limited. These two materials require light activation and resin-dentin bonding agents to attach to the tooth.

Geristore has been recommended both as a root-end filling material[88] and for use in restoring subgingival surface defects such as root surface caries, external root resorption lesions, iatrogenic root perforations, and subgingival oblique fractured roots. Clinical evaluation of Geristore as a restorative material for root caries and cervical erosions showed it to be an acceptable material.[174,353,457,522] When it is used for surgical repair of root perforations and as an adjunct to guided tissue regeneration, the results have been favorable in isolated case reports.[4,5,47,421,466] Geristore's dual-curing paste/paste formulation is a hydrophilic bis-GMA with long-term fluoride release. Light activation for 40 seconds cures the material to approximately 4 mm. However, the top layer is harder until the material achieves uniform hardness at 1 day after activation.[487] In vitro leakage assessment of Geristore and Dyract indicates that the materials leak less than root-end fillings made of IRM, amalgam, or SuperEBA.[64,197] Geristore has a leakage pattern similar to that of MTA.[456] An acid pH significantly reduces dye leakage of Geristore.[427] These materials are less sensitive to moisture than conventional glass-ionomer cement; however, dry environments produce stronger bonds.[96] The effect of blood contamination during the bonding phase in a clinical scenario is unknown. Geristore appears to have the potential

*References 23, 26, 342, 433-437, and 439-442.

to allow regeneration of the periradicular tissue. In one study, PDL and gingival fibroblasts attached to Geristore, and the attachment improved with time and cell proliferation.[83] Studies investigating epithelial and connective tissue adherence to Geristore found clinical and histologic evidence of cellular attachment when the material was placed in subgingival cavities.[143,144,457] However, the healing response in the periradicular region is best described as unpredictable. In a recent study in dogs, 10 of the 18 root end–filled teeth developed abscesses. The author attributed this to the technical difficulty of placing Geristore root-end filling, but a small number of specimens developed cementum on the root-end fillings. The cemental covering was never greater than 25% of the root-end filling surface, which was considerably less than the amount of cementum developed on both white and gray MTA.[298]

Mineral Trioxide Aggregate

MTA (ProRoot MTA; DENTSPLY, Tulsa Dental, Tulsa, OK), a material developed specifically as a root-end filling,[503] has undergone numerous in vitro and in vivo investigations comparing its various properties to SuperEBA, IRM, and amalgam. In vitro sealing ability and biocompatibility studies comparing root-end filling materials have shown MTA to be superior to other commonly used materials.* When various in vitro leakage models were used, MTA prevented leakage as well as composite resin and GIC,[7,123,162,560] but the setting and subsequent leakage of MTA are not affected by the presence of blood.[501] Torabinejad et al.[509] developed the original product (gray MTA). The main constituents of this material are calcium silicate ($CaSiO_4$), bismuth oxide (Bi_2O_3), calcium carbonate ($CaCO_3$), calcium sulfate ($CaSO_4$), and calcium aluminate ($CaAl_2O_4$). Hydration of the powder produces a colloidal gel that solidifies into a hard structure consisting of discrete crystals in an amorphous matrix. The crystals are composed of calcium oxide, and the amorphous region is composed of 33% calcium, 49% phosphate, 2% carbon, 3% chloride, and 6% silica.[503] In a study comparing the setting time, compressive strength, radiopacity, and solubility of MTA to those of amalgam, SuperEBA, and IRM, MTA was found to be less radiopaque than amalgam but more radiopaque than SuperEBA and IRM.[503] MTA had the longest setting time (2 hours, 45 minutes) and the lowest compressive strength at 24 hours after mixing (40 MPa), although compressive strength increased to 67 MPa at 21 days after mixing. The solubility of MTA after setting was similar to that of amalgam and SuperEBA. Initially MTA has a pH of 10.2, which rises to 12.5 at 3 hours after mixing.[503] The pH has been reported to be approximately 9.5 at 168 hours after mixing.[145] MTA is less cytotoxic than amalgam, SuperEBA, or IRM root-end fillings.[505] Endodontic surgery studies in dogs and monkeys have reported less periradicular inflammation and cementum deposition immediately adjacent to the root-end filling material.[28,164,223,502,506] Other investigators[223,224] theorized that the tricalcium oxide in MTA reacts with tissue fluids to form calcium hydroxide, resulting in hard-tissue formation.

The importance of the presence of cementum-like tissue adjacent to MTA cannot be understated. Cementum deposition is essential to regeneration of the periodontal apparatus.[293] Augmentation of new cementum across the root end and root-end restoration is essential for ideal healing of the periodontium. A layer would also enhance the integrity of the apical barrier, making it more resistant to penetration by microorganisms—in effect, establishing a biologic barrier.[23] This is seen most frequently in sections where MTA was used as the filling material. MTA appears to be able to induce cementoblastic cells to produce hard tissue. Recently, cementogenesis in the presence of MTA has been evaluated by assessment of the expression of osteocalcin (OCN), cell growth, and the morphology of cementoblast-like cells.[496] Scanning electron microscope (SEM) analysis indicated that cementoblasts could attach to and grow on MTA. In addition, strong expression of the OCN gene was seen after application of MTA. MTA can also increase the production of both proinflammatory and antiinflammatory cytokines from osteoblasts. The clinical significance of this reaction is not known. The effect of MTA on periradicular tissues probably is partly due to these reactions.

In a human outcomes assessment study comparing ProRoot MTA to IRM, the rate of persistent disease with MTA was 16% at 12 months and 8% at 24 months.[100] The rate of persistent disease with IRM was 24% at 12 months and 13% at 24 months. These authors concluded that the use of MTA as a root-end filling material resulted in a high success rate that was not significantly better than that obtained with IRM. A recent prospective clinical trial using MTA as a root-end filling material along with current microsurgical techniques reported 89% clinical success, with follow-up time ranging from 4 to 72 months.[450]

In 2002, a variation of the original formula of gray MTA was introduced. This material, which is a white cream color, is often called *white MTA*. The chemical composition of white MTA is very similar to that of the original. White and gray ProRoot-MTA materials differ by less than 6% in any one component. Both are fine powders with a mean particle size of approximately 10 μm (the range in particle size is approximately 0.1 to 100 μm). The radiopacity of both materials is equivalent to approximately 3.04 mm of aluminum.[45] When white MTA was implanted in the subcutaneous connective tissue of rats, the results were similar to those reported for gray MTA.[225] One study compared the tissue reaction evoked by the two materials when used as root-end fillings in canines.[298] The only statistically significant difference observed was in the presence of macrophages and/or multinucleated giant cells adjacent to the material. Gray MTA had more samples with mild to moderate infiltration of macrophages and/or multinucleated giant cells, and white MTA had more samples with no macrophages and/or multinucleated giant cells adjacent to the material. All other parameters assessed were essentially the same.

Overview of Root-End Filling Materials

Many different materials have been advocated for use as root-end filling materials, and each has specific advantages and disadvantages. However, from the biologic perspective of regeneration of the periradicular tissues, MTA, followed by Retroplast, appear to have a clear advantage over the other available materials. Retroplast and other composite resin–based filling materials require meticulous hemostasis and a dry surgical field for optimum results. The most commonly cited disadvantage of MTA is its handling properties. Even when properly prepared, MTA is more difficult to place in the root-

*References 263, 283, 501, 504, 505, and 507-509.

end cavity than most other materials. Several devices have been modified or developed specifically for use with MTA (see Figs. 21-18 to 21-22 and Fig. 21-45). Typical clinical cases showing the surgical procedures described in the previous sections are presented in Figs. 21-46 to 21-48.

CLOSURE AND SUTURING

Closure of the Surgical Site

The surgical site should be closed only after careful visual and radiographic inspection of the area. Before suturing, a radiograph should be taken with the flap held loosely in place to detect any foreign objects in the crypt or adhering to the flap. This image is also important for confirming the depth and density of the root-end filling. The osteotomy site is then gently curetted and irrigated with sterile saline or water to remove any remnants of hemostatic agents and packing materials. Some bleeding is encouraged at this point, because the blood clot forms the initial scaffold for subsequent healing and repair. If indicated, grafting materials or barriers may be placed at this time. Slight undermining of the unreflected soft tissue adjacent to the flap facilitates the placement of sutures. The flap is then repositioned and gently compressed with a piece of chilled, sterile, moist cotton gauze to express excess blood and tissue fluids.

For the common flap designs discussed in this chapter, the corners are first identified and sutured in place with a single interrupted suture. Interrupted sutures are initially passed through the free portion of the flap approximately 2 to 3 mm from the edge and then connected to the attached tissue. The suture is secured with a simple surgeon's knot, which is positioned away from the incision line. The center of the flap is then located and sutured with either an interrupted or a sling suture. A continuous locking suture technique may be used to close a submarginal (Ochsenbein-Luebke) flap.[271] The primary advantage of a continuous suture technique is the ease of suture removal compared with multiple interrupted sutures. The disadvantages are possible difficulty with precise control of tension in each area, and the fact that the entire suture may loosen if one suture pulls through the flap. A sling suture is commonly used for the central tooth in the surgical site to close a full-thickness intrasulcular (rectangular or triangular) flap. The tension on this type of suture can be varied slightly to allow some control of the apicocoronal positioning of the flap. Interrupted sutures then are placed as needed.

When suturing is complete, chilled, sterile, moist cotton gauze is again placed over the flap, and pressure is applied for 5 minutes. Pressure to the area provides stability for the initial fibrin stage of clot formation and reduces the possibility of excessive postoperative bleeding and hematoma formation under the flap. The iced gauze also supports hemostasis. Final inspection of the area should confirm that all soft-tissue margins have been closely approximated and bleeding has been controlled. An additional injection of long-acting local anesthetic may be administered at this time, although care must be taken not to inject it directly under the newly repositioned flap. The patient is given a cold compress and instructed to hold it on the face in the surgical area—on for 20 minutes then off for 20 minutes—for the rest of the day. The patient also is given verbal and written postoperative instructions, including after-hours contact information (Fig. 21-49). The patient should sit in an upright position for approximately 15 minutes, and the surgical site should be inspected one more time before the patient is discharged.

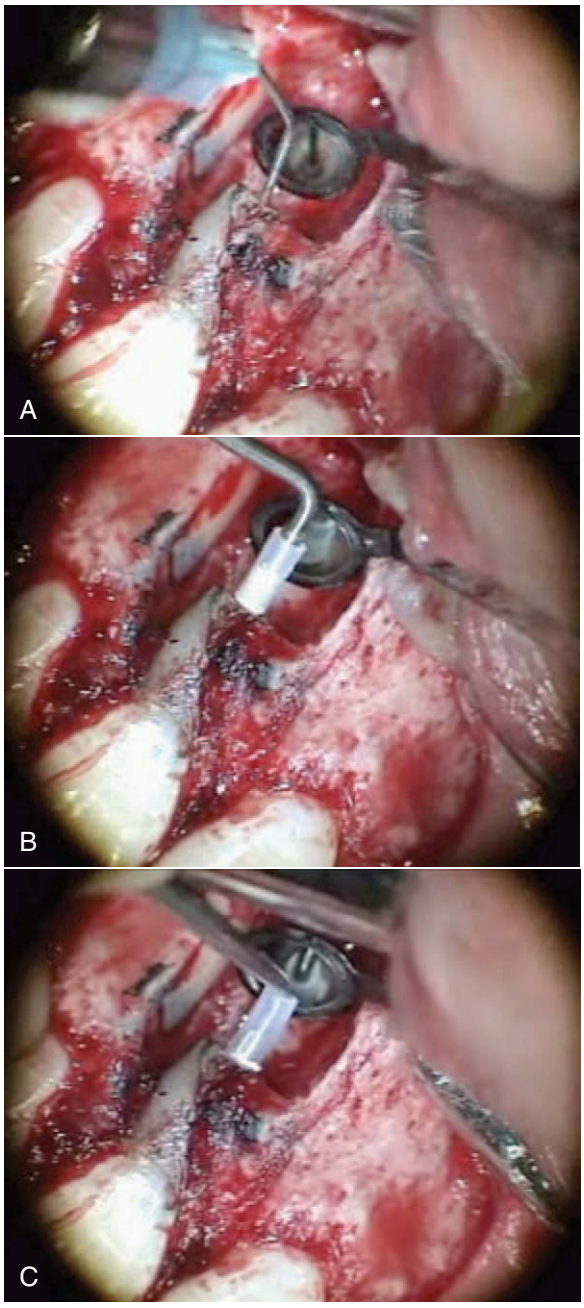

FIG. 21-45 A, Stropko syringe used to dry a root-end preparation before placement of the root-end filling material. **B,** Clinical use of an MTA delivery system (DENTSPLY Tulsa Dental). The device is loaded with MTA and placed over the root-end preparation. **C,** Pressing the plugger into the sleeve delivers the filling material to the root-end cavity preparation. The filling material then is compacted with microcondensers, and additional filling material is placed as needed.

Selection of the Suture Material

The properties of an ideal suture material for periradicular surgery include pliability for ease of handling and knot tying, a smooth surface that discourages bacterial growth and wicking

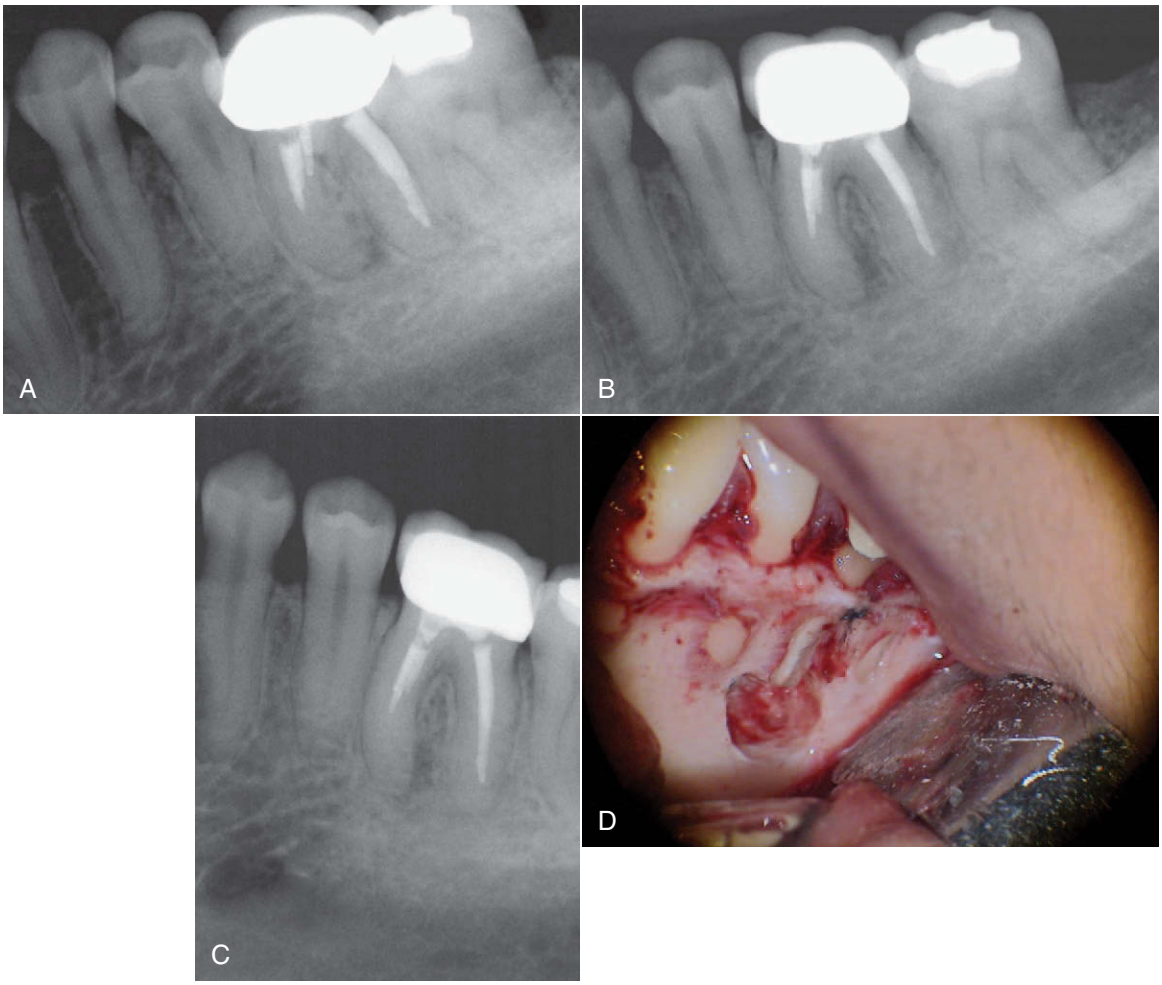

FIG. 21-46 A, Preoperative radiograph (mesial angle) of a left mandibular first molar. Periradicular disease and symptoms had persisted after nonsurgical retreatment by an endodontic resident. The mesial canals were completely obstructed at the midroot level. The preoperative evaluation included three periapical radiographs, two different horizontal angulations, and one vertically positioned radiograph. **B,** Straight view preoperative radiograph. **C,** Vertical periapical view preoperative radiograph. **D,** Osteotomy and root resection perpendicular to the long axis of the root were performed; a partial bony dehiscence over the mesial root can be seen. *Continued*

of oral fluids, and a reasonable cost. Suture material in size 5-0 is most commonly used, although some clinicians prefer slightly larger (4-0) or smaller (6-0) suture. Sutures smaller than 6-0 tend to cut through the relatively fragile oral tissues when tied with the tension required to approximate wound margins. Silk suture material has been commonly used in dental surgery for decades and is both inexpensive and easy to handle, but it tends to support bacterial growth and allows for a wicking effect around the sutures. For these reasons, other materials are preferable to silk.[89]

Resorbable suture materials (plain gut and chromic gut) are not routinely used for periradicular surgery, although this material may be indicated if the patient will be unavailable for the regular suture-removal appointment (48 to 96 hours after surgery) or if the suture will be used in areas of the mouth where access is very difficult. The primary problem with resorbable suture materials is the variable rate of resorption; that is, sutures may weaken and dissolve too soon or, more commonly, remain in the incision area for longer than desired. Gut suture materials are packed in isopropyl alcohol. The handling properties of gut sutures can be improved by immersion in sterile water for 3 to 5 minutes before use.[411]

Suture materials with a smooth Teflon or polybutilate coating (e.g., Tevdec and Ethibond, respectively) are particularly well suited for use in periradicular surgery. Synthetic monofilament suture materials (e.g., Supramid and Monocryl) are also commonly used. These materials are easy to handle and do not promote bacterial growth or wicking of oral fluids to the same extent as silk. Gortex (expanded PTEE-Teflon) sutures have many desirable properties but are more expensive than the previously mentioned materials.

Tissue adhesives such as cyanoacrylate and fibrin glues may hold promise for wound closure after periradicular surgery.[109,186,384,568] Although the currently available research is insufficient to recommend these adhesives as a routine replacement for more traditional suture materials, future applications in periradicular surgery are possible.

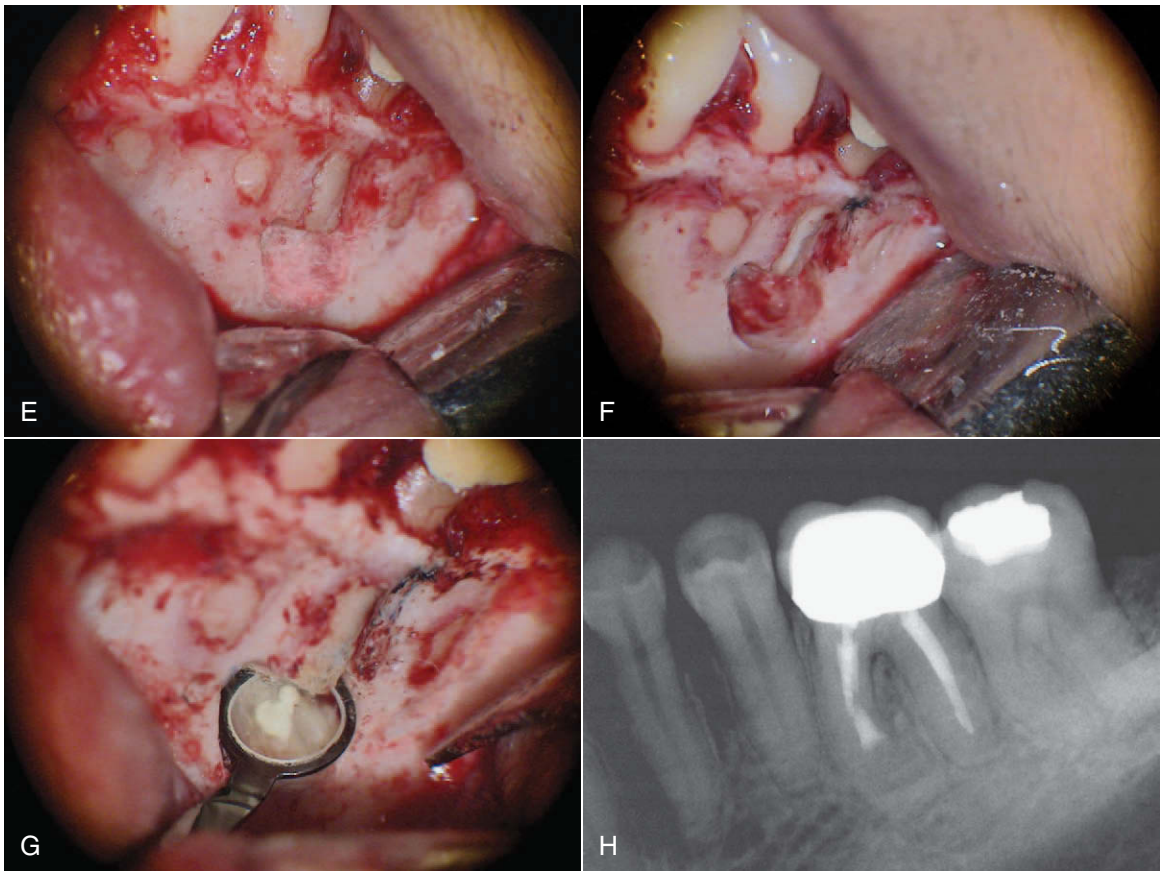

FIG. 21-46, cont'd E, Racellets were packed into the bony crypt to establish hemostasis. **F,** Racellets were removed (one usually is left in deepest part of crypt during root-end preparation and filling), and root end was beveled perpendicular to long axis of root. Methylene blue dye can be useful for identifying root outline and locating any cracks. Ultrasonic root-end preparation was completed to a depth of 3 mm, connecting MB and ML canals. **G,** MTA root-end filling was placed and inspected. Bony crypt was then gently curetted to initiate bleeding and remove any remnants of hemostatic materials. Flap was repositioned and radiograph taken. **H,** Immediate postoperative radiograph confirmed depth and density of root-end filling and absence of any foreign objects. (NOTE: Calcium sulfate and bone grafting material placed in osseous defect and over root because of large buccal dehiscence, although this is not routinely required in these cases.) *(Courtesy Dr. Vince Penesis.)*

GUIDED TISSUE REGENERATION AND ENDODONTIC SURGERY

The amount and location of bone adjacent to the root structures affect the prognosis of periradicular surgery. In one study[267] the authors propose a six-category classification system to assist in predicting surgical prognosis and determining the need for bone grafting and barrier techniques. Class A (no lesion), class B (small periapical lesion), and class C (large periapical lesion without periodontal communication) all represent situations that are favorable for healing without supplemental grafting or barriers. Class D (similar to class C with independent periodontal pocketing), class E (endodontic-periodontal communication to the apex), and class F (apical lesion with complete loss of buccal bone) represent situations with a more guarded prognosis and usually require concurrent use of bone grafting and barrier techniques. Figs. 21-50 and 21-51 are examples of cases that required guided tissue regeneration (GTR).

An apicomarginal defect[134] or a localized bony defect distinguished by a total deficiency of alveolar bone over the entire root length has a significant adverse affect on the outcome, reducing the rate of complete healing to 27% to 37%.[220,477] The presence of a periradicular lesion 15 mm or greater in diameter also has been linked to a poorer prognosis.[220] Advanced periodontitis with deep pocket formation has been associated with chronic periradicular inflammation after endodontic surgery and subsequent failure of the root-end surgery.[432] The cause of failure has been identified as ingrowth of nonosteogenic tissues into the periradicular surgical site and downgrowth of epithelial tissue along the root surface. Successful treatment may depend more on controlling epithelial proliferation than root-end management. Guided tissue regeneration techniques have been advocated for use in such cases.

The basic principle of guided tissue and bone regeneration is that different types of cells repopulate a wound at different rates during healing. Soft-tissue cells are considerably more motile than hard-tissue cells, therefore they tend to migrate into the wound more quickly during healing. A barrier interposed between the gingival tissue and the exposed root surfaces and supporting alveolar bone prevents colonization of the exposed root surface by gingival cells. This encourages selective repopulation of the root surface by PDL cells. The use of an absorbable barrier theoretically would allow PDL cells and

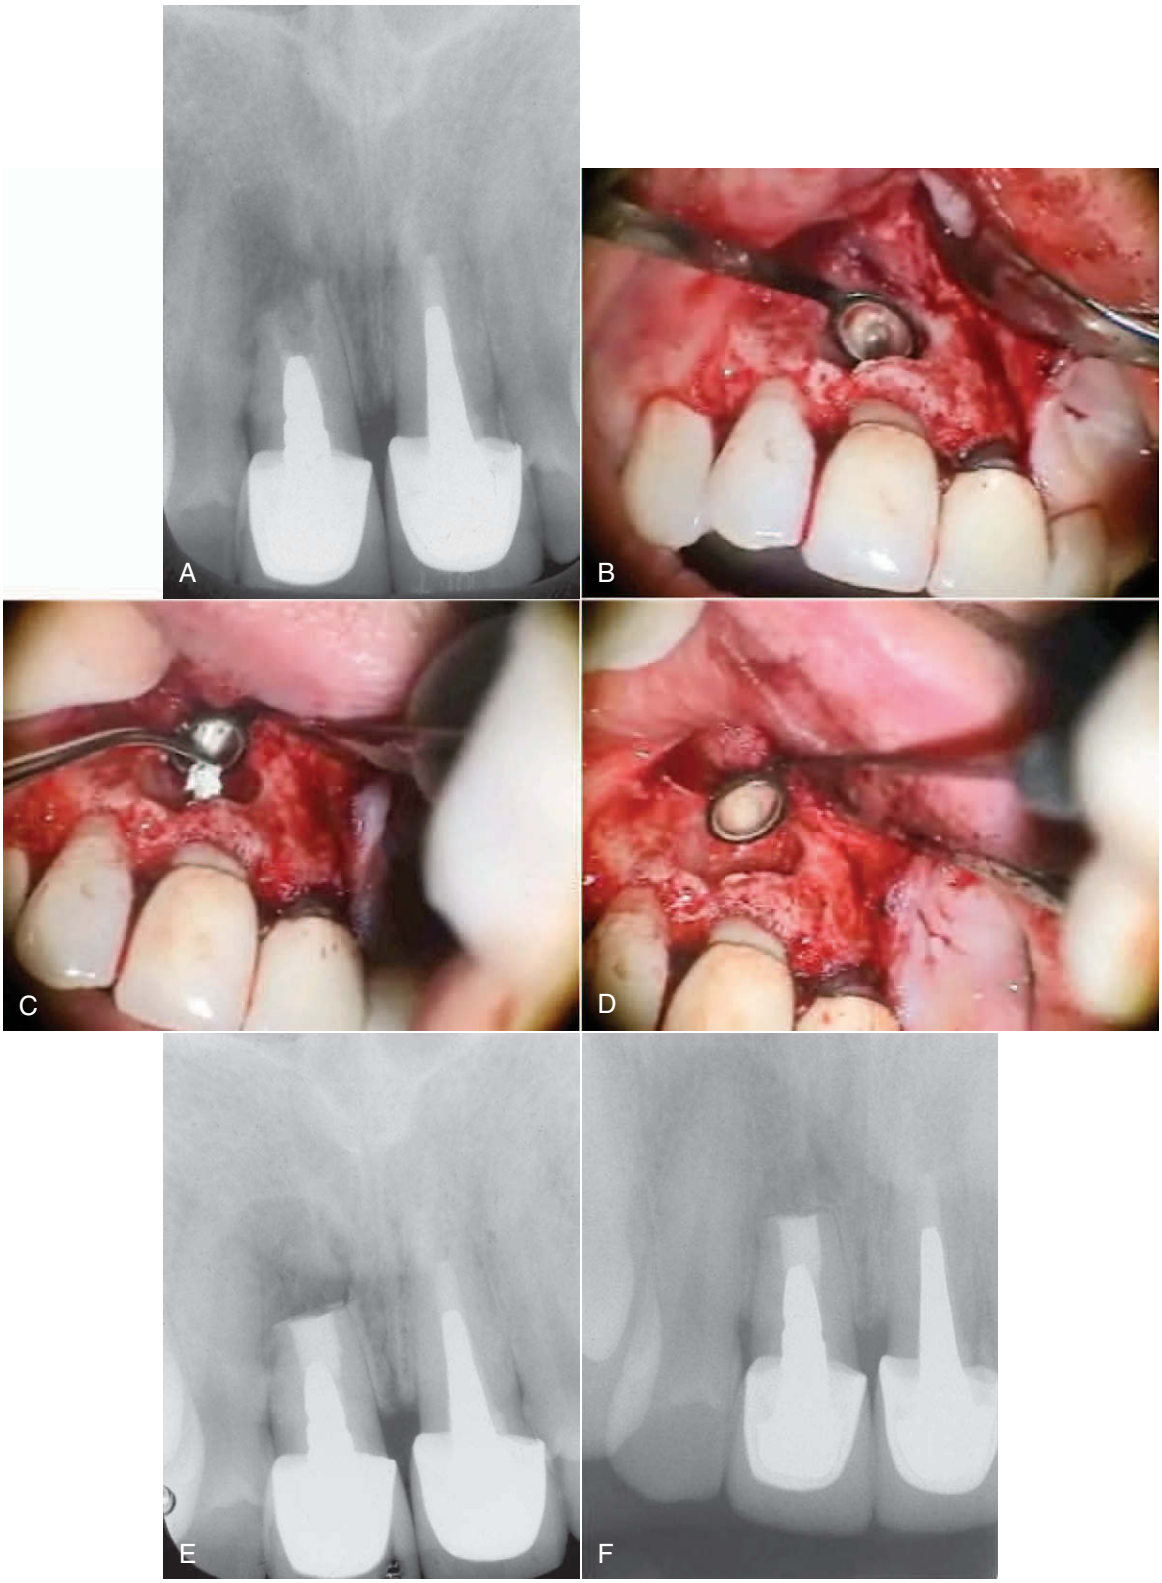

FIG. 21-47 A, Preoperative radiograph of a maxillary left central incisor showing evidence of previous surgery but no apparent root-end filling. Because of short root length and inadequate band of keratinized gingiva, an intrasulcular incision and full-thickness triangular mucoperiosteal flap design were selected. **B,** Root was minimally resected, and root-end cavity was prepared ultrasonically. **C,** MTA was placed and condensed into root-end cavity preparation. **D,** Root-end filling was inspected before flap was repositioned and sutured. **E,** Immediate postoperative radiograph. **F,** Six-month follow-up radiograph showed good initial periradicular healing. *(Courtesy Dr. Shawn Velez.)*

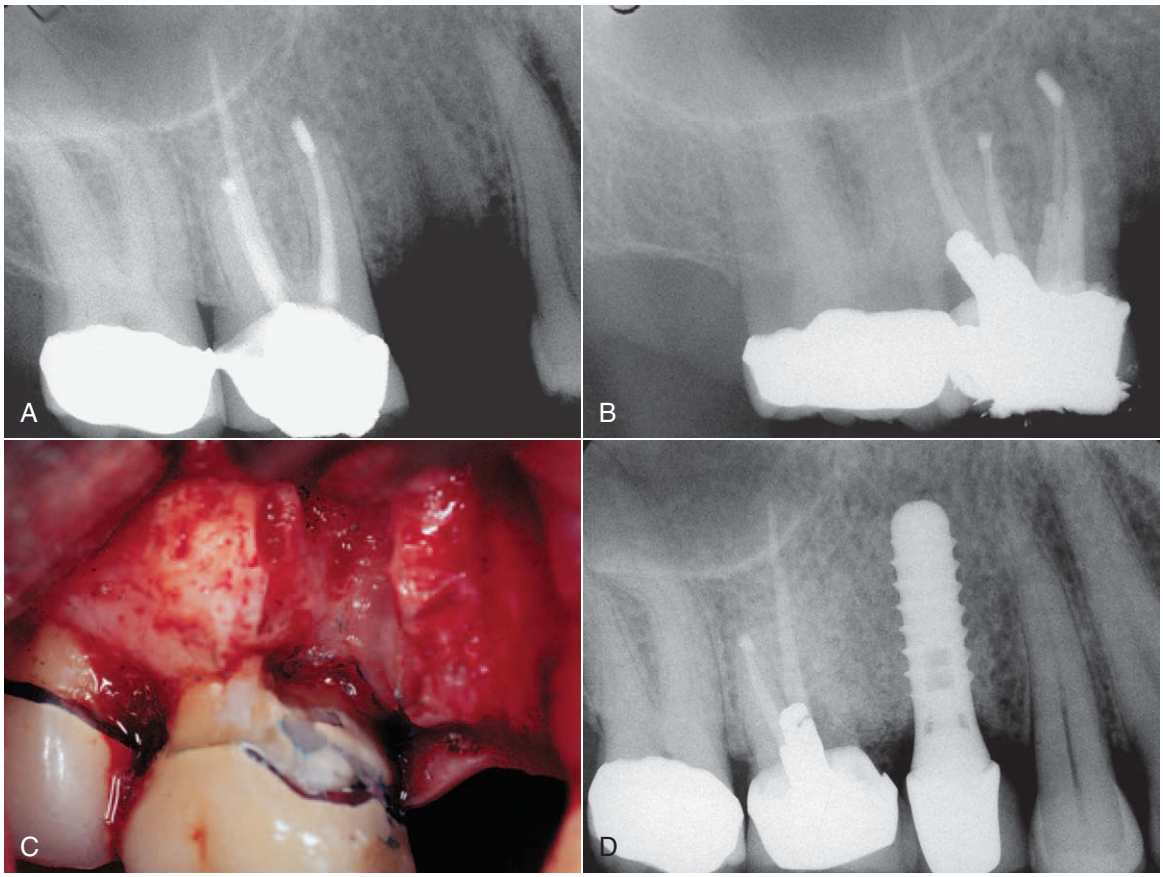

FIG. 21-48 A, A maxillary right first molar that was sensitive to percussion and tender to palpation over the MB root. Periodontal probing revealed a deep, narrow bony defect on the facial aspect of the MB root. Presence of a vertical root fracture was confirmed visually using magnification and methylene blue dye. Maxillary right second premolar had been recently extracted because of a vertical root fracture. **B,** A bonded amalgam core buildup was placed in the DB and P canals, and Geristore was placed in the MB canal system. **C,** The MB root was resected, and methylene blue dye was used to help define the extent of the fracture. **D,** At the 3-year follow-up visit, a new crown had been fabricated for the molar, and the premolar had been replaced with an implant.

other cells with osteogenic potential to repopulate the defect, resulting in new connective tissue attachment and bone formation. Researchers[114,115] demonstrated that in monkeys, a significant increase in osseous healing occurs when membranes are used in through-and-through bone defects in periradicular surgery of the lateral maxillary incisors. The use of resorbable guided tissue regeneration (GTR) membranes in endodontic surgery with buccal apicomarginal-type defects also has been shown to enhance regeneration of the periodontium and surrounding bone in dogs.[142] This type of matrix barrier promoted greater amounts of connective tissue and alveolar bone and minimized the formation of junctional epithelium.

Several case reports have discussed the use of guided tissue regeneration techniques in conjunction with endodontic surgery.* These studies largely have reported favorable outcomes in cases involving large periradicular lesions, through-and-through bone defects, and repair of a surgical perforation or loss of the buccal cortical plate adjacent to the root.

Researchers[381] compared the healing of 20 large periradicular defects (>10 mm diameter) with and without the use of resorbable membrane. They reported that at 12 months after surgery, the sites in which membranes had been used had healed more quickly, and the quality and quantity of the regenerated bone was superior. A study evaluated periradicular and periodontal healing in cases involving apicomarginal defects when guided tissue regeneration (Bio-Oss and Bio-Gide membrane; Osteohealth, Shirley, NY) was performed in conjunction with periradicular surgery. At 12 months after surgery, 86% were considered healed clinically and radiographically. It was concluded that GTR should be considered as an adjunct to periradicular surgery in cases of apicomarginal defects.[135] However, use of a resorbable membrane when a standard apical osteotomy is performed and the buccal bone over the remainder of the root is intact has no beneficial effect on healing.[177]

Several different types of membranes are available. They can be grouped into two broad categories: nonresorbable and resorbable (Table 21-1). Resorbable membranes are generally better suited for endodontic uses because a second surgical procedure is not required to remove the membrane.

Membranes frequently require support so that the membrane does not collapse into the defect itself. Support for the membrane may be provided by using either a titanium-tented membrane or a graft material. Graft materials have two main

Care of Your Mouth After Endodontic Surgery

1.) Apply an ice pack to your face next to the surgery area (on for 20 minutes and off for 20 minutes) for the next 5 to 6 hours to help decrease postoperative swelling. Swelling is usually greatest the day after surgery and may be at its worst to 2 or 3 days after surgery.

2.) Take all medications as directed. Approximately 45 minutes should be allowed for you to feel the effect of pain medication.

3.) Clean your mouth as usual (brushing, flossing, etc.) in all areas except the surgical site. Modify cleaning procedures of the teeth in the area of the surgical site to keep from disturbing the area. Do not rinse vigorously during the first 24 hours following surgery. Continue using the prescribed mouth rinse twice a day until after you return to have the sutures removed.

4.) Minor oozing of blood from the surgical site may occur in the first 24 hours after surgery. This will produce a pink tinge in the saliva and is not a cause for concern. However, if bleeding is excessive, please contact our office. You may apply pressure to the area with a tea bag or moist cotton gauze.

5.) Sutures have been placed and will need to be removed at your next appointment. Please do not lift or pull on your lip to examine the surgical site during the first 2 to 3 days because this may disturb the healing process.

6.) A soft diet is recommended for the first 2 or 3 days. Try to avoid foods that are hot, spicy, or hard to chew. It is very important that you drink plenty of fluids (nonalcoholic). This will help your mouth heal.

7.) Avoid cigarettes and all other tobacco products.

8.) A slight increase in body temperature may occur during the first 24 hours following surgery. This is normal. Infection after endodontic surgery is not typical but can occur. If an infection develops, it usually occurs 2 to 3 days after the surgery. Signs of an infection include sudden increase in pain or swelling, feverish feeling, sore glands in the neck area, and a general flulike feeling. If you think an infection has developed, please contact the office immediately.

If you have any questions, please contact the office during normal office hours at 312-XXX-5555. If you are experiencing problems after office hours, you may contact Dr. _____ at: 312-XXX-1212.

FIG. 21-49 Example of postoperative instructions. Written instructions provide an essential reference for the patient; verbal instructions often are difficult to remember after surgery. Instructions may be modified as needed to provide instructions the patient can understand. Readability of these instructions is at approximately eighth-grade level using the Flesch-Kincaid Grade Level scale.

functions: to act as a mechanical substructure that supports the membrane and overlying soft tissues and to serve as a biologic component that enhances bone formation. Bone graft materials (Table 21-2) can be categorized as osteoconductive or osteoinductive. An *osteoconductive material* provides a framework into which bone can grow. The pore size of the material is similar to that of normal bone, and the material eventually is absorbed and remodeled. An *osteoinductive material* stimulates the production of new bone cells such that healing occurs more quickly. The bone morphogenic protein (BMP) family has been investigated extensively for use in this role. A combination of osteoconductive and osteoinductive materials also can be used for bone grafts.

The use of GTR techniques raises several additional issues that should be discussed with the patient before surgery. These include the cost of the additional material, the origin of the material (synthetic, animal, or human), the need to manage the wound for a longer period, and potential postoperative complications related specifically to these techniques and materials. Discussion of the composition of the materials to be used is very important because some patients may have concerns based on religious or ethical grounds. The surgeon must discuss all the ramifications of using these materials with the patient before beginning the procedure; it is not always possible to predict before surgery when grafting materials may be needed.

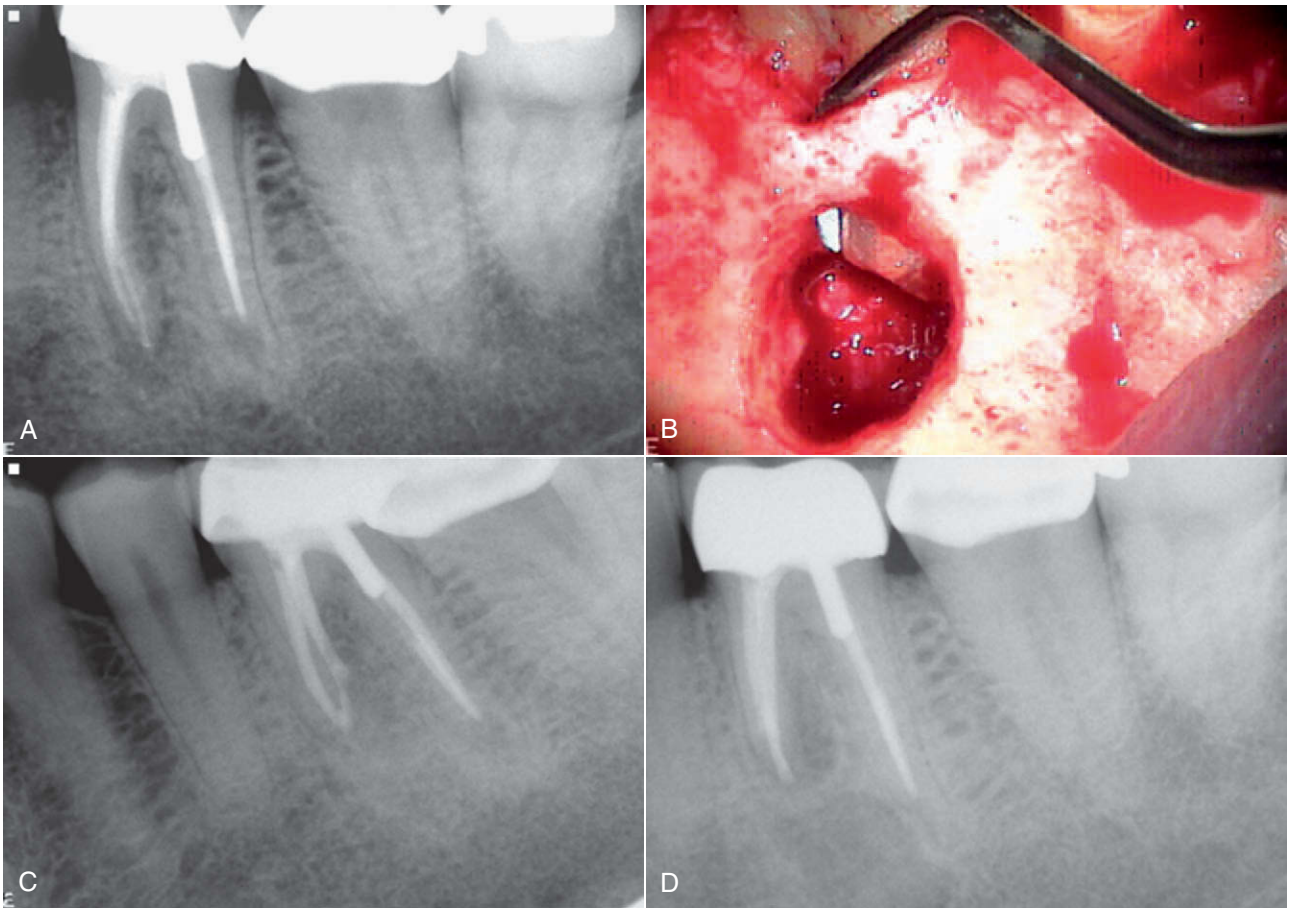

FIG. 21-50 A, Preoperative periapical radiograph of tooth #19. **B,** Clinical image demonstrating periodontal defect along facial aspect of the mesial root. **C,** Immediate postsurgical radiograph. The mesial root end was prepared with ultrasonics and filled with MTA. A mixture of DFDBA and Capset was placed for guided tissue regeneration. **D,** One-year follow-up radiograph demonstrating good healing. Periodontal probings within normal limits.

If GTR techniques are to be used during periradicular surgery, a resorbable membrane should be chosen, and a protocol should be followed (Figs. 21-52 and 21-53):

1. The membrane is extended to cover 2 to 3 mm of bone peripheral to the margins of the crypt. It should be supported with a bone-substitute graft material so that it does not collapse into the crypt or onto underlying tooth structures.
2. Tissue closure techniques should ensure total tissue coverage of the membrane. The traditional postoperative compression is eliminated because this would collapse the membrane onto the underlying structures.
3. Smoking is contraindicated with GTR techniques because it consistently has been shown to adversely affect the outcome.*

Ridge Preservation

With the growing use of dental implants for the replacement of missing teeth, clinicians should be aware of ridge preservation strategies, even if they do not place implants.[291] As an example, ridge preservation should be considered when a tooth is determined to have a vertical root fracture during an exploratory surgical procedure and is extracted. In this situation, there is often a complete absence of the buccal bony plate, and simple extraction of the tooth would predispose to loss of ridge height and width, thereby complicating future implant placement. GTR with graft and barrier placement (as previously described) at the time of extraction may be indicated to create a more favorable site for future implant placement.[32,238,324,577] An atraumatic extraction technique is desirable, since one of the goals is to preserve the maximum amount of existing bone. Periotomes are particularly useful for this type of bone-preserving extraction technique.

INTENTIONAL REPLANTATION

Intentional replantation may be an option when surgical access is very limited or presents unacceptable risks. Mandibular second molars are a common example for this technique because of the typically thick overlying buccal bone, shallow vestibular depth, and proximity of the root apices to the mandibular canal (Fig. 21-54). However, any tooth that can be atraumatically removed in one piece is a potential candidate

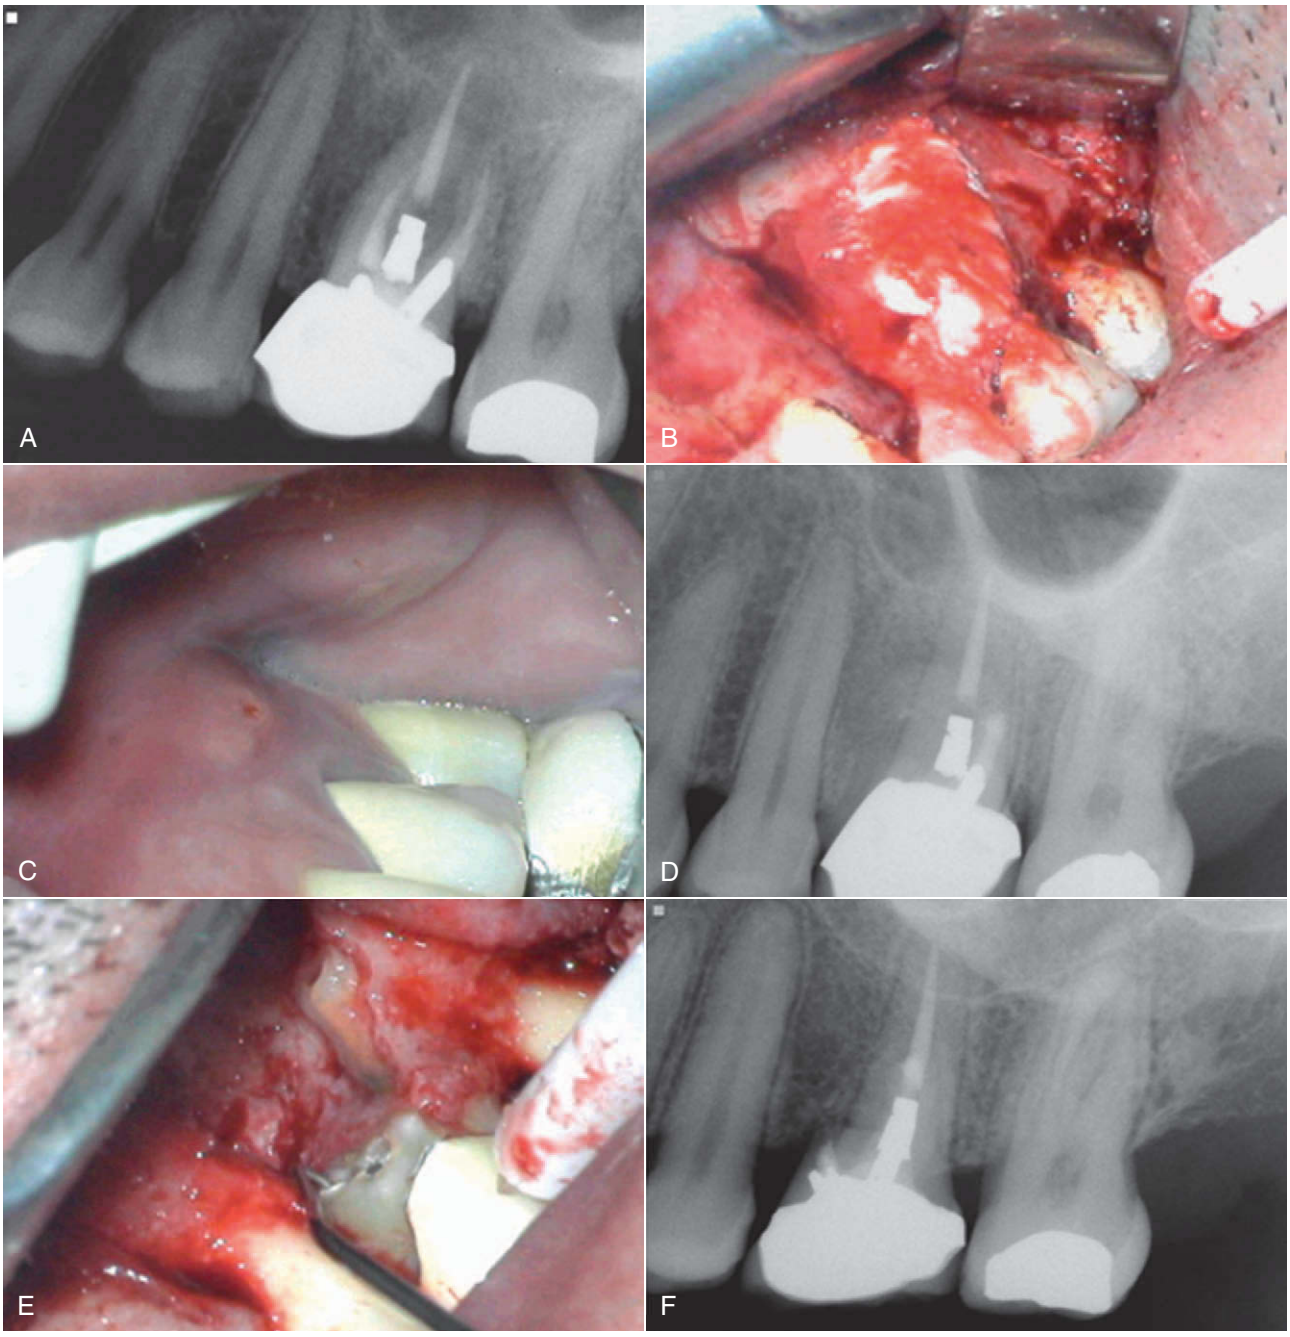

FIG. 21-51 A, Preoperative periapical radiograph of tooth #14. **B,** Clinical image. **C,** The MB root was removed owing to root fracture. Ultrasonic root-end preparation with MTA fill was performed on the DB root and remnant of the MB root. A significant amount of buccal bone is now missing and GTR is indicated. **D,** A mixture of DFDBA and Capset was placed in the bony defect. **E,** Immediate postoperative radiograph. **F,** Two-year follow-up radiograph.

for intentional replantation. Contraindications include teeth with flared or moderately curved roots and the presence of periodontal disease. Vertical root fracture has often been considered a contraindication,[382] although some investigators recently demonstrated moderate success using a dentin-bonded resin and intentional replantation for the treatment of teeth with root fractures.[214,254,481] The prognosis was generally better for incisors and for teeth with fractures less than two-thirds of the root length. Clinical success after 1 year was about 89% and decreased to 59% at 5 years.[214]

The tooth should be extracted with minimal trauma to the tooth and socket. Ideally, elevators are not used, and the root surface is not engaged with forceps. All instruments and materials for root-end preparation and filling should be arranged before extraction to minimize extraoral working time. The root surface must be kept moist by wrapping the root with gauze

TABLE 21-1

Examples of Membrane Materials

Composition	Trade Name/Manufacturer
NONRESORBABLE	
Polytetrafluoroethylene	Gortex (WL Gore & Associates Inc, Flagstaff, AZ) TefGen FD (Lifecore Biomedical, Chaska, MN) Bicon Barrier Membrane (Bicon, Boston, MA) Cytoflex (Unicare Biomedical, Laguna Hills, CA)
RESORBABLE	
Laminar bone	Lambone (Pacific Coast Tissues Bank, Los Angeles, CA)
Polylactic acid	Guidor* This product was used extensively in early research with very favorable results (Guidor USA) Atrisorb (CollaGenex Pharmaceuticals, Newtown, PA)
Polyglactic acid	Vicyl Mesh (Ethicon, Somerville, NJ)
Polylactic acid, polyglycolic acid, and trimethylene carbonate	Resolut (WL Gore & Associates Inc, Flagstaff, AZ)
Collagen	Biomend (Zimmer Dental, Carlsbad, CA) Bio-Guide (Osteohealth, Shirley, NY) Bicon Resorbable Collagen Membrane (Bicon, Boston, MA)

*No longer available.

TABLE 21-2

Examples of Bone Graft Materials

Graft Type	Description	Product/Manufacturer or Source
Autogenous graft	Obtained from patient's own body	Ramus, chin, iliac crest
Allograft	Demineralized freeze-dried human bone (DFDBA)	Osteofil (Regeneration Technologies, Alachua, FL) Grafton (Osteotech, Eatontown, NJ) Dynagraft (GenSci, Toronto, Ontario, Canada) Opteform (Exactech, Gainesville, FL) Puros (Zimmer Dental, Carlsbad CA) MTF DeMin Bone (DENTSPLY Friadent CeraMed, Lakewood, CO)
Xenograft	Inorganic bovine/porcine bone particles	BioOss (Osteohealth, Shirley, NY) OsteoGraf (DENTSPLY Friadent CeraMed, Lakewood, CO)
Ceramic/synthetic grafts	Calcium sulfate, calcium phosphate/ hydroxyapatite, bioactive glass	CapSet (Lifecore Biomedical, Chaska, MN) OsteoSet (Wright Medical Technology, Arlington, TN) HTR (Bioplant HTR, Kerr Corporation, West Collins, CA) Biogran (3i, Palm Beach Gardens, FL) Norian SRS (Synthes, West Chester, PA) NovaBone-C/M (NovaBone Products, LLC, Sales and Manufacturing, Alachua, FL) PerioGlas (NovaBone Products, LLC, Sales and Manufacturing, Alachua, FL)
Bioactive proteins	Bone morphogenic proteins (BMP)	Experimental
Combination graft	Allograft, xenograft, or ceramic/synthetic grafts plus bioactive protein	PepGen P15 (DENTSPLY Friadent CeraMed, Lakewood, CO)

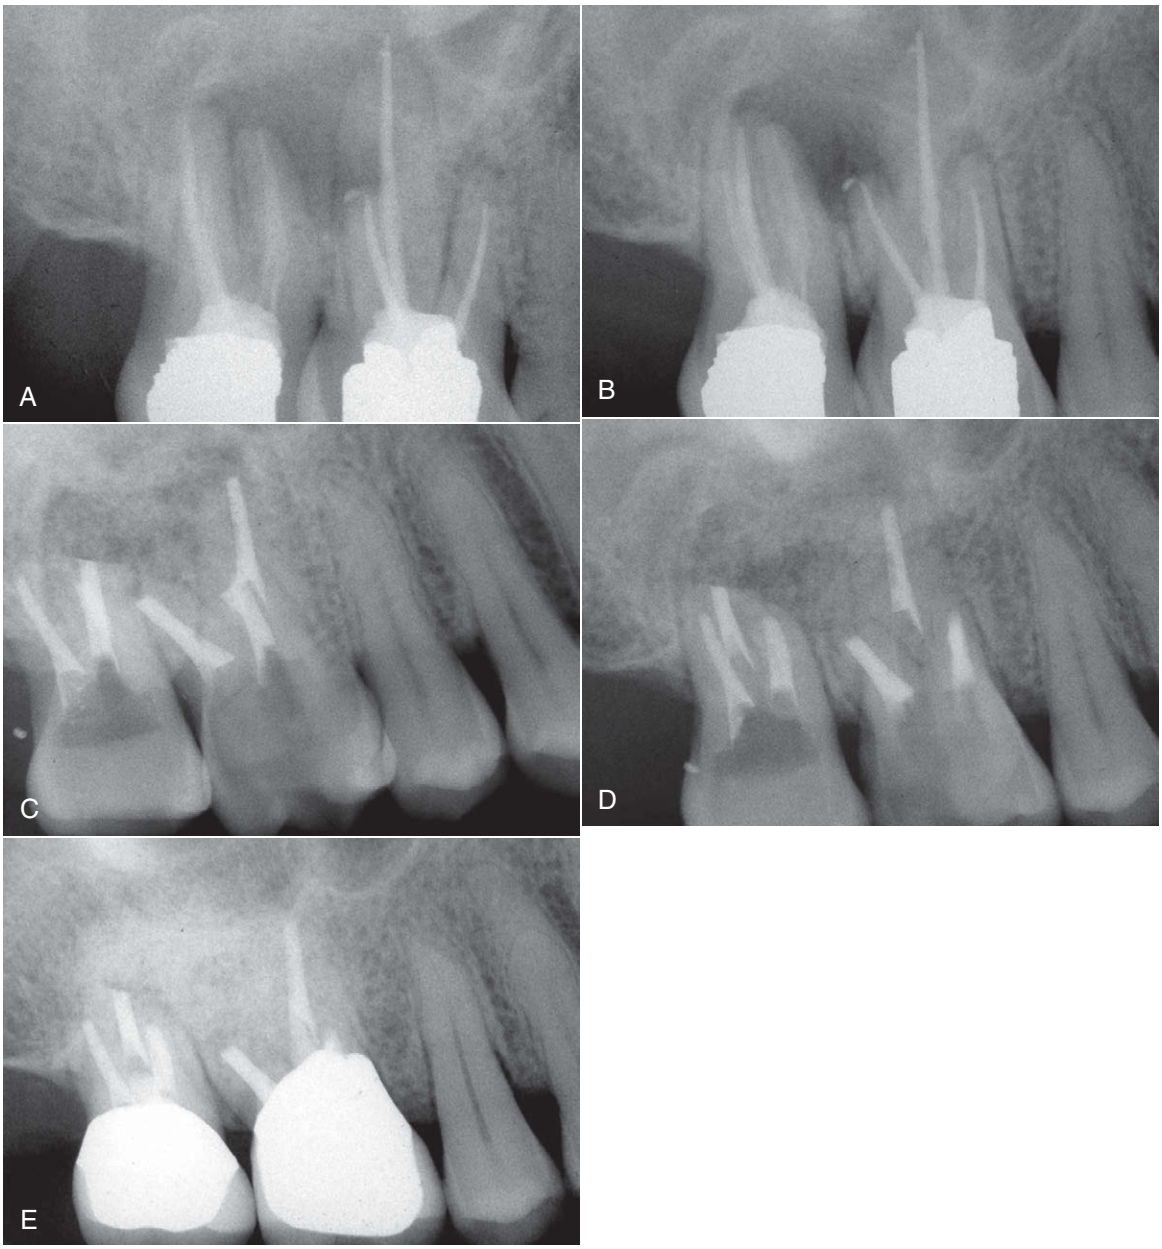

FIG. 21-52 A, Preoperative angled radiograph of maxillary right first and second molars. Both teeth had been treated previously, and patient reported a history of pain in the area for the past 5 years. Treatment plan included nonsurgical retreatment followed by periradicular surgery with bone grafting and guided tissue regeneration (GTR). **B,** Preoperative straight-on radiograph of the maxillary right first and second molars. **C,** Immediate postoperative radiograph showing root-end resections and fillings. Root ends were prepared with ultrasonics, conditioned with 17% ethylenediamine tetra-acetic acid (EDTA), filled with Diaket, and smoothed with a superfine diamond finishing bur. Crypt was packed with BioOss xenograft material, and a Guidor resorbable membrane was placed. **D,** Immediate postoperative radiograph (straight-on view). **E,** Four-year follow-up radiograph. The patient was asymptomatic, and all objective findings were within normal limits. The teeth were restored with porcelain fused to metal crowns.

soaked in a physiologic solution such as Hank's Balanced Salt Solution. After root-end preparation and filling (described previously), the tooth is replanted, and the buccal bone is compressed. The patient may be instructed to bite on a cotton roll or other semisolid object to help position the tooth properly in the socket. Occlusal adjustment is indicated to minimize traumatic forces on the tooth during the initial stage of healing. A splint may be applied, but this is often not necessary. The patient should eat a soft diet and avoid sticky foods, candy, and chewing gum for at least 7 to 10 days. Based on clinical observations and several animal model studies, the prognosis for successful healing after replantation is most closely related to avoiding trauma to the PDL and cementum during extraction and minimizing extraoral time.[22,24,371]

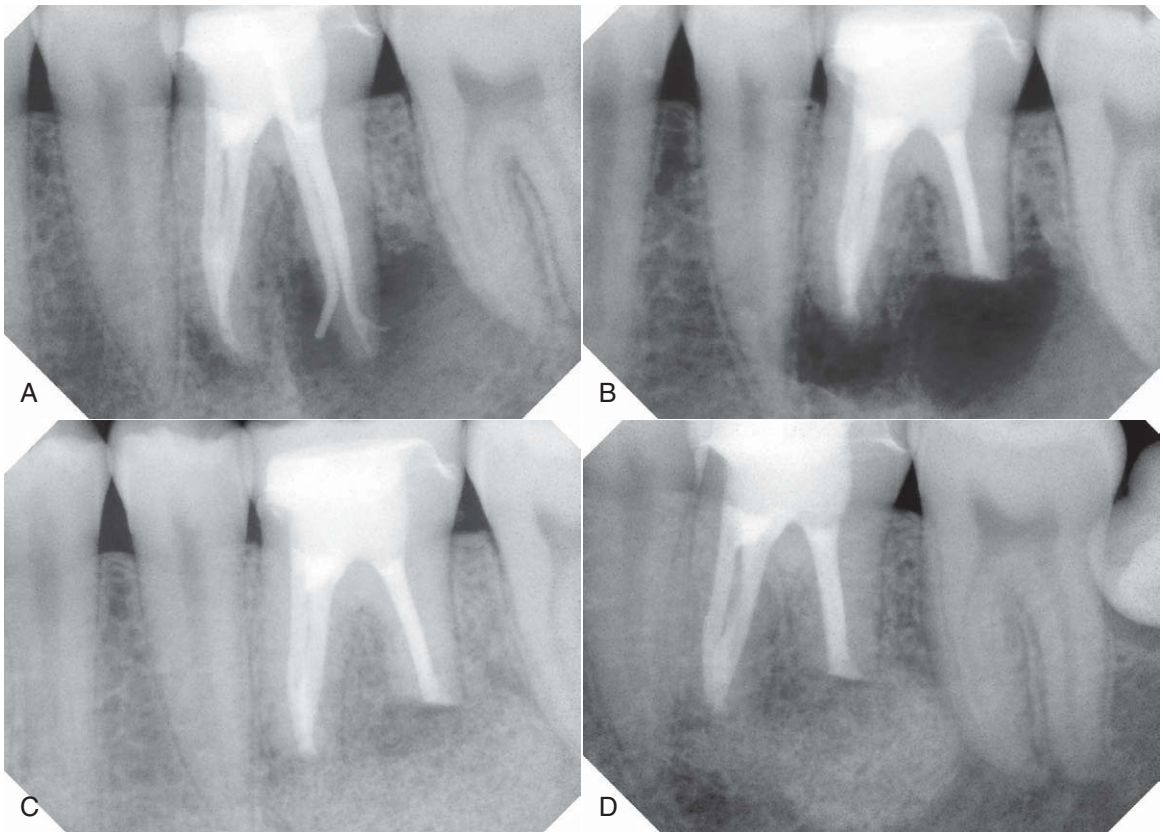

FIG. 21-53 A, Preoperative radiograph of a mandibular left first molar. Gutta-percha was inserted into the buccal sulcus and traced to the apex of the distal root. Nonsurgical root canal treatment had been performed 12 months earlier. **B,** Root-end resection and MTA root-end fillings (M and D roots). **C,** Immediate postoperative radiograph. BioOss xenograft material was placed. **D,** The 19-month follow-up radiograph showed good periradicular healing.

POSTOPERATIVE CARE

As previously noted, NSAIDs generally are the preferred class of drugs for managing postoperative pain (also see Chapter 19).[10,41,53,136] Ibuprofen (400 to 800 mg) or an equivalent NSAID typically is given before or immediately after surgery and can be continued for several days postoperatively as needed. When additional pain relief is required, a narcotic such as codeine, hydrocodone, or tramadol may be added to the standard NSAID regimen. This strategy may result in a synergistic effect, and therefore greater pain relief, than would be expected with the separate analgesic value of each drug.[141] A useful short-term approach to the management of moderate to severe pain is a "by-the-clock" alternating schedule of an NSAID and an acetaminophen/narcotic combination.[237,330] Pain after periradicular surgery typically is only mild to moderate. Postoperative pain usually is managed quite well with NSAIDs only, especially when the previously recommended strategy of preoperative NSAID therapy and a long-acting local anesthetic is combined with a minimally traumatic surgical approach.

Sutures commonly are removed 2 to 4 days after surgery.[89,200] This recommendation is based on the current understanding of wound healing and the desire to remove any potential irritants from the incision area as soon as possible. Local anesthesia is rarely required, although application of a topical anesthetic may be helpful, especially to releasing incisions in nonkeratinized mucosa. Sharp suture scissors or a #12 scalpel blade can be used to cut the sutures before they are removed with cotton pliers or tissue forceps. A transient bacteremia can be expected after suture removal, even when a preprocedural chlorhexidine mouth rinse is used.[76] Antibiotic coverage should be considered only for patients at high risk of developing bacterial endocarditis.

If healing is progressing normally at the suture removal appointment, the patient does not need to be seen again in the office until the first scheduled recall examination, typically 3 to 12 months after surgery. Phone contact with the patient approximately 7 to 10 days after suture removal is recommended to confirm the absence of problems. Patients with questionable healing at the suture-removal appointment should be reevaluated in the office in 7 to 10 days or sooner if necessary.

MANAGEMENT OF SURGICAL COMPLICATIONS

Although serious postoperative surgical complications are rare, the clinician should be prepared to respond to patient concerns and recognize when additional treatment may be necessary. Careful case evaluation, adherence to a minimally traumatic surgical technique, and proper patient management should

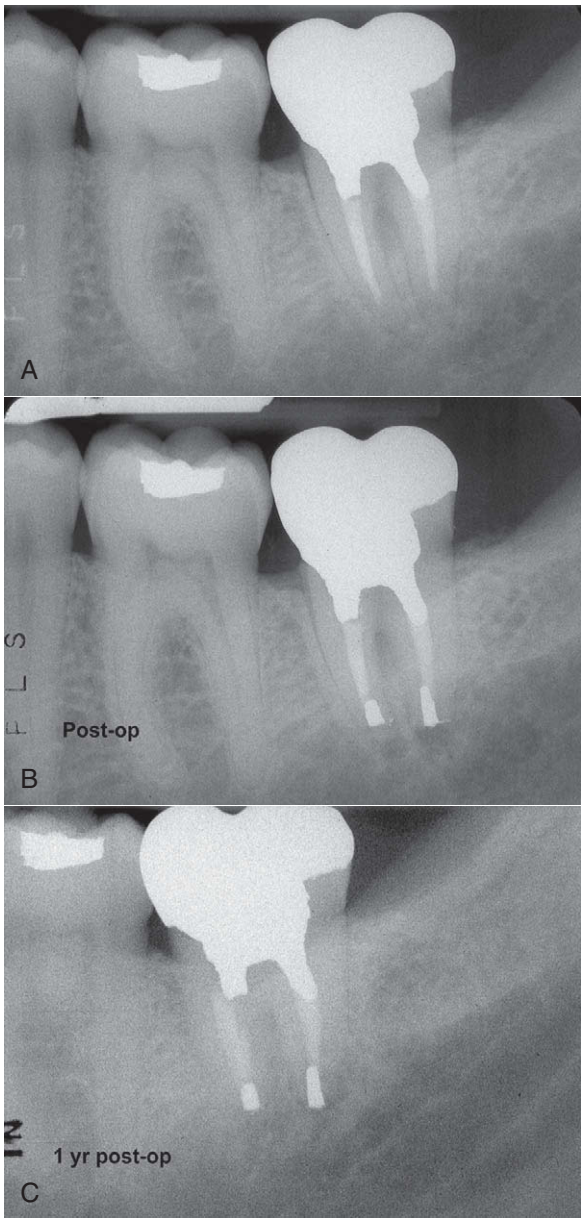

FIG. 21-54 Intentional replantation. **A**, Preoperative radiograph of a mandibular left second molar. The tooth was persistently sensitive to percussion and biting after nonsurgical retreatment. **B,** Radiograph of the tooth immediately after extraction, root-end preparation and filling, and replantation. **C,** At the 1-year follow-up visit, the tooth was asymptomatic and showed good periradicular healing. *(Courtesy Dr. Matt Davis.)*

result in a low incidence of postoperative complications. Even so, some patients experience mild to moderate postoperative pain, swelling, ecchymosis, or infection. In a prospective study of 82 patients undergoing endodontic surgical treatment, investigators[519] reported that 76.4% were pain free 1 day after surgery, and 64.7% did not report any swelling. Only 4% of the patients in this study experienced moderate pain, and this sequela was closely related to the presence of presurgical symptoms. Postoperative pain typically peaks the day of surgery, and swelling reaches its maximum 1 to 2 days after

FIG. 21-55 Postoperative ecchymosis can be alarming to the patient but resolves spontaneously within 7 to 14 days.

surgery.[276] As previously noted, good evidence supports the use of prophylactic NSAID therapy and a long-acting local anesthetic to reduce the magnitude and duration of postoperative pain.

Patients should be advised that some postoperative oozing of blood is normal, but significant bleeding is uncommon and may require attention. Most bleeding can be controlled by applying steady pressure for 20 to 30 minutes, typically with a piece of moist cotton gauze or a tea bag. Bleeding that persists requires attention by the clinician. Pressure to the area and injection of a local anesthetic containing 1:50,000 epinephrine are reasonable first steps. If bleeding continues, it may be necessary to remove the sutures and search for a small severed blood vessel. When located, the blood vessel can be crushed or cauterized to control bleeding. Cauterization may be performed with a heat source commonly used for warm obturation techniques. Local hemostatic agents, as previously described, may also be used. Occasionally, a patient may require hospitalization and surgical intervention to control bleeding, but this is an extremely rare event. Extraoral ecchymosis (Fig. 21-55) occurs when blood seeps through the interstitial tissues; although it may be alarming to the patient and clinician, this condition is self-limiting and does not affect the prognosis.[265] Moist heat applied to the area may be helpful, although complete resolution of the discoloration may take up to 2 weeks. Heat should not be applied to the face during the first 24 hours after surgery.

Sinus exposure during surgical root canal procedures on maxillary posterior teeth is not uncommon. Postoperative antibiotics and decongestants are often recommended,[17,30,265,542] but this practice is controversial, and no evidence supports the routine use of antibiotics and decongestants in these cases. An academician[546] makes a persuasive argument that antibiotics are not routinely indicated for the management of sinus exposures during periradicular surgery when primary closure of the oral-antral communication is possible. Further support for this position is provided by other clinicians who have observed excellent healing and minimal complications after sinus exposure during periradicular surgery.[274,438,548] Clinical judgment

should guide the use of antibiotics and decongestants on a case-by-case basis until more conclusive evidence on this practice is available.

No reliable data are available to provide an accurate estimate of the likelihood of paresthesia after surgical root canal treatment. The incidence of paresthesia after third molar removal is estimated to be 1% to 4.4%[424]; however, most reported cases of paresthesia after third molar extraction involved the lingual nerve, which is rarely encountered in mandibular periradicular surgery. The incidence of damage to the inferior alveolar nerve after third molar surgery is approximately 1.3%, with only about 25% of these cases resulting in permanent injury.[525] Unless the nerve is resected during surgery, most patients can be expected to return to normal sensation within 3 to 4 months. If the paresthesia does not show signs of resolving within 10 to 12 weeks, referral and evaluation for possible neuromicrosurgical repair should be considered.[158,412] Robinson and Williams[424] presented a useful method for charting and documenting paresthesias. The area of altered sensation is determined by pinching the skin or mucosa with cotton pliers or, alternatively, a pinprick or sharp instrument can be applied. The area of paresthesia is noted with a series of marks on a diagram of the face and mouth. This method provides a graphic and chronologic record of the paresthesia.

SUMMARY

Periradicular surgery today bears little resemblance to the surgical procedures commonly performed just 15 years ago. Enhanced magnification and illumination, microsurgical instruments, ultrasonics, new materials for hemostasis and root-end filling, and a greater understanding of the biology of wound healing and the etiology of persistent periradicular disease all have contributed to the rapid evolution of periradicular surgery. With proper case selection and operator skill, periradicular surgery can be considered a predictable, cost-effective alternative to extraction and tooth replacement.

CHAPTER

22

Restoration of the Endodontically Treated Tooth

DIDIER DIETSCHI, SERGE BOUILLAGUET, and AVISHAI SADAN

CHAPTER OUTLINE

SPECIAL FEATURES OF ENDODONTICALLY TREATED TEETH
- Compositional Changes in Nonvital Teeth and Influence of Endodontic Therapy
- Dentin Structure and Properties of Endodontically Treated Teeth
- Fracture Resistance and Tooth Stiffness of Endodontically Treated Teeth
- Esthetic Changes in Nonvital and Endodontically Treated Teeth

RESTORATIVE MATERIALS AND OPTIONS
- Direct Composite Restorations
- Indirect Restorations: Composite or Ceramic Onlays and Overlays
- Full Crowns
- Luting Cements

PRETREATMENT EVALUATION AND TREATMENT STRATEGY
- Pretreatment Evaluation
- Treatment Strategy

CLINICAL PROCEDURES
- Tooth Preparation
- Post Placement
- Adhesive Procedures
- Partial Restorations
- Foundation Restorations for Full Crowns
- Crown Preparation and Temporary Restoration

SPECIAL FEATURES OF ENDODONTICALLY TREATED TEETH

Endodontically treated teeth are structurally different from vital teeth; major changes include altered tissue physical characteristics, loss of tooth structure, and possibly also discoloration. Tissue modifications must therefore be analyzed at different levels, including tooth composition, dentin microstructure and tooth macrostructrure. It is fundamental to understand the implication of such features on tooth biomechanics, since they will largely influence restorative approach and means (Table 22-1). Numerous in vitro studies dealing with the complexity of the nonvital tooth substrate are reported in the literature; ultimately, in vivo trials describe the global effect of tissue qualitative and quantitative changes on restoration, long-term behavior, and survival.

Compositional Changes in Nonvital Teeth and Influence of Endodontic Therapy

The loss of pulpal vitality is accompanied by a slight change in tooth moisture content. This loss of moisture (9%) is attributed to a change in free water but not in bonded water.[69,73] This alteration was associated with a slight change in values for the Young modulus and proportional limit.[79] However, no decrease in compressive and tensile strength values was associated with this change in water content.[79] Only one study showed no difference in moisture content between vital and nonvital teeth.[129] No difference in collagen cross-linkage was found between vital and nonvital dentin.[147] There is no other evidence of chemical alteration due to the removal of pulpal tissue.

Sodium hypochlorite and chelators such as ethylenediamine tetra-acetic acid (EDTA), cyclohexane-1,2-diaminetetra-acetic acid (CDTA), ethylene glycol-bis-(β-amino-ethyl ether) N,N,N′,N′-tetra-acetic acid (EGTA), and calcium hydroxide ($Ca[OH]_2$) commonly used for canal irrigation and disinfection interact with root dentin, either with mineral content (chelators) or organic substrate (sodium hypochlorite).[82,115,122] Chelators mainly deplete calcium by complex formation and also affect noncollagenous proteins (NCP), leading to dentin erosion and softening.[82,88,151] Sodium hypochlorite supposedly demonstrates a proteolytic action by extensive fragmentation of long peptide chains such as collagen.[72] These alterations are likely to fragilize dentin and root structure and reduce adhesion to this substrate.

Dentin Structure and Properties in Nonvital and Endodontically Treated Teeth

It is important to know about the normal variations in dentin physical properties, which must be differentiated from alterations related to loss of vitality or endodontic treatment. For instance, dentin microhardness and elasticity actually varies

TABLE 22-1

Specific Tissue Modifications and Possible Clinical Implications Following Loss of Vitality or Endodontic Treatment

Alteration Level	Specific Changes	Possible Clinical Implication
Composition	Collagen structure Tooth moisture Mineral composition and content	Increased tooth fragility Reduced adhesion to substrate
Dentin structure	Elasticity modulus and behavior Tensile and shear strength Microhardness	Increased tooth fragility
Tooth macrostructure	Resistance to deformation Resistance to fracture Resistance to fatigue	Increased tooth fragility Reduced retention/stability of the prosthesis

between peritubular and intertubular dentin and depends on tooth location. Peritubular dentin presents an elasticity modulus of 29.8 GPa, whereas intertubular dentin ranges from 17.7 GPa (close to pulp) to 21.1 GPa (close to root surface).[74,91,107] Most if not all the decrease in hardness on approaching the pulp can be attributed to changes in hardness of the intertubular dentin.[90,91] Overall dentin elasticity modulus is considered to be in the range of 16.5 to 18.5 GPa[16,33,52] even though variations can be observed due to the measuring methods.[92,127,145]

The changes in mineral density due to the variation in the number and diameter of tubules within the tooth may also explain variations in the properties of dentin. It was shown that dentin hardness values are inversely related to dentin tubule density.[130] Ultra microindentation measurements also demonstrated significantly higher values for hardness and elasticity modulus when forces were parallel to the tubules rather than perpendicular.[139] Differences in maximum strength and compressive strength were also found to vary according to tubule orientation.[127] The ultimate tensile strength (UTS) of human dentin is lowest when the tensile force is parallel to tubule orientation, showing the influence of dentin microstructure and anisotropy of the tissue.[99] No difference was found in the Young modulus of aged, transparent dentin (also called *sclerotic*) and normal dentin,[20,93,175] but the mineral concentration significantly increases and crystallite size is slightly smaller in transparent dentin, in relation with closure of the tubule lumens. Transparent dentin, unlike normal dentin, exhibits almost no yielding before failure. Its fracture toughness is also lowered by about 20% while the fatigue lifetime is deleteriously affected.[93]

However, no or only minor differences in microhardness values were found between vital and nonvital dentin of contralateral teeth after periods varying from 0.2 to 10 years.[100,161] The literature does not support a widely held belief that attributes particular weakness or brittleness to nonvital dentin. It is also believed that the age-related reduction of pulp volume, progressively replaced by secondary or tertiary dentin, could account for a reduced fracture resistance of aged, nonvital teeth; this assumption is evaluated in the literature. The only impact of age-related tissue changes are the aforementioned reduction in fracture toughness and fatigue lifetime attributed to dentin sclerosis.[93]

The chemicals used for canal irrigation and disinfection, as already mentioned, interact with mineral and organic contents and then reduce dentin elasticity and flexural strength to a significant extent,[68,164] as well as microhardness.[34,81,153] On the contrary, disinfectants like eugenol and formocresol increase dentin tensile strength by way of protein coagulation and chelation with hydroxyapatite (eugenol). Dentin hardness, however, did not prove to be influenced by the latter products.[118]

In conclusion, possible decrease in tooth strength can be attributed to dentin aging and to a smaller extent to dentin alteration by endodontic irrigants.

Fracture Resistance and Tooth Stiffness of Nonvital and Endodontically Treated Teeth

The major changes in tooth biomechanics are attributed to the loss of tissue following decay, fracture, or cavity preparation, including the access cavity prior to endodontic therapy.

The loss of tooth structure following a conservative access cavity preparation affects tooth stiffness by only 5%.[177] The influence of subsequent canal instrumentation and obturation lead only to a slight reduction in the resistance to fracture[177] and ultimately have little effect on tooth biomechanics.[144,177] Practically, one can expect alteration of tooth biomechanics only in cases of nonconservative canal preparation or through the chemical or structural alteration triggered by endodontic irrigants, as previously mentioned.

In fact, the largest reduction in tooth stiffness results from additional preparation, especially the loss of marginal ridges. The literature reports 20% to 63% and 14% to 44% reduction in tooth stiffness following occlusal and MOD cavity preparations, respectively.[45,98,144] It was shown that an endodontic access cavity combined with an MOD preparation results in maximum tooth fragilization. The cavity depth, isthmus width, and configuration are therefore highly critical to the reduction in tooth stiffness and risk of fracture (Fig. 22-1).[78,89,102,128]

The presence of residual tissue in the cervical area (which comprises the *ferrule* for restorations) and a larger amount of residual tissue in general increase tooth resistance to fracture. It actually allows the axial walls of the crown to encircle the tooth, providing restoration retention and stabilization and reducing cervical tensile stresses.[7,24,169] Crown preparations with as little as 1 mm coronal extension of dentin above the margin doubles the fracture resistance of preparations, compared to those where the core terminates on a flat surface immediately above the margin[109,169]; therefore, a minimal 1-mm ferrule is considered necessary to stabilize the restoration.[169] However, the widths of preparation shoulder and crown margin do not appear to influence fracture strength.[2]

It is critical to understand that the most important part of the restored tooth is the tooth itself, and no restorative material or combination of materials will perfectly substitute for tooth structure.

FIG. 22-1 The negative impact of poor initial biomechanical status on restoration success. **A-B,** Preoperative radiographic views following the removal of the old metallic foundation. **C,** A new amalgam core, using post and self-anchorage into mesial root structure, was performed. **D,** Prosthetic restorations on working model. **E,** Full arch view after 3 years. **F,** The tooth is symptomatic due to furcation involvement and periapical lesion. **G,** This untreatable tooth was finally extracted and replaced by an implant. **H,** Eight-year postoperative radiograph showing a stable situation. Other teeth with less extensive biomechanical damage overcame functional stresses.

FIG. 22-2 Severe discoloration can significantly disturb esthetics, even in the lateral area of the smile. When not treatable with bleaching agents or veneers, this condition might justify tooth preparation for a full crown.

Esthetic Changes in Nonvital and Endodontically Treated Teeth

Color change and darkening of nonvital teeth is a common clinical observation (Fig. 22-2), and improper endodontic techniques can contribute to discoloration. For instance, inadequate cleaning and shaping can leave necrotic tissue in coronal pulp horns, resulting in tooth darkening. As well, root canal filling materials (gutta-percha and root canal cements) retained in the coronal aspect of anterior teeth can detract from the esthetic appearance. Opaque substances also adversely affect the color and translucency of most uncrowned teeth. Biochemically altered dentin modifies tooth color and appearance. It is generally accepted that organic substances present in dentin (e.g., hemoglobin) might play an important role in this color change and also food and drink pigment penetration triggered by the absence of pulpal pressure. However, the respective contribution of these two phenomena and precise physicochemical mechanisms leading to discoloration are poorly understood or described in the literature.[35,71,137]

Thin gingival tissue or in general, thin biotype is considered a negative factor for esthetic outcome of restorative and prosthetic treatment of discolored teeth.[116,117,124]

Endodontic treatment and subsequent restoration of teeth in the esthetic zone require careful control of procedures and materials to retain a translucent, natural appearance. It is therefore strongly recommended to avoid the use of potentially staining endodontic cements and to clean all material residues in the pulpal chamber and access cavity.

RESTORATIVE MATERIALS AND OPTIONS

Endodontic treatment can result in significant loss and weakening of tooth structure. Tooth structure lost during endodontic treatment increases the risk of crown fracture, with fatigue mechanisms mediating the fracture of roots over time. Restorations of endodontically treated teeth are designed to (1) protect the remaining tooth from fracture, (2) prevent reinfection of the root canal system, and (3) replace the missing tooth structure.

According to the amount of tissue to be replaced, restorations of endodontically treated teeth will rely on different materials and clinical procedures. As a general rule, most structurally damaged teeth should be restored with an artificial crown.

Although the use of a crown built on post and core is a traditional approach, others have advocated the use of direct composite resins for restoring small defects in endodontically treated teeth. More recently, indirect restorations such as overlays or endocrowns made of composite resins or ceramics have also been used. The selection of appropriate restorative materials and techniques is dictated by the amount of remaining tooth structure. This is far more relevant to the long-term prognosis of endodontically treated teeth than any properties of post, core, or crown materials.

Direct Composite Restorations

When a minimal amount of coronal tooth structure has been lost after endodontic therapy, a direct resin composite restoration may be indicated. Composite resins are a mixture of a polymerized resin network reinforced by inorganic fillers. Contemporary composites have compressive strengths of about 280 MPa, and the Young modulus of composite resins is generally about 10 to 16 GPa, which is close to that of dentin.[140]

When properly cured, resin composites are highly esthetic, exhibit high mechanical properties, and can reinforce the remaining tooth structure through bonding mechanisms. Typically, 500 to 800 mW/cm^2 of blue light for 30 to 40 seconds is necessary to polymerize an increment of composite which must be 1 to 3 mm thick. Unfortunately, the shrinkage that accompanies polymerization of contemporary composite resins remains a significant problem to the long-term success of these restorations. The use of an incremental filling technique, which helps to reduce shrinkage stresses during polymerization, is highly recommended. The amount of shrinkage will also depend on the shape of the cavity preparation and the ratio of bonded to unbonded (or free) surfaces.[37,55] This so-called C-factor is a clinically relevant predictor of the risk of debonding and leakage; restorations with high C-factors (>3.0) are at greatest risk for debonding.[183] In other words, a direct composite restoration may be indicated when only one proximal surface of the tooth has been lost; using an incremental filling technique is mandatory.

Classically, direct composite restorations have been placed in anterior teeth that have not lost tooth structure beyond the endodontic access preparation. In such cases, the placement of a direct composite restoration offers an immediate sealing of the tooth, which prevents coronal leakage and recontamination of the root canal system with bacteria. In vitro studies have demonstrated that the fracture resistance of small bonded restorations is nearly as great as that of intact teeth.[61,142]

Although direct composite resins may also be used for small restorations in posterior teeth, they are contraindicated when more than a third of coronal tissue has been lost. In one study,[142] it was reported that the resistance to fracture of endodontically treated teeth is reduced by 69% in cases where MOD cavities are present.[143] Under such conditions, a direct composite restoration may not be appropriate to prevent the tooth structure from fracture and reinfection. Furthermore, resin composite materials may require the use of reinforcing

in vitro fibers to increase their mechanical resistance. Although most studies on the clinical performance of direct composite restorations were conducted on vital teeth, a recent clinical report indicates that direct in vitro fiber-reinforced composite restorations may represent a valuable alternative to conventional restorations of endodontically treated teeth.[38] On the contrary, inserting an in vitro fiber post in the root canal of an endodontically treated tooth before bonding a direct MOD restoration significantly reduces its fracture resistance compared to the same composite restoration without a post.[167]

Indirect Restorations: Composite or Ceramic Onlays and Overlays

Ceramic or resin composite onlays and endocrowns can also be used to restore endodontically treated teeth. Whereas overlays incorporate a cusp or cusps by covering the missing tissue, endocrowns combine the post in the canal, the core, and the crown in one component.[94] Both onlays and endocrowns allow for conservation of remaining tooth structure, whereas the alternative would be to completely eliminate cusps and perimeter walls for restoration with a full crown.[62] Onlays and overlays are generally constructed in the laboratory from either hybrid resin composite or ceramics.

Ceramics are a material of choice for long-term esthetic indirect restorations because their translucency and light transmission mimic enamel. Whereas traditional feldspathic porcelains were sintered from a slurry, new ceramic materials may be cast, machined, pressed, or slip-cast in addition to being sintered. New materials are either variations of feldspathic porcelains (e.g., In-Ceram, Cerec, IPS Empress) or may be fabricated from other ceramic systems, including alumina, zirconia, or silica.[3,39] Among these newer compositions is lithium disilicate, which offers high strength, high fracture toughness, and a high degree of translucency. Physical properties of these materials have improved to the point where they can survive high stress-bearing situations such as posterior restorations in endodontically treated teeth.[46,77] Researchers have examined 140 partial Cerec restorations (Vita MKII, feldspathic porcelain) adhesively cemented to endodontically treated teeth and found this treatment approach satisfactory after an observation period of 55 months.[10] Their results indicate that survival rates are higher for molars than for premolars.

Onlays, overlays, and endocrowns can also be fabricated from resin composites processed in the laboratory. Using various combinations of light, pressure, and vacuum, these fabrication techniques are claimed to increase the conversion rate of the polymer and consequently the mechanical properties of the restorative material. Other investigations have described the application of glass fiber–reinforced composite endocrowns on premolars and molars as single restorations or as abutment for fixed partial dentures.[62,63] A recent in vitro study by another research team indicates that composite inlays can partially restore the resistance to fracture of endodontically treated molars and prevent catastrophic fractures after loading.[29] Other investigators reported that composite resin MZ100 increased the fatigue resistance of overlay-type restorations in endodontically treated molars when compared to porcelain MKII.[103] Another recent study used three-dimensional finite element analysis to estimate bone resorption around endocrowns made up of high- (alumina) or low-elastic modulus materials (resin composites). They concluded that the higher resilience of resin composite restorations acts positively against the risk of periodontal bone resorption by reducing the amount of force transferred to root dentin.[4]

Full Crowns

When a significant amount of coronal tooth structure has been lost by caries, restorative procedures, and endodontics, a full crown may be the restoration of choice. In a few cases, the crown can be directly built on the remaining coronal structure which has been prepared accordingly (see Core Materials heading). More frequently, the cementation of a post inside the root canal is necessary to provide retention for the core material and the crown.[172] The core is anchored to the tooth by extension into the root canal through the post and replaces missing coronal structure. The crown covers the core and restores the esthetics and function of the tooth.

An additional role of the post and core is to protect the crown margins from deformation under function and thereby to prevent coronal leakage. Because most endodontic sealers do not completely seal the root canal space, the coronal seal provided by the placement of a post and core will positively influence the outcome of the endodontic treatment.[155] The post's ability to anchor the core is also an important factor for successful reconstruction, since the core and the post are usually fabricated of different materials. Finally, the luting material used to cement the post, the core, and the crown to the tooth will also influence the longevity of the restoration. The post, the core, and their luting or bonding agents together form a *foundation restoration* to support the future crown.[112]

The Foundation Restoration: General Considerations

Although there are many materials and techniques to fabricate a foundation restoration, no combination of materials can substitute for tooth structure. As a general rule, the more tooth structure that remains, the better the long-term prognosis of the restoration. The coronal tooth structure located above the gingival level will help to create a ferrule.[6,85,106,134] The *ferrule* is formed by the walls and margins of the crown, encasing at least 2 to 3 mm of sound tooth structure. A properly executed ferrule significantly reduces the incidence of fracture in endodontically treated teeth by reinforcing the tooth at its external surface and dissipating forces that concentrate at the narrowest circumference of the tooth.[101,181] A longer ferrule increases fracture resistance significantly.[86] The ferrule also resists lateral forces from posts and leverage from the crown in function and increases the retention and resistance of the restoration. To be successful, the crown and crown preparation together must meet five requirements:

1. The ferrule (dentin axial wall height) must be at least 2 to 3 mm.
2. The axial walls must be parallel.
3. The restoration must completely encircle the tooth.
4. The margin must be on solid tooth structure.
5. The crown and crown preparation must not invade the attachment apparatus.

Root anatomy can also have significant influence over post placement and selection. Root curvature, furcations, developmental depressions, and root concavities observed at the external surface of the root are all likely to be reproduced inside the root canal. Within the same root, the shape of the canal

will vary between the cervical level and the apical foramen.[66] As a result, severe alteration of the natural shape of the canal is often necessary to adapt a circular post inside the root. This increases the risk of root perforation, especially in mesial roots of maxillary and mandibular molars which exhibit deep concavities on the furcal surface of their mesial root.[17,95] The tooth is also weakened if root dentin is sacrificed to place a larger-diameter post. A study using three-dimensional electronic speckle-pattern interferometry (ESPI) evaluated the effects of root canal preparation and post placement on the rigidity of human roots.[99] ESPI has the major advantage of being able to assess tooth deformation in real time and can be used repeatedly on the same root because of the nondestructive nature of the test. Study results indicate that root deformability is significantly increased after the preparation of a post space. Thus, preservation of root structure is also a guiding principle in the decision to use a post, the selection of the post, and the preparation of the post space. This is a reason why not every endodontically treated tooth needs a post and why more conservative approaches that do not rely on the use of a post are currently being developed.

However, a post may be used in the root of a structurally damaged tooth in which additional retention is needed for the core and coronal restoration. Posts should provide as many of the following clinical features as possible:

- Maximal protection of the root from fracture
- Maximal retention within the root and retrievability
- Maximal retention of the core and crown
- Maximal protection of the crown margin seal from coronal leakage
- Pleasing esthetics, when indicated
- High radiographic visibility
- Biocompatibility

From a mechanical point of view, an endodontic post should not break, should not break the root, and should not distort or allow movement of the core and crown. An ideal post would have an optimal combination of resilience, stiffness, flexibility, and strength. *Resilience* is the ability to deflect elastically under force without permanent damage. It is a valuable quality in endodontic posts, but too much flexibility in a narrow post compromises its ability to retain the core and crown under functional forces. *Stiffness* describes a material's ability to resist deformation when stressed. The stiffness of a material is an inherent physical property of that material, regardless of size. However, the actual flexibility of a post depends both on the diameter of a specific post and on the modulus of elasticity of the post's material. Posts with a lower modulus of elasticity are more flexible than posts of the same diameter with a higher modulus of elasticity. Posts made of non-stiff materials (low modulus of elasticity) are more resilient, absorb more impact force, and transmit less force to the root than stiff posts, but low-modulus posts fail at lower levels of force than high-modulus posts.[105,126,150]

Excessive flexing of the post and micromovement of the core are particular risks in teeth with minimal remaining tooth structure, because these teeth lack their own cervical stiffness as a result of the missing dentin. Post flexion can also distort and open crown margins. Open margins can result in potentially devastating caries or endodontic leakage and apical reinfection. Extensive caries extending into the root can be as irreparable as root fracture. Because rigid posts flex and bend less than nonrigid posts, they can limit movement of the core and possible disruption of the crown margins and cement seal. However, the force must go somewhere. Force from a stiff post is transmitted to the root, next to the apex of the post. An attempt to strengthen a weak root by adding a stiff post can instead make the root weaker as a result of the force concentration of a stiff rod in a more flexible material. Stress concentration in the post/root complex can lead to the self-destructive process of cracking and fracturing. Root fracture is particularly a risk in teeth with minimal remaining tooth structure to support a ferrule.

Roots also flex under force, which is a function of both the modulus of elasticity of dentin and the diameter of the root. Dentin is relatively flexible, and posts can be flexible or stiff. Although no material can behave exactly like dentin, a post with functional behavior similar to that of dentin is beneficial when the post must be placed next to dentin. Posts have been developed with a modulus of elasticity closer to dentin than that offered by traditional metal posts. But posts are significantly narrower than roots, and the actual deflection of a post within dentin is a function of both the modulus of elasticity and the diameter. The modulus of elasticity of various posts, compared with that of dentin, represents only one aspect of flexion.

In summary, an ideal post would be resilient enough to cushion an impact by stretching elastically, thereby reducing the resulting stress to the root. It would then return to normal without permanent distortion. At the same time, this ideal post would be stiff enough not to distort, permanently bend, or structurally fail under mastication forces. Finally, the perfect post would combine the ideal level of flexibility and strength in a narrow-diameter structure, which is dictated by root canal morphology. Current post systems are designed to provide the best compromise between the desired properties and inherent limitations of available materials.

Why Roots Fracture

Structures subjected to low but repeated forces can appear to fracture suddenly for no apparent reason. This phenomenon, also known as *fatigue failure,* occurs when a material or a tissue is subjected to cyclic loading. Fatigue may be characterized as a progressive failure phenomenon that proceeds by the initiation and propagation of cracks; many failures of teeth or materials observed in the mouth are fatigue-related. Because teeth are subjected to fluctuating cycles of loading and unloading during mastication, fatigue failure of dentin, posts, cores, crown margins, or adhesive components are all likely to occur.[160] Mechanical loading will favor the propagation of microcracks that will progress from the coronal to the apical region of the tooth.

Initial failure of crown margins from fatigue loading is clinically undetectable. However, when measured in vitro, early failure resulted in significant leakage of crown margins, extending between the tooth, restoration, and post space.[48] Particularly in teeth with minimal remaining tooth structure, fatigue can cause endodontic posts to bend permanently or break, or it can cause a fiber-matrix complex to disintegrate.

Fatigue failure of nonvital teeth restored with a post is more catastrophic because it may result in a complete fracture of the root. A post placed into a dentin root will function physically like any structural rod anchored in another material.

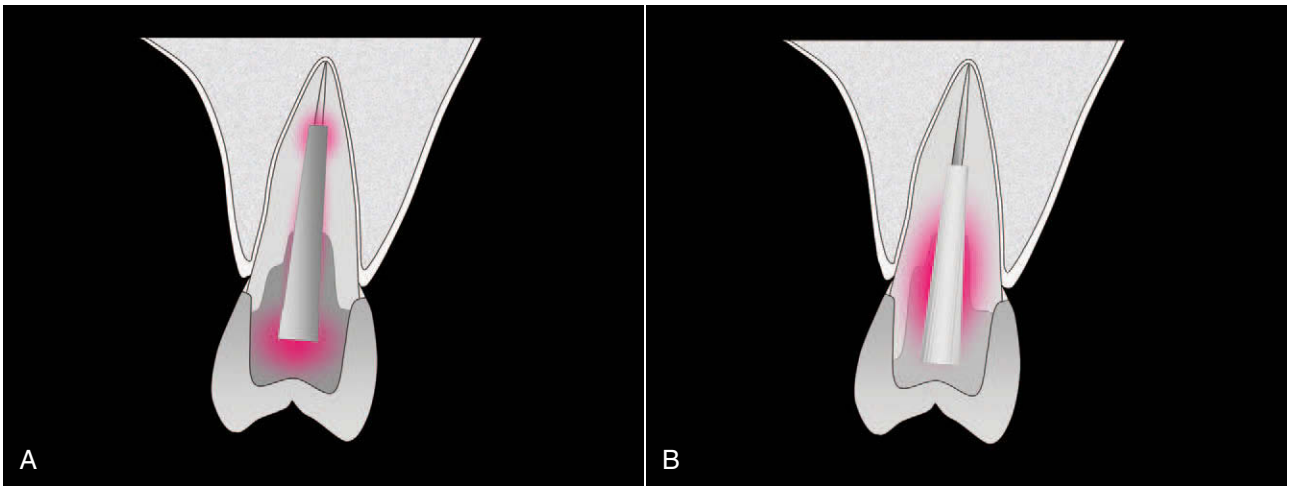

FIG. 22-3 A, Stress distribution within a metallic post and core foundation and residual tooth structure, according to photoelastic and FEM studies. The post is cemented and usually penetrates the apical portion of the root. Functional stresses accumulate inside the foundation, slightly around the post and further inside the canal, around the apex of the post; there is less stress buildup in the cervical area compared to that with a fiber post (as shown in Fig. 22-3, *B*). This configuration more ideally protects the coronocervical structures but when failing, results in severe untreatable root fractures. **B,** Stress distribution within a fiber post/composite foundation and residual tooth structure, according to photoelastic and FEM studies. The post is bonded to the canal walls and penetrates the canal less apically. Functional stresses mainly accumulate around the post in the cervical area. This configuration protects the cervical area less efficiently but tends to prevent untreatable root fractures. The presence of a ferrule is mandatory. (*Adapted from Dietschi D, Duc O, Krejci I, Sadan A: Biomechanical considerations for the restoration of endodontically treated teeth: a systematic review of the literature—Part 1. Composition and micro- and macrostructure alterations.* Quintessence Int *38:733–743, 2007.*)

This means that the forces applied on the post are transmitted to the root dentin with characteristic patterns depending on the modulus of elasticity of both the post and the dentin. If the post has a higher modulus than the dentin, the stress concentration is adjacent to the bottom of the post (Fig. 22-3). This is evident in clinical cases of root fracture originating at the apex of a rigid post.

When the stiffness of the endodontic post is similar to that of dentin, stresses are not concentrated in the dentin adjacent to the apex of the post but rather dissipated by both the coronal and the root dentin (see Fig. 22-3). A resilient post can also prevent a sudden blow by stretching elastically, which reduces the transient forces against the tooth, but a post that is too elastic becomes too flexible for retaining a core and a crown when the tooth cannot do so on its own. A resilient post that is overloaded fails with less force than a stiffer post. This limits the amount of resilience that can be designed into a post.

Direct Foundation Restorations

In general, the evolution of foundation restorations has been to diminish invasiveness and eliminate some components in selected cases. When a sufficient amount of tissue is present at the periphery of the prepared tooth, a direct foundation restoration is indicated. In the direct technique, a prefabricated post is cemented inside the root canal, and the core is built directly on the prepared tooth. For other clinical situations, an indirect custom-cast post and core may be indicated.

Various materials can be used to fabricate a direct foundation restoration. Although there is growing interest in using resin-based materials such as resin composites or fiber-reinforced resin posts, more traditional materials such as amalgam are still used for that purpose.[28] For clarity, the components used for fabricating a direct foundation restoration (e.g., the endodontic post and core material) are described individually.

POSTS

The large number of post designs and materials available on the market reflects the absence of consensus in that field. Based on what manufacturers or clinicians consider the most important properties, posts can be fabricated from metal (gold, titanium, stainless steel), ceramic, or fiber-reinforced resins. As a general rule, a post needs retention and resistance. Whereas *post retention* refers to the ability of a post to resist vertical forces, *resistance* refers to the ability of the tooth/post combination to withstand lateral and rotational forces. Resistance is influenced by the presence of a ferrule, the post's length and rigidity, and the presence of antirotational features. A restoration lacking resistance form is not likely to be a long-term success, regardless of the retentiveness of the post.

Prefabricated Metallic Posts Prefabricated metallic posts are frequently used for the fabrication of a direct foundation restoration. These posts are classified several ways, including by alloy composition, retention mode, and shape. Materials used to fabricate metallic posts include gold alloys, stainless steel, or titanium alloys. Metallic posts are very strong, and with the exception of the titanium alloys, very rigid.[96] A recent study indicates that the flexural strength of stainless steel posts is about 1430 MPa and that flexural modulus approximates 110 GPa.[136] On the other hand, titanium posts are less rigid (66 GPa) but exhibit a flexural strength (1280 MPa) similar to stainless steel.

The retention of prefabricated posts inside the root canal is also essential for successful restorations. Two basic concepts have been used to promote the retention of endodontic posts:

active posts and passive posts. Active posts derive their primary retention directly from the root dentin by the use of threads. Most active posts are threaded and are intended to be screwed into the walls of the root canal. A major concern about threaded posts has been the potential for vertical root fracture during placement. As the post is screwed into place, it introduces great stresses within the root, causing a wedging effect.[171] Therefore, it is generally accepted that *the use of threaded posts should be avoided.* Furthermore, the improved retention once offered by threaded posts can now be achieved with adhesive luting cements (see later).[123] Passive posts are passively placed in close contact to the dentin walls, and their retention primarily relies on the luting cement used for cementation. The shape of a passive post may be either tapered or parallel.[146] A parallel post is more retentive than a tapered post but also requires removal of more root dentin during the preparation of the post space. Parallel posts are reported to be less likely to cause root fractures than tapered posts, although they are less conforming to the original shape of the root.[83,158,170] Unfortunately, modern techniques for root canal preparation use tapered nickel-titanium (NiTi) rotary shaping files, which results in a very wide tapered and unretentive canal exhibiting a significant divergence from apical to coronal.[152] Longer posts are often necessary to accommodate this problem and offer adequate retention; adequate length in the root canal is considered to be greater than 6 mm. When teeth are protected by crowns with an adequate ferrule, longer posts do not further increase fracture resistance.[84] Posts designed with mechanical locking features in the heads and roughened surface texture can show better retention of the core.[30]

Fiber Posts A fiber post consists of reinforcing fibers embedded in a resin polymerized matrix. Monomers used to form the resin matrix are typically bifunctional methacrylates (Bis-GMA, UDMA, TEGDMA), but epoxies have also been used. Common fibers in today's fiber posts are made of carbon, glass, silica, or quartz but the type, volume content, and uniformity of the fibers and the matrix are proprietary and vary among fiber post systems. These differences in the manufacturing process may reflect the large variations observed among different types of fiber posts subjected to a fatigue resistance test.[67] Fibers are commonly 7 to 20 μm in diameter and are used in a number of different configurations, including braided, woven, and longitudinal. The original fiber posts consisted of carbon fibers embedded in epoxy resin, but quartz-fiber posts are currently preferred for their favorable mechanical properties, esthetic qualities, and their ability to chemically bond to the polymer matrix.[51] A recent study indicates that the flexural strength of glass-, silica-, or quartz-fiber posts approximates 1000 MPa and that flexural modulus is about 23 GPa.[36] Current fiber posts are radiopaque and may also conduct the light for polymerization of resin-based luting cements. A light-transmitting post results in better polymerization of resin composites in the apical area of simulated root canals, as measured by hardness values.[148,182] To enhance bonding at the post/core/cement interfaces, several physicochemical pretreatments such as silanization or sand blasting of the post surface have been described. Recent research indicates that silanization, hydrofluoric etching, and sandblasting (with 30 to 50 μm Al_2O_3) do not modify the mechanical properties of different glass-, silica-, or quartz-fiber posts.[5]

It is generally accepted that bonding fiber posts to root canal dentin can improve the distribution of forces applied along the root, thereby decreasing the risk of root fracture and contributing to the reinforcement of the remaining tooth structure.[13,19,58] A well-adapted adhesively cemented fiber post is considered the most retentive with the least stress generated on the canal walls. In a retrospective study which evaluated three types of bonded fiber posts, investigators reported 3.2% failure of 1306 fiber posts in recalls of 1 to 6 years.[57] More recently, another study reported survival rates of 98.6% and 96.8% for parallel-sided and tapered fiber posts, respectively, placed in anterior teeth covered with full-ceramic crowns after a mean observation period of 5.3 years.[163]

Zirconia Posts Zirconia posts are composed of zirconium dioxide (ZrO_2) partially stabilized with yttrium oxide and exhibit a high flexural strength. Zirconia posts are esthetic, partially adhesive, very rigid, but also brittle. Zirconia posts cannot be etched, and available literature suggests that bonding resins to these materials is less predictable and requires substantially different bonding methods than conventional ceramics.[12] When a composite core is built on a zirconia post, core retention may also be a problem. Controversies exist about the efficiency of airborne particle abrasion at establishing a durable resin bond to zirconia posts treated or not treated with a coupling agent.[1,133] Overall, there are concerns about the rigidity of zirconia posts, which tends to make those posts too brittle. Other reports indicate that the rigidity of zirconia posts negatively affects the quality of the interface between the resin core material and dentin when subjected to fatigue testing.[41,44]

CORE MATERIALS

The core replaces carious, fractured, or missing coronal structure and helps to retain the final restoration. Desirable physical characteristics of a core include (1) high compressive and flexural strength, (2) dimensional stability, (3) ease of manipulation, (4) short setting time, and (5) the ability to bond to both tooth and post. Core materials include composite resin, cast metal or ceramic, amalgam, and sometimes glass ionomer materials. The core is anchored to the tooth by extension into the coronal aspect of the canal or through the endodontic post. The importance of retention between the post, the core, and the tooth increases as remaining tooth structure decreases.

Composite Resin Core Composite core materials take a number of strategies to enhance their strength and resistance; metal may be added, filler levels may be greater, or faster-setting ionomers may be used.[140] Composite core materials have been shown to exhibit slightly better mechanical values than conventional materials, but improvements are negligible.[184] However, they appear to be superior to silver-glass-ionomer cement and amalgam.[31] The advantages of composite core resins are adhesive bonding to tooth structure and many posts, ease of manipulation, rapid setting, and translucent or highly opaque formulations. Composite cores have been shown to protect the strength of all-ceramic crowns equally to amalgam cores. Bond strength of composite cores to dentin depends on a complete curing of the resin materials, so dentin bonding agents must be chemically compatible with composite core materials. Self-cure composite resins require self-cure adhesives and are mostly incompatible with light-

cure adhesives.[27] However, no adhesive has been shown to completely eliminate microleakage at the margins of the restoration.[18] A degradation of the resin core or the marginal integrity of the crown can result in invasion of oral fluids. Therefore, as with all buildup materials for decimated teeth, more than 2 mm of sound tooth structure should remain at the margin for optimal composite resin core function.

Composite core materials can be used in association with metallic, fiber, or zirconia posts. This is frequently observed in the presence of structurally compromised teeth. They may provide some protection from root fracture in teeth restored with metal posts compared with amalgam or gold cores. Loosening of the post, core, and crown with composite core can occur, but composite cores have been shown to fail more favorably than amalgam or gold.[135] A recent retrospective study of the clinical performance of fiber posts indicates that fiber posts and cores have a failure rate ranging between 7% and 11% after a service period of 7 to 11 years and that post loosening may also occur.[56] Composite core materials are typically two-paste, self-cured composites, but light-curing materials are also available. The use of light-curing composite core materials generally eliminates the risk of chemical incompatibility between adhesives and self-curing resin core materials. Bonding light-cured resin composites to the irregular structure of the pulp chamber and canal orifices might eliminate the need for a post when sufficient tooth structure remains. Research indicates that bonding to the dentin walls of the pulp chamber is easier and superior to resin dentin bonds made on dentin canal walls.[8]

Amalgam Core Dental amalgam is a traditional core buildup material with a long history of clinical success. Although there are many variations in the alloy's composition, more recent formulations have high compressive strength (400 MPa after 24 hours), high tensile strength, and a high modulus of elasticity. High-copper alloys tend to be stiffer (60 GPa) than low-copper alloys.

Amalgam can be used with or without a post. Thirty years ago, investigators described the amalcore.[119] With the amalcore technique, amalgam is compacted into the pulp chamber and 2 to 3 mm coronally of each canal. The following criteria were considered for the application of this technique: the remaining pulp chamber should be of sufficient width and depth to provide adequate bulk and retention of the amalgam restoration, and an adequate dentin thickness around the pulp chamber was required for the tooth-restoration continuum rigidity and strength. The fracture resistance of the amalgam coronal-radicular restoration with four or more millimeters of chamber wall was shown to be adequate, although the extension into the root canal space had little influence.[87]

Amalgam can also be used in combination with a prefabricated metallic post when the retention offered by the remaining coronal tissue needs to be increased. Amalgam cores are highly retentive when used with a preformed metal post in posterior teeth; they require more force to dislodge than cast posts and cores.[108] Others have suggested the use of adhesive resins to bond amalgam to coronal tissue.[162]

Significant disadvantages of amalgam cores are the "non-adhesive nature" of the material, the potential for corrosion, and subsequent discoloration of the gingiva or dentin. Amalgam use is declining worldwide because of legislative, safety, and environmental issues.

Glass Ionomer Core and Modified Glass Ionomer Core Glass ionomer and resin-modified glass ionomer cements are adhesive materials useful for small buildups or to fill undercuts in prepared teeth. The rationale for using glass ionomer materials is based on their cariostatic effect resulting from fluoride release. However, their low strength and fracture toughness result in brittleness, which contraindicates the use of glass ionomer buildups in thin anterior teeth or to replace unsupported cusps. They may be indicated in posterior teeth in which (1) a bulk of core material is possible, (2) significant sound dentin remains, and (3) caries control is indicated.[180]

Resin-modified glass ionomer materials are a combination of glass ionomer and composite resin technologies and have properties of both materials. Resin-modified glass ionomers have moderate strength, greater than glass ionomers but less than composite resins. As a core material, they are adequate for moderate-sized buildups, but hygroscopic expansion can cause fracture of ceramic crowns and fragilized roots.[165] The bond to dentin is close to that of dentin-bonded composite resin and significantly higher than traditional glass ionomers. Today, resin composites have replaced glass ionomer materials for core fabrication.

Indirect Foundation Restorations: Cast Post and Core

For many years, the cast metal post and core has been the traditional method for fabricating the foundation restoration of a prosthetic crown. Classically, smooth-sided, tapered posts conforming to the taper of the root canal are fabricated from high noble alloys, although noble and base-metal classes of dental alloys have also been used. Noble alloys used for post and core fabrication have high stiffness (approximately 80 to 100 GPa), strength (1500 MPa), hardness, and excellent resistance to corrosion.[32]

One advantage of the cast post/core system is that the core is an integral extension of the post, and that the core does not depend on mechanical means for retention on the post. This construction prevents dislodgment of the core from the post and root when minimal tooth structure remains. However, the cast post/core system also has several disadvantages. Valuable tooth structure must be removed to create a path of insertion or withdrawal. Second, the procedure is expensive because two appointments are needed, and laboratory costs may be significant. The laboratory phase is technique sensitive. Metal casting of a pattern with a large core and a small-diameter post can result in porosity in the gold at the post/core interface. Fracture of the metal at this interface under function results in failure of the restoration. Most important, the cast post/core system has a higher clinical rate of root fracture than preformed posts.[47,166]

Studies on cast post retention have shown that the post must fit the prepared root canal as closely as possible to be perfectly retained. When a ferrule is present, custom cast posts and cores exhibit a higher fracture resistance compared to composite cores built on prefabricated metallic posts or carbon posts.[104] Cast posts are also known to exhibit the least amount of retention and are associated with a higher failure rate compared to prefabricated parallel-sided posts. In a classic retrospective study (1 to 20 years) of 1273 endodontically treated teeth in general practice, 245 (19.2%) were restored with tapered cast posts and cores. Among these, 12.7% were deemed failures. This failure rate was higher than that for the other

passive post systems used. Of particular concern was the fact that 39% of the failures led to unrestorable teeth requiring extraction. Thirty-six percent of the failures were due to loss of retention, and 58% were due to the fracture of the root. It has been suggested that tapered smooth-sided posts have a "wedging" effect under functional loading, and it is this that leads to increased risk of root fracture.[168]

One 6-year retrospective study reported a success rate higher than 90% using a cast post and core as a foundation restoration.[9] The lower failure rate and fewer root fractures were attributed to the presence of an adequate ferrule and careful tooth preparation. Attention has also been drawn to the fact that the higher failure rate may be due to the fact that nearly half of the posts were shorter than recommended from the literature. A venting groove for the cement along the axis of the post results in less stress on residual tissues.

Luting Cements

A variety of cements have been used to cement endodontic posts and include traditional cements, glass ionomer cements, and resin-based luting cements.

Traditional Cements

Zinc phosphate cements or polycarboxylate cements are still used for cementation of posts and crowns. They are generally supplied as a powder and a liquid and their physical properties are highly influenced by the mixing ratio of the components. Their compressive strength is about 100 MPa, and elastic moduli are lower than that of dentin (5 to 12 GPa). Zinc phosphate cement is mostly used for cementing metal restorations and posts; film thickness of the zinc phosphate cement is less than 25 μm. These cements provide retention through mechanical means and have no chemical bond to the post or to dentin but provide clinically sufficient retention for posts in teeth with adequate tooth structure.

Glass Ionomer Luting Cements

Glass ionomer cements are a mixture of glass particles and polyacids, but resin monomers may also be added. Depending on the resin content, glass ionomer cements can be classified as either conventional or resin-modified glass ionomer cements. Conventional glass ionomer cements have compressive strengths ranging between 100 and 200 MPa; the Young modulus is generally about 5 GPa. They are mechanically more resistant than zinc phosphate cements, and they can bond to dentin with values ranging between 3 and 5 MPa. Some authors still recommend the use of glass ionomer cements for the cementation of metallic posts. Major advantages of conventional glass ionomer cements are their ease of manipulation, chemical setting, and ability to bond to both tooth and post.

On the contrary, resin-modified glass ionomer cements are not indicated for post cementation, because these cements exhibit hygroscopic expansion that can promote fracture of the root.

Resin-Based Luting Cements

Today there is a trend toward the use adhesive cements for bonding endodontic posts during the restoration of nonvital teeth. The rationale for using adhesive cements is based on the premise that bonding posts to root canal dentin will reinforce the tooth and help retain the post and the restoration.[50] Contemporary resin-based luting cements have been shown to exhibit compressive strengths around 200 MPa and elastic moduli between 4 and 10 GPa.[25] These materials may be polymerized through a chemical reaction, a photopolymerization process, or a combination of both mechanisms. Photopolymerization of these resin-based materials is often necessary to maximize strength and rigidity.

Most luting cements require a pretreatment of the root canal dentin with either etch-and-rinse or self-etching adhesives. Both types of adhesives have been shown to form hybrid layers along the walls of the post spaces.[11] However, bonding to root canal dentin may be compromised by the use of endodontic irrigants such as sodium hypochlorite, hydrogen peroxide, or their combination.[121] Because these chemicals are strong oxidizing agents, they leave behind an oxygen-rich layer on the dentin surface that inhibits the polymerization of the resin.[159] Previous research has shown that the bond strength of C&B Metabond to root canal dentin was reduced by half when the dentin was previously treated with 5% sodium hypochlorite (NaOCl) or 15% EDTA/10% urea peroxide (RC Prep, Premier Dental, Plymath Meeting, PA).[113] Other reports indicate that the contamination of the dentin walls by eugenol diffusing from endodontic sealers may also affect the retention of bonded posts.[70,176] Further, it is difficult to control the amount of moisture left in a root canal after acid etching, making impregnation of collagen fibers with etch-and-rinse adhesives problematic. The use of self-etching adhesives has been proposed as an alternative for the cementation of endodontic posts, because self-etching adhesives are generally used on dry dentin and do not require rinsing of the etchant. However, their efficiency at infiltrating thick smear layers like those produced during post space preparation remains controversial.[110,179] More recently, dual-curing adhesives have been developed to ensure a better polymerization of the resin deep inside the root canal. Dual-cured adhesives contain ternary catalysts to offset the acid-base reaction between the acidic monomers and the basic amines along the composite/adhesive interface.[111]

Although both self-curing and light-curing luting cements can be used for cementation of prefabricated endodontic posts, most resin cements have a dual-curing process that requires light exposure to initiate the polymerization reaction. Dual-curing cements are preferred because there are concerns as to whether light-curing materials are properly cured, especially in areas of difficult light access such as the apical portion of the root canal. However, it has been reported that photocured composites generate more shrinkage stress and exhibit less flow than chemically cured composites.[54] Contraction stresses induced by polymerization also depend on the geometry of the post space and the thickness of the resin film. Previous research indicates that the restriction of flow of resin cements by the configuration of the root canal can significantly increase the contraction stress at the adhesive interface.[53,174]

In recent years, a number of techniques have been used to measure the adhesion of resin-based luting cements to root canal dentin. These methods include the pull-out tests, the microtensile bond strength tests and the push-out tests.[49,65] Although laboratory tests confirmed that bond strengths ranging between 10 and 15 MPa can be obtained with modern resin-based luting cement, there is also evidence that frictional retention is a factor contributing to post retention.[15] It is generally accepted that bonding to dentin of the pulp chamber is

more reliable than to root canal dentin, especially at the apical level.[132] The lowered bond strength values recorded at the apical third of the root canal are likely to be related to the reduced number of dentinal tubules available for dentin hybridization. Shorter posts may be used when successful bonding occurs between fiber-reinforced posts and root dentin, because current adhesive luting cements can assist in the retention of posts in the root canal space.[138]

Another factor that may influence the performance of resin-based luting cements is the thickness of the cement layer. The cementation of endodontic fiber posts with thicker cement layers might be required when posts do not perfectly fit inside the root canal. Although a slight increase in cement thickness (up to 150 microns) does not significantly affect the performance of adhesive luting cements applied to root canal dentin, thicker layers may be detrimental to bond quality.[80,157]

A recent study indicates that bond strength to radicular dentin might be maximized by adopting procedures that compensate for polymerization stresses.[14] The bonding procedures are realized in two separate steps. The initial step allows optimal resin film formation and polymerization along the root canal walls, leading to more ideal resin-dentin hybridization without stresses imposed by the placement of the post. A second step bonds the post to the cured resin film. The polymerization shrinkage that occurs during the initial adhesive coating step will reduce the effects of stress imposed when the resin-coated post polymerizes, thereby preserving the bond integrity.

Although the bonding performance of resin-based luting cements is well documented, there are other reports indicating that resin-dentin bonds degrade over time.[23,60] The loss of bond strength and seal are attributed to the degradation of the hybrid layer created at the dentin-adhesive interface. This is particularly true for etch-and-rinse adhesives, because the gelatinization of collagen fibers caused by phosphoric acids may restrict the diffusion of the resin within the interfibrillar spaces and may leave unprotected fibers available for degradation. Removing organic components from the demineralized dentin prior to bonding procedures was recently suggested. The use of dilute NaOCl (0.5%) after acid etching or the conditioning of dentin smear layers with EDTA (0.1 M, pH 7.4) have been shown to produce more durable resin-dentin bonds made with single-step etch-and-rinse adhesives.[156]

Other research indicates that the degradation of denuded collagen fibrils exposed in incompletely infiltrated hybrid layers is driven by an endogenous proteolytic mechanism involving the activity of matrix metalloproteinases (MMPs).[22,131] The release of MMPs such as collagenases has been evidenced in both coronal and root dentin of fully developed teeth of young patients.[154] Researchers suggest that conditioning root canal dentin with a broad-spectrum protease inhibitor such as chlorhexidine (2 wt% chlorhexidine digluconate solution) might be useful for the preservation of dentin bond strength over time.[21]

Interestingly, these dentin-conditioning procedures, which may improve the resistance of the resin-dentin bond to chemical degradation, also act as antibacterial agents; this might be of interest in the endodontic context.

Self-Adhesive Cements

More recently, self-adhesive resin cements have been introduced as an alternative to conventional resin-based luting cements. Self-adhesive luting cements contain multifunctional phosphoric acid methacrylates that react with hydroxyapatite and simultaneously demineralize and infiltrate dental hard tissue.[114] They do not require any pretreatment of the tooth substrates, and their clinical application is accomplished in a single step. Therefore, the self-etching capability of these new cements reduces the risk for incomplete impregnation of the conditioned tissue by the resins and reduces technique sensitivity. The elastic moduli of chemically cured self-adhesive resin cements are relatively low (4 to 8 GPa) but generally increase when a dual-curing process is used. It is therefore recommended that all dual-cured resin cements receive maximal light to achieve superior material properties wherever clinically possible.[141] Adhesion performance to dentin was found comparable to multistep luting cements, but bonding to enamel without prior phosphoric acid etching is not recommended.[76] However, their long-term clinical performances need to be assessed before making a general recommendation for their use.

PRETREATMENT EVALUATION AND TREATMENT STRATEGY

Before any therapy is initiated, the tooth must be thoroughly evaluated to ensure treatment success. Each tooth must be examined individually and in the context of its contribution to the overall treatment plan and rehabilitation. This assessment includes endodontic, periodontal, biomechanical, and esthetic evaluations. Planning of the restoration for endodontically treated teeth brings together all aforementioned biomechanical and clinical factors, as well as the various materials and procedures designed to address them.

Pretreatment Evaluation

Endodontic Evaluation

The prerestorative examination should include an inspection of the quality of existing endodontic treatment. New restorations, particularly complex restorations, should not be placed on abutment teeth with a questionable endodontic prognosis. Endodontic retreatment is indicated for teeth showing radiographic signs of apical periodontitis or clinical symptoms of inflammation. Restorations that require a post need a post space, which is prepared by removal of gutta-percha from the canal. Canals obturated with a silver cone or other inappropriate filling material should be endodontically retreated before starting any restorative therapy. Because the probability for periapical tissue to heal after endodontic retreatment is reasonably high, the chances to retain a well-restored tooth in asymptomatic function over time are excellent.[125]

Periodontal Evaluation

Maintenance of periodontal health is also critical to the long-term success of endodontically treated teeth. The periodontal condition of the tooth must therefore be determined before the start of endodontic therapy and restorative phase. The following conditions are to be considered as critical for treatment success:

- Healthy gingival tissue
- Normal bone architecture and attachment levels to favor periodontal health

- Maintenance of biologic width and ferrule effect before and after endodontic and restorative phases

If one or more of the aforementioned conditions are not met owing to preexisting pathology or structural defects, treatment success or even feasibility can be compromised, sometimes suggesting extraction of weak teeth and replacement with dental implants rather than conventional therapy.

Biomechanical Evaluation

All previous events, from initial decay or trauma to final root canal therapy, influence the biomechanical status of the tooth and the selection of restorative materials and procedures. The biomechanical status can even justify the decision to extract extremely mutilated teeth that do not deserve extensive treatments that carry a limited probability of success. Important clinical factors include the following:

- The amount and quality of remaining tooth structure
- The anatomic position of the tooth
- The occlusal forces on the tooth
- The restorative requirements of the tooth

Teeth with minimal remaining tooth structure are at increased risk for the following clinical complications[120,173,178] (see Fig. 22-1; Fig. 22-4):

- Root fracture
- Coronal-apical leakage
- Recurrent caries
- Dislodgment or loss of the core/prosthesis
- Periodontal injury from biologic width invasion

The amount and quality of remaining tooth substrate are far more important to the long-term prognosis of the restored tooth than any restorative material properties. One must consider that no restorative material can truly substitute for dentin or enamel and that a minimal amount of intact structure is mandatory to justify tooth maintenance and its strategic importance to the overall treatment plan. The presence of healthy adjacent teeth available as abutments or the option of dental implants are additional factors to be analyzed when justifying the restoration of endodontically treated teeth.

FIG. 22-4 Failure of prosthetic foundations can have dramatic consequences on both overlying restorations and surrounding tissues. A better understanding of compositional and structural changes that affect tooth resistance to repeated functional forces is mandatory to improve treatment success in endodontically treated teeth.

Tooth Position, Occlusal Forces, and Parafunctions

Teeth are subjected to cyclic axial and nonaxial forces. The teeth and associated restorations must resist these forces to limit potential damages such as wear or fracture. The degree and direction of forces depend on the location of the tooth in the arch, the occlusal scheme, and the patient's functional status.

In most occlusal schemes, anterior teeth protect posterior teeth from lateral forces through anterolateral guidance. In the context of very steep anterior guidance and deep vertical overbite, maxillary anterior teeth are sustaining higher protrusive and lateral forces from the mandibular anterior teeth. Restorations of damaged anterior teeth with heavy function should therefore be designed to resist flexion. Restorative components should be stronger than would be required for teeth with an edge-to-edge relationship and therefore vertical forces.

Posterior teeth normally carry more vertical forces, especially when canine and anterior guidance are maintained; they also sustain greater occlusal loads than anterior teeth, and restorations must be planned to protect posterior teeth against fracture. In the case of parafunctions, protection by anterior contacts are likely to be reduced or lost and posterior teeth then submitted to more lateral stresses, generating higher demand for restorative materials.

The literature reports average biting forces varying between 25 and 75 N in the anterior region and between 40 and 125 N for the posterior region of the mouth, depending on food type, dental status (dentate or edentulous), and patient anatomy and functional habits.[59,75] Those forces can easily reach 1000 N or above in case of parafunctions, showing how potentially destructive they can be for intact teeth and even more so for nonvital, fragilized teeth. Parafunctional habits (clenching and bruxism) are major causes of fatigue or traumatic injury to teeth, including wear, cracks, and fractures. Teeth that show extensive wear or sequelae from parafunctions, especially heavy lateral function, require components with the highest physical properties to protect restored teeth against fracture.

In general, modern strategy focuses on tissue preservation and also on the use of adhesion to achieve stabilization of the restoration for improved short- and long-term service. However, in certain conditions like reduced tooth support, conventional materials are not obsolete.

Esthetic Evaluation and Requirements

Anterior teeth, premolars, and often the maxillary first molar, along with the surrounding gingiva, compose the esthetic zone of the mouth. Changes in the color or translucency of the visible tooth structure, along with thin soft tissues or biotype, diminish the chance for a successful esthetic treatment outcome.

Potential esthetic complications should be investigated before endodontic therapy is initiated. For instance, metal or dark carbon fiber posts or amalgam placed in the pulpal chamber can result in unacceptable esthetic results, such as a grayish appearance of the overlying prosthetic restoration (especially with modern, more translucent full-ceramic crowns) or gingival discoloration from the underlying cervical area or root (see Fig. 22-1). All teeth located in the esthetic zone also require critical control of endodontic filling materials in the coronal third of the canal and the pulp chamber to avoid

or reduce the risk of discoloration. Careful selection of restorative materials, careful handling of tissues, and timely endodontic intervention are important to preserving the natural appearance of nonvital teeth and gingiva.

Treatment Strategy

General Principles and Guidelines

The post, the core, and their luting or bonding agents form together the *foundation restoration* to support the coronal restoration of endodontically treated teeth. The recent evolution of foundation restorations has been to diminish invasiveness, to use adhesion rather than macromechanical anchorage, and to eliminate intraradicular components in selected cases. These changing clinical concepts derive from both an improved understanding of tooth biomechanics and advances in restorative materials.

The foundation and its different constituents are then aimed at providing the best protection against leakage-related caries, fracture, or restoration dislodgment. Therefore, all aforementioned local and general parameters are to be systematically analyzed in order to select the best treatment approach and restorative materials. Prosthetic requirements are also to be taken into consideration to complete each case analysis. In general, abutments for fixed or removable partial dentures clearly dictate more extensive protective and retentive features than do single crowns, owing to greater transverse and torquing forces. This modern biomechanical treatment strategy is summarized in Fig. 22-5.

Structurally Sound Anterior Teeth

Anterior teeth can lose vitality as a result of a trauma with no or minimal structural damage. They generally do not require a crown, core, or post; restorative treatment is limited to sealing the access cavity and direct composite fillings. Discoloration, whenever present, is addressed by nonvital bleaching, or for untreatable or relapsing ones, with conservative restorative approaches such as direct or indirect veneers (Table 22-2).

Nonvital Posterior Teeth With Minimal/Reduced Tissue Loss

The loss of vitality in posterior teeth resulting from trauma, decay, or restorative procedure does not necessarily lead to extreme biomechanical involvement and therefore allow in certain conditions for conservative restorations.

Occlusal cavities or mesio/disto-occlusal cavities can be restored with either direct- or indirect-adhesive intracoronal restorations, providing residual walls are thick enough (proximal ridges and buccolingual walls more then 1.5 mm thickness). The three additional clinical factors which must be analyzed to ensure optimal treatment success are the configuration factor (C-factor), cavity volume, and dentin quality. For instance, a large class I cavity with contaminated and sclerotic dentin would clearly be a contraindication to the direct approach, despite the fact it apparently falls within the indications of direct techniques. Conservative options must, however, always be analyzed under the light of functional and occlusal environment. They can only be considered in the absence of parafunctions and with anterior guidance, which limits overall functional loading and lateral or flexural forces. In less favorable biomechanical conditions (group guidance, steep occlusal anatomy, bruxism, clenching, etc.), a protective approach with full occlusal coverage (onlay or overlay) is mandated to minimize the risk of fatigue failures (see Table 22-2).

Structurally Compromised Teeth

The decision for placing a post as well as the selection of a post system (rigid or nonrigid) depends once again on the amount and quality of remaining tooth structure and the anticipated forces sustained by this tooth (Table 22-3).

In general, rigid posts made of stiff materials (metal and ceramics) are indicated for teeth with minimal tooth structure which rely on the post to hold the core and crown. Because rigid posts flex and bend less than other types of posts, they are supposed to limit movement of the core and possible disruption of the crown margins and cement seal. But one must remember that stiff posts transmit more stresses to the root, next to the post apex, when conventionally cemented. An attempt to strengthen a weak root by adding a stiff post can instead make the root weaker as a result of the force concentration behavior of a stiff rod in a more flexible material. Adhesion therefore plays a crucial role, since a well-bonded post can help absorb stresses more evenly throughout the remaining tooth structure. Benefit and increased risk of fissure and fracture must then be appropriately weighed against adhesion potential inside the root and post type, composition, and surface treatment.

In structurally sound teeth, nonrigid posts flex with the tooth under functional forces, reducing the transfer of force to the root and reducing the risk of root fracture. Flexion is of course related to post diameter. In structurally compromised teeth, which lack cervical stiffness from dentin and ferrule effect, excessive post flexion can be detrimental to the marginal seal and prosthesis longevity, so fiber posts are generally contraindicated.

White or translucent fiber posts are generally preferred underneath full-ceramic restorations, whereas stronger black carbon fiber posts, which can reflect through gingiva, tooth structure, or ceramic restorations, are usually used in teeth to be restored with gold or porcelain fused to metal crowns, as well as in zirconia-based restorations. The literature has largely overemphasized the impact of post color on restoration esthetics. Metal or carbon post color can be masked with resin opaquer and gold post and core ceramized to enhance esthetic integration. Such procedures can help to approach a more ideal restoration biomechanical behavior through the fabrication of rigid but more esthetic foundations. Upper lateral and lower incisors, together with extremely thin biotype, are probably the only real esthetic contraindication for metal or carbon fiber posts.

In cases of extreme tooth fragility secondary to caries, fracture, previous overenlargement of the root canal system, or immaturity, residual root structure can be unified and reinforced with adhesive bonding and composite before placing a normal-diameter post, forming altogether a cohesive unit, as previously described.

In conclusion, in a damaged tooth that is to be restored with a nonrigid post, 2 to 3 mm of cervical tooth structure must ideally remain to allow creation of a restoration as a whole that is resistant to flexion. Teeth with minimal tooth structure and limited ferrule effect need additional cervical stiffness from a more rigid post to resist distortion. In this

situation, adhesive cementation is preferred to conventional cementation.

Structurally Compromised Anterior Teeth

Restoration of endodontically treated teeth becomes more complex as teeth or supporting structures become increasingly affected. A nonvital anterior tooth that has lost significant tooth structure requires restoration with a crown, supported and retained by a core and possibly a post as well.

When less than half the core height is present, or when remaining walls are extremely thin (less than 1 mm on more than three-fourths of the tooth circumference), a post is needed to increase retention and stabilize and reinforce the foundation. Many post options are available nowadays, including titanium, fiber-reinforced resin, and ceramics. Adhesion is now the preferred mode of post cementation unless a long-term contamination of root dentin is obvious (e.g., with eugenol), making adhesion highly questionable.

In the latter situation or in the presence of flared canals (possibly as well when a limited ferrule effect is present), cast gold post and core are still considered a feasible option. Actually, in this extremely unfavorable biomechanical environment, this traditional treatment approach provides a higher rigidity in the cervical area, which is mandatory for restoration stability. Here, a fiber-reinforced composite foundation having higher flexibility might present less favorable biomechanical behavior, such as suggested by FEM studies[43] (see Fig. 22-3 and Table 22-2). Tooth extraction and implant placement or bonded bridge (particularly for lateral incisors) are also to be considered in this situation.

In the esthetic zone, the post should not detract from the esthetics of the coronal tooth structure, ceramic crown, or gingiva. Current restorative procedures allow fabrication of highly esthetic ceramic coronal restorations that have no metal substructure. When such restorations with remarkable lifelike color and vitality are selected, it usually implies the use of nonmetal esthetic posts, either ceramic or resin fiber-reinforced ones.

Structurally Compromised Posterior Teeth

Slightly decayed posterior teeth in the context of parafunctions or significantly fragilized premolars and molars require cuspal protection afforded by onlay restoration, endocrown, or a full crown. The need for a post and core depends on the amount of remaining tooth structure. When remaining walls (buccal and lingual) provide more than 3 to 4 mm height (from pulpal chamber floor) and 1.5 to 2 mm thickness, core and restoration stability are granted through macromechanical retention and/or adhesion; then, posts are not needed (see Fig. 22-5). With current treatment strategy, *the post has become the exception rather than the rule for the restoration of nonvital posterior teeth.*

Additional Procedures

Periodontal crown lengthening surgery or orthodontic extrusion can expose additional root structure to allow restoration of a severely damaged tooth. In the smile frame, crown lengthening might however be limited by esthetic adverse consequences (proximal attachment reduction); basically, buccal crown lengthening only can be considered as a potential indication for this procedure. In the posterior region, crown lengthening is limited by tooth and furcation anatomy or by loss of bone structure, which complicates future implant placement. As regards to orthodontic extrusion, root length and anatomy are the limiting factors of this procedure; short

TABLE 22-3

Clinical Protocols for Restoring Nonvital Teeth With Full Prosthetic Restorations (Most Likely Procedures)

Treatment Approach	Indications	Tooth Preparation (Critical Guidelines)	Foundation		Restoration	
			Post	Core	Fabrication	Luting
Composite core	Reduced walls but >½ crown height	Maintain all residual structures >1 mm thickness (after core prep.)	—	DBA + composite Dual or LC, incremental	*In laboratory:* PFM or full ceramic restoration: slip-casting, pressed, or CAD-CAM	Coating, sandblasting, or etching + silane and Dual or SA cement
Composite core + ceramic post	More than ½ coronal structure lost, reduced wall height	Maintain all residual structures >1 mm thickness (after core prep.)	Sandblasting or coating/silane + DBA + Dual cement or SA cement	DBA + composite Dual or LC, incremental	*In laboratory:* PFM or full ceramic restoration: slip-casting, pressed, or CAD-CAM	Coating, sandblasting, or etching + silane and Dual or SA cement
Composite core + in vitro fiber post	More than ½ coronal structure lost, reduced wall height	Maintain all residual structures >1 mm thickness (after core prep.)	Sandblasting or coating/silane + DBA + Dual cement or SA cement	DBA + composite Dual or LC, incremental	*In laboratory:* PFM or full ceramic restoration: slip-casting, pressed, or CAD-CAM	Coating, sandblasting, or etching + silane and Dual or SA cement
Composite core + metal post	More than ⅔ coronal structure lost, reduced wall height	Maintain all residual structures >1 mm thickness (after core prep.)	Sandblasting or coating/silane + DBA + Dual cement or SA cement	DBA + composite Dual or LC, incremental	*In laboratory:* PFM or full ceramic restoration: slip-casting, pressed, or CAD-CAM	Coating, sandblasting, or etching + silane and Dual or SA cement
Amalgam core (+/– metal post)	Alternative to composite core with metal post	Maintain all residual structures >1 mm thickness (after core prep.)	No tt + nonadhesive cement or sandblasting/ coating/silane + DBA + Dual cement or SA cement	Amalgam placement in retentive cavity/ preparation	*In laboratory:* PFM restoration	Coating, sandblasting, or etching + silane and Dual or SA cement
Cast gold post and core (+/– porcelain)	More than 3/4 coronal structure lost	Maintain all residual structures >1 mm thickness (after core prep.) Internal walls are divergent	No tt/sandblasting + nonadhesive cement or sandblasting/ coating/silane + DBA + Dual cement or SA cement	No tt + nonadhesive cement or DBA + Dual cement or SA cement	*In laboratory:* PFM or full ceramic restoration: Zirconia/ CAD-CAM	Coating, sandblasting, or etching + silane and Dual or SA cement

CAD-CAM, Computer-aided design/computer-aided machined; *CER,* ceramic; *CP,* composite; *DBA,* dentin bonding agent; *Dual,* dual curing; *LC,* light curing; *PFM,* porcelain fused to metal; *SA,* self-adhesive.

roots or conical anatomy are contraindications to orthodontic extrusion. Once again, when a long-lasting, functional restoration cannot be predictably created, tooth extraction might be better than to pursue heroic efforts to restore extremely weak teeth, using complex, expensive, and unpredictable procedures.

CLINICAL PROCEDURES

The restoration of a nonvital tooth may include several restorative components such as the post, the core, and the overlying restoration. Within the same tooth, several interfaces such as post to radicular dentin, core to coronal dentin, core to post, and core to overlying restoration will be created. According to the biomechanical status, some or all restorative components and interfaces will be present and need to be addressed.

General clinical guidelines for restoring endodontically treated teeth with either partial or full crown restorations are presented in Table 22-2, with specific procedures for tooth preparation and treatment of the different interfaces involved. Clinical steps for all recommended treatment options are presented in Figs. 22-6 through 22-14.

Tooth Preparation

The most important part of the restored tooth is the tooth itself. As described earlier, thickness and height of remaining dentin walls or cusps along with functional occlusal conditions are the determining factors in choosing the most appropriate restorative solution.

For partial intracoronal restorations, maximal tissue conservation is the only consideration for the clinician. In other situations, the selected restorative approach will usually necessitate some tooth preparation to comply with restoration design and thickness. Onlays, overlays, and endocrowns require about 1.5 to 2 mm occlusal space to guarantee restoration resistance to functional loads. For full crowns, a ferrule is needed to encircle the vertical walls of sound tooth structure above the restoration margin (1.5 to 3 mm), thus preventing a coincidence between core and restoration limits. Other preparation requirements presented in this chapter are to be respected to ensure treatment success. This means that a 4- to 5-mm height and 1-mm thickness of sound, suprabony tooth structure should be available to accommodate both the periodontal biologic width and the restorative ferrule.

Post Placement

The post is an extension of the foundation into the root of structurally damaged teeth, needed for the core and coronal restoration stability and retention. The post is cemented or bonded into the root, according to tissue quality and post and core choice. The post performs both a mechanical and biologic function by protecting the apical seal from bacterial contamination in case of coronal leakage. These functions should not be attained at the expense of tooth strength; post space preparation should be as conservative as possible to avoid an increased risk of root fracture. It is important to point out again that a post does not strengthen or reinforce a tooth. This elusive goal would only be achieved in a case of perfect cohesion between post and tooth substrate, nowadays only partially achievable. Therefore, the clinician must keep in mind that inherent strength of the tooth and its resistance to root fracture comes mostly from the remaining tooth structure and the surrounding alveolar bone. The tooth is weakened if dentin is sacrificed to place a larger-diameter post.

The post should be long enough to meet aforementioned biomechanical demands without jeopardizing root integrity. The standard parameters for post placement in a tooth with normal periodontal support are:

1. In case of nonadhesive cementation (metal posts only)[64]:
   - Two thirds the length of the canal
   - A radicular extension at least equal to the coronal length of the core
   - One half the bone-supported length of the root
2. In case of adhesive cementation (fiber posts)[42,142]:
   - One third to one half the length of the canal, maximum
   - A radicular extension about the coronal length of the core

The first step for all types of post and core restorations is removal of gutta-percha and endodontic cement from the future post space. This procedure generally is best accomplished by the clinician providing the endodontic service, because that person has a clear knowledge of the size and form of the canal system. The initial post space preparation procedure is similar for most standardized post and core systems. The space, cleared of gutta-percha, has the form of the canal after cleaning and shaping. Proprietary systems are supplied with a series of drills to prepare the internal surface of the canal. The goal of post space formation is to remove little or no dentin from the root canal.

Adhesive Procedures

In general, both self-etch and etch-and-rinse adhesive systems can be used successfully on root dentin, both systems having a well-documented proof of efficacy. However, the use of etch-and-rinse adhesive systems may be advantageous in the presence of highly sclerotic or contaminated dentin, because phosphoric acids will etch dentin more deeply than self-etching primers. When treating the canal in the perspective of post cementation, a dual-curing adhesive system is preferably used to optimize polymerization. Self-adhesive cements have also demonstrated satisfactory performance for post cementation.

Partial Restorations

In the case of limited to moderate coronal substance loss, the restorative strategy for endodontically treated front teeth varies, from direct composite restoration using the same layering or application techniques as for vital teeth (possibly with the contribution of intracoronal or extracoronal bleaching) to full veneers, when discoloration is not fully treatable or tends to relapse. From a restorative standpoint, it is only necessary to mention that a 1- to 2-week delay is mandatory prior to adhesively restoring a bleached tooth. For more extensive restoration, it is even advised to wait up to 6 weeks or more (depending on the extent and duration of bleaching treatment) to allow for tooth final color stabilization and to proceed with shade selection.[40] Figs. 22-6 and 22-7 describe the clinical steps involved in the restoration of moderately decayed front teeth using direct composite and bleaching or veneers.

In posterior teeth exhibiting limited to moderate tissue loss, direct to indirect partial or full occlusal restorations are proposed. Their benefit is to take advantage of residual tooth structure to stabilize the restoration and minimize the potential impact of a prosthetic rehabilitation on periodontal tissues. For instance, second molars definitely profit from a conservative approach using adhesively luted intracoronal and full occlusal coverage restorations. Endocrown is a modification of the aforementioned concept, with extension of the restoration into the pulpal chamber as additional retentive and stabilization structure. Figs. 22-8, 22-9, and 22-10 describe the clinical steps involved in the restoration of moderately decayed posterior teeth using onlays, overlays, and endocrowns.

Foundation Restoration Underneath Full Crowns

If significant coronal substance loss justifies a full-tooth coverage, the strategy for foundation fabrication varies from:

- Amalgam core with/without metal post
- Composite core without post
- Composite post with fiber or ceramic post
- Composite with prefabricated metal post
- Cast gold post and core

FIG. 22-6 Direct composite restorations on front teeth (following bleaching). Nonvital anterior tooth with sufficient amount of residual tissue and intact, healthy neighboring teeth, usually in rather young patients. **A,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha were removed from the cavity to expose a clean dentin substrate. Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for the later placement of a post. **B,** Bleaching procedures. Two sessions of internal bleaching were needed to adapt the color of both traumatized anterior teeth (tooth #11), using a mixture of 3% hydrogen peroxide and sodium perborate powder. Each bleaching session extended over a 10-day period. Between sessions and until the given delay to proceed with final restoration (1 to 2 weeks up to 6 to 8 weeks), access cavity is closed with either a temporary filling material or flowable resin composite. **C-D,** Restorative procedures. A layer of adhesive is applied over all cavity surfaces. An etch-and-rinse system is frequently preferred when the dentinal tissue is highly sclerotic or was contaminated (e.g., by eugenol). A hard cement such as glass ionomer (not a resin-modified glass ionomer because of water uptake and further expansion) was used for dentin replacement, before adding enamel composite to close the lingual cavity. A full resin composite restoration can also be considered to fill in the lingual cavity (dentin + enamel masses) in consideration of the material's hydrophobic nature, which could presumably prevent or limit penetration of water-soluble pigments from the oral cavity. Two or three layers are usually used to replace the missing tissue, preferably following the "natural layering concept," which aims to build up the restoration with two basic masses, namely dentin and enamel, with help of a silicone index. **E-F,** Postoperative views. The two conservative restorations are shown after finishing and polishing, with rubber dam still in place **(E)** and after several weeks **(F)**. Note that esthetic integration can not be evaluated before full rehydration has occurred (4 to 6 hours at least).

FIG. 22-7 Direct composite restoration on posterior tooth. Nonvital posterior tooth with sufficient amount of residual tissue and mostly intact, rather healthy neighboring teeth. No significant discoloration of buccal tooth substrate and absence of severe parafunctions and/or group guidance or other unfavorable occluso-functional condition. **A,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for a later placement of a post. **B,** Adhesive procedure. An etch-and-rinse adhesive system was used here owing to the presence of sclerotic and contaminated dentin. **C-E,** Restoration base and layering technique. Resins or glass ionomer cements can be used for dentin replacement, before adding enamel composite to close the lingual cavity. A full resin composite restoration can also be considered to fill in the lingual cavity (dentin + enamel masses) in consideration of the material's hydrophobic nature, which could presumably prevent or limit penetration of water-soluble pigments from the oral cavity. A dentin composite mass is used to replace missing dentinal tissue, and enamel composite is used to build up proximal walls and the occlusal anatomy. **F,** Postoperative view. The postoperative view demonstrates the advantage of this conservative approach in the context of teeth with appropriate biomechanical status.

FIG. 22-8 Veneer. Nonvital anterior tooth with sufficient amount of residual tissue and rather healthy neighboring teeth. Discoloration resisted bleaching or relapsed, despite several retreatments. Preferably thick biotype to limit the risk of gingival recession and loss of esthetic integration. **A,** Closing the lingual cavity. A hard cement such as glass ionomer (not resin-modified glass ionomer because of water uptake and possible expansion) can be used for dentin replacement, before adding enamel composite to close the lingual cavity. A full resin composite restoration can also be considered to fill in the lingual cavity (dentin + enamel masses) in consideration of the material's hydrophobic nature, which could presumably prevent or limit penetration of water-soluble pigments from the oral cavity. **B,** Preparation. A sufficient amount of buccal tooth structure must be removed to allow for a good esthetic result (preparation depth is dictated by the discoloration severity). Cervical margins closely follow gingival contours, preventing soft-tissue impingement, but they assume complete coverage of discolored tooth structure. **C-D,** Adhesive procedure. Hydrophobic bonding systems are preferred to wet-etched enamel when no dentin is exposed. An etch-and-rinse adhesive system is preferred when dentin is exposed (here, in the presence of significant areas of sclerotic dentin). Restoration. Ceramic is etched and silanated. Just before cementation, a last layer of bonding resin is applied but not light-cured until placement. **E,** Luting technique. A light-curing, highly filled, translucent and fluorescent restorative material is preferably used for cementation. This allows better control of restoration placement and minimal wear and fatigue of the cement layer. **F,** Postoperative view. The postoperative view demonstrates satisfactory esthetics. This approach is sometimes suitable to meet patient's high esthetic demands.

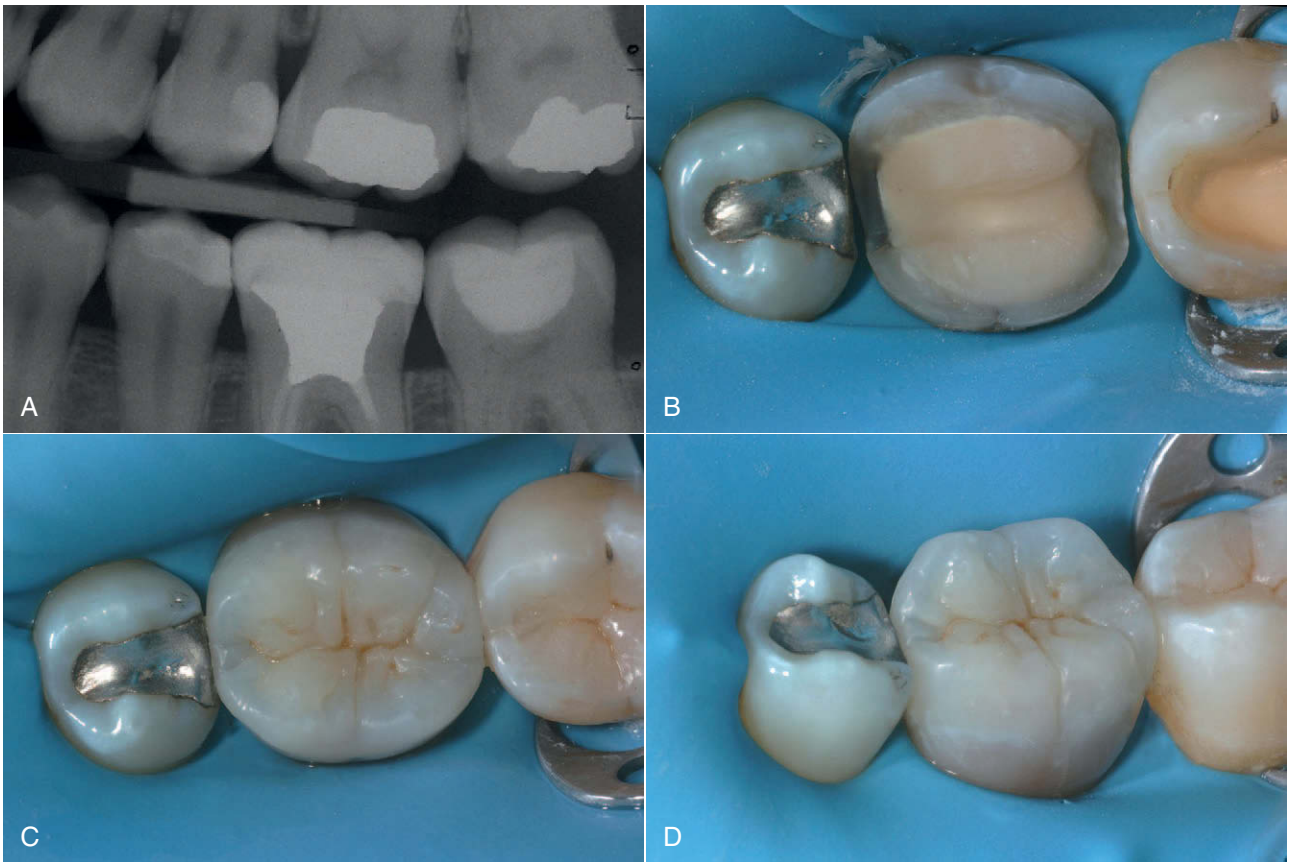

FIG. 22-9 Onlay/Overlay. Nonvital posterior tooth with sufficient amount of residual tissue to justify partial restoration. Preparation involves both proximal surfaces or only two surfaces, but in a less favorable occluso-functional environment (thin walls). No significant discoloration of visible buccal tooth substrate. Option is favorable for short clinical crowns. **A-B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for the later placement of a post. Thin and weak occlusal walls are removed until reaching sufficient thickness for the restoration (1.5 to 2 mm in occlusal-free and occlusal areas, respectively). Adhesive procedure: an etch-and-rinse adhesive system is preferably used here owing to the presence of sclerotic and contaminated dentin (a self-etch adhesive system can also be used). A resin composite base is made with a restorative composite or preferably with flowable composite (for limited volume and thickness) to smooth internal angles, fill undercuts, and when needed, to relocate cervical margins occlusally. **C-D,** After impression and model fabrication, the restoration is generated in the laboratory to optimize restoration anatomy, function, and esthetics. The restoration can be made of different tooth-colored materials: ceramics (fired, pressed, or CAD-CAM generated) or resin composite. This treatment option provides optimal tissue conservation, function, and esthetics and is a good alternative to full crowns.

Amalgam Core

A coronal-radicular amalgam foundation may be realized with or without post (Figs. 22-11 through 22-14). The amalgam coronal-radicular core without post is indicated for posterior teeth that have a large pulp chamber and lateral walls at least 4 mm high. This restoration extends slightly into the coronal portion of the canals (1 to 1.5 mm). The core is then retained by a combination of the divergence of the canals and natural undercuts in the pulp chamber. A single, homogenous material is used for the entire restoration, rather than the dual phases of a conventional preformed post and core.

When shorter lateral walls are present, a post is mandatory to improve core stability and retention. The preferred roots for post placement for molars are the palatinal root in the upper jaw and the distal root in the lower jaw. Other roots, thinner and presenting more pronounced curvatures, are normally not indicated for post placement. Coronal-radicular amalgam foundations are not indicated for premolars owing to their smaller dimensions; adhesive foundations or cast gold post and core are preferred.

Cast Gold Post and Core

Cast gold post and core restorations can be fabricated with either direct or indirect techniques.

DIRECT TECHNIQUE

In the direct technique, a castable post and core pattern is fabricated in the mouth on the prepared tooth. A preformed plastic post pattern is seated in the post space. To gain a path of withdrawal, undercuts are blocked out with resin composite rather than by removing healthy dentin structure. Acrylic resin is added to create a core directly attached to the post pattern. The finished pattern is removed from the tooth and cast in the laboratory.

FIG. 22-10 Endocrown. Nonvital posterior tooth with reduced amount of residual cervical tissue but sufficient to provide supragingival restoration margins and good stabilization within former pulpal chamber. No or limited discoloration in visible buccal tooth substrate. Favorable option for short clinical crowns. **A-B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Opaque cement can be used to mark the entrance of the roots to facilitate eventual retreatment or for the later placement of a post. Thin and weak walls are removed until reaching sufficient thickness (1.5 mm minimum); as much residual cervical structure as possible is then maintained to avoid restoration interference with periodontal tissues. **C,** Prosthetic restoration on working model. **D,** Restoration base. Adhesive procedures: An etch-and-rinse adhesive system is preferably used here owing to the presence of sclerotic and contaminated dentin (a self-etch adhesive system can also be used). Restoration base: A resin composite base is made with a restorative composite or preferably with flowable composite (for limited volume and thickness) to smooth internal angles, fill undercuts, and when needed, to relocate cervical margins occlusally. **E,** Impression and restoration fabrication. After impression and model fabrication, the restoration is generated in the laboratory to optimize restoration anatomy, function, and esthetics. The restoration can be made of different tooth-colored materials: ceramics (fired, pressed, or CAD-CAM generated) or resin composite. **F,** Postoperative result. Despite their relatively rare application, endocrowns combine biomechanical advantages with facilitation of clinical procedures and minimal if any involvement of biologic width. It is an interesting alternative to full crowns. *(From Rocca GT, Bouillaguet S: Alternative treatments for the restoration of nonvital teeth.* Rev Odont Stomat *37:259–272, 2008.)*

FIG. 22-11 Amalgam core. Nonvital posterior teeth with reduced tooth structure and wall height. Amalgam core stability is granted by extension of the restoration into the coronal portion of the canal (curved roots) and post (only if straight root anatomy) and remaining pulpal chamber undercuts. Today, this option is considered obsolete or historical because of the intrinsic staining of amalgam, the nonadhesive technique, and the less-than-ideal biomechanical behavior of amalgam. **A-B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. Thin and weak walls are removed until reaching sufficient thickness (1.5 to 2 mm); existing retentions are used to stabilize the amalgam core, together with a post. The metal post (with passive and anatomic design, preferably made of titanium) extends into the root for about the same length as its coronal extension. **C-E,** Restoration fabrication. After placing a matrix or cupper ring to envelop the preparation, amalgam is compacted into the cavity, superior root canal portion and around the post, until restoring the appropriate coronal volume. Preparation of cores is made to manage optimal space for PFM crowns. **F,** Posttreatment result. This treatment approach is feasible for teeth already restored with amalgam cores and when PFM restorations are mandated. Satisfactory esthetics can be attained with intrasulcular restoration margins.

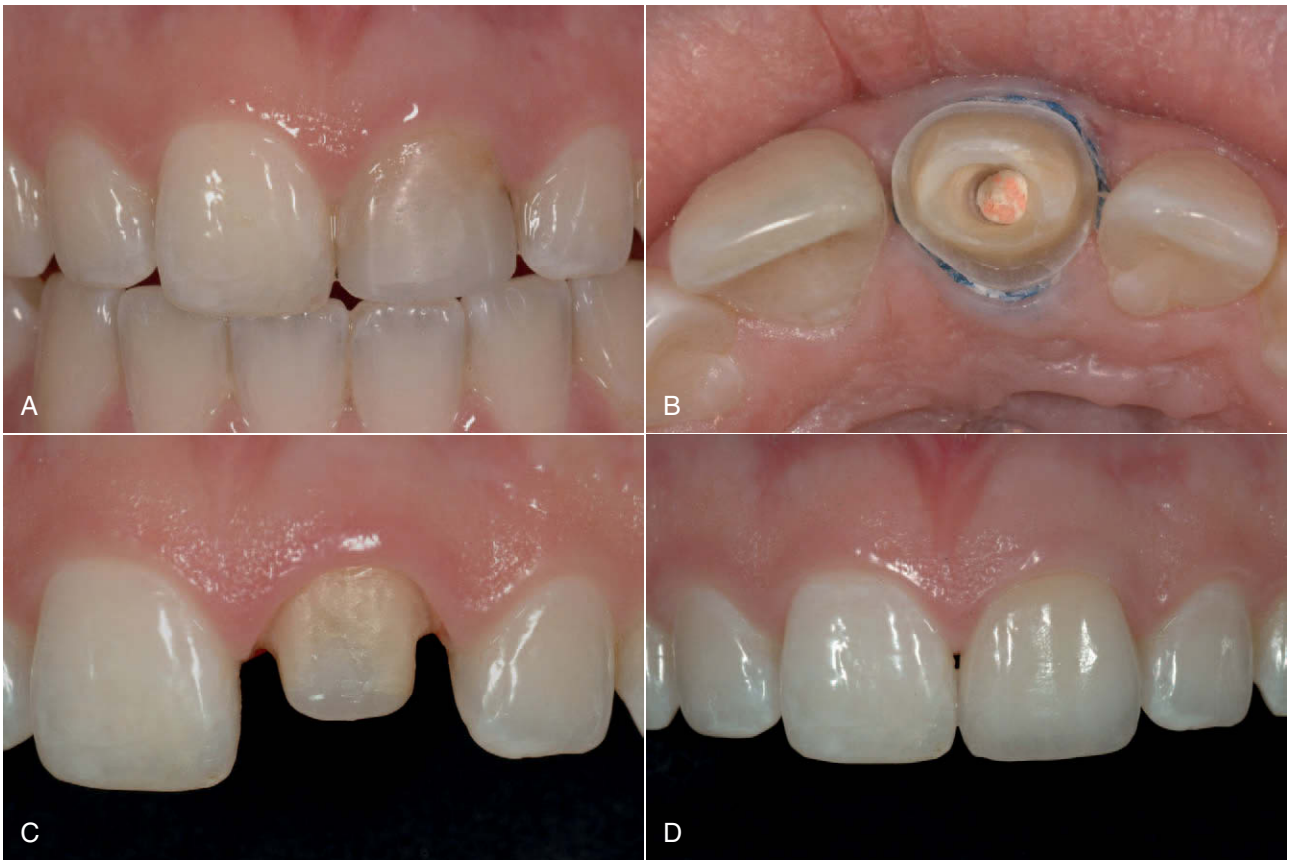

FIG. 22-12 Composite core (without post). Nonvital tooth with more than half the coronal structure left and sufficient wall thickness. Core stability is granted by adhesion, remaining pulpal chamber, and residual wall height. **A-B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. The tooth is prepared to evaluate precisely the height and thickness of residual tooth structure. Half of the abutment height and more than 1.5 mm wall thickness must be present to restore the tooth without post. If aforementioned conditions are met, a thin layer of hard cement (calcium hydroxide, zinc phosphate, or glass ionomer; not resin-modified glass ionomer) is applied at the entrance of the root canal to enable possible retreatment in the future. **C,** Adhesive procedures and core fabrication. All walls are covered with the adhesive system (etch-and-rinse or self-etch) before applying in layers a direct light-curing restorative composite or a self-curing material, in case of limited restoration volume. **D,** Postoperative view. The advantage of this approach is the ease of application and excellent esthetics. It is considered a good restorative solution for highly esthetic ceramic crowns placed on teeth with limited tissue loss and discoloration.

INDIRECT TECHNIQUE

With the indirect technique, a final impression of the prepared tooth and post space is made (Fig. 22-15). As with the direct technique, the path of withdrawal is made by undercut blockout, not by dentin removal. The castable final post and core pattern are fabricated on a die from this impression. The crown margins need not be accurately reproduced at this stage. Proprietary systems provide matched drills, impression posts, and laboratory casting patterns of various diameters. An impression post (preferably a repositionable one) is fitted to the post space, and a final impression is made that captures the form of the remaining coronal tooth structure and picks up the impression post. In the laboratory, a die reproduces the post space and the residual coronal tooth structure for fabrication of the post and core pattern.

With both techniques, the fabrication of a temporary crown with intraradicular retention is needed. This provisional restoration must stay only for a limited time in the mouth to prevent decementation or canal reinfection. This is why this approach is less popular today and replaced by direct techniques in most cases.

The cast post and core is cemented at the second appointment. The cementation process must be passive in nature and an evacuation groove made on post side to facilitate cement expulsion and limit seating pressure. Rapid seating, excessive cement, and heavy seating pressure (e.g., occlusal force) can produce high hydraulic pressures inside the root that may be great enough to crack the root.

Crown Preparation and Temporary Restoration

When a coronal restoration is indicated, the amount of tooth structure remaining after final preparation is the most important determinant of the design of the post and core. In addition, the underlying sound tooth structure provides greater resistance to fracture than any post and core type, design, or material. Natural tooth structure should always be carefully preserved during all phases of post space and crown preparation. Otherwise, preparation of endodontically treated teeth is

FIG. 22-13 Composite core with white post (resin reinforced fiber or zirconia post). Nonvital tooth with less than half the coronal structure left and/or insufficient wall thickness. Core stability is improved through adhesion and a tooth-colored post (resin reinforced fiber or ceramic posts). **A,** Preoperative view. **B-C,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose a clean dentin substrate. The tooth is prepared to evaluate precisely the height and thickness of residual tooth structure. If less than half of the abutment height or 1.5 mm wall thickness remain, the abutment requires a post to increase core retention and foundation stability. **D-E,** Post-and-core fabrication. Post placement: The post space is prepared with ad hoc instruments until reaching a length equivalent to core height or slightly less depending on remaining wall height. Increased length is not needed, since retention is predominantly achieved through adhesion. Any tooth-colored post can be used, but fiber posts are usually preferred to limit stress buildup into the root structure, even though they provide less rigidity to the foundation. Post cementation: A self-curing adhesive system is applied on all cavity walls and into post preparation before luting the post with a dual-cured composite cement or, as a simple alternative, a self-adhesive cement (then, no adhesive is used). Core fabrication: The remaining core volume is built up in layers, using a direct light-curing restorative composite or with a single increment of a self-curing material when only limited volume is to be completed. **F,** Postoperative view. The primary advantage of this approach is the excellent esthetic outcome. It is considered a good restorative solution for highly esthetic ceramic crowns placed on teeth with more tissue loss but moderate discoloration.

FIG. 22-14 Composite core with prefabricated metal post. Nonvital tooth with reduced coronal structure and ferrule effect and/or insufficient wall thickness. Core stability is improved through adhesion and a metal (opacified) post (titanium posts are usually preferred). **A,** Preoperative view. **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose remaining tooth structure and a clean dentin substrate. The absence of coronal tissue and ferrule effect mandates the use of a more rigid post (ceramic posts are considered too rigid and contraindicated in this situation). **C-F,** Post and core fabrication. Post space preparation: The post space is prepared with ad hoc instruments until reaching a length equivalent to about core height. More length is not needed, since retention is predominantly achieved through adhesion. Post preparation: The metal post (titanium here) is sandblasted (silicoating can be used to increase adhesion; i.e., Rocatec or CoJet systems, 3M), followed by silane application. An opaque resin or flowable composite can be used to mask metal dark color and improve esthetics. Post cementation: A self-curing adhesive system is applied on all cavity walls and into post preparation before luting the post with a dual-cured composite cement or, as a simple alternative, a self-adhesive cement (then, no adhesive is used). Core fabrication: The remaining core volume is built up in layers, using a direct light-curing restorative composite or a single increment of a self-curing material when only limited volume is to be completed.

FIG. 22-15 Nonvital teeth with limited coronal structure and/or numerous abutments. Indirect post and core fabrication helps to achieve proper parallelism and core anatomy. Core retention is assumed by a conventional or adhesive cement. Today, this solution is considered mostly for extended metal-ceramic restorations or sometimes for multiple full-ceramic restorations. **A,** Preoperative view. **B,** Preparation. Existing restorative material and all remnants of endodontic sealer and gutta-percha are removed from the cavity to expose remaining tooth structure and a clean dentin substrate. Despite the indirect approach, all healthy coronal structures must be maintained to improve foundation stability. Access cavity and coronal walls are prepared with minimal convergence (6 to 10 degrees) to allow for easy insertion. **C-D,** Cast gold post and core fabrication and luting. Post space preparation: The post space is prepared with ad hoc instruments until reaching a length equivalent to about core height or more. More length is needed here, since retention cannot always be achieved through adhesion (endodontic retreatment or highly sclerotic contaminated dentin). Then a conventional glass ionomer or zinc phosphate cement is used.

Post and core preparation: The gold post is sandblasted (or eventually sandblasted and coated if adhesive procedures are possible) using Rocatec or CoJet systems, 3M + silane. Post cementation: The post and core is luted with the aforementioned conventional cements or adhesive technique. Next, a self-curing adhesive system is applied on all cavity walls and into post preparation (before the insertion of the post and core) and covered with a dual-cured composite cement or, as a simple alternative, a self-adhesive cement (then, no adhesive is used). **E-F,** Restoration fabrication and placement. A second impression is needed for the final prosthetic work to optimize restoration precision and quality. Lab-made PFM or full ceramic crowns are made with optimal foundation design and alignment.

not different from vital teeth, with the exception of severely discolored teeth, which require a slightly deeper chamfer to hide discoloration with the prosthetic structure and intrasulcular margins to reduce the visibility of dark cervical tooth structure.

Provisional crowns for endodontically treated teeth must be used only for short periods of time because the loss of cement seal—which is of course symptom free—can lead to leakage, canal reinfection, and even serious carious invasion, thereby jeopardizing the success of endodontic treatment and even result in tooth loss.

SUMMARY

Endodontically treated teeth represent a singular situation because of the attendant qualitative and quantitative alterations of the dental substrate. Current literature indicates that treatment success relies on an effective coronal seal that will prevent canal reinfection and an adequate restoration that will resist functional stresses applied to the remaining tooth structure. The purpose of this chapter is to help the clinician make decisions about the restorative options available to restore endodontically treated teeth with predictable clinical results.

CHAPTER

23

Pediatric Endodontics: Endodontic Treatment for the Primary and Young Permanent Dentition

PAULA J. WATERHOUSE, JOHN M. WHITWORTH, JOE H. CAMP, and ANNA B. FUKS

CHAPTER OUTLINE

THE PULP-DENTIN COMPLEX IN PRIMARY AND YOUNG PERMANENT TEETH
- Fundamentals of Dentin/Pulp Histology
- Dentinogenic Response to Injury
- Reactions to Dental Caries
- Reactions to Restorative Procedures
- Reactions to Dental Materials

DIFFERENCES IN PRIMARY AND PERMANENT TOOTH MORPHOLOGY
- Root Formation
- Primary Root Canal Anatomy
- Primary Anterior Teeth
- Primary Molars

CLINICAL PULPAL DIAGNOSIS IN CHILDREN
- History and Characteristics of Pain
- Clinical Examination
- Palpation, Percussion, and Mobility
- Pulp Tests
- Radiographic Examination
- Restorative Diagnosis: Pulpal Exposures and Hemorrhage
- Diagnosis Following Traumatic Injuries in Children
- Pulp Diagnosis and Treatment Planning After Trauma

PRINCIPLES OF ENDODONTIC TREATMENT IN CHILDREN

PULP THERAPY FOR THE PRIMARY DENTITION
- Indirect Pulp Therapy in Primary Teeth
- Direct Pulp Capping in Primary Teeth
- Pulpotomy in Primary Teeth
- Formocresol Pulpotomy

ALTERNATIVES TO FORMOCRESOL PULPOTOMY
- Glutaraldehyde Pulpotomy
- Ferric Sulfate Pulpotomy
- Mineral Trioxide Aggregate Pulpotomy
- Electrosurgical Pulpotomy
- Laser Pulpotomy

NONVITAL PULP THERAPY ON PRIMARY TEETH
- Pulpectomy in Primary Teeth
- Access Openings for Pulpectomy
- Root-Filling Materials for the Primary Root Canals
- Follow-Up After Pulpectomy in the Primary Dentition

PULPAL THERAPY FOR THE YOUNG PERMANENT DENTITION
- Indirect Pulp Therapy: Avoiding Pulp Exposure
- Managing Pulp Exposure

PULPOTOMY
- The Cvek Pulpotomy on Immature Permanent Teeth
- Partial Pulpotomy on Asymptomatic Young Permanent Posterior Teeth
- Pulpotomy on Symptomatic Young Permanent Teeth
- Follow-Up After Pulp Capping and Pulpotomy
- Formocresol Pulpotomy on Young Permanent Teeth

APEXOGENESIS

APEXIFICATION
- Apexification Technique
- Artificial Apical Barrier Techniques
- Restoration After Apexification

NEW HORIZONS FOR PULP REGENERATION

Despite the dental profession's emphasis on prevention, threats to pulp survival such as caries, restorative dental treatment, and traumatic injuries have not been eliminated. As a consequence, children continue to lose teeth prematurely, and procedures aimed at preventing and treating pulp disease in the primary and immature permanent dentitions remain an integral part of contemporary dental practice.

Some may question why efforts to preserve pulpally involved primary teeth are important, since they may present a risk to developing permanent successors and will in any case

be lost before long. Preservation of arch space is one of the principal objectives of pediatric dentistry. Premature loss of primary teeth may cause aberration of the arch length, resulting in mesial drift of the permanent teeth and consequent malocclusion. Whenever possible, the tooth with pulp involvement should be maintained within the dental arch in a functional and disease-free condition.

Other objectives of preserving primary teeth are to safeguard esthetics and mastication, prevent aberrant tongue habits, aid in speech, and prevent the psychological effects that may be associated with tooth loss. Premature loss of the maxillary incisors before 3 years of age has been shown to cause speech impairment that may persist in later years.[242]

It is equally undesirable for children to suffer the unplanned loss of permanent teeth, and it should be noted that the prognosis for lifelong retention of an immature tooth with a short root and fragile dentinal walls is far worse than for a mature permanent tooth. Special treatments for the immature permanent tooth thus focus on preserving pulp vitality, at least until dental development is complete (see also Chapter 16).

This chapter attempts to provide a review of current therapies for the prevention and treatment of pulpal disease in primary and young permanent teeth. The biologic basis of these procedures will be emphasized and supported with clinically relevant evidence to help clinicians preserve functional and disease-free teeth in children.

THE PULP-DENTIN COMPLEX IN PRIMARY AND YOUNG PERMANENT TEETH

Pulp therapies should be based on an understanding of dental tissues and their innate reaction patterns. Some fundamentals of tissue structure and behavior merit review (see also Chapter 12).

Fundamentals of Dentin/Pulp Histology

The pulps of primary and permanent teeth are histologically and functionally similar.[248,249] Odontoblasts are the dentin-forming cells that line the periphery of the pulp chamber and extend their cytoplasmic processes into its tubular structure. They become increasingly crowded as they retreat centrally, and tubular density therefore increases in deep dentin (Fig. 23-1). A cell-free zone is located just below the odontoblastic layer and contains an extensive plexus of nerves (Raschkow's plexus) and blood capillaries that may support and regulate odontoblast activity and provide sensory innervation to the pulp. Raschkow's plexus does not fully mature until the late stages of root formation, and pulp sensitivity tests may therefore be inconclusive in immature permanent teeth. Beneath the cell-free zone is the cell-rich zone of Höhl, a band of tissue containing uncommitted cells capable of differentiation into odontoblast-like cells should primary odontoblasts be lost.[110] The core of the dental pulp contains larger blood vessels and nerves which are surrounded by loose connective tissue.[204] The volume of perfusion through the incomplete apices of immature teeth is considerable and underpins the enormous reparative capacity of young pulps in the face of injury.

Chapter 12 provides a more detailed review of tissue structure and functions within the dentin-pulp complex, and Box 23-1 provides relevant key points.

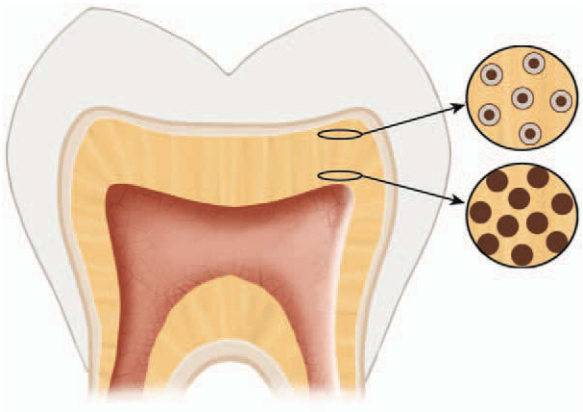

FIG. 23-1 Odontoblasts move closer as they retreat centrally on an ever-diminishing pulp circumference. Deep dentin contains wider and more closely arranged dentinal tubules, making it more porous than superficial dentin.

BOX 23-1

The Pulp-Dentin Complex—Key Points of Clinical Relevance

- Deep dentin is more porous than superficial dentin, and in primary and young permanent teeth, the dentin is thinner and more porous than in their mature permanent counterparts. The pulps of primary and immature permanent teeth are therefore at special risk from deep carious lesions, deep cavities, and traumatic injuries.
- Sensory innervation to the pulp does not mature until the late stages of root formation; pulp testing may therefore be inconclusive in immature teeth.
- Young, well-perfused pulps have enormous reparative capacity in the face of injury.

Dentinogenic Response to Injury

Without dentin, the pulp would be a highly sensitive and vulnerable organ, and in the absence of a pulp, the defensive capacity of dentin would be limited. The tissues are therefore inseparable and work together as a functional complex.

Key responses of the dentin-pulp to injury include the deposition of tertiary dentin, which increases the distance between the injury and the pulp, and a reduction in dentin permeability by the formation of sclerotic dentin.[309] Chapter 13 further discusses pulpal responses to injury.

The nature and quality of the tertiary dentin depend on its tubular structure and influence local dentin permeability. In the case of a *mild injury,* the odontoblasts responsible for primary odontogenesis can frequently survive the challenge and are stimulated to secrete tertiary, *reactionary dentin* (Fig. 23-2) beneath the site of injury.[275] Because the original odontoblasts are responsible for this matrix secretion, tubular continuity and communication with the primary dentin matrix will be present [see Fig. 23-2, *B*; Fig. 23-3, A].[184]

When the injury is *severe,* as in pulp exposure, the affected odontoblasts may die. Since odontoblasts are postmitotic cells with no capacity for renewal, their replacement must come from elsewhere. If suitable conditions exist in the pulp, a new

generation of odontoblast-like cells may differentiate, probably from the cell-rich zone, and secrete a tertiary, *reparative* dentin matrix (Fig. 23-4). Because this dentin is formed by a new generation of cells, discontinuity in the tubular structure will occur, with a subsequent reduction in tissue permeability (Fig. 23-3, *B*).[31]

A critical question that arises is "What are the factors responsible for triggering the stimulation of odontoblastic activity?" Although much still has to be learned about the molecular control of cell activity in general and odontoblastic activity in particular, one family of growth factors, the transforming growth factor superfamily (specifically TGF-βs)[110] has been reported to have extensive effects on the mesenchymal cells of many connective tissues.[180]

During tooth development, the odontoblasts secrete TGF-βs, and some of them remain sequestered within the dentin matrix. These TGF-βs may be released during any process leading to tissue dissolution, such as dental caries or the use of acid etching.[309] Dentin matrix should not be considered an inert dental hard tissue but rather a potential tissue store of a cocktail of bioactive molecules (particularly growth factors) waiting to be released if appropriate tissue conditions prevail.[309]

In contrast to reactionary responses, reparative dentinogenesis represents a more complex sequence of biologic processes. Migration and differentiation of pulpal progenitor cells must take place, creating a new generation of odontoblast-like cells before matrix secretion. A series of stereotypic wound-healing reactions will occur in the pulpal connective tissue, including vascular and cellular inflammatory reactions.

In vitro and in vivo experiments on reparative odontogenesis demonstrate that the noninflamed pulp constitutes an appropriate environment where competent pulp cells (potential preodontoblasts) can differentiate into new odontoblast-like cells, forming reparative dentin.[171,203,212]

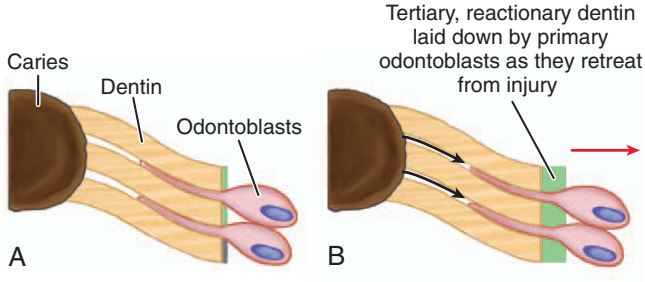

FIG. 23-2 Schematic representation of tertiary reactionary dentin. **A,** A mild insult to dentin, such as dental caries that does not extend deeply to threaten survival of primary odontoblasts. **B,** Liberation of dentin matrix components such as TGF-β leads to upregulation of odontoblast activity, with deposition of a reactionary dentin matrix whose tubular pattern is continuous with underlying tissue.

Reactions to Dental Caries

When the carious process advances from enamel into dentin, sclerotic dentin is formed by the apposition of minerals into

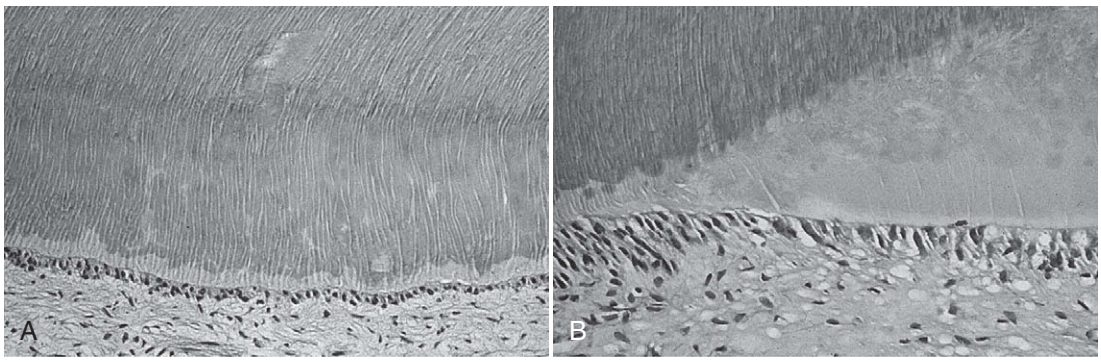

FIG. 23-3 Histologic sections of tertiary reactionary and reparative dentin. **A,** Reactionary dentin: histologic section showing tubular continuity. **B,** Reparative dentin: histologic section showing lack of continuity. *(From Pinkham JR, Casamassimo PS, McTigue DJ, et al:* Pediatric dentistry: infancy through adolescence, *ed 4, St Louis, 2005, Saunders; Courtesy Carlos Alberto S. Costa, DMD, PhD.)*

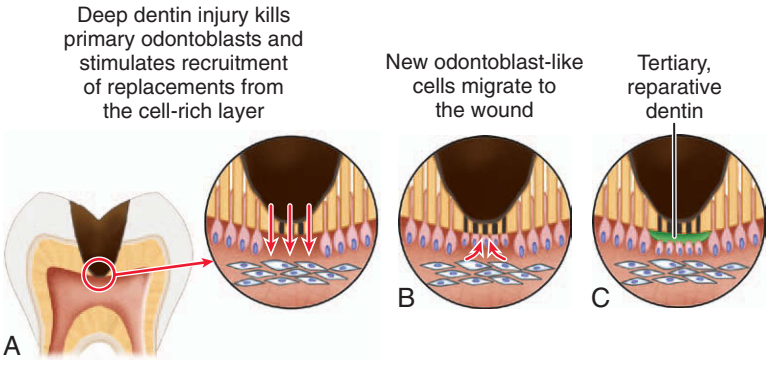

FIG. 23-4 Schematic representation of tertiary reparative dentin. **A,** A significant insult, such as deep caries, which kills primary odontoblasts in a localized area of pulp. **B,** New odontoblast-like cells differentiate from cell-rich zone. **C,** Secretion of a tertiary reparative dentin matrix commences. Tubular structure is irregular and has no continuity with underlying tissue.

and between the dentinal tubules (intratubular and intertubular dentin), and reactionary tertiary dentin is secreted. Sclerotic dentin can be seen in radiographs as a radiopaque area as the aforementioned apposition of minerals increases the radiopacity of this dentin.

The quality and amount of tertiary dentin depend on the depth and rate of progression of the carious lesion. The faster the lesion progresses, the poorer and more irregular the reactionary dentin. In addition, if the noxious irritant is too intense, the cytoplasmic processes of the odontoblasts degenerate, and "dead tracts" are formed.

When the carious process advances more rapidly than the elaboration of reactionary dentin, blood vessels of the pulp dilate, and scattered inflammatory cells become evident, particularly subjacent to the area of the involved dentinal tubules. If the carious lesion remains untreated, a frank exposure will eventually occur. The pulp will react, resulting in an acute inflammatory infiltrate, and the previously chronic pulpitis will become acute. A small abscess may develop under the region of the exposure, and cells of the chronic inflammatory series may accumulate farther away from the central area of irritation. The remainder of the pulp may be uninflamed (chronic partial pulpitis with acute exacerbation). As the exposure progresses, the pulp may undergo partial necrosis, followed in some instances by total necrosis.

Drainage is apparently the factor determining whether partial or total necrosis occurs. If the pulp is open and drainage can occur, the apical tissue may remain uninflamed or chronically inflamed. If drainage is impeded by food packing or a restoration, the entire pulp may become necrotic.[110]

Reactions to Restorative Procedures

The principal factors affecting the dentin-pulp complex during restorative procedures (e.g., cavity and crown preparation) are the cutting of the dentin, the generation of heat, and the desiccation of the tissue. When uninvolved dentin is operated on, as in extension for prevention or in crown preparation, tubules unprotected by reactionary dentin are cut. The tissue reaction that occurs is similar to that occurring with caries: intratubular and intertubular mineralization takes place, resulting in sclerotic dentin, followed by the formation of tertiary dentin. Remaining dentin thickness (RDT) is apparently the most significant factor determining pulp survival and the secretion of tertiary reactionary dentin. Maximal reactionary dentin was observed in a study wherein the cavity RDT was between 0.5 and 0.25 mm. The reduced reactionary dentin beneath cavities with an RDT below 0.25 mm (described in the same study) appeared to be related to reduced odontoblastic survival.[188] In these deep cavities, little more than 50% of the odontoblasts survived, whereas in shallow cavities, odontoblastic survival was about 85% or greater, and despite the cutting of the odontoblastic process, the cells responded by secreting reactionary dentin. The same authors demonstrated that the choice of restorative material influenced the secretion of reactionary dentin to a lesser extent than the RDT. The effect of cutting dentin can be observed histologically as a calciotraumatic band, which represents an interruption of the apposition between the secondary and tertiary dentin.

Pulp reactions to restorative procedures can be mild or severe, depending on the technique used. When the technique is gentle, the reaction will be mild, and minor alterations in the odontoblastic layer can be observed as a result of fluid accumulation. In a severe reaction, the nuclei of the odontoblasts may be aspirated into the dentinal tubules, hemorrhage may be present, and inflammation is extensive, sometimes resulting in cell necrosis. A gentle technique implies using appropriate cooling and minimal pressure. Cutting a cavity without using water cooling might lead to irreversible changes in the pulp because of the heat generated at the tip of the bur. The application of pressure increases the damage. Prolonged air blasts are also deleterious to the pulp. To prevent the generation of heat and damage to the pulp, the following measures should be taken: (1) The cavity preparation should be as shallow as possible, respecting the principles of cavity preparation and embracing contemporary partial and serial caries excavation techniques (see later); (2) suitably sized, sharp burs should be used, balancing the need for conservatism with the risks of localized overcutting with small burs; (3) appropriate cooling should be employed and minimum pressure exerted; and (4) excessive drying of dentin by air syringe should be avoided.[226]

Reactions to Dental Materials

There is substantial evidence that adverse responses within the dentin-pulp complex to restorative materials are more closely linked with microbial agents than with irritant or toxic components of the materials themselves.[22]

The routine lining of cavities has long been advocated as a means of pulp protection. Both calcium hydroxide ($Ca[OH]_2$) and zinc oxide eugenol (ZOE) cements have proven track records for promoting pulp health by destroying residual microorganisms in the depths of cavity preparations.[14,69,147,153] The antimicrobial and remineralizing potential of glass ionomer cements has been recognized during the last 2 decades,[166] and the importance of marginal seal has been supported by evidence on favorable pulp outcomes following bonded composite restorations.[42-44,145,277,292]

Researchers[201] have begun to use the term *artificial enamel* to describe their aspirations of hybrid-layer formation[202] and impervious, pulp-protecting barriers formed by resin-based materials. The response of the pulp to direct contact with dental materials is of special importance in the primary and young permanent teeth of children where pulp capping, pulpotomy, and apexification procedures are important modalities of treatment.

A variety of materials, medicaments, antiseptics, anti-inflammatory agents, antibiotics, and enzymes have been used as pulp-capping agents, but $Ca(OH)_2$ has been the standard by which all others were judged.[9,58,110] Before 1930, when Hermann[115] introduced $Ca(OH)_2$ as a successful pulp-capping agent, pulp therapy consisted of devitalization with arsenic and other fixative agents. Hermann demonstrated the formation of "secondary dentin" (now termed *tertiary dentin*) over the amputation sites of vital pulps capped with $Ca(OH)_2$.

In 1938, Teuscher and Zander[296] introduced $Ca(OH)_2$ in the United States, confirming complete dentinal bridging with healthy radicular pulp under $Ca(OH)_2$ dressings. Further reports firmly established $Ca(OH)_2$ as the pulp-capping agent of choice. After these early works, many studies have reported on various forms of $Ca(OH)_2$, with success rates ranging from 30% to 98%.[82] The dissimilar results have been attributed to variables in study design, including the model (human or

animal), tooth selection, area of the pulp involved (coronal or cervical), type of $Ca(OH)_2$ employed, outcome criteria, and study duration.

When $Ca(OH)_2$ is applied directly to pulp tissue, necrosis of the adjacent pulp tissue and inflammation of the contiguous tissue occur. Dentin bridge formation occurs at the junction of the necrotic tissue and the vital inflamed tissue. Although $Ca(OH)_2$ works effectively, the exact mechanisms are not fully understood. Compounds of similar alkalinity (pH 11) cause liquefaction necrosis when applied to pulp tissue, but $Ca(OH)_2$ maintains a local state of alkalinity necessary for bone or dentin formation. Beneath the region of coagulation necrosis, cells of the underlying pulp tissue differentiate into odontoblast-like cells and elaborate dentin matrix.[110]

Occasionally, in spite of successful bridge formation, the pulp remains chronically inflamed or becomes necrotic. Internal resorption may occur after pulp exposure and capping with $Ca(OH)_2$. In other cases, complete mineralization of the remaining pulp tissue occludes the canals and greatly complicates any future attempts at root canal treatment.

It was postulated[330] that calcium diffused from a $Ca(OH)_2$ dressing into the pulp to participate in reparative dentin formation. Experiments with radioactive ions, however, have shown that calcium ions from the circulation, not from the $Ca(OH)_2$ pulp cap are involved in bridge formation.[16,227,260] Calcium hydroxide promotes bridge formation by creating low-grade irritation in the underlying pulpal tissue, a phenomenon observed even after short-term application and removal of the material.[54]

Different forms of $Ca(OH)_2$ have produced markedly different responses when applied as a pulp cap.[291,305] The reactions to Dycal (DENTSPLY/Caulk, Milford, DE), Prisma VLC Dycal (DENTSPLY/Caulk), Life, and Nu-Cap (GC America, Alsip, IL) have been shown to be similar.[279,280,291] The chemically altered tissue created by application of these compounds is resorbed first, and the bridge is then formed in contact with the capping material.[302,305] With $Ca(OH)_2$ powder and nonsetting products such as Pulpdent Paste (Pulpdent Corp, Watertown, MA) the bridge forms at the junction of the chemically altered tissue and the remaining subjacent vital pulp tissue. The altered tissue degenerates and disappears, leaving a void between the capping material and the dentin bridge. For this reason, a bridge can be visualized better on radiographs with products such as Pulpdent Paste than with the other commercial compounds. The quality of the dentin bridging was equally good with either material. Investigators have, however, highlighted the frequent occurrence of porosities and tunnel defects in $Ca(OH)_2$-generated dentin bridges.[48] A related study[47] further demonstrated long-term evidence that $Ca(OH)_2$ becomes softened and allows leakage, resulting in recurrent pulpal inflammation and necrosis after 1 to 2 years. Despite its widespread use, the body of good evidence on $Ca(OH)_2$ pulp capping is surprisingly limited,[214] and efforts to improve the body of evidence or develop well-documented alternatives are justified.

Direct Bonding of Pulp Exposures

Although direct bonding of pulp exposures is controversial, it has been advocated by numerous researchers.[42,213] This may be explained by investigators[45,46] who have demonstrated that immediate and long-term biologic seal are more important to the healing of pulp exposures than the stimulatory effects of any particular wound dressing material. This was revealed graphically in surface-sealing experiments[44,45] where severe pulp inflammation followed direct pulp capping with composite, silicate cement, zinc phosphate cement, and amalgam. When similar pulp caps were surface sealed with ZOE to prevent microbial ingress, cell reorganization and dentin bridge formation occurred under the acid cements and composite. Although healing occurred beneath the surface-sealed amalgam, there was no evidence of bridge formation. The conclusion is that in the absence of microbial contamination, the pulp has an inherent healing capacity, with low-grade irritation promoting hard-tissue repair. These findings agree with experiments[142,222] on gnotobiotic animals that showed pulpal healing in the absence of bacterial contamination, whereas the introduction of bacteria prevented healing.

Numerous bonding materials and composite resin systems have been tested as pulp-capping agents, with reported healing of the pulp and deposition of hard tissue at the exposure site.[4,43-45,106,213,323] Unanimity exists among these researchers that healing does not depend on the material but on its capacity to provide a biologic seal.

Although direct bonding of pulp exposures has gained widespread popularity, it should be noted that no long-range histologic studies have been published. Also, unfavorable effects with direct bonding have been reported. In a comparison of acid-etched, bonded, composite pulp caps, and Dycal, Pameijer and Stanley[218] found 45% versus 7% pulpal necrosis and 25% versus 82% dentin bridging, respectively. Another report[112] comparing All Bond 2 (Bisco, Schaumburg, IL) with $Ca(OH)_2$ showed persistent inflammatory reactions and hyaline alteration of extracellular matrix inhibiting complete pulpal repair or bridge formation in the bonded specimens. Conversely, the $Ca(OH)_2$ specimens produced complete dentin bridge formation. These results led the authors to conclude that direct bonding is not recommended for human pulp, and vital pulp therapy using acidic agents and adhesive resins is contraindicated.

This remains a controversial area with no universally-adopted conclusions. However, the advent of new materials such as mineral trioxide aggregate (MTA) offer much promise in pulp capping and may make the debates over bonded pulp caps academic.

Mineral Trioxide Aggregate

Favorable pulp responses have been reported following the use of MTA.[1,140,198,200,228] When compared with $Ca(OH)_2$, MTA produced significantly more dentinal bridging in a shorter period of time with significantly less pulpal inflammation. Dentin deposition also began earlier with MTA.

MTA is a biocompatible material with an antibacterial effect similar to that of $Ca(OH)_2$ and the property of providing a biologically active substrate for cell attachment. This feature makes it effective in preventing microleakage and improving the prognosis of treatment. MTA has been shown to promote pulp healing with dentin bridge formation and minimal inflammatory reaction in exposed pulps in monkeys[228] and humans,[200] and its dentinogenic effect in short-term capping experiments was demonstrated in dogs.[71] The material was approved for use by the United States Food and Drug Association (FDA). Following promising preliminary studies,[2] it has been shown to provide impressive results for pulp capping (Fig. 23-5) and

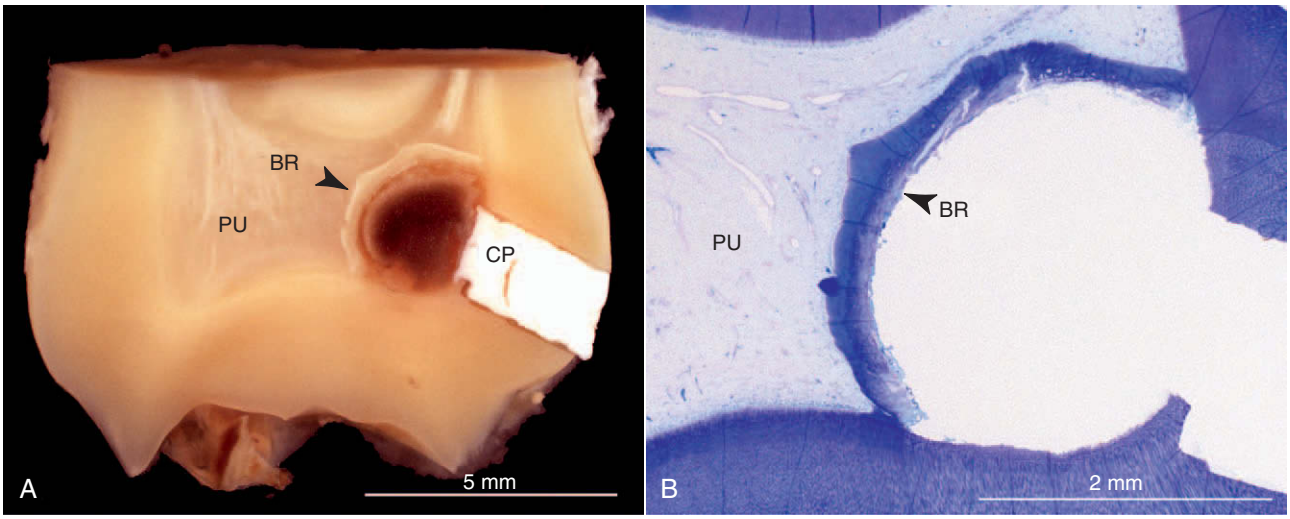

FIG. 23-5 Pulpal response to mineral trioxide aggregate (MTA) capping after 3 months observation. Distal macrophotographic view of the mesial half of a maxillary left third molar (tooth 28 [FDI]) shows remnants of restorative and capping material (CP) and a distinct hard-tissue bridge (BR) across the exposed pulp (PU). pulpotomy treatments in young permanent teeth[27,326] and for pulpotomies in the primary dentition.[3,63]

DIFFERENCES IN PRIMARY AND PERMANENT TOOTH MORPHOLOGY

Successful pulpal therapy in the primary dentition requires a thorough understanding of primary pulp morphology, root formation, and the special features associated with physiologic resorption of primary tooth roots. These factors are considered in the following sections.

According to Finn[78] and Nelson and Ash,[205] there are 12 basic differences between primary and permanent teeth (Fig. 23-6):

1. Primary teeth are smaller in all dimensions than corresponding permanent teeth.
2. Primary crowns are wider in the mesial-to-distal dimension compared with crown length than permanent crowns.
3. Primary teeth have narrower and longer roots compared to crown length and width in permanent teeth.
4. The facial and lingual cervical thirds of the crowns of anterior primary teeth are much more prominent than those of permanent teeth.
5. Primary teeth are markedly more constricted at the dentinoenamel junction (DEJ) than permanent teeth.
6. The facial and lingual surfaces of primary molars converge occlusally so that the occlusal surface is much narrower in the faciolingual than the cervical width.
7. The roots of primary molars are comparatively more slender and longer than the roots of permanent molars.
8. The roots of primary molars flare out nearer the cervical area and more at the apex than do the roots of permanent molars.

FIG. 23-6 Cross section of primary and permanent molars. Divergence of the primary molar roots allows space for the developing permanent premolar.

9. The enamel is thinner (approximately 1 mm) on primary teeth than on permanent teeth, and it has a more consistent depth.
10. The thickness of the dentin between the pulp chamber and enamel in primary teeth is less than that in permanent teeth.
11. The pulp chambers in primary teeth are comparatively larger than those in permanent teeth.
12. The pulp horns, especially the mesial horns, are higher in primary molars than in permanent molars.

Root Formation

According to Orban,[215] development of the roots begins after enamel and dentin formation has reached the future cementoenamel junction (CEJ). The epithelial dental organ forms Hertwig's epithelial root sheath, which initiates formation and

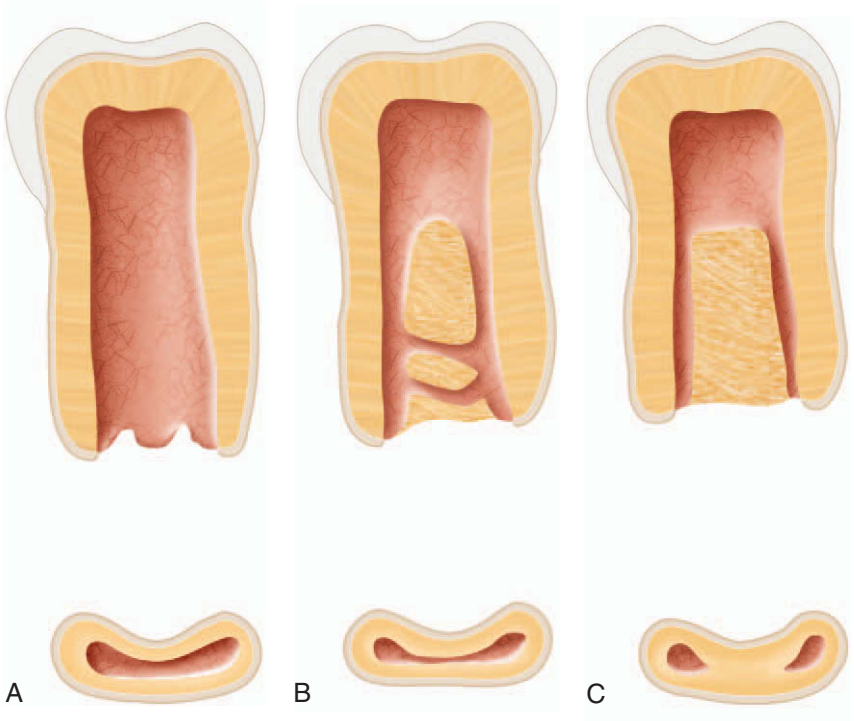

FIG. 23-7 Faciolingual cross section of the mesial root of a mandibular primary molar. **A,** Formation of the root at the time the root length is completed; only one canal is present. **B,** Differentiation of the root into separate canals by the continued deposition of dentin (*shaded areas*). Small fins and branches are present between the two canals. **C,** Canals are completely divided; root resorption has begun.

molds the shape of the roots. Hertwig's sheath takes the form of one or more epithelial tubes (depending on the number of roots of the tooth, one tube for each root). During root formation, the apical foramen of each root has a wide opening limited by the epithelial diaphragm. The dentinal walls diverge apically, and the shape of the pulp canal is like a wide-open tube. Each root contains one canal at this time, and the number of canals is the same as the number of roots (Fig. 23-7, *A*). When root length is established, the sheath disappears, but dentin deposition continues internally within the roots.

Differentiation of a root into separate canals, as in the mesial root of the mandibular molars, occurs by continued deposition of dentin. This narrows the isthmus between the walls of the canals and continues until there is formation of dentin islands within the root canal and eventual division of the root into separate canals. During the process, communications exist between the canals as an isthmus and then as fins connecting the canals (Fig. 23-7, *B*). (See Chapter 12 for a complete description of pulp and dentin formation.)

As growth proceeds, the root canal is narrowed by continued deposition of dentin, and the pulp tissue is compressed. Additional deposition of dentin and cementum closes the apex of the tooth and creates the apical convergence of the root canals common to the completely formed tooth (Fig. 23-7, *C*).

Root length is not completed until 1 to 4 years after a tooth erupts into the oral cavity. In the primary dentition, root length is completed in a shorter period of time than in the permanent tooth because of the shorter length of the primary roots.

The root-to-crown ratio of the primary teeth is greater than that of the permanent teeth. The primary roots are narrower than the permanent roots. The roots of the primary molars diverge more than those of the permanent teeth. This feature allows more room for the development of the crown of the succeeding premolar (see Fig. 23-6).[204]

The primary tooth is unique insofar as resorption of the roots begins soon after formation of the root length has been completed. At this time, the morphology of the root canals roughly corresponds to the form and shape of the external anatomy of the teeth. Root resorption and the deposition of additional dentin within the root canal system, however, significantly change the number, size, and shape of the root canals within the primary tooth. A more detailed description of how this affects the primary teeth is presented later in this section.

It should be noted that most variations within the root canals of primary and permanent teeth are in the faciolingual plane; dental radiographs do not visualize this plane but show the mesiodistal plane. Therefore, when reviewing clinical radiographs, many of the variations that may be present are not visible. Figs. 23-8 and 23-9 show silicone models of root canals, and Fig. 23-10 shows a reconstructed digital image to illustrate morphology not visible with plain radiographs. The increasing availability of three-dimensional imaging techniques such as cone-beam computerized tomography[221] is bringing greater understanding of such anatomic features to practicing clinicians.

Primary Root Canal Anatomy

To treat the pulps of primary teeth successfully, the clinician must have a thorough knowledge of the anatomy of the primary root canal systems and the variations that exist within them.[205] To understand some of the variations in the primary root canal systems requires an understanding of root formation (see previous discussion and Box 23-2).

Primary Anterior Teeth

The morphology of root canals in primary anterior teeth resembles the form and shape of the roots of the teeth themselves (see Figs. 23-8 and 23-9). The permanent tooth

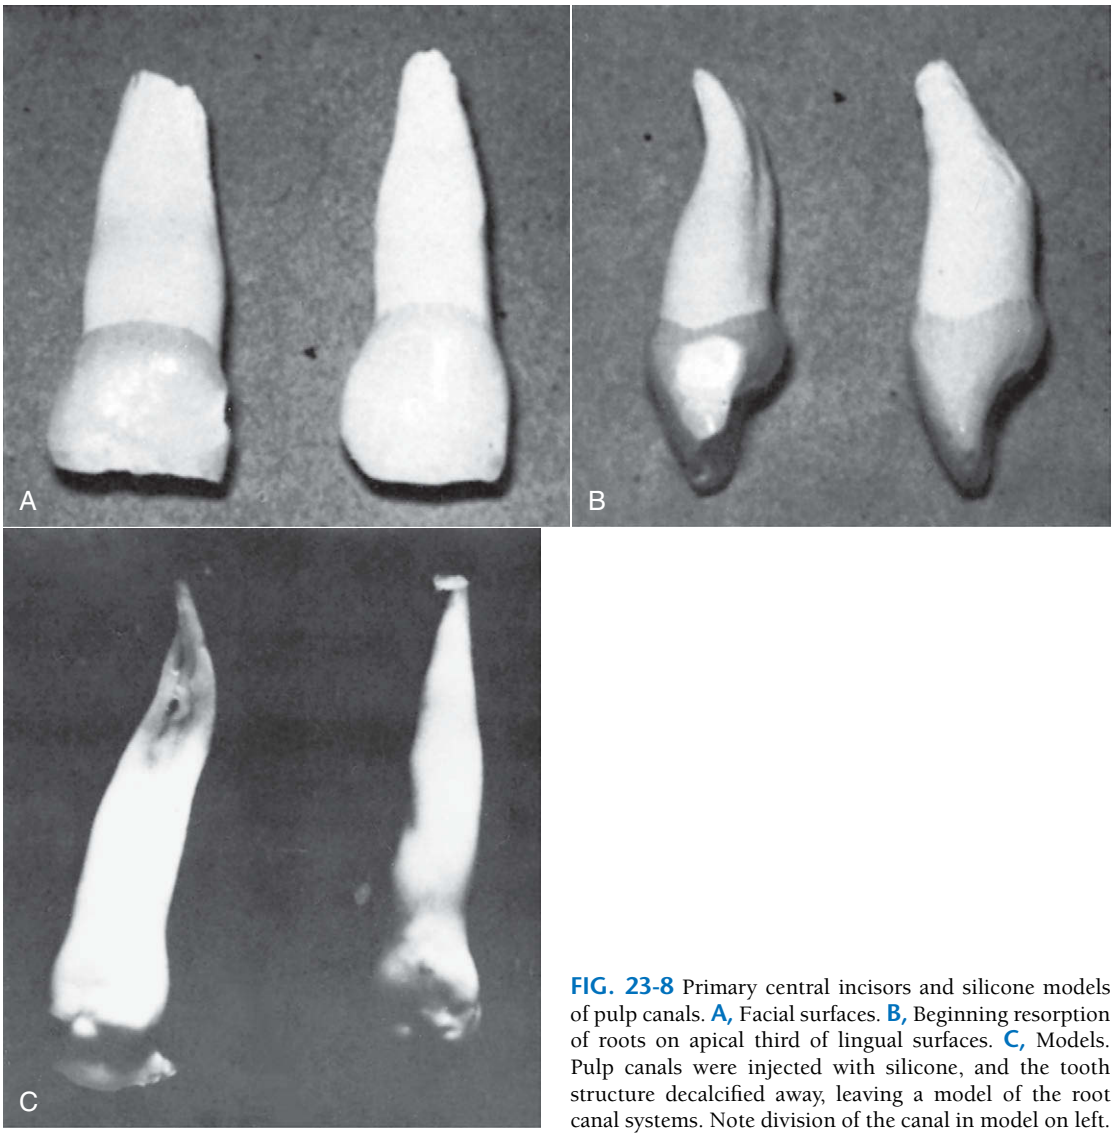

FIG. 23-8 Primary central incisors and silicone models of pulp canals. **A,** Facial surfaces. **B,** Beginning resorption of roots on apical third of lingual surfaces. **C,** Models. Pulp canals were injected with silicone, and the tooth structure decalcified away, leaving a model of the root canal systems. Note division of the canal in model on left.

BOX 23-2

Root Canal Anatomy in Primary Teeth

- After root-length completion, dentin deposition continues in the root canal.
- After root-length completion, dentin deposited in a root canal may change the number, size, and shape of the root canals.
- Often, root canal variations are not visible on clinical radiographic images.
- In anterior teeth, one root canal is usually present, although mandibular incisors occasionally have two.
- In anterior teeth, accessory and lateral canals and apical ramifications are rare.

bud lies lingual and apical to the primary anterior tooth, so physiologic root resorption of primary incisors and canines begins on the lingual aspect of the apical third of the roots (see Fig. 23-8, *A*).

Maxillary Incisors

The root canals of maxillary primary incisors are almost round in cross section but somewhat compressed in a faciolingual direction. Commonly these teeth have one canal without bifurcations. Apical ramifications and accessory and lateral canals are rare but may occur (see Fig. 23-8).[331]

Mandibular Incisors

The root canals of primary mandibular incisors are flattened on the mesial and distal surfaces and are sometimes grooved, progressing in an apical direction to an eventual division into two canals (facial and lingual). The presence of two canals is

seen less than 10% of the time. Occasionally, lateral or accessory canals are observed.[331]

Maxillary and Mandibular Canines

The root canals of primary maxillary and mandibular canines correspond to the exterior root shape: a rounded, triangular shape with the base toward the facial surface. Sometimes the lumen of the root canal is compressed in the mesiodistal dimension. The canines have the simplest root canal systems of all the primary teeth and offer few challenges during endodontic treatment. Bifurcation of the canal does not normally occur. Lateral canals and accessory canals are rare (see Fig. 23-9).[331]

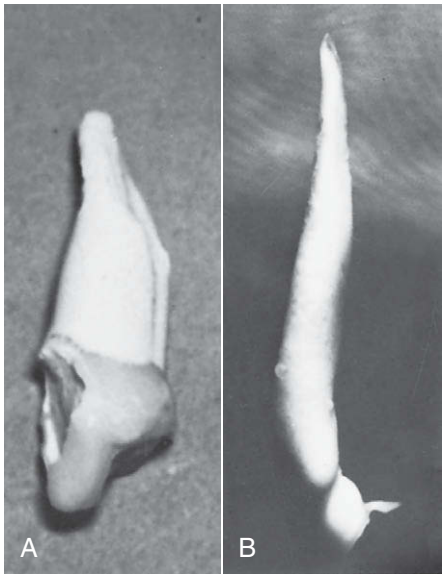

FIG. 23-9 Maxillary primary canine and silicone model of the root canal. **A,** Mesial surface. **B,** Model of the root canal.

Primary Molars

Often, primary molars have the same number and position of roots as the corresponding permanent molars (see Fig. 23-10). Maxillary molars have three roots, two facial and one palatal; mandibular molars have two roots, mesial and distal. The roots of the primary molars are long and slender compared with crown length and width, and they diverge to allow for permanent tooth bud formation.

When full-length root formation has just been completed in the primary molars, only one root canal is present in each of the roots. The continued deposition of dentin internally may divide the root into two or more canals. During this process, communications exist between the canals and may remain in the fully developed primary tooth as isthmi or fins connecting the canals (see Fig. 23-7, *B* and Fig. 23-10).

In primary teeth, the deposition of secondary dentin has been reported to occur after root-length completion.[24,117,134] This may result in changes to the basic root canal morphology, producing variations and alterations in the number and size of the root canals. This deposition begins at about the time root resorption begins. Variations in form are more pronounced in teeth that show evidence of root resorption.[117]

Greatest variation in morphology of the root canals occurs in the mesial roots of maxillary and mandibular primary molars. This variation originates in the apical region as a thinning of the narrow isthmus between the facial and lingual extremities of the apical pulp canals. Subsequent deposition of secondary dentin may produce complete separation of the root canal into two or more individual canals. Many fine connecting branches or lateral fibrils form a connecting

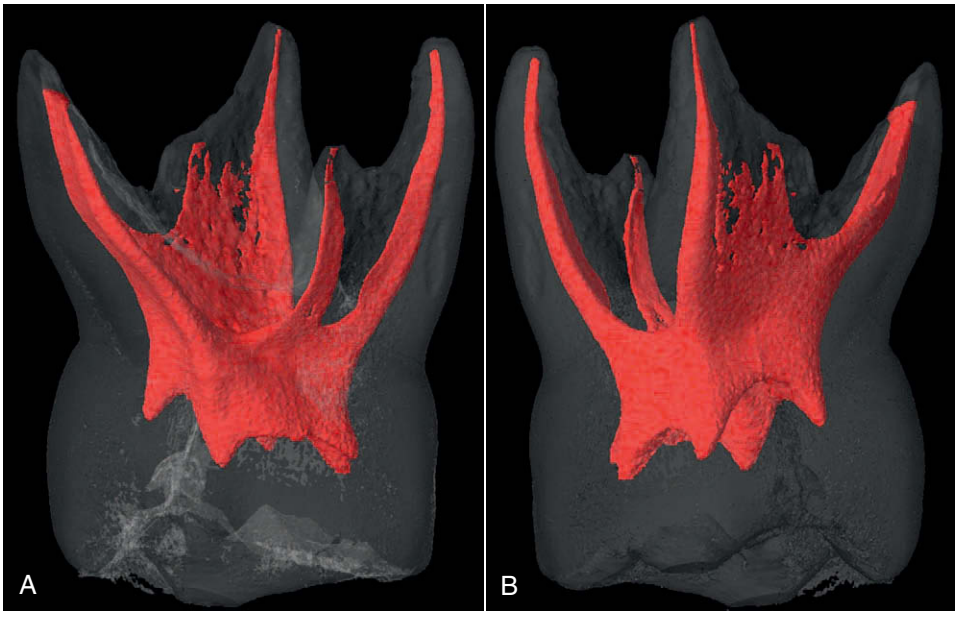

FIG. 23-10 Three-dimensional tomographic images of a maxillary second primary molar. **A,** Mesial view of primary molar with four root canals. network between the facial and lingual aspects of the root canals (see Fig. 23-10).

The variations found in the mesial roots of the primary molars are also found in the distal and lingual roots but to a lesser degree. Accessory canals, lateral canals, and apical ramifications of the pulp are common in primary molars, occurring in 10% to 20%.[117,331]

In the primary molars, resorption usually begins on the inner surfaces of the roots next to the interradicular septum. The effects of resorption on canal anatomy and root canal filling on the primary teeth are discussed in detail later in this chapter.

Maxillary First Primary Molar

The maxillary first primary molar has two to four canals that correspond approximately to the exterior root form, with much variation. Usually, the palatal root is round and often longer than the two facial roots. Bifurcation of the mesiofacial root into two canals is common and occurs in approximately 75% of maxillary first primary molars.[204,331]

Fusion of the palatal and distofacial roots occurs in approximately a third of maxillary primary first molars. In most of these teeth, two separate canals are present, with a very narrow isthmus connecting them. Islands of dentin may exist between the canals, with many connecting branches and fibrils.

Maxillary Second Primary Molar

The maxillary second primary molar has two to five canals roughly corresponding to the exterior root shape. The mesiofacial root usually bifurcates or contains two distinct canals. This occurs in approximately 85% to 95% of maxillary second primary molars.[117,331]

Fusion of the palatal and distofacial roots may occur. These fused roots may have a common canal, two distinct canals, or two canals with a narrow connecting isthmus of dentin islands between them and many connecting branches or fibrils.

Mandibular First Primary Molar

The mandibular first primary molar usually has three canals, again corresponding approximately to the external root anatomy, but it may have two to four canals. It is reported that approximately 75% of the mesial roots contain two canals, whereas only 25% of the distal roots contain more than one canal.[117,331]

Mandibular Second Primary Molar

The mandibular second primary molar may have two to five canals, but it usually has three. The mesial root has two canals approximately 85% of the time, whereas the distal root contains more than one canal only 25% of the time.[117,331]

CLINICAL PULPAL DIAGNOSIS IN CHILDREN

Restorative dental treatment should never commence without a working diagnosis and treatment plan. Chapter 1 provides a comprehensive account of diagnostic procedures, but certain points demand emphasis for the child patient. As always, the diagnostic process should follow an orderly pattern, with attention to the medical and dental history, clinical examination, and special tests, including radiographs where appropriate. Parents or caregivers may be helpful in clarifying the case history and may need to be involved if any systemic condition is likely to influence clinical management. The medicolegal dimensions of careful history taking, diagnostic procedures, and case documentation should also be recognized.

Every effort should be made to establish a working pulp diagnosis before anesthetizing the suspect tooth and isolating it with a rubber dam. These conditions are rarely conducive to accurate history taking or diagnostic reliability, especially in young children. The opportunity should also be taken before treatment to discuss contingent alternatives that may become necessary as a result of an unexpected event, such as the exposure of a pulp during deep caries excavation.

Established tests to determine the extent of pulpal inflammation are crude at the best of times and may be of little or no value in young and anxious children and on primary or immature permanent teeth. The literature on pulp diagnosis in children is mostly outcome reports based on empirical treatment and anecdotal case reports. Assumptions regarding pulpal status prior to treatment have often been based on retrospective findings rather than histologic or microbiologic data to support the prerestorative diagnosis. Histologic investigation remains the only true method of determining the nature and extent of pulp inflammation, and any correlation with clinical signs and symptoms is limited.[58,176,282]

Although every effort should be made to discern the condition of the pulp before treatment, exhaustive pulp provocation tests may not be helpful in children. From a clinical standpoint, the characteristics of the presenting pain are often critical to the working diagnosis, especially when summated with additional information from the clinical and radiographic examination. Further evidence can be provided by clinical observations during the procedure, such as the nature, volume and ability to control hemorrhage from an exposed pulp. It should be recognized that pulp diagnosis in children is as much an art as a science.

History and Characteristics of Pain

The character of any presenting pain is first identified in the history. Distinction should, wherever possible, be made between provoked and spontaneous pain.

Provoked pain is usually triggered by a thermal or osmotic stimulus (e.g., cold drinks, eating candy) and usually ceases when the stimulus is removed. This history is indicative of minor, reversible pulp inflammation. Provoked pain may sometimes be confused with that caused by interproximal impaction of food (Fig. 23-11), soreness associated with tooth exfoliation, or eruption of permanent teeth.

By contrast, spontaneous pain is not consistently associated with an external stimulus, may arise at any time of the day, or wake the child from sleep. In both primary and young permanent teeth, spontaneous pain and provoked pain which continues long after the causative factor is withdrawn are usually associated with extensive, irreversible pulpal inflammation extending into the root canals.[105] Primary teeth with a history of spontaneous toothache are unreliable candidates for vital pulp therapy and should not be considered for any form of treatment short of pulpectomy or extraction. The situation is quite different for immature permanent teeth. Since the consequences of losing vital pulp functions are so serious, immature permanent teeth with a similar pain history should always be considered for pulpotomy, apexogenesis, or even regenera-

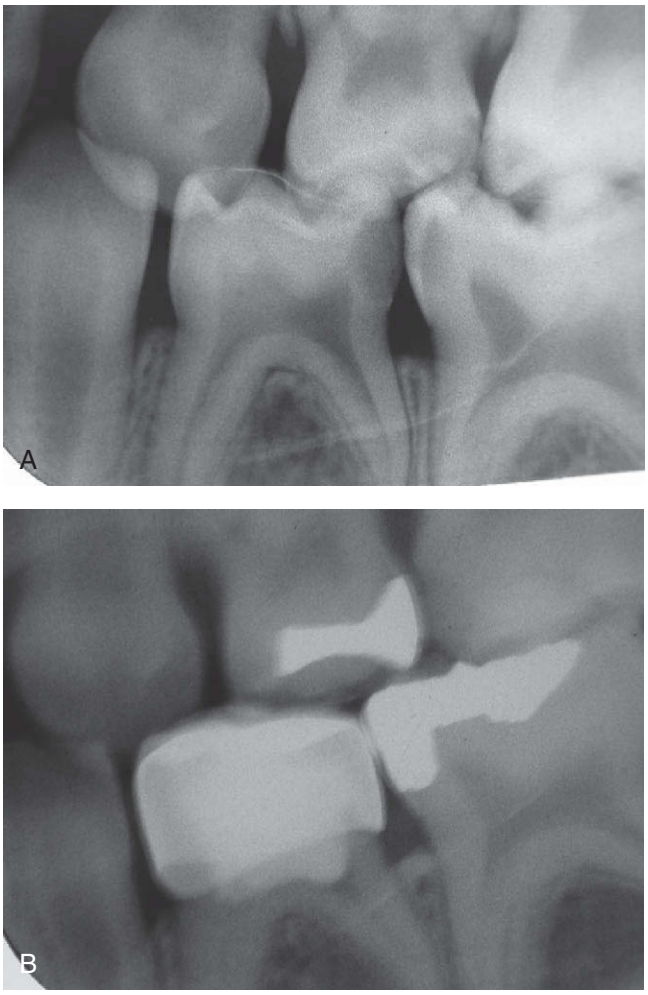

FIG. 23-11 Pain and bone loss caused by food impaction in interproximal space between primary molars. **A,** First and second mandibular primary molars with caries and marginal bone loss caused by food impaction. **B,** Healthy bone after restoration of teeth.

tive techniques in an effort to safeguard tooth development (see later sections on immature permanent teeth).

Clinicians faced with an apparently graphic pain history should not, however, neglect to conduct a proper clinical examination, since other conditions such as papillitis caused by interproximal food impaction may mimic pulpitic pain.

Equally, the absence of pain should not encourage clinical complacency, since varying degrees of pulp degeneration or even complete necrosis can be encountered without any report of pain. Children may thus present without any complaint, despite extensive carious lesions and draining parules. Those who have developed early childhood caries (e.g., nursing bottle caries), may equally have no experience of their teeth feeling any other way and have no special pain history to report.[226]

Clinical Examination

A careful extraoral and intraoral examination is of great importance in identifying teeth with pulpal involvement. Signs such as tooth discoloration, gross caries, redness and swelling of the vestibulum, or draining parules may strongly suggest pulpal pathoses. In addition, attention should be paid to teeth with extensive fractured and missing restorations or restorations with carious marginal breakdown. All may indicate involvement of the pulp through the relatively thin and porous dentin of the cavity floor.

Palpation, Percussion, and Mobility

Fluctuation, felt by palpating a swollen mucobuccal fold, may be the expression of an acute dentoalveolar abscess before exteriorization. Bone destruction following a chronic dentoalveolar abscess can also be detected by palpation.

Though significant inflammatory bone loss can make primary teeth mobile, this is not a reliable, objective test of pulpal status. Teeth with varying degrees of pulpal inflammation may have very little mobility, whereas mobility can be significant during phases of active physiologic root resorption in primary teeth with healthy pulps.

Comparing the mobility of a suspicious tooth with its ipsilateral equivalent can be especially helpful in clarifying such quandaries. If a significant difference in mobility is noted, this along with other diagnostic information may suggest pulpal inflammation.

Sensitivity to percussion may reveal a painful tooth in which pulpal breakdown has resulted in acute periradicular periodontitis. Exceptions include recently traumatized teeth. Care should be taken in percussing the teeth of children; one author[226] has recommended the gentle use of a fingertip rather than the end of a dental mirror.

Pulp Tests

Standard electrical and thermal pulp provocation tests are of limited value in the primary dentition and in young permanent teeth with incompletely developed apices.[9] Although these tests may indicate the presence of some vital responsive tissue, they will not give reliable data on the extent of pulpal inflammation. Many children with perfectly normal teeth do not respond to the electrical pulp tester even at the higher settings. Equally, young patients may give unreliable responses to such provocation tests because of apprehension, fear, or general management problems.

The unreliability of electronic methods in immature permanent teeth has been reported in several studies.[91,92,94,148] One author[148] showed responses ranging from 11% in 6- to 11-year-olds with completely open apices to 79% in older children with complete root formation.

Thermal tests may be more reliable than electrical methods for ascertaining the presence of vital responsive tissue in immature permanent teeth, and carbon dioxide snow has been shown to be more effective than ice and ethyl chloride.[91,92,94,148] Heat is unreliable as a diagnostic test in young children.[92]

Laser Doppler flowmetry has been reported[68,272,328] to be reliable for diagnosing pulpal vitality in immature permanent teeth, but the equipment has not been perfected for clinical use[68] and is cost prohibitive. It is also affected by blood pigmentation in discolored crowns.

Radiographic Examination

Clinical examination should be supplemented where appropriate with high-quality radiographs. Interradicular radiolucencies, a common finding in primary posterior teeth with pulpal pathoses, are best observed in bite-wing radiographs. If the apical area cannot be clearly observed, a periapical view should

be obtained, exposed on a small film by a paralleling technique. The integrity of the lamina dura of the affected tooth should be compared with that of adjacent or contralateral teeth.[226]

Current radiographs are essential in examining for caries, restoration integrity, previous endodontic treatments, and resorptive and periapical changes in primary and young permanent teeth. In children, interpretation of radiographs is complicated by physiologic root resorption of primary teeth and incompletely formed roots of permanent teeth. If the clinician is not familiar with interpreting radiographs of children or does not have radiographs of good quality, these normal conditions can easily be misinterpreted as pathologic changes in need of treatment. In the case of immature permanent teeth, comparison of root formation with the antimere should always be considered.

The radiograph does not always demonstrate periapical pathosis, nor can the proximity of caries to the pulp always be accurately determined. What may appear as an intact barrier of secondary or tertiary dentin overlying the pulp may actually be a perforated mass of irregularly calcified and carious dentin overlying a pulp with extensive inflammation.[58]

The presence of calcified masses within the pulp is an important diagnostic sign (Fig. 23-12). Mild, chronic irritation to the pulp stimulates tertiary reactionary dentin formation. When the irritation is acute and of rapid onset, the defense mechanism may not have a chance to lay down reactionary dentin. When the disease process reaches the pulp, the pulp may form calcified masses away from the exposure site. These calcified masses can be associated with degeneration of the coronal pulp and inflammation of the radicular pulp in primary teeth.[58] In the absence of other clinical evidence, it is unclear whether this warrants invasive treatment in all cases. Certainly for immature permanent teeth, the presence of calcific metamorphosis within the coronal pulp chamber would not in isolation warrant pulpectomy and root canal treatment.

Pathologic changes in the periapical tissues surrounding primary molars are most often apparent in the bifurcation or trifurcation areas rather than at the apices (as generally seen in permanent teeth) (see Fig. 23-12). Pathologic bone and root resorption indicates advanced pulpal degeneration that has spread into the periapical tissues. The pulpal tissue may remain vital even with such advanced degenerative changes. Periapical radiolucencies of primary anterior teeth, like those in permanent teeth, are usually at the apices.

Internal resorption occurs frequently in the primary dentition after pulpal involvement. It is always associated with extensive inflammation,[105] and it usually occurs in the molar root canals adjacent to the bifurcation or trifurcation area. Because of the thinness of primary molar roots, once the internal resorption has become advanced enough to be seen on radiographs, there is usually a perforation of the root by the resorption (Fig. 23-13). In some instances, however, the process is reversible and self-correcting, and the resorbed area becomes filled with mineralized tissue.[110,219] If a perforation of the root occurs in a primary tooth because of internal resorption, all forms of pulp therapy are contraindicated. The treatment of choice is observation (if the area of the resorption is confined to the tooth) or extraction (if the process has reached the bone).[110,219]

In immature permanent teeth, it is often difficult to assess the extent of apical closure. Plain-film images are frequently misleading, since under normal conditions, they show the mesiodistal plane of the tooth but give little information in the faciolingual dimension. Except for the maxillary central and lateral incisor, all other root canals of the permanent teeth are wider in the faciolingual plane than the mesiodistal. The faciolingual aspect of the root canal is two to three times as wide as the mesiodistal width and is the last to become convergent apically as the root develops. Therefore it is possible to have a dental radiograph showing an apically convergent root canal, whereas in the faciolingual plane, the root canal is divergent. Equally, canals which are apically diverging in the faciolingual view may be parallel or converging in the mesiodistal view. Again, contemporary three-dimensional imaging techniques are beginning to improve understanding, both in the research laboratory (Fig. 23-14) and in the clinic.[221]

In summary, radiographs add to the diagnostic process by visualizing the presence or absence of:

1. Deep caries with possible or definite pulp involvement.
2. Deep restorations close to a pulp horn.

FIG. 23-12 Calcified mass in the pulp chamber. There is internal and external root resorption. Calcified mass *(arrow)* is an attempt to block a massive carious lesion. Because of resorption, this tooth should be extracted. Note bone loss in the bifurcation area.

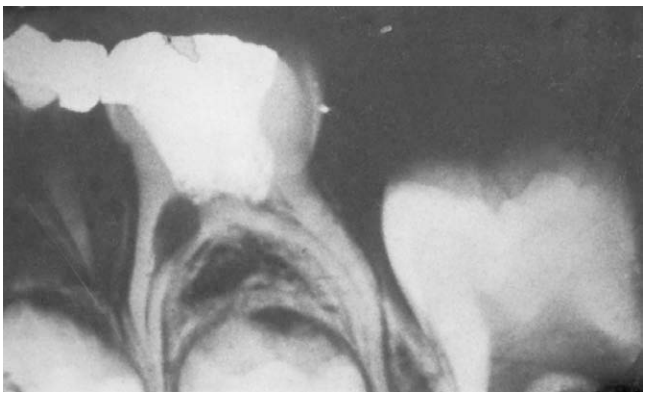

FIG. 23-13 Pulpotomy failure. Note internal resorption that has perforated the pulp chamber floor and resulted in a furcal radiolucency.

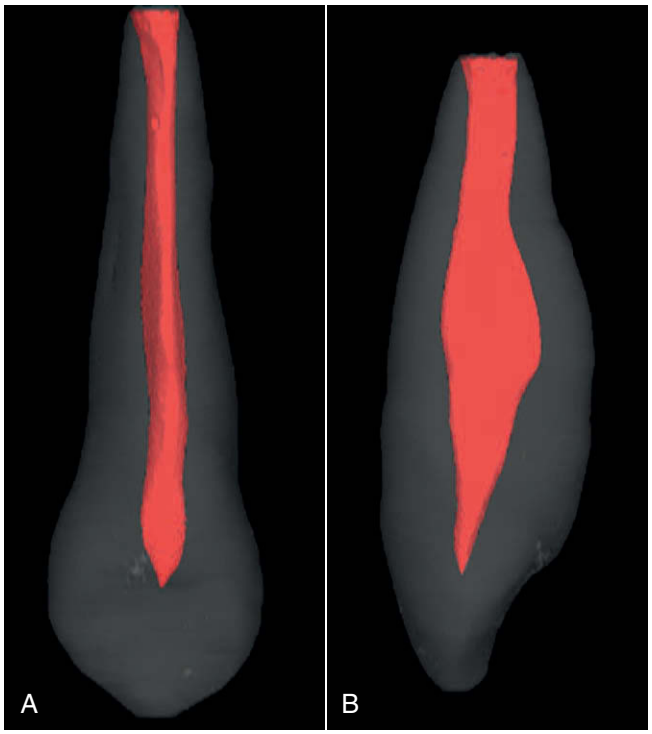

FIG. 23-14 Three-dimensional tomographic images of an immature maxillary canine. **A,** Faciolingual view. **B,** Mesiodistal view. Such imaging techniques are bringing new anatomic awareness to both the research laboratory and the clinic. *(Courtesy Paul Dummer and Sue Bryant, Cardiff University, UK.)*

3. Successful or failing pulp cap, pulpotomy, or pulpectomy.
4. Changes within the pulp such as calcific barrier formation, calcific metamorphosis, and pulp stones (denticles).
5. Pathologic root resorption, which may be internal (within the root canal) or external (affecting the root or the surrounding bone). Internal inflammatory resorption indicates inflammation of a vital pulp, whereas external inflammatory resorption demonstrates a nonvital pulp with extensive inflammation, including resorption of the adjacent bone. External, replacement resorption usually follows trauma and is discussed more fully in Chapter 17.
6. Periapical and interradicular radiolucencies of bone. In primary molar teeth, any radiolucency associated with a nonvital tooth is usually located in the furcation area, not at the apices. This is because of the presence of accessory canals on the pulpal floor area. A bite-wing film is frequently a useful diagnostic aid, particularly in maxillary molars where the developing premolar obscures the furca in a periapical radiograph.
7. The degree of root formation in young permanent teeth.

It is important to emphasize once again that the clinician should be familiar with the normal factors that complicate interpretation of radiographs in children: larger bone marrow spaces, superimposition of developing tooth buds, normal resorption patterns of the teeth, and immature root apices.[226]

Restorative Diagnosis: Pulpal Exposures and Hemorrhage

It has been reported that the size of the exposure, the appearance of the pulp, and the color and amount of hemorrhage are important factors in diagnosing the extent of inflammation in a pulp exposed by caries. The presence of excessive[58,226,282] or deep purple colored[226] hemorrhage from an exposed or amputated pulp is evidence of extensive inflammation in both primary and young permanent teeth. A true carious exposure is always accompanied by pulpal inflammation (see Chapter 13),[58,282] and even a pinpoint carious exposure can be associated with pulpal inflammation ranging from minimal to extensive or even complete necrosis. However, massive exposure in primary teeth is always associated with widespread inflammation or necrosis and makes the tooth a poor candidate for any form of vital pulp therapy. This rule does not apply for young permanent teeth with incomplete root development, where the premature loss of vital pulp functions is so catastrophic that every effort should be made to safeguard tooth development. (See later section on the management of pulpal exposure in immature permanent teeth.)

Sometimes a final working diagnosis can be reached only by direct evaluation of the pulp tissue, and a decision about treatment is made accordingly. For example, if a pulpotomy is planned in a primary molar, the nature of the bleeding from the amputation site should be normal, and hemostasis should be evident after 2 to 3 minutes of light pressure with a moistened cotton pellet. Significant bleeding beyond this point indicates inflammation of the radicular pulp, and a more radical treatment such as pulpectomy or extraction should be considered. Conversely, if a pulp polyp is present and bleeding stops normally after coronal pulp amputation, a pulpotomy may be performed instead of a more radical procedure.[226]

In the case of an immature permanent tooth, persistent hemorrhage after several minutes of sodium hypochlorite application is an indication of serious pulp inflammation, and a tooth initially scheduled for a direct MTA pulp cap may be a better candidate for a pulpotomy, apexification, or pulp regeneration (see later section on immature permanent teeth).

Investigators[105] attempted to use the first drop of hemorrhage from an exposed pulp site as a diagnostic aid for determining the extent of degeneration within the pulp. A white blood cell differential count (i.e., hemogram) was made for each of 53 teeth included in the study. A detailed history, including percussion, electrical pulp test, thermal tests, mobility, and history of pain, was obtained. The teeth were extracted and histologically examined. On correlation of the histologic findings with the hemogram and history, it was determined that percussion, electrical and thermal pulp tests, and mobility were *unreliable* in establishing the degree of pulpal inflammation. The hemogram did not give reliable evidence of pulpal degeneration, although teeth with advanced degeneration of the pulp involving the root canals did have an elevated neutrophil count. A consistent finding of the study, however, was advanced degeneration of pulpal tissue in teeth with a history of spontaneous toothache.

The outward clinical signs of inflammation represent a succession of cellular, vascular, and immunologic processes involving many endogenous mediators. Inflammatory mediators (vascular-mediated and cell-released) and their role in

pulpal inflammation have been the subject of much research. The relationship between the concentration of a known cell-released inflammatory mediator (prostaglandin E_2 [PGE_2]) in pulpal blood samples and treatment outcome following vital pulpotomy in extensively carious primary molars has been reported.[319] Thirty-nine primary molars with no history of spontaneous pain had blood samples harvested from the radicular pulp stumps immediately following coronal pulp amputation. Enzyme immunoassay of the samples for PGE_2 detected the inflammatory mediator in all samples. A wide range of concentrations was detected, and it was shown that the concentration of PGE_2 detected correlated positively with radiologic signs of failure following treatment. The authors tempered their findings by describing the dependence upon a single inflammatory mediator to predict prognosis as oversimplistic and suggested the "trauma" of pulp amputation would stimulate prostaglandin production irrespective of the underlying inflammatory status of the tissue. Similarly, a rapid and low-cost, chairside diagnostic kit to assess the extent of pulp inflammation does not yet exist. Therefore, despite research in this area, clinicians still rely upon empirical clinical findings to diagnose the inflammatory status of the pulp.

Diagnosis Following Traumatic Injuries in Children

The details of trauma management are considered in Chapter 17. Injuries to the primary dentition are common, occurring in 1 in 3 children by the age of 5 years.[11,99] Diagnosis following traumatic injuries requires consideration of other factors in addition to those previously discussed. The most frequent injury in the primary dentition is tooth displacement due to less dense bone and shorter roots. Healing varies from normal without sequela to canal calcification or pulpal necrosis. Canal calcification may vary from an amorphous material resembling osteodentin to a partial or complete closure of the canal.[121,247]

Pulp Diagnosis and Treatment Planning After Trauma

Treatment guidelines are almost nonexistent concerning healing and complications following trauma in primary teeth. The literature is devoid of histologic or microbiologic studies in this area. Borum and Andreasen[29] in a study of 545 traumatized primary maxillary incisors found that 53% developed pulpal necrosis, and 25% developed canal obliteration. The age of the patient, degree of tooth displacement, concurrent crown fracture, and amount of root resorption were factors influencing pulpal necrosis and calcification. Teeth with a coronal fracture were less likely to suffer calcific obliteration of the root canal than those which had been luxated.

When making a decision upon treatment, the proximity of the primary tooth to the permanent successor is an important consideration. Treatment least likely to damage the permanent tooth should be chosen.[9,29] Studies present conflicting data on the merits of treating or extracting traumatized primary teeth. Some have suggested no relationship,[11,12] others have shown more extensive developmental disturbances if the primary tooth is treated and preserved.[266]

Transient or permanent discoloration of the crown occurs in approximately 50% of traumatized primary incisors, varying from yellow to dark gray and usually becoming evident in 1 to 3 weeks. The yellow discolorations are frequently associated with canal calcification but are not commonly associated with pulp necrosis.[29,125]

Pulpal necrosis ranging from 50% to 82% is reported[29,120,125,263] in traumatized primary incisors with dark gray discoloration, compared to 25% in those with no discoloration. One author[49] points out that color change in the absence of other clinical findings is unreliable. Diagnosis of pulpal necrosis is usually based on dark gray color and radiographic evidence of periapical pathology or cessation of root development.

In immature permanent teeth, discoloration of the crown is also one of the best diagnostic indicators after traumatic injuries.[130,136] Yellow or brown-tinted discoloration usually indicates calcification of the pulp space; a gray color is usually associated with pulpal necrosis. A return to normal after transient coronal discoloration[8,38] and transient apical breakdown up to 4 months' duration[38] have been reported.

PRINCIPLES OF ENDODONTIC TREATMENT IN CHILDREN

Endodontic procedures are undertaken to preserve teeth in a comfortable, functional, and ideally disease-free condition. The following sections describe a range of clinical procedures which aim to achieve these goals in the primary and young permanent dentitions, but they should not be seen merely as technical exercises. Readers should bear in mind that clinical management goes beyond the simple restorative procedure. The general care of anything from a preschool child requiring pulp therapy on a carious primary molar to an 8-year-old who has sustained trauma to an immature maxillary incisor requires special skills. In purely dental terms, the principle adopted is that the best root filling is a healthy pulp, and emphasis is given to methods of pulp preservation in both the primary and young permanent dentitions. Pulpotomy techniques for the partial preservation of pulp tissue are also presented as legitimate therapies—in primary teeth where young and well-perfused tissues combine with the relatively transient nature of the dentition to win success, and in young permanent teeth where therapies strive to maintain the well-perfused and resilient apical pulp, at least until root formation is complete. None of this diminishes the potential for pulpectomy and root canal treatment, should this become necessary, but as new opportunities open for regenerative therapies, traditional approaches to the root canal treatment of pulpless immature teeth may be coming into question.

PULP THERAPY FOR THE PRIMARY DENTITION

Indirect Pulp Therapy in Primary Teeth

Indirect pulp treatment (IPT) in the primary dentition is considered a contemporary, effective approach to a deep carious lesion in the absence of signs or symptoms of irreversible pulp pathosis.[265] It involves the removal of caries to leave a layer of stained dentin at the cavity floor in areas where its removal would result in exposure of pulp tissue. A decision to use this treatment is derived from clinical and radiographic examination, direct evaluation of the cavity preparation, and a good knowledge of tooth anatomy and the caries process.[14]

The aims of IPT are[250] to arrest the carious process, provide conditions conducive to the formation of reactionary dentin, and promote remineralization of the altered dentin that was

left. This in turn is expected to promote pulpal healing and preserve/maintain the vitality of the pulp.

Technique

In outline, the clinical steps involved may be divided into stages involving partial caries removal, placement of an antibacterial agent, and restoration of the crown in a way that provides optimum coronal seal.

Some studies using IPT in primary teeth advocated a two-stage approach.[70,305] After initial partial caries removal without local anesthetic, the cavity was restored for 1 to 3 months, using a reinforced ZOE cement or glass ionomer restoration. Following this, further caries removal and definitive restoration was undertaken using local anesthetic. It has been suggested that this approach may have a use in the very young or very anxious child, but it may be argued that a single-visit approach is more appropriate and successful.[72] Thinner dentin in the primary tooth compared with the permanent tooth may result in a higher risk of pulp exposure if a primary tooth is reentered to remove residual caries.[278]

The following technique is based upon a recommended approach[250]:

1. Local anesthetic
2. Isolation with rubber dam
3. Removal of all caries at the enamel-dentin junction of the cavity, ensuring caries-free walls
4. Judicious removal of soft, deep carious dentin, using large, round steel burs (#6 to #8). Hand excavators should only be used to remove caries at the dentin-enamel junction and angled outward at the dentin-enamel junction, taking care not to produce a pulp exposure.
5. Placement of an appropriate lining material such as glass ionomer cement, hard-setting $Ca(OH)_2$, ZOE, or a directly bonded restoration
6. Definitive restoration providing optimum coronal seal, such as an adhesive restoration or preformed metal (stainless steel) crown

Unfortunately, there is presently insufficient evidence to promote a definitive choice for the lining material placed over the residual stained dentin.[250]

Although additional prospective clinical evaluation of IPT is required, studies involving the primary dentition show good success rates of over 90% at 3 years.[6,70,72,316] However, it has been suggested that successful outcome is highly dependent upon optimum coronal seal to eradicate the nutrient supply to residual cariogenic microorganisms. When intracoronal amalgam restorations were compared with extracoronal preformed metal (stainless steel) crowns post IPT, failure was 7.7 times more likely to occur with the use of amalgam. Similarly, adhesive restorations were also reported to provide optimum coronal seal after pulp therapy.[108] Therefore, to secure the best possible outcome following IPT, or indeed any pulp therapy for the primary tooth, definitive restoration should involve a bonded restoration and/or preformed metal (stainless steel) crown.

The Hall Technique

This emerging technique of managing dental caries in primary molars is noteworthy within this section of indirect pulp therapy. The technique itself was introduced by a primary care clinician in Scotland who was overwhelmed by the number of children with dental caries. In Scotland, by the age of just 5 years, 55% of children had visible decay into dentin, and 16% had experienced tooth extraction. In response, this clinician decided to manage lesions in primary molars (that were symptom free and free from radiographic signs of periradicular pathology) by cementing a preformed metal (stainless steel) crown in place without local anesthesia, tooth preparation, or any attempt at caries removal. This is viewed in the United Kingdom as an undoubtedly novel approach to caries management and caught the attention of clinical academics in Scotland. Audit data from Dr Hall's records indicate that her technique may have similar results to more conventional approaches in the primary care setting.[132]

Subsequently, a randomized, controlled clinical trial was undertaken comparing the Hall technique with conventional restorations in carious primary molars in primary care.[131] Interestingly, the Hall technique was preferred to conventional restorations by the majority of children, guardians, and clinicians. After a review period of 2 years, comparing the teeth managed using Hall preformed metal (stainless steel) crowns with conventional restorations, the "Hall crowns" showed better treatment outcomes for both pulpal health and restoration longevity. In the United Kingdom, this has further stimulated an already ongoing debate related to whether restorative treatment provided by general clinicians in primary care is an effective way of managing caries in the primary dentition.[74,183]

Certainly this new and novel approach would appear to encompass present-day theory. Potentially cariogenic microorganisms require a very specific environment to start or progress a carious lesion. By sealing the lesion within the tooth, this removes nutrient supply and so stops or slows the lesion's progress.[173] Notwithstanding this, the importance of an effective and complete coronal seal should be of utmost importance.

Direct Pulp Capping in Primary Teeth

The lifespan of the average primary tooth from initial development to exfoliation is significantly shorter than that of a permanent tooth. Primary teeth undergo dramatic physiologic and physical changes over a relatively short period. Clinicians should keep in mind that pulp tissue is not static in nature, and outcomes for the same procedure may differ depending on the age of the patient. Further, because of the aging process within dental pulp, the likelihood of successful pulp capping diminishes with age. This may be explained by the increase in intrapulpal fibrous and calcific deposits seen with aging, together with a reduction in both pulpal volume and pulp fibroblast proliferation.[110]

Carious pulpal exposures in primary teeth should not be direct pulp capped. *Guidelines developed by both the American Academy of Pediatric Dentistry (AAPD) and the British Society of Paediatric Dentistry (BSPD) recommend that direct pulp capping should be reserved only for small mechanical or traumatic exposures in primary teeth.*[7,250] Under these circumstances, it is presumed that the conditions for a favorable pulpal response are optimal.

Pulpotomy in Primary Teeth

The AAPD guidelines[7] for pulp therapy for primary and young permanent teeth describe the pulpotomy procedure in primary

BOX 23-3

Evidence of Successful Pulp Therapy

- Vitality of the majority of the radicular pulp
- No prolonged adverse clinical signs or symptoms (e.g., sensitivity, pain, or swelling)
- No radiographic evidence of internal resorption reaching the alveolar bone
- No breakdown of periradicular tissue
- No harm to permanent successor teeth
- Pulp canal obliteration (abnormal calcification): not considered a failure

BOX 23-4

Contraindications for Pulpotomy in a Primary Tooth

- A history of spontaneous toothache (not caused by papillitis resulting from food impaction)
- A nonrestorable tooth where postpulpotomy coronal seal would be inadequate
- A tooth near to exfoliation or if no bone overlies the crown of the permanent successor tooth
- Evidence of periapical or furcal pathosis
- Evidence of pathologic root resorption
- A pulp that does not bleed (necrotic)
- Inability to control radicular pulp hemorrhage following a coronal pulp amputation
- A pulp with serous or purulent drainage
- Presence of a sinus tract

teeth as the amputation of the affected or infected coronal portion of the dental pulp, preserving the vitality and function of all or part of the remaining radicular pulp. Evidence of successful pulp therapy includes those features listed in Box 23-3.

For all pulpotomy procedures for the cariously exposed vital pulp of primary teeth, the procedure common to all is the complete amputation of coronal pulp tissue. Following this, and once hemostasis has been achieved, a decision is made on the wound dressing or technique to apply to the pulp stumps.

Some of the options available are listed below, and the success of all depends upon ensuring that the residual pulp tissue is correctly diagnosed as healthy or reversibly inflamed.

- Hemostasis and maintenance of vital tissue (e.g., ferric sulfate solution, electrosurgery, laser)
- Dentin bridge formation and maintenance of vital tissue (e.g., MTA)
- Superficial (partial) pulp tissue fixation and maintenance of vital tissue (e.g., dilute formocresol solution, glutaraldehyde solution)

Many pharmacotherapeutic agents have been used for pulp therapy in the past. Formocresol has been the most popular agent, mainly because of its ease of use and good clinical success. Yet despite these, formocresol and in particular one of its constituents, formaldehyde (FAD), has come under close scrutiny because of reported concerns related to the systemic distribution of FAD and its potential for toxicity, allergenicity, carcinogenicity, and mutagenicity. Other medicaments (e.g., glutaraldehyde, $Ca[OH]_2$, collagen, ferric sulfate, MTA) have been suggested as possible replacements. However, varying success rates and questions over the safety of these materials make it clear that additional research on the use of these and other pharmacotherapeutic agents is required.

Nonpharmacologic hemostatic techniques have been recommended, including electrosurgery[169,253,269,270] and laser therapy.[64] Research involving human clinical trials on both these techniques is sparse; nevertheless, electrosurgical pulpotomy is currently being taught in several dental schools. Comprehensive reviews of the techniques and agents used in vital pulp therapy and discussion of possible new modalities are available in the literature.[236,278,318]

Indications and Contraindications for Pulpotomy

The pulpotomy is indicated for *pulp exposure on primary teeth in which the inflammation or infection is judged to be confined to the coronal pulp.*[146,295] If inflammation has spread into the tissues within the root canals, the tooth should be considered a candidate for pulpectomy and root canal filling or extraction. The contraindications for pulpotomy on a primary tooth are outlined in Box 23-4.

Technique

Pulpotomy is used for primary teeth with radicular pulp tissue judged to be free from inflammation and infection. Compromise on this principle leads to a diminished success rate. If inflamed vital (coronal) pulp tissue is amputated to leave residual healthy pulp tissue (radicular), the tissue remaining has the capacity to remain healthy if managed correctly. The overall success of vital pulp therapy in the primary dentition depends upon:

- Effective control of infection.
- Complete removal of inflamed coronal pulp tissue.
- Appropriate wound dressing.
- Effective coronal seal during and after treatment.

An accurate diagnosis of pulp status is very important in aiding appropriate pulpal management. However, this can be challenging, particularly in young children. The points that follow highlight the diagnostic aids available:

- An accurate pain history is helpful in deciding the possible stage/extent of pulpal inflammation, but it may be difficult to elicit such information from a child.
- Radiographic findings can guide treatment decisions. Pretreatment radiographs are essential to assess the extent of the carious lesion and its proximity to the pulp horns/chamber. They also provide information relating to periradicular pathosis.
- Clinically, pulpal involvement can be assessed immediately following caries removal by looking very carefully for evidence of a pulp exposure.

Technique of Coronal Pulp Amputation

Removal of the coronal pulp tissue is a process common to whichever pulpotomy procedure is chosen for the cariously exposed vital primary tooth. Following successful coronal amputation and hemostasis (Fig. 23-15, *A-B*), the subsequent management of the radicular pulp stumps is defined by which pulpotomy technique the clinician chooses. For example, once hemostasis has been achieved, a wound dressing may be applied to the pulp wounds, or alternatively the exposed tissue

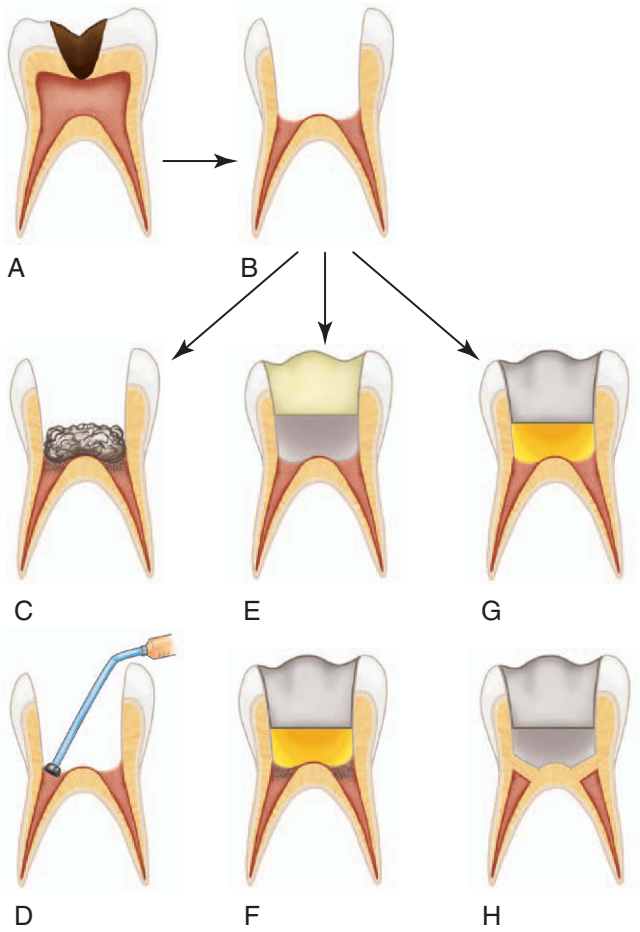

FIG. 23-15 Illustration to show three different approaches to the radicular pulp following coronal pulp amputation during pulpotomy in an extensively carious primary molar. **A,** Primary molar with caries extending to the pulp. Note inflammatory response in coronal pulp. **B,** Tooth has undergone removal of the coronal pulp. Radicular pulp tissue is healthy and has stopped bleeding. **C,** A 1:5 dilute solution of formocresol may be applied to pulp stumps for 5 minutes. This produces partial tissue fixation which is greatest near the point of application. **D,** Intracoronal restoration: zinc oxide eugenol (ZOE) is placed directly over the pulp stumps and an intracoronal restoration placed. Vital radicular pulp may remain apically. **E,** A 15.5% ferric sulfate solution is applied to the pulp stumps for 15 seconds. This produces mechanical blockage of open capillaries by a protein-iron complex. **F,** Intracoronal restoration has been provided as in **D.** Healthy, vital pulp tissue remains within the root canals. **G,** Mineral trioxide aggregate (MTA) is placed directly over the radicular pulp stumps, and the tooth is provided with an intracoronal restoration as before. **H,** The radicular pulp tissue remains vital beneath the MTA; a calcific bridge may form over time beneath the MTA.

might be subjected to electrosurgery or laser application. Fig. 23-15, *C-H* provides a schematic overview of the options and expected outcomes.

Stages in the Technique of Coronal Pulp Amputation

1. Following the initial diagnosis of probable vital pulpal involvement, the primary tooth is anesthetized and isolated with a rubber dam.
2. All caries are removed, and the observation of bleeding from exposure sites indicates vital (if inflamed) coronal pulp tissue (Fig. 23-16, *A-B*).
3. The entire roof of the pulp chamber is removed using a high-speed non-end cutting bur and copious water spray.
4. All the coronal pulp is amputated with a slow-speed #6 or #8 round bur or spoon excavator. Care must be exercised to fully unroof the chamber and extirpate all filaments of the coronal pulp (Fig. 23-16, *C-D*). If any filaments remain in the pulp chamber, hemorrhage will be impossible to control.
5. The pulp chamber is thoroughly washed with sterile water or saline to remove all debris, and the site is dried by vacuum and sterile cotton pellets.
6. Hemorrhage is controlled by slightly moistened cotton pellets (wetted and blotted almost dry) placed against the stumps of the pulp at the openings of the root canals. Completely dry cotton pellets should *not* be used; fibers of the cotton will be incorporated into the clot and when removed will cause hemorrhage. Dry cotton pellets are placed over the moist pellets, and pressure is exerted on the mass. Hemorrhage should be controlled in this manner within 3 minutes. It may be necessary to change the pellets to control all hemorrhage.
7. If bleeding persists, the clinician should carefully check that all filaments of the pulp were removed from the pulp chamber and that the amputation site is clean. If the bleeding persists from one of the canals, it can be reentered with a small round bur to amputate the suspected inflamed tissue; the canal is then rinsed again, and cotton pellet pressure is applied.
8. If hemostasis is not achieved within 2 to 3 minutes, the pulp tissue within the canals is probably inflamed, and the tooth is not a candidate for a pulpotomy. The clinician should then proceed with pulpectomy, or the tooth should be extracted.

Once bleeding has stopped at the radicular pulp stumps, the wounds are managed according to one of the following pulpotomy techniques (see Fig. 23-15):

- Application of dilute formocresol solution for 5 minutes
- Application of 15% ferric sulfate solution for 15 seconds (Fig. 23-16, *E-F*)
- Permanent placement of MTA
- Electrosurgical manipulation of the wound surfaces
- Laser manipulation of the wound surfaces

Formocresol Pulpotomy

Technique (see Fig. 23-15, C-D*)*

1. Following coronal pulp amputation and once hemostasis has been achieved, *one-fifth dilution formocresol solution* (Box 23-5) on a cotton pellet is blotted to remove excess formocresol and then placed in direct contact with the pulp stumps for 5 minutes. Formocresol is caustic and creates a severe tissue burn if allowed to touch the gingiva.
2. When the pellet is removed, the tissue appears brown, and no hemorrhage should be evident.
3. If an area of the pulp was not in contact with the medication, the procedure must be repeated for that tissue. Small cotton pellets for applying the medication usually work

FIG. 23-16 Clinical stages of a vital pulpotomy using ferric sulfate solution. **A,** Extensive dental caries affecting a mandibular first primary molar. Note proximity of radiographic lesion to the mesial pulp horn. **B,** Caries removal showing a carious pulpal exposure; bleeding is evident. **C,** Partial unroofing of the pulp chamber; note bleeding coronal pulp prior to amputation. **D,** Roof of pulp chamber removed completely. **E,** A 15.5% solution of ferric sulfate is applied to radicular pulp stumps using a dento-infuser tip supplied by the manufacturer. **F,** Hemostasis is evident at radicular pulp stumps. **G,** Definitive restoration involves placement of zinc oxide eugenol, overlaid with glass ionomer intracoronally, followed by a preformed metal (stainless steel) crown. *(Courtesy of Vidya Srinivasan, Edinburgh Dental Institute, UK.)*

BOX 23-5

Formulation of a One-Fifth Dilution of Formocresol Solution

1 part Buckley's formocresol solution is mixed with:
- 1 part distilled water and 3 parts glycerin.

BOX 23-6

Formulation of Full-Strength Buckley's Formocresol

Formaldehyde	19%
Tricresol	35%
Glycerin	15%
Water	31%

best because they allow closer approximation of the material to the pulp.

4. A cement base of ZOE is placed over the pulp stumps and allowed to set. The tooth may then be restored permanently.
5. The restoration of choice is a preformed metal (stainless steel) crown for primary molars. On anterior primary teeth, a composite tooth-colored restoration is the treatment of choice unless the tooth is so badly broken down that it requires a crown.

The use of formocresol in dentistry remains controversial. Formaldehyde (FAD), a volatile organic compound, is toxic and corrosive, especially at the point of contact. Formocresol's other active constituent, cresol, is also an irritant and corrosive in nature.[225]

Local and Systemic Accumulation of Formaldehyde

Localized accumulation of formocresol or FAD has been demonstrated in pulp, dentin, periodontal ligament, and bone surrounding the apices of pulpotomized teeth.[93,193]

Although animal studies have identified radioisotope-labeled formocresol or FAD in major organs following systemic injection or multiple pulpotomies, researchers concluded that the doses of formocresol were far in excess of those used in normal clinical practice. It has therefore been suggested that the findings should not be extrapolated to clinical use in humans.[192,196,197] More recently, a review of the safety of formocresol, including FAD metabolism, suggested that FAD is rapidly metabolized, so the findings of previous studies may have been identifying FAD metabolites systemically and not FAD itself.[182] Notwithstanding this, the amount of formocresol absorbed systemically by way of the pulpotomy route is small and may not contraindicate the use of the drug.[220]

Formocresol as an Allergen

The results of studies investigating the allergenic risks of formocresol are equivocal. Studies have shown no evidence of an allergic response in non-presensitized animals,[273] and presensitized animals showed only a weak allergic potential.[314] The demonstration of an immune response to formocresol-fixed, autologous tissue implanted in connective tissues or injected into root canals has, however, been reported.[26,298]

Is Formocresol Carcinogenic?

In respect of mutagenicity and carcinogenicity of FAD, it is generally accepted that FAD is genotoxic in vitro, inducing mutations and DNA damage in cells from a variety of organisms, including humans.[101,208,217,288,324] The possible link between FAD and carcinogenesis has been investigated within the field of occupational health medicine. In a review of several large longitudinal studies, the International Agency for Research on Cancer (IARC) reported that "*sufficient evidence*" exists that FAD had caused nasopharyngeal cancer in humans.[133] This was suggested to be linked to a localized combination of irritation and genotoxicity of FAD, which repeat-dose inhalation studies using rodents has corroborated.[317] In the dental context, the amount of FAD within a diluted solution of formocresol is small, but there are no data relating to the amounts of FAD vapor inhaled by patients or dental personnel during pulpotomy procedures and whether this may constitute a potential risk. Moreover, the often disregarded cresol ingredient itself may pose a genotoxic risk to mammalian cells.[109]

Despite these concerns, the formocresol pulpotomy continues to be one treatment choice available for primary teeth with vital, carious exposures of the pulp in which inflammation or degeneration is judged to be confined to the coronal pulp. The last reported worldwide survey of dental schools (in 1989)[17] showed a majority of pediatric dentistry departments and pediatric dentists advocated the formocresol pulpotomy technique, and it may still be widely used in clinical practice. In the United Kingdom since 2004, there has been a general trend away from using formocresol, driven by several factors: difficulty obtaining the medicament, concerns related to its safety, and promising clinical results of newer, nonaldehyde techniques.[318] However, the recent U.K. Clinical Guideline, *Pulp Therapy for Primary Molars,* still includes the formocresol pulpotomy as an option,[250] as does the AAPD guidance.[7] Although formocresol pulpotomy is still widely taught in predoctoral pediatric dentistry programs in the United States,[231] there is a lack of consensus over its use for vital pulp therapy in primary teeth.

The current formocresol pulpotomy technique is a modification of that reported by Sweet in 1930.[287] The effect of formocresol on pulp tissue (i.e., the amount of tissue fixation) is controlled by the quantity that diffuses into the tissue and depends on length of time of application, concentration used, the method of application, or a combination of all these factors.[66,96,172,177]

A one-fifth dilution of formocresol solution has been widely advocated based upon the outcomes of both in vitro and in vivo studies comparing dilute formocresol (see Box 23-5) with the undiluted solution (Box 23-6). Histochemical investigations comparing dilute and undiluted formocresol noted little difference between initial effects on pulp tissue fixation but earlier recovery of enzyme activity and improvement in the rate of recovery from the localized cytotoxic effects of formocresol with diluted formocresol.[164,165,286] Clinical studies have shown diluted formocresol to be as successful as full-strength formocresol.[85,86,185,186]

There is enough evidence today to conclude that ***if formocresol is to be used at all,*** *the one-fifth concentration should be preferred*

for pulpotomy procedures because it is as effective as and less damaging than the traditional preparation.

Formocresol and the Permanent Successor

The fear of damage to the succedaneous tooth has been offered as an argument against formocresol pulpotomy on primary teeth. Results from studies are inconsistent, ranging from the same incidence of enamel defects in treated and untreated contralateral teeth[187,251] to an increase in defects and positional alterations of the underlying permanent tooth.[181] It should be pointed out that studies of this nature are follow-up studies long after treatment, without knowledge of the existing status of the pulp before pulpotomy.

The effect of a formocresol pulpotomy upon the exfoliation time of primary molars is also equivocal, with some studies finding no consistent effect[187,312] and some reporting early exfoliation.[119,185]

Unlike the tissue response to $Ca(OH)_2$, no dentin bridge should be anticipated after applying formocresol to exposed pulp tissue (see Fig. 23-15, *C-D*). However, narrowing of the root canal through the continued deposition of dentin by the preserved radicular pulp may be observed in some cases (Fig. 23-17).

Criteria for Success

Failure of a formocresol pulpotomy is usually detected on radiographs (see Fig. 23-13). The first signs of failure are often internal resorption of the root adjacent to the area where the formocresol was applied. This may be accompanied by external resorption, especially as the failure progresses. Sometimes, however, the internal resorption is self-corrected with the deposition of calcified tissue. In the primary molars, radiolucency develops in the bifurcation or trifurcation area. In the anterior teeth, a radiolucency may develop at the apices or lateral to the roots. With more destruction, the tooth becomes excessively mobile; a sinus tract usually develops. It is rare for pain to occur with the failure of a formocresol pulpotomy. Consequently, unless patients receive follow-up checks after a formocresol pulpotomy, failure may be undetected. When the tooth loosens and is eventually exfoliated, the parents and child may consider the circumstances normal.

The development of cystic lesions after pulp therapy in primary molars has been reported.[32,259] An amorphous, eosinophilic material shown to contain phenolic groupings similar to those present in medicaments was found in the lesions. Other researchers[194] have observed furcal lesions in untreated, pulpally involved primary molars containing granulomatous tissue with stratified squamous epithelium, suggesting the potential for cyst formation. In a subsequent study involving failed, pulpotomized primary molars, most specimens were diagnosed as furcation cysts.[195] These findings emphasize the importance of periodic follow-up to endodontic treatment on primary teeth. Fig. 23-18 shows a favorable long-term outcome following a formocresol pulpotomy in a mandibular primary molar.

ALTERNATIVES TO FORMOCRESOL PULPOTOMY

A 2006 comprehensive review is suggested for readers requiring a detailed look at the numerous alternative techniques available.[278]

Glutaraldehyde Pulpotomy

Glutaraldehyde has been a suggested alternative to formocresol as a tissue fixative for vital pulpotomy. Histologic studies showed that it produced rapid surface fixation of pulp tissue but with limited depth of penetration, so a larger amount of radicular pulp tissue remained vital.[290,322] Fixed pulp tissue may be replaced with dense collagenous tissue over time.[150] Studies have also demonstrated less systemic distribution than was thought to occur with formocresol.[57,159,196,220,321]

Glutaraldehyde has been shown to be rapidly metabolized with little toxic effect.[118,137,143,196,240] It has also been demonstrated that although glutaraldehyde has antigenic action similar to formocresol, it is of a lower potential.[237,239] However, there are perceived problems with the use of glutaraldehyde as a pulpotomy agent:

- Glutaraldehyde solutions are reported to be unstable.[235]
- Neither the optimum concentration nor time of application of glutaraldehyde solution has been established conclusively.[97,162,238]
- Clinical studies reported increasing failure rates with increasing time post pulpotomy,[89] with lower levels of clinical success than formocresol.[5]

Despite the perceived enhanced safety of glutaraldehyde with respect to formocresol, it did not gain favor over formocresol for pulpotomy in the primary dentition.[17,76]

Ferric Sulfate Pulpotomy

Technique

1. After completion of coronal pulp amputation and achievement of hemostasis with moist cotton pellets, a 15.5% solution of ferric sulfate is applied to the radicular pulp stumps for 10 to 15 seconds.
2. The ferric sulfate may be applied using a cotton pellet or by allowing small droplets of the solution to drip from a burnisher tip onto the surface of the pulp tissue. The manufacturers also supply a special dento-infuser tip for this purpose (Astrigident, Ultradent Products Inc, Salt Lake City, UT) (see Fig. 23-15, *E;* Fig. 23-16, *E*).

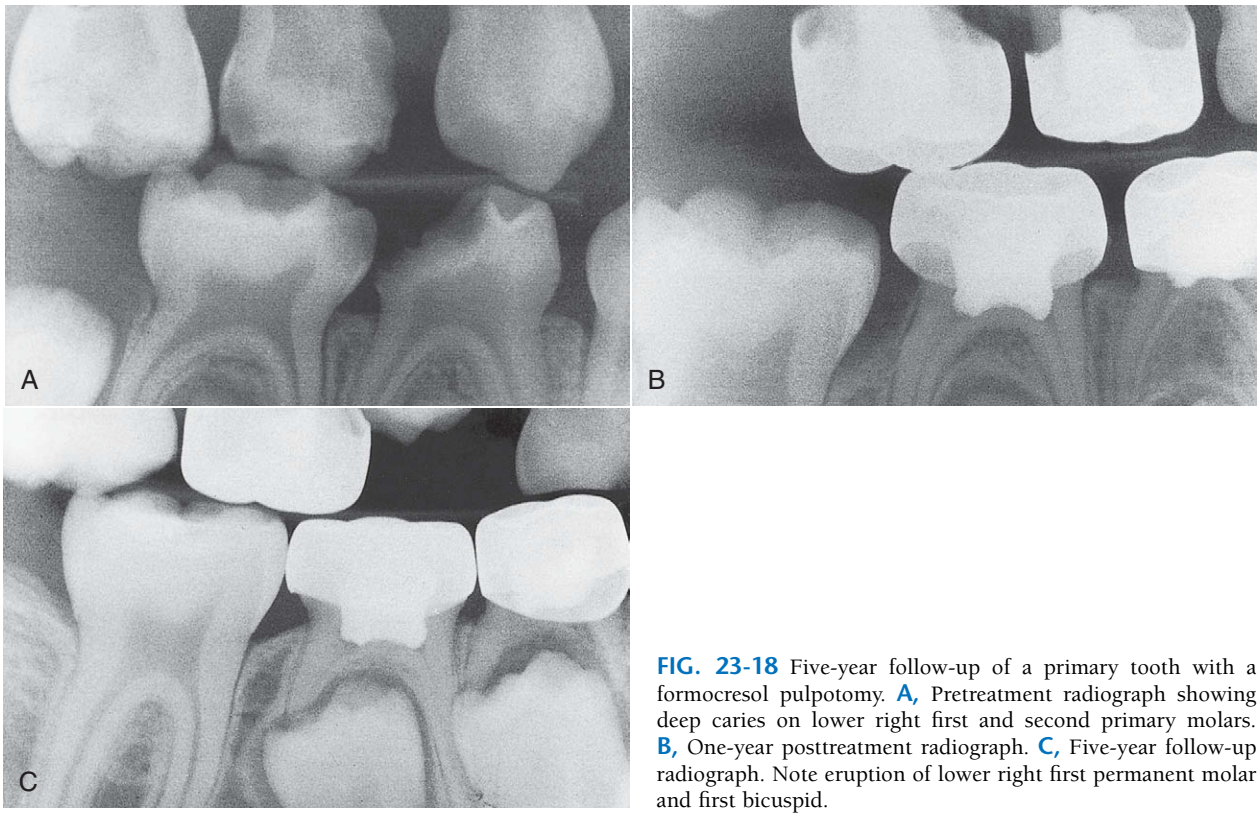

FIG. 23-18 Five-year follow-up of a primary tooth with a formocresol pulpotomy. **A,** Pretreatment radiograph showing deep caries on lower right first and second primary molars. **B,** One-year posttreatment radiograph. **C,** Five-year follow-up radiograph. Note eruption of lower right first permanent molar and first bicuspid.

3. Upon removal of the cotton pellet, the wounds appear brown, and no bleeding should be evident. If a small amount of residual bleeding does occur, one further application of ferric sulfate should be considered.
4. A cement base of ZOE is placed over the pulp stumps and allowed to set. The tooth may then be restored permanently as described for the formocresol pulpotomy (see Fig. 23-15, *F*).

Ferric sulfate has been used as a hemostatic agent for crown and bridge impressions.[79] Its hemostatic action occurs by the reaction of blood with ferric and sulfate ions within the acidic pH of the solution. The agglutinated proteins form plugs that occlude the capillary orifices and prevent blood clot formation.[160] Initially the use of ferric sulfate was recommended as a hemostatic agent during the $Ca(OH)_2$ pulpotomy on the grounds that it may prevent problems arising from clot formation after coronal pulp amputation and minimize the chances for inflammation and internal resorption[262]—considered by some to be important factors contributing to the failure of pulpotomies using $Ca(OH)_2$. Its first documented use in this way was in primate teeth.[152]

The use of ferric sulphate itself as a hemostatic pulpotomy agent was investigated by researchers using animal models (rat[40] and baboon).[88] From the relatively few clinical studies that have been published using ferric sulfate as a pulpotomy medicament, four are prospective comparative,[75,88,129,219] and two are retrospective.[30,276]

In all the comparative studies, formocresol was used as the gold standard. The materials and methods used in all these studies are similar, which allows more meaningful comparison of their findings. Pulpotomies were performed in primary molars of healthy children who were selected on the basis of symptomless exposure of vital pulp by caries, absence of clinical or radiographic evidence of pulp degeneration, and possibility of proper restoration.

In all of the aforementioned ferric sulfate studies, the teeth were treated using the pulpotomy technique already outlined, and the teeth were restored with preformed metal (stainless steel) crowns. In one study,[219] half of the teeth were restored with composite resin and the remaining half with preformed metal (stainless steel) crowns.

Prospective Studies

In another study,[75] 27 teeth were included in the formocresol group and 29 in the ferric sulfate group. Although the sample size was small, the recall rate was excellent, and in the 3- and 6-month intervals, no statistically significant difference was found between the two groups. However, at the end of this 1-year study, there was a statistically significant difference in the success rate in favor of ferric sulfate (97% for ferric sulfate, 78% for formocresol). The most frequent evidence of failure in this short-term study in both groups was furcation radiolucency. In the study by Fuks et al.,[88] the sample consisted of 37 teeth in the formocresol group and 55 in the ferric sulfate group. The follow-up period ranged from 6 to 34 months, with a mean of 20.5 months. In this study, the sample size was bigger and the evaluation period much longer than the previous one. The total success rate between the two groups over the total period of 34 months did not present any statistically significant difference and was 92.7% for ferric sulfate and

83.8% for formocresol. Calcific metamorphosis and internal resorption were the most common radiographic findings. In this study, internal resorption that was stable and unchanged throughout the study was not recorded as failure.

In a later study,[129] 34 teeth were used in each group, and identical results were obtained 24 months post treatment for both ferric sulfate and formocresol: a 97% total success rate was recorded. In each group, only one tooth presented internal resorption and was therefore considered a failure.
