Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

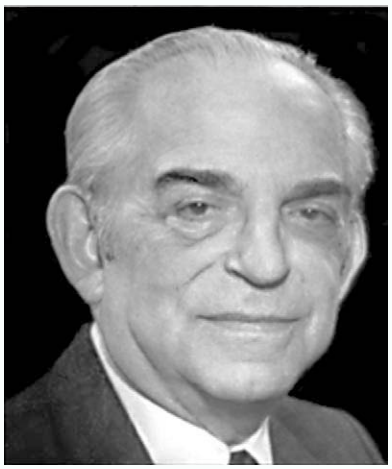
About the Editors

KENNETH M. HARGREAVES

Dr. Kenneth M. Hargreaves is professor and Chair of the Department of Endodontics at the University of Texas Health Science Center at San Antonio. He completed his endodontic residency at the University of Minnesota in 1993. Dr. Hargreaves is a Diplomate of the American Board of Endodontics and maintains a private practice limited to endodontics. He is an active researcher, lecturer, and teacher and serves as the Editor of the *Journal of Endodontics*. He is principal investigator on several nationally funded grants that combine his interests in pain, pharmacology, and regenerative endodontics. He has received several awards, including a National Institutes of Health MERIT Award for pain research, the AAE Louis I. Grossman Award for cumulative publication of research studies, and two IADR Distinguished Scientist Awards.

STEPHEN COHEN



Dr. Stephen Cohen is one of the foremost endodontic clinicians in the country and a worldwide lecturer on endodontics. Dr. Cohen completed his studies in the Endodontic Postgraduate Program at the University of Pennsylvania in 1969 and began his private practice. From 1970 until 1988, Dr. Cohen served as Chairman of the Department of Endodontics at The Arthur A. Dugoni School of Dentistry of the University of the Pacific, and he has continued his involvement with the university as an Adjunct Clinical Professor of Endodontics. He is also a Clinical Professor of Endodontics in the Department of Preventive and Restorative Dental Sciences at the University of California School of Dentistry, San Francisco. Dr. Cohen was senior editor of the first nine editions of *Pathways of the Pulp* and continues to serve as editor of the tenth edition. He is a Diplomate of the American Board of Endodontics, and has held leadership positions in many of the major professional and academic organizations in endodontics. He maintains a full-time endodontic practice in San Francisco, where he has practiced since 1969.

LOUIS H. BERMAN

Dr. Louis H. Berman has been in full-time private practice limited to endodontics in Annapolis, Maryland since 1983. Dr. Berman completed his endodontic residency at the Albert Einstein Medical Center in Philadelphia. He was formerly a Clinical Instructor and Assistant Professor of Endodontics at the University of Maryland School of Dentistry. An active lecturer and author, he is a past president of the Maryland State Association of Endodontics, and is a member of the *Journal of Endodontics* Scientific Advisory Panel. Dr. Berman is the senior editor of the textbook *Dental Traumatology* and is a Diplomate of the American Board of Endodontics and a Fellow of the American College of Dentistry.

Dr. I.B. Bender

For a man of short stature, I.B. Bender was a giant in shaping the field of endodontics. Dr. Bender started his remarkable career as an educator in 1942 at the Albert Einstein Medical Center in Philadelphia, and continued with his passionate pursuit of endodontic teaching for the next 61 years. He authored more than 130 articles in medicine and dentistry and was co-author of the classic textbook, *The Dental Pulp*. Recipient of the most prestigious awards given to endodontists, he also served as President of the American Association of Endodontists and as a Director of the American Board of Endodontics. In 1989, the endodontic residency program at the Albert Einstein Medical Center honored him by dedicating their program as the I.B. Bender Division of Endodontics and established the I.B. Bender Research Endowment Fund.

A true Renaissance man, I.B. was internationally known not just for his boundless knowledge of endodontic literature and extraordinary insight into the biological aspects of our specialty, but also for his quick wit, enjoyable sense of humor, and persistent quest to challenge "conventional" beliefs and let science lead us into the future. I.B. was a wise man who once stated, "The clinical practice of yesterday's endodontics becomes the heresy of today, and today's endodontic practice becomes the heresy of tomorrow. So don't be so rigid in your techniques or beliefs."

I.B. took much pride in inspiring and imbuing his students with a passion for endodontic excellence. During lectures he was well known to compliment their correct answers with his wide smile, a tilt of his head while pointing his finger, and a statement that they had been "Bender-ized." He always welcomed a challenge to the intellectual status quo, and took great pleasure in a duel of intellect. I.B. referred to himself as "the oldest living functional endodontist … who has helped to move the status of endodontics from the 'outhouse' to the 'penthouse'." He valued his close friendships and always finished his personal notes, in his uniquely recognizable penmanship, with "Azever, I.B."

At a 1995 lecture at the I.B. Bender Conference, "The Biological Basis and Clinical Practice of Endodontics," I.B. closed by stating: "The implementation of extended research and teaching is a means by which endodontics will be able to meet the future demands for its service. Service itself in a specialty cannot make progress. Other developments in our discipline will come from people who can touch tomorrow." And I.B. touched tomorrow by touching the lives of all of us.

I.B. was instrumental in shaping our past, directing our present, and providing the foundation and vision for our ever-changing future. His inspiring passion for knowledge and excellence set the standards for the legions of students who will always remain indebted to him for role-modeling what a healer and teacher does for others. To commemorate this iconic role model of our specialty, we are pleased to dedicate this tenth edition of *Pathways of the Pulp* to Dr. I.B. Bender.

Preface

The co-editors and publisher are pleased to present the tenth edition of a textbook that has been continuously evolving since 1976. We are also proud to announce the renaming of this text to ***Cohen's Pathways of the Pulp*** to reflect the leadership, passion, and expertise of Dr. Stephen Cohen, who has guided the production of all 10 editions. This current edition has been completely updated and expanded to provide the latest clinically relevant, evidence-based knowledge, while also introducing exciting new chapters on subjects such as Regenerative Endodontics, Cone Beam Technologies, and Endodontic Practice Management. The companion Expert Consult version of the book has also been greatly enhanced with supplemental content available only online. With its exceptional capacity to provide continuous updates, the Expert Consult site is reflective of the dynamic nature of our specialty, empowering our readers with not only the most current clinical information available, but also with an invaluable feature that permits the downloading of any figure in the book as a PowerPoint or jpeg image for the reader's personal study or lectures. Moreover, the online Challenge section provides self-assessment of knowledge with a unique collection of hyperlinks that connects all of the multiple choice questions to relevant sections of the text. As editors, we feel privileged and honored to offer this thoroughly updated and expanded version of the first interactive textbook in dentistry that enables the reader to continuously stay on the "cutting edge" of endodontics.

We welcome your feedback at any time.

Kenneth M. Hargreaves
Stephen Cohen
Louis H. Berman

Acknowledgments

Working with such a talented, patient, and highly professional team at Elsevier has been an enriching experience. In the future, when we look back to the time that was devoted to developing this tenth edition, we'll always remember fondly the special people with whom we've forged a bond through hard work and how they helped us at every level. Some of the many people that we'd like to express our gratitude to include:

- *John Dolan, Executive Editor*
- *Courtney Sprehe, Senior Developmental Editor*
- *Karen Rehwinkel, Senior Project Manager*
- *Jill Norath, Multimedia Producer*
- *Jessica Williams, Designer*
- *Jaime Pendill, Freelance Editor*

And to the many people who helped those named above we extend a heartfelt "Thank You"!

About the Tenth Edition

With the publication of this milestone tenth edition, the staff at Elsevier would like to thank Dr. Stephen Cohen for his many years of dedication to *Pathways of the Pulp*. In recognition of Dr. Cohen's leadership in making this a world-renowned text and for his many contributions to the field of endodontics, the new edition has been renamed *Cohen's Pathways of the Pulp*.

Pathways of the Pulp has a longstanding reputation of providing high-level, comprehensive content that conveys the most current endodontic information, materials, and techniques to an international audience. The tenth edition builds on this solid reputation with a book that delivers more than ever! Renowned contributors from across the country and around the world offer expert perspectives and expand on observations made by previous contributors. Full-color photographs, illustrations, and a wide range of radiographs clearly demonstrate core concepts and reinforce the essential principles and techniques unique to the specialty of endodontics.

CHAPTERS NEW TO THIS EDITION

Chapter 14: Pathobiology of the Periapex by Louis M. Lin and George T-J Huang. This chapter looks at topics such as apical periodontitis, infection, asymptomatic apical periodontitis (apical granuloma), the relationship between apical periodontitis and systemic diseases, and wound healing of apical periodontitis.

Chapter 16: Regenerative Endodontics by Kenneth M. Hargreaves and Alan S. Law. This chapter describes the biological basis for regenerating the pulp-dentin complex of teeth with necrotic pulps and reviews the clinical procedures reported to date on this newly emerging procedure.

Chapter 22: Restoration of Endodontically Treated Teeth by Didier Dietschi and Serge Bouillaguet. Topics covered in this chapter include a description of the unique physical characteristics of endodontically treated teeth, restorative materials, pretreatment evaluation and treatment strategies, and a variety of clinical procedures, including direct composite restorations, veneers, selection of posts and core materials, and much more.

Chapter 29: Cone Beam Imaging for Endodontics (online) by Dale A. Miles and Thomas V. McClammy. With the recent advent of cone beam computerized tomography's use in the dental office, this chapter elaborates on the enhanced radiographic capabilities now available for endodontic diagnosis and treatment planning.

Chapter 30: Key Principles of Endodontic Practice Management (online) by Roger P. Levin. Providing insight on marketing, staff development, patient management, and referral relationships, this chapter describes endodontic management systems and the goals necessary for the development of a successful endodontic practice.

ORGANIZATION

As in the previous edition, the tenth edition is divided into three parts, Part I: The Core Science of Endodontics, Part II: The Advanced Science of Endodontics, and Part III: Related Clinical Topics.

Part I begins with chapters that focus on the process of developing an endodontic diagnosis, how to effectively diagnose and manage acute dental pain, and how to identify pain of nonodontogenic origin. The next chapter reviews the process of case selection and treatment planning, which is followed by chapters that prepare the clinician for endodontic treatment, including a thorough review of armamentarium, sterilization, and disinfection, where appropriate. The next chapter describes tooth morphology and how it relates to techniques crucial for achieving access to the entire root canal system. Following are three chapters that extensively describe the latest instruments, materials, techniques, and devices used for canal cleaning, shaping, and obturation. The concluding chapter in Part I reviews the legal responsibilities of the clinician and gives guidance for avoiding potential legal issues pertaining to patient care.

Part II starts with a chapter that brings together what is known about the development, structure, and function of the dentinal-pulpal complex and is followed by a chapter on how the pulp reacts to different stimuli, materials, and dental procedures. Following are chapters on the pathobiology of the periapex and the diverse aspects of endodontic microbiology, with special emphasis placed on the underlying principles for sound antimicrobial treatment of endodontic infections.

Part III begins with a new chapter on the rapidly developing field of regenerative endodontics and continues with a chapter that details the endodontic management necessary for optimizing favorable healing for the various types of traumatic dental injuries. The next chapter looks at the relationship between pulpal and periodontal tissues, and the following chapter presents insight into the medications used in endodontics, especially as it relates to the pharmacologic management of odontogenic pain. The chapter on periradicular surgery reviews how it has evolved into a precise, biologically-based adjunct to

nonsurgical root canal therapy and is followed by a new chapter designed to help clinicians make informative decisions about the restorative options available to endodontically-treated teeth. Part III concludes with a chapter that looks at the special considerations that must be addressed when treating geriatric, pediatric, and medically compromised patients, followed by a chapter that provides the information necessary for proper treatment-planning considerations and management of nonsurgical endodontic retreatment.

In addition to the 25 chapters in the text there are also five new chapters included on *Expert Consult*, the book's online component. These chapters address topics such as management of the fearful dental patient, the law and dental technology, the role of digital technology in practice, cone beam computerized tomography, and endodontic practice management. *Expert Consult* also provides access to a wide range of essential educational and clinically-based topics, which are further described on the next page.

About Expert Consult

Elsevier's *Expert Consult* platform is an online collection of evidence-based reference titles that cross a wide range of specialties. Combining authoritative, world-class book content with full-search functionality and many additional online features, Expert Consult is one of the most efficient tools available to healthcare professionals today.

Access to the *Expert Consult* platform is part of the content package for the tenth edition of *Cohen's Pathways of the Pulp*. Simply activate your title at **expertconsult.com** to see a wide range of supplemental material. Activation instructions can be found on the inside front cover of the book.

When you register and activate your book on *Expert Consult*, you gain access to the complete, fully searchable contents of the book online, which enables you to:

- Find guidance and clinical answers quickly.
- Follow links from bibliographical citations to the corresponding MEDLINE abstracts.
- Consult your book from any computer, anywhere in the world.
- Keep up-to-date with the latest information and view video clips and other material supplementing and expanding the print edition.

In addition, a wide range of premium content is offered, including the following:

- **Five chapters available only online:**
  - Chapter 26: Understanding and Managing the Fearful Dental Patient
  - Chapter 27: The Law and Dental Technology: Focus on Endodontics
  - Chapter 28: Digital Technology in Endodontic Practice
  - Chapter 29: Cone Beam Imaging for Endodontic Procedures
  - Chapter 30: Key Principles of Endodontic Practice Management
- **Updates:** Quarterly updates that address the latest developments in the field.
- **Full image library online:** All of the book's images, organized by chapter, in a user-friendly format that allows you to search for what you want and then either save images into a virtual "Light Box" or straight into a PowerPoint presentation.
- **Videos:** Key procedures demonstrated in both animations and videos. Topics addressed include procedures and techniques for almost all aspects of endodontics.
- **Drug database:** Drug information accessible by indications, contraindications, and adverse reactions. Powered by Gold Standard—the leading developer of drug information.
- **Challenge:** Multiple-choice questions stemming from chapter-specific discussions or case scenarios, including answers and references to pages in the book.
- **Glossary and SORT:** Articles from *The Journal of Evidence-Based Dentistry—The Glossary of Evidence-Based Terms* and *JEBDP Improves Grading System and Adopts Strength of Recommendation Taxonomy Grading (SORT) for Guidelines and Systematic Reviews*—provided in their entirety.

Introduction

Welcome reader, to this tenth edition of *Pathways of the Pulp,* a reconceptualized textbook that blends form, content, print, and digital formats to describe and detail the transformative future of endodontics. The first edition of *Pathways of the Pulp* was published in 1976, with the aim of describing in a single print volume the basic and clinical science of what was then the emerging specialty of endodontics. Nine editions later, we have continued to refine and redefine the scope and organization of our textbook to mirror and represent the changing science of endodontics and the evolving landscape of learning and communication. Now offered in 14 different languages, *Pathways of the Pulp* is the most comprehensive and innovative evidence-based endodontic textbook available.

Beginning with the ninth edition, *Pathways of the Pulp* has been available anytime, anywhere to readers in an online version, enhanced with instructional images and graphics and periodic content updates. The new format of the tenth edition has expanded the use of digital resources to achieve a seamless blending of print and online content through the addition of narrated video clips and animations, and quarterly content updates drawn from the peer-reviewed literature.

Although the evolving form and format of *Pathways of the Pulp* defines its commitment to education, the steady and selfless dedication of the more than 150 contributors to the 10 editions honors and extends our tradition of collaborating with the most qualified and highly regarded authors, academicians, and researches in our field. Working with all of the dedicated teachers and scientists who author our chapters continues to be the signature honor and privilege for the editors. We are especially grateful to Dr. Lou Berman, who in his capacity as Webmaster has made our promise of online availability and digital features a reality. We are all indebted as well to Elsevier for its willingness to explore and support ever more dynamic and engaging ways of imparting knowledge and communicating with our readers.

The nine prior editions of *Pathways of the Pulp* have begun with a chapter on the history of endodontics and the inspiring story of the intense interplay between basic science and clinical care that established and certified our specialty. The vision and dedication of our founders who lived that history are now embedded in the field and practice of endodontics, and to call them out separately would seem to distance them rather than bring them closer to us. What now connects us more productively and most effectively with our storied past is our commitment to redefining that critical interplay between basic science and clinical care in terms of new technologies, new possibilities, and new expectations.

In this tenth edition, through evidence-based discussions in all of our 30 chapters, including five that are only available online, we have meticulously detailed that what was once regarded as science fiction in clinical care is now rapidly becoming clinical endodontic fact. The quality of care available to patients has never been higher, from the administrative efficiency and privacy protection afforded to patients through electronic medical records, to the greatly enhanced effectiveness of infection management through real-time PCR. A sampling of the innovative and paradigm shifting developments outlined in this edition include the following:

- More accurate devices to determine pulp vitality and inflammation
- Greater control of the duration of local anesthesia on a case-by-case basis
- Cleaning and shaping root canals in less than 5 minutes with a single device
- Regeneration of the pulp to replace canal obturation
- Nonsurgically accelerating the remineralization of periapical lesions through the apical foramen

As clinicians we must meet this rich convergence of discovery and invention with an equally rich commitment to continuous learning, exposing ourselves to all the science our field has to offer. This is our duty to our founders, this is our responsibility to our patients, and this is our gift to ourselves.

As I conclude this Introduction I also bring to a close my 35 years as editor of *Pathways of the Pulp*. It is with complete confidence and great excitement that I pass the editorship of our book to Dr. Kenneth Hargreaves, a uniquely qualified and accomplished scientist, educator, and clinician.

I am deeply grateful for the privilege of editing and contributing to *Pathways of the Pulp*. It has been a true labor of love, which has allowed me to indulge my passion for science and my love of teaching. Perhaps most importantly, however, my editorship has taught me what it means to practice endodontics, a true healing art.

Stephen Cohen

CHAPTER 1

Diagnosis

LOUIS H. BERMAN and GARY R. HARTWELL

CHAPTER OUTLINE

ART AND SCIENCE OF DIAGNOSIS
- Chief Complaint
- Medical History
- Dental History

EXAMINATION AND TESTING
- Extraoral Examination
- Intraoral Examination
- Pulp Tests
- Special Tests
- Radiographic Examination and Interpretation
- Root Fractures and Cracks
- Referred Pain

CLINICAL CLASSIFICATION OF PULPAL AND PERIAPICAL DISEASES
- Pulpal Disease
- Apical (Periapical) Disease
- Pain of Nonodontogenic Origin

ART AND SCIENCE OF DIAGNOSIS

Almost a century ago, Dr. Hermann Prinz wrote: "The object of the practice of clinical dentistry … is to institute preventive measures, to relieve suffering, and to cure disease. These purposes are not achieved by the haphazard utilization of a few therapeutic formulas or of certain mechanical procedures, but they are based on a thorough knowledge of clinical pathology."[75] This statement has truly withstood the test of time and remains a cornerstone in diagnosis. But the gathering of scientific data is not enough to formulate an accurate clinical diagnosis. The data must be interpreted and processed in order to determine what information is significant, and what information might be questionable. The facts need to be collected with an active dialogue between the clinician and the patient, with the clinician asking the right questions and carefully interpreting the answers. In essence, the process of determining the existence of dental pathosis is the culmination of the art and science of making an accurate diagnosis.

The purpose of a diagnosis is to determine what problem the patient is having, and why the patient is having that problem. Ultimately, this will directly relate to what treatment, if any, will be necessary. No appropriate treatment recommendation can be made until all of the *whys* are answered. Therefore a planned, methodical, and systematic approach to this investigatory process is crucial.

The process of making a diagnosis can be divided into five stages:

1. The patient tells the clinician why the patient is seeking advice.
2. The clinician questions the patient about the symptoms and history that led to the visit.
3. The clinician performs objective clinical tests.
4. The clinician correlates the objective findings with the subjective details and creates a tentative differential diagnosis.
5. The clinician formulates a definitive diagnosis.

This information is accumulated by means of an organized and systematic approach that requires considerable clinical judgment. The clinician must be able to approach the problem by crafting what questions to ask the patient and how to ask these pertinent questions. Careful listening is paramount to begin painting the picture that details the patient's complaint. The diagnostic tests that are used become the science behind the creation of the diagnosis.

Neither the art nor the science is effective alone. Establishing a differential diagnosis in endodontics requires a unique blend of knowledge, skills, and ability to interpret and interact with a patient in real time. Questioning, listening, testing, interpreting, and finally answering the ultimate question of *why* will lead to an accurate diagnosis and in turn result in a more successful treatment plan.

Chief Complaint

On arrival for a dental consultation, the patient should complete a thorough registration that includes information pertaining to medical and dental history (Figs. 1-1 and 1-2). This should be signed and dated by the patient, as well as initialed by the clinician as verification that all of the submitted information has been reviewed (see Chapter 11 for more information).

The reasons patients give for consulting with a clinician are often as important as the diagnostic tests performed. These remarks serve as important clues for the clinician that will help in formulating a correct diagnosis. Without these direct and unbiased comments, objective findings may lead to an incorrect diagnosis. The clinician may find dental pathosis, but it

TELL US ABOUT YOUR SYMPTOMS

LAST NAME _____ **FIRST NAME** _____

1. Are you experiencing any pain at this time? If not, please go to question 6. Yes _____ No _____
2. If yes, can you locate the tooth that is causing the pain? Yes _____ No _____
3. When did you first notice the symptoms? _____
4. Did your symptoms occur suddenly or gradually? _____
5. Please check the frequency and quality of the discomfort, and the number that most closely reflects the intensity of your pain:

LEVEL OF INTENSITY (On a scale of 1 to 10) 1 = Mild 10 = Severe	FREQUENCY	QUALITY
1___2___3___4___5___6___7___8___9___10___	_____ Constant	_____ Sharp
	_____ Intermittent	_____ Dull
	_____ Momentary	_____ Throbbing
	_____ Occasional	

Is there anything you can do to relieve the pain? Yes _____ No _____

If yes, what? _____

Is there anything you can do to cause the pain to increase? Yes _____ No _____

If yes, what? _____

When eating or drinking, is your tooth sensitive to: Heat _____ Cold _____ Sweets _____

Does your tooth hurt when you bite down or chew? Yes _____ No _____

Does it hurt if you press the gum tissue around this tooth? Yes _____ No _____

Does a change in posture (lying down or bending over) cause your tooth to hurt? Yes _____ No _____

6. Do you grind or clench your teeth? Yes _____ No _____
7. If yes, do you wear a night guard? Yes _____ No _____
8. Has a restoration (filling or crown) been placed on this tooth recently? Yes _____ No _____
9. Prior to this appointment, has root canal therapy been initiated on this tooth? Yes _____ No _____
10. Is there anything else we should know about your teeth, gums, or sinuses that would assist us in our diagnosis? _____

Signed: Patient or Parent _____ **Date** _____

FIG. 1-1 Dental history form that also allows the patient to record pain experience in an organized and descriptive manner.

TELL US ABOUT YOUR HEALTH

LAST NAME _____ **FIRST NAME** _____

How would you rate your health? **Please circle one.** **Excellent Good Fair Poor**

When did you have your last physical exam? _____

If you are under the care of a physician, please give reason(s) for treatment.

_____

FIG. 1-2 Succinct, comprehensive medical history form designed to provide insight into systemic conditions that could produce or affect the patient's symptoms, mandate alterations in the modality of treatment, or change the treatment plan.

may not be the pathologic condition that mediates the patient's chief complaint. Investigating these complaints may indicate that the patient's concerns are secondary to a medical condition or possibly a result of recent dental treatment. On occasion, the chief complaint is simply that another clinician correctly or incorrectly advised the patient that he or she had a dental problem, with the patient not necessarily having any symptoms. Therefore, the clinician must pay close attention to the actual expressed complaint, determine the chronology of events that led up to this complaint, and question the patient as to any other pertinent issues, including medical and dental history. For future reference and in order to ascertain a correct diagnosis, the patient's chief complaint should be properly documented, using *the patient's own words.*

Medical History

The clinician is responsible for taking a proper medical history from every patient who presents for treatment. Numerous examples of medical history forms are available from a variety of sources, or individual clinicians may choose to customize their own forms. After the form is completed by the patient, or by the parent or guardian in the case of a minor, the clinician should review the responses with the patient, parent, or guardian and indicate that this review has been done by initialing the medical history form. Any patient "of record" should be questioned at each treatment visit to determine any changes in the patient's medical history or medications. A more thorough and complete update of the patient's medical history should be completed if the patient has not been seen for over a year.[35,56]

Baseline blood pressure and pulse should be recorded for a patient at each treatment visit. Elevation in blood pressure or a rapid pulse rate may indicate an anxious patient who may require a reduced stress protocol, or it may indicate that the patient has hypertension or other cardiovascular health problems. It is imperative that vital signs be gathered at each treatment visit for any patient with a history of major medical problems. The temperature of patients presenting with subjective fever or any signs or symptoms of a dental infection should be taken.[42,56,78]

The clinician should evaluate a patient's response to the health questionnaire from two perspectives: (1) those medical conditions and current medications that will necessitate altering the manner in which dental care will be provided and (2) those medical conditions that may have oral manifestations or mimic dental pathosis.

Patients with serious medical conditions may require either a modification in the manner in which the dental care will be delivered or a modification in the dental treatment plan (Box 1-1).

In addition, the clinician should be aware if the patient has drug allergies or allergies to dental products, an artificial joint prosthesis, or organ transplants or is taking medications that may negatively interact with common local anesthetics, analgesics, and antibiotics.

The previous listing may seem overwhelming, but it emphasizes the importance of attaining a thorough and accurate medical history before any dental treatment is provided. A multitude of textbooks and journal articles are available to keep the dental community current on the appropriate ways to provide dental care for patients with medical problems (e.g., *The Merck Manual* at http://www.merck.com/mrkshared/mmanual/home.jsp). These sources provide the clinician with details about the various medical conditions and the dental treatment modifications that must be made in order to provide the appropriate care.

BOX 1-1

Medical Conditions That Warrant Modification of Dental Care or Treatment

Cardiovascular: High- and moderate-risk categories of endocarditis, pathologic heart murmurs, hypertension, unstable angina pectoris, recent myocardial infarction, cardiac arrhythmias, poorly managed congestive heart failure[42,56,78]

Pulmonary: Chronic obstructive pulmonary disease, asthma, tuberculosis[56,95]

Gastrointestinal and renal: End-stage renal disease; hemodialysis; viral hepatitis (types B, C, D, and E); alcoholic liver disease; peptic ulcer disease; inflammatory bowel disease; pseudomembranous colitis[17,21,22,33,56]

Hematologic: Sexually transmitted diseases, HIV and AIDS, diabetes mellitus, adrenal insufficiency, hyperthyroidism and hypothyroidism, pregnancy, bleeding disorders, cancer and leukemia, osteoarthritis and rheumatoid arthritis, systemic lupus erythematosus[22,28,53,59,64,73,99]

Neurologic: Cerebrovascular accident, seizure disorders, anxiety, depression and bipolar disorders, presence or history of drug or alcohol abuse, Alzheimer's disease, schizophrenia, eating disorders, neuralgias, multiple sclerosis, Parkinson's disease[23,29]

Several medical conditions have oral manifestations, which must be carefully considered when attempting to arrive at an accurate dental diagnosis. Many of the oral soft tissue changes that occur are more related to the medications used to treat the medical condition than the medical condition itself. More common examples of medication side effects are stomatitis, xerostomia, petechiae, ecchymoses, lichenoid mucosal lesions, and bleeding of the oral soft tissues.[56]

In arriving at an accurate dental diagnosis, a clinician must also be aware that some medical conditions can have clinical presentations that mimic oral pathologic lesions.[91] Tuberculosis involvement of the cervical and submandibular lymph nodes can lead to a misdiagnosis of lymph node enlargement as a result of an odontogenic infection. Lymphomas can also involve these same lymph nodes.[56] Immunocompromised patients and patients with uncontrolled diabetes mellitus respond poorly to dental treatment and may exhibit recurring abscesses in the oral cavity that must be differentiated from abscesses of dental origin.[28,53,56,59] Patients with iron deficiency anemia, pernicious anemia, and leukemia frequently exhibit paresthesia of the oral soft tissues. This finding may complicate making a diagnosis when other dental pathosis is also present in the same area of the oral cavity. Sickle cell anemia has the complicating factor of bone pain, which mimics odontogenic pain and loss of trabecular bone pattern on radiographs, which can be confused with radiographic lesions of endodontic origin. Multiple myeloma can result in unexplained mobility of teeth. Radiation therapy to the head and neck region can result in increased sensitivity of the teeth and osteoradionecrosis.[56] Trigeminal neuralgia, referred pain from cardiac angina,

and multiple sclerosis can also mimic dental pain (see also Chapter 3). Acute maxillary sinusitis is a common condition that may create diagnostic confusion because it may mimic tooth pain in the maxillary posterior quadrant. In this situation the teeth in the quadrant will be extremely sensitive to cold and percussion, thus mimicking the signs and symptoms of pulpitis. This is certainly not a complete list of all the medical entities that can mimic dental disease, but it should alert the clinician that a medical problem could confuse and complicate the diagnosis of dental pathosis; this is discussed in more detail in subsequent chapters.

If at the completion of a thorough dental examination, the subjective, objective, clinical testing, and radiographic findings do not result in a diagnosis with an obvious dental etiology, then consideration must be given that an existing medical problem could be the true etiology. In such instances a consultation with the patient's physician is always appropriate. As noted previously, there are many current textbooks and journal articles that can serve as reference materials for clinicians who encounter some of these medical problems on an infrequent basis.

Dental History

The chronology of events that lead up to the chief complaint is recorded as the *dental history*. This information will help guide the clinician as to which diagnostic tests are to be performed. The history should include any past and present symptoms, as well as any procedures or trauma that might have evoked the chief complaint. Proper documentation is imperative. It may be helpful to use a premade form to record the pertinent information obtained during the dental history interview and diagnostic examination. Often an S.O.A.P. format is used, designating the *S*ubjective *O*bjective *A*ppraisal *P*lan for the diagnostic workup. There are also built-in features within some practice management software packages that allow digital entries into the patients' electronic file for the diagnostic workup (Figs. 1-3 and 1-4).

History of Present Dental Problem

The dialogue between the patient and the clinician should encompass all of the details pertinent to the events that led up to the chief complaint. The conversation should be directed by the clinician in order to produce a clear and concise narrative that chronologically depicts all of the necessary information about the patient's symptoms and the development of these symptoms. To help elucidate this information, the patient is first instructed to fill out a dental history form as a part of the patient's office registration. This information will help the clinician decide which approach to use when asking the patient questions. The interview first determines *what is going on* in an effort to determine *why is it going on* for the purpose of eventually determining *what is necessary for the resolution of the chief complaint*.

Dental History Interview

After starting the interview and determining the nature of the chief complaint, the clinician continues the conversation by documenting the sequence of events that promulgated the request for an evaluation. The dental history is divided into five basic directions of questioning: localization, commencement, intensity, provocation, and duration.

Localization: *"Can you point to the offending tooth?"* Often the patient can point to or "tap" the offending tooth. This is the most fortunate scenario for the clinician because it helps direct the interview toward the events that might have caused any particular pathosis in this tooth. In addition, localization allows subsequent diagnostic tests to focus more on this particular tooth. When the symptoms are not well localized, the diagnosis is a greater challenge.

Commencement: *"When did the symptoms first occur?"* A patient who is having symptoms may remember when these symptoms started. Sometimes, the patient will even remember the initiating event: It may be spontaneous in nature, it may have begun after a dental visit for a restoration, trauma may be the etiology, or biting on a hard object may have initially produced the symptoms. However, the clinician should resist the tendency to make a premature diagnosis based on these circumstances. The clinician should not simply assume "guilt by association" but instead should use this information to enhance the overall diagnostic process.

Intensity: *"How intense is the pain?"* It often helps to quantify how much pain the patient is actually having. The clinician might ask, "On a scale from 1 to 10, with 10 the most severe, how would you rate your symptoms?" Hypothetically, a patient could present with "an uncomfortable sensitivity to cold" or "an annoying pain when chewing" but might rate this "pain" only as a 2 or a 3. These symptoms certainly contrast with the type of symptoms that prevent a patient from sleeping at night. Often the intensity can be subjectively measured by what is necessary for the diminution of pain, for example, acetaminophen versus a narcotic pain reliever. This intensity level may affect the decision to treat or not to treat with endodontic therapy.

Provocation and Relief of Pain: *"What produces or reduces the symptoms?"* Mastication and locally applied temperature changes account for the majority of initiating factors that cause dental pain. The patient may relate that drinking something cold causes the pain or possibly that chewing or biting is the only stimulus that "makes it hurt." The patient might say that the pain is only reproduced on "release from biting." On occasion, a patient may present to the dental office with a cold drink in hand and state that the symptoms can only be *reduced* by bathing the tooth in cold water. Some symptoms may be relieved by nonprescription pain relievers, and others may require narcotic medication for the reduction of symptoms (see Chapter 19 for more information). Note that patients who are using narcotic pain relievers may respond differently to questions and diagnostic tests, which may alter the objectivity of the diagnostic results. These provoking and relieving factors may help to determine which diagnostic tests should be performed to establish a more objective diagnosis.

Duration: *"Do the symptoms subside shortly, or do they linger after they are provoked?"* The difference between a cold sensitivity that subsides in seconds and one that subsides in minutes may determine whether a clinician repairs a defective restoration or provides endodontic treatment. The duration of symptoms after a stimulating event should be recorded as to how long the sensation is felt by the patient, and documented in terms of seconds or minutes.

FIG. 1-3 When taking a dental history and performing a diagnostic examination, often a premade form can be helpful in facilitating complete and accurate documentation. *(Courtesy Dr. Ravi Koka, San Francisco, Calif.)*

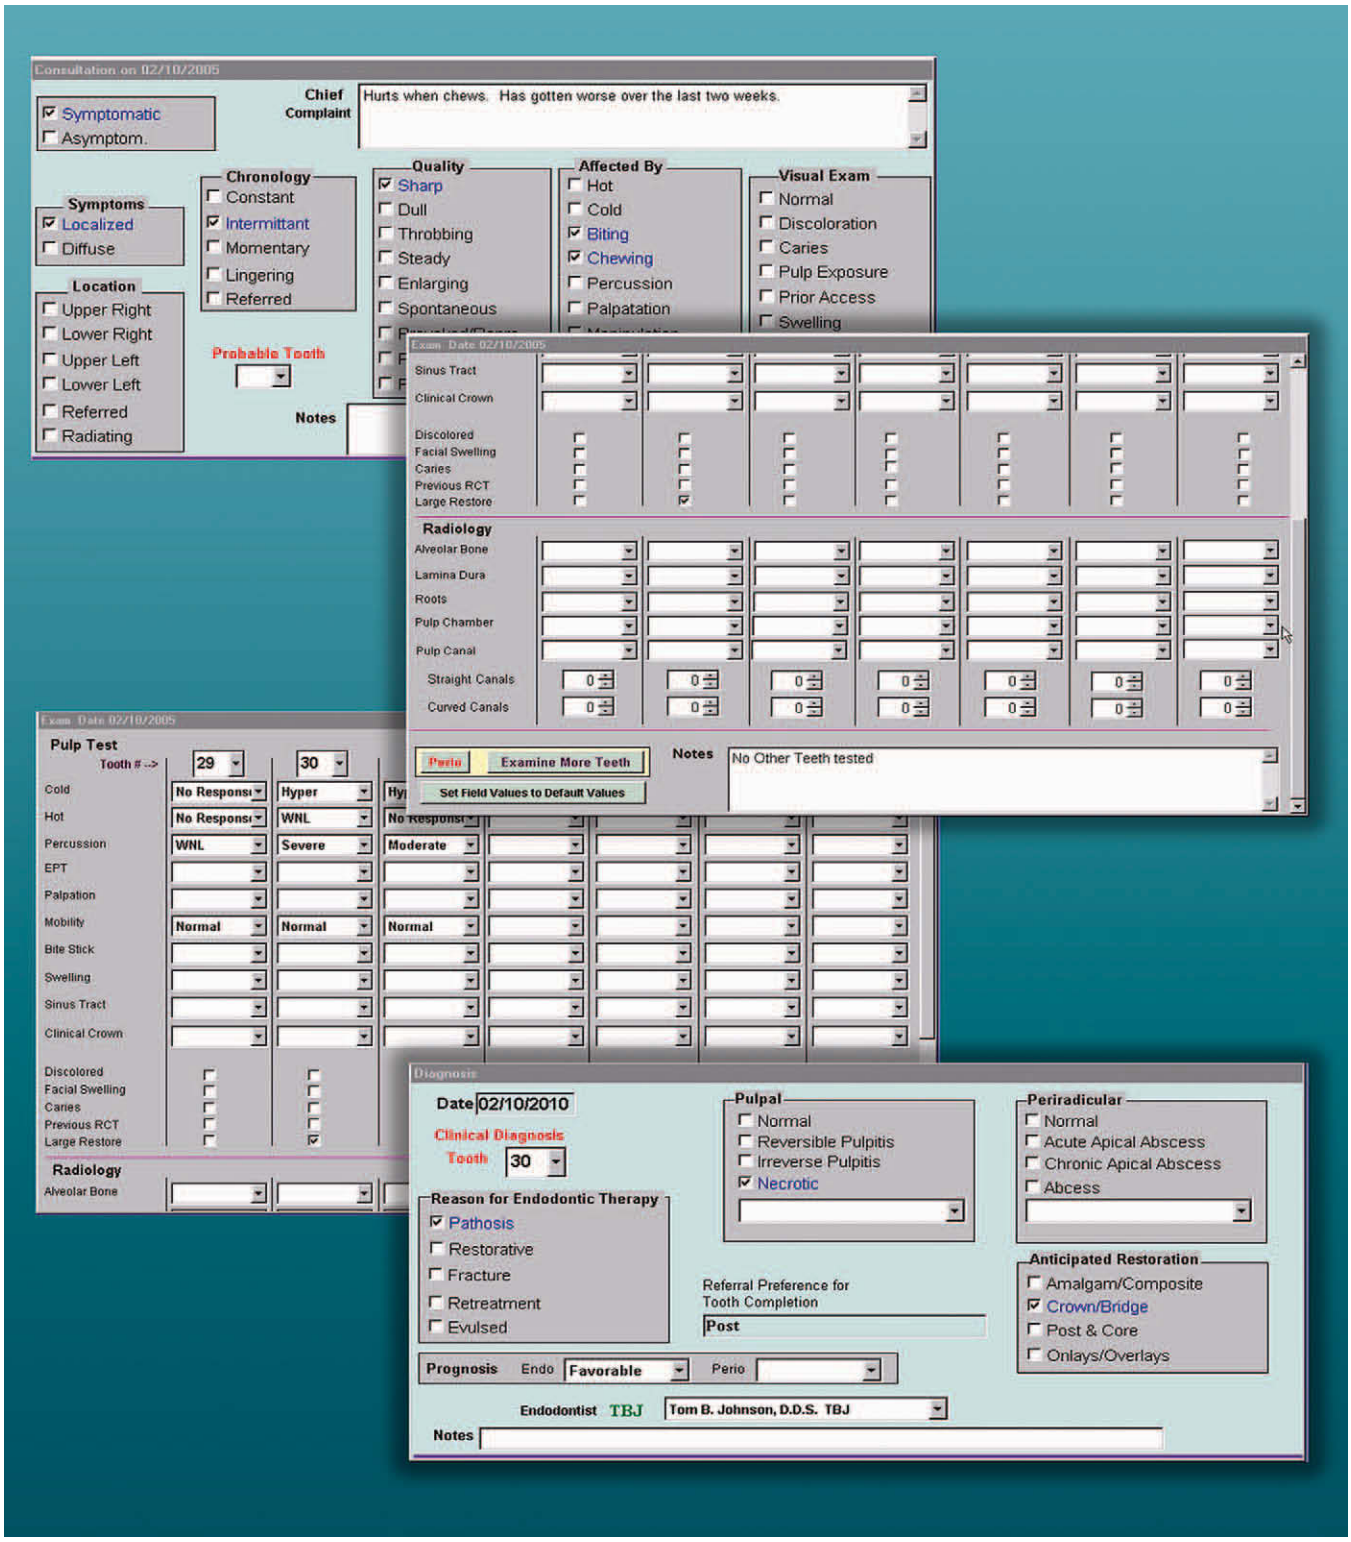

FIG. 1-4 Several practice management software packages have features for charting endodontic diagnosis using mouse-driven inputs, user-defined drop-down menus, and areas for specific notations. Note that for legal purposes, it is desirable that all recorded documentation have the ability to be locked, or if any modifications are made after 24 hours, the transaction should be recorded with an automated time/date stamp. This is necessary so that the data cannot be fraudulently manipulated. *(Courtesy PBS Endo, Cedar Park, Texas.)*

FIG. 1-5 A, Canine space swelling of the left side of the face extending into and involving the left eye. **B,** Swelling of the upper lip and the loss of definition of the nasolabial fold on the patient's left side, which is indicative of an early canine space infection.

With the dental history interview complete, the clinician has a better understanding of the patient's chief complaint and can concentrate on making an objective diagnostic evaluation, although the subjective (and artistic) phase of making a diagnosis is not yet complete and will continue after the more objective testing and scientific phase of the investigatory process.

EXAMINATION AND TESTING

Extraoral Examination

Basic diagnostic protocol suggests that a clinician observe patients as they enter the operatory. Signs of physical limitations may be present, as well as signs of facial asymmetry that result from facial swelling. Visual and palpation examinations of the face and neck are warranted to determine whether swelling is present. Many times a facial swelling can be determined only by palpation when a unilateral "lump or bump" is present. The presence of bilateral swellings may be indicative of a normal finding for any given patient; however, it may also be a sign of a systemic disease or the consequence of a developmental event. Palpation allows the clinician to determine whether the swelling is localized or diffuse, firm or fluctuant. These latter findings will play a significant role in determining the appropriate treatment.

Palpation of the cervical and submandibular lymph nodes is an integral part of the examination protocol. If the nodes are found to be firm and tender along with facial swelling and an elevated temperature, there is a high probability that an infection is present. The disease process has moved from a localized area immediately adjacent to the offending tooth to a more widespread systemic involvement.

Extraoral facial swelling of odontogenic origin typically is the result of endodontic etiology because diffuse facial swelling resulting from a periodontal abscess is rare. Swellings of nonodontogenic origin must always be considered in the differential diagnosis especially if an obvious dental etiology is not found.[54] This is discussed in subsequent chapters.

FIG. 1-6 Buccal space swelling associated with an acute periradicular abscess from the mandibular left second molar.

A subtle visual change such as loss of definition of the nasolabial fold on one side of the nose (Fig. 1-5) may be the earliest sign of a canine space infection.[55,94] Pulpal necrosis and periradicular disease associated with a maxillary canine should be suspected as the source of the problem. Extremely long maxillary central incisors may also be associated with a canine space infection, but most extraoral swellings associated with the maxillary centrals express themselves as a swelling of the upper lip and base of the nose. Further discussions of fascial space infections may be found in Chapter 15.

If the buccal space becomes involved, the swelling will be extraoral in the area of the posterior cheek (Fig. 1-6). These swellings are generally associated with infections originating from the buccal root apices of the maxillary premolar and molar teeth and the mandibular premolar (Fig. 1-7) and first molar teeth. The mandibular second and third molars may also be involved, but infections associated with these two teeth have as much likelihood to exit to the lingual where other spaces would be involved. For infections associated with these teeth, the root apices of the maxillary teeth must lie superior

FIG. 1-7 A, Buccal space swelling of the left side of the patient's face. Note the asymmetry of the left side of the face. **B,** Swelling in this case is also present in the left posterior mucobuccal fold. **C,** This buccal space infection was associated with periradicular disease from the mandibular left second premolar. Note on the radiograph the periradicular radiolucency and large restoration associated with this tooth.

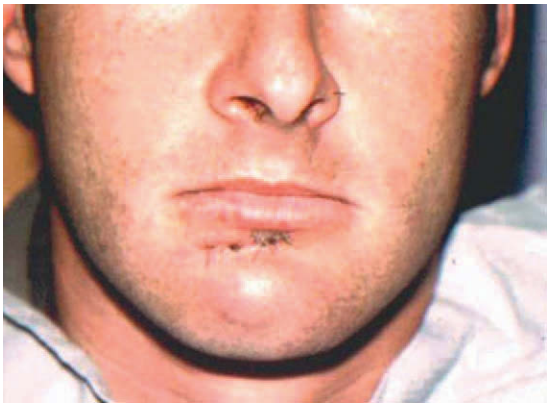

FIG. 1-8 Swelling of the submental space associated with periradicular disease from the mandibular incisors.

to the attachment of the buccinator muscle to the maxilla, and the apices of the mandibular teeth must be inferior to the buccinator muscle attachment to the mandible.[55,94]

Extraoral swelling associated with mandibular incisors will generally exhibit itself in the submental (Fig. 1-8) or submandibular space. Infections associated with any mandibular teeth, which exit the alveolar bone on the lingual and are inferior to the mylohyoid muscle attachment, will be noted as swelling in the submandibular space.[55,94] There is a complete review of fascial space infections in Chapter 15.

Sinus tracts of odontogenic origin may also open through the skin of the face (Figs. 1-9 and 1-10). These openings in the skin will generally close once the offending tooth is treated and healing occurs. A scar is more likely to be visible on the skin surface in the area of the sinus tract stoma than on the oral mucosal tissues (Fig. 1-11; see also Fig. 1-9). Many patients with extraoral sinus tracts will give a history of being treated by general physicians and dermatologists with systemic or topical antibiotics and/or surgical procedures in attempts to heal the extraoral stoma. In these particular cases, only after multiple treatment failures are the patients finally referred to a dental clinician to determine whether there is a dental etiology.[46]

Intraoral Examination

The extraoral examination may give the clinician insight as to which intraoral areas may need a more focused evaluation. Extraoral swelling, localized lymphadenopathy, or an extraoral sinus tract should provoke a more detailed assessment of related and proximal intraoral structures.

Soft Tissue Examination

As with any dental examination, there should be a routine evaluation of the intraoral soft tissues. The gingiva and

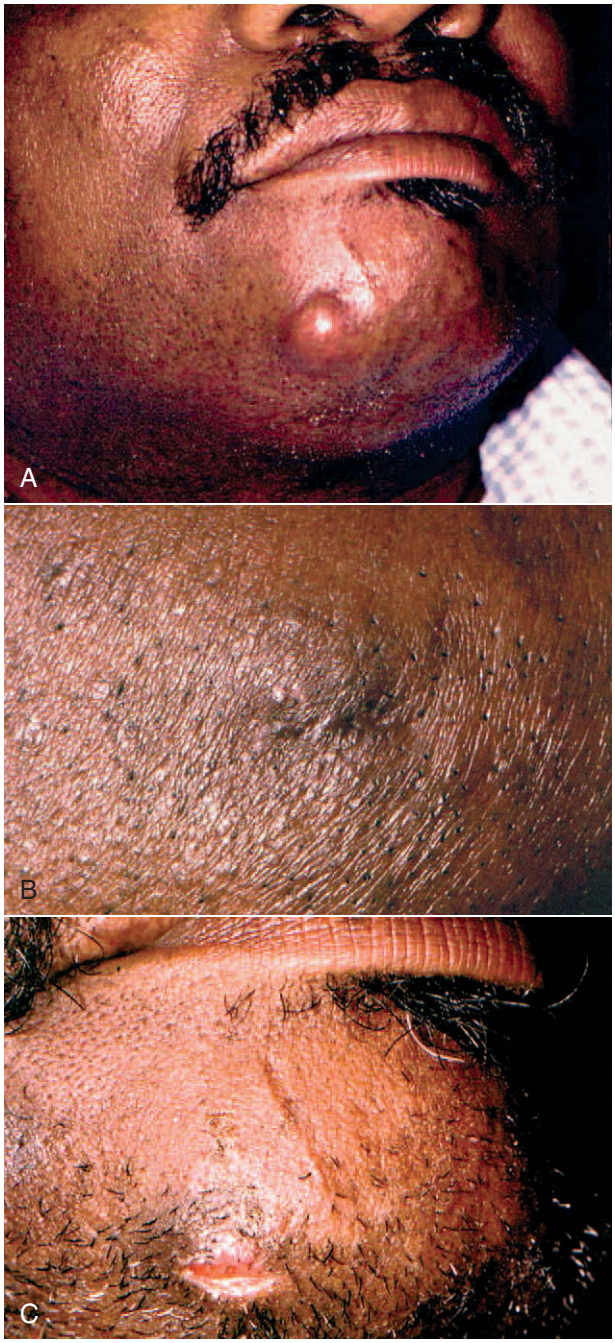

FIG. 1-9 A, Note the parulis on the right anterior side of the face. The extraoral drainage was found to be associated with periradicular disease from the mandibular right canine. **B,** Note the initial scar associated with the extraoral drainage incision after the parulis was drained and root canal therapy was performed on the canine. **C,** The healed incision area 3 months after drainage was achieved. Note the slight inversion of the scar area.

mucosa should be dried, either with an air syringe or a 2 × 2-in. gauze pad. By retracting the tongue and cheek, all of the soft tissue should be examined for any abnormalities in color or texture. Any raised lesions or ulcerations should be documented and, when necessary, evaluated with a biopsy or referral.[58]

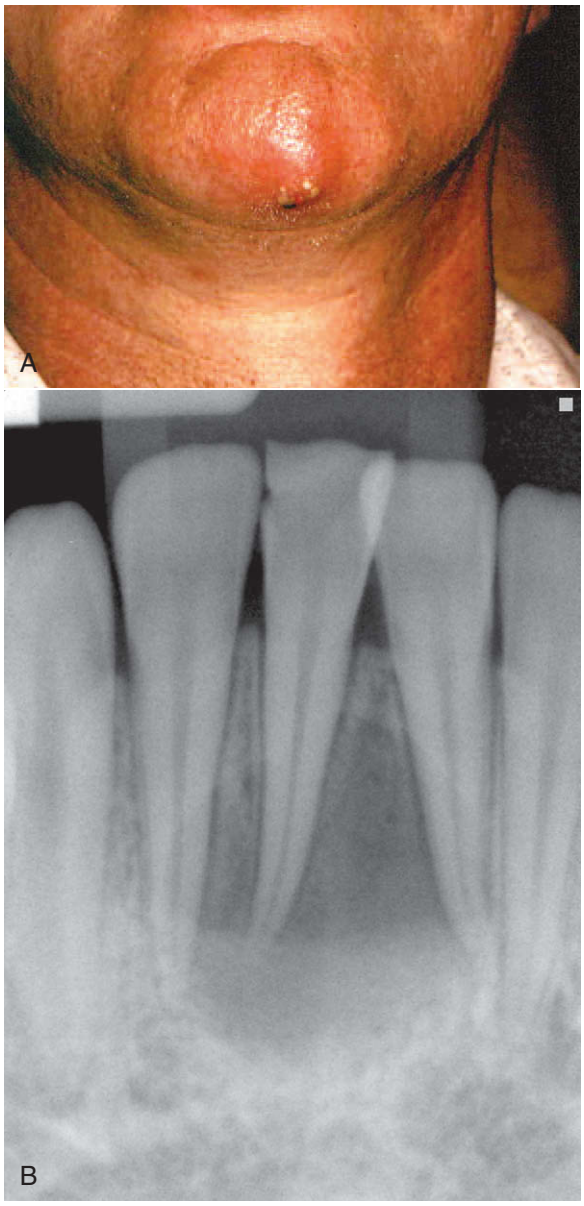

FIG. 1-10 A, Extraoral sinus tract opening on the skin in the central chin area. **B,** Radiograph of mandibular incisors and canine after root canal therapy.

Intraoral Swelling

Intraoral swellings should be visualized and palpated to determine whether they are diffuse or localized and whether they are firm or fluctuant. These swellings may be present in the attached gingiva, alveolar mucosa, mucobuccal fold, palate, or sublingual tissues. Other testing methods are required to determine whether the etiology is endodontic, periodontic, or a combination of these two or whether it is of nonodontogenic origin.

Swelling in the anterior part of the palate (Fig. 1-12) is most frequently associated with an infection present at the apex of the maxillary lateral incisor or the palatal root of the maxillary first premolar. More than 50% of the maxillary lateral incisor root apices deviate in the distal or palatal directions. A swelling

FIG. 1-11 A, A culture is obtained from the drainage from the extraoral sinus tract. **B,** The healed opening of the extraoral sinus tract 1 month after root canal therapy was completed. Note the slight concavity of the skin in the area of the healed extraoral opening.

FIG. 1-13 Fluctuant swelling in the posterior palate associated with periradicular disease from the lingual root of the maxillary first molar.

FIG. 1-12 Fluctuant swelling in the anterior palate associated with periradicular disease from the lingual root of the maxillary first premolar.

FIG. 1-14 Fluctuant swelling in mucobuccal fold associated with periradicular disease from the maxillary central incisor.

in the posterior palate (Fig. 1-13) is most likely associated with the palatal root of one of the maxillary molars.[55,94]

Intraoral swelling present in the mucobuccal fold (Fig. 1-14) can result from an infection associated with the apex of the root of any maxillary tooth that exits the alveolar bone on the facial aspect and is inferior to the muscle attachment present in that area of the maxilla (see also Chapter 15). The same is true with the mandibular teeth if the root apices are superior to the level of the muscle attachments and the infection exits the bone on the facial. Intraoral swelling can also occur in the sublingual space if the infection from the root apex spreads to the lingual and exits the alveolar bone superior to the attachment for the mylohyoid muscle. The tongue will be elevated and the swelling will be bilateral because the sublingual space is contiguous with no midline separation. If the infection exits the alveolar bone to the lingual with mandibular

molars and is inferior to the attachment of the mylohyoid muscle, the swelling will be noted in the submandibular space. Severe infections involving the maxillary and mandibular molars can extend into the parapharyngeal space, resulting in intraoral swelling of the tonsillar and pharyngeal areas. This can be life-threatening if the patient's airway becomes obstructed.[55,94]

Intraoral Sinus Tracts

On occasion a chronic endodontic infection will drain through an intraoral communication to the gingival surface and is known as a *sinus tract*. This pathway,[7] which is sometimes lined with epithelium, extends directly from the source of the infection to a surface opening, or *stoma,* on the attached gingival surface. As previously described, it can also extend extraorally. The term *fistula* is often inappropriately used to describe this type of drainage. The fistula, by definition, is actually an abnormal communication between two internal organs or a pathway between two epithelium-lined surfaces.[1]

Histologic studies have found that most sinus tracts are not lined with epithelium throughout their entire length. Harrison and Larson[40] found only 1 of the 10 sinus tracts they studied were lined with epithelium. The other nine specimens were lined with granulation tissue. In a study with a larger sample size, Baumgartner and colleagues[7] found 20 of 30 specimens did not have epithelium that extended beyond the level of the surface mucosa rete ridges. The remaining 10 specimens had some epithelium that extended from the oral mucosa surface to the periradicular lesion. The presence or absence of an epithelial lining does not seem to prevent closure of the tract as long as the source of the problem is properly diagnosed and adequately treated and the endodontic lesion has healed. Failure of a sinus tract to heal will necessitate further diagnostic procedures to determine whether other etiologic factors are present or whether a misdiagnosis occurred.

In general, a periapical infection that has an associated sinus tract is not painful, although often there is a history of varying magnitude before the sinus tract development. Besides providing a conduit for the release of infectious exudate and the subsequent relief of pain, the sinus tract can also provide a useful aid in determining the source of a given infection. Sometimes objective evidence as to the origin of an odontogenic infection is lacking. The stoma of the sinus tract may be located directly adjacent to or at a distant site from the infection. Tracing the sinus tract will provide objectivity in diagnosing the location of the problematic tooth. To trace the sinus tract, a size #25 gutta-percha cone is threaded into the opening of the sinus tract. Although this may be slightly uncomfortable to the patient, the cone should be inserted until resistance is felt. After a periapical radiograph is exposed, the termination of the sinus tract is determined by following the path taken by the gutta-percha cone (Fig. 1-15). This will direct the clinician to which tooth is involved, and more specifically, which root of that tooth is the source of the pathosis. Once the causative factors related to the development of the sinus tract are removed, the stoma and the sinus tract will close within a few days.

The stomata of intraoral sinus tracts may open in the alveolar mucosa, in the attached gingiva, or through the furcation or gingival crevice. They may exit through either the facial or lingual tissues depending on the proximity of the root apices to the cortical bone. If the opening is in the gingival crevice, it is normally present as a narrow defect in one or two isolated areas along the root surface. When a narrow defect is present, the differential diagnosis must include the opening of a periradicular endodontic lesion, a vertical root fracture, or the presence of a developmental groove on the root surface. This

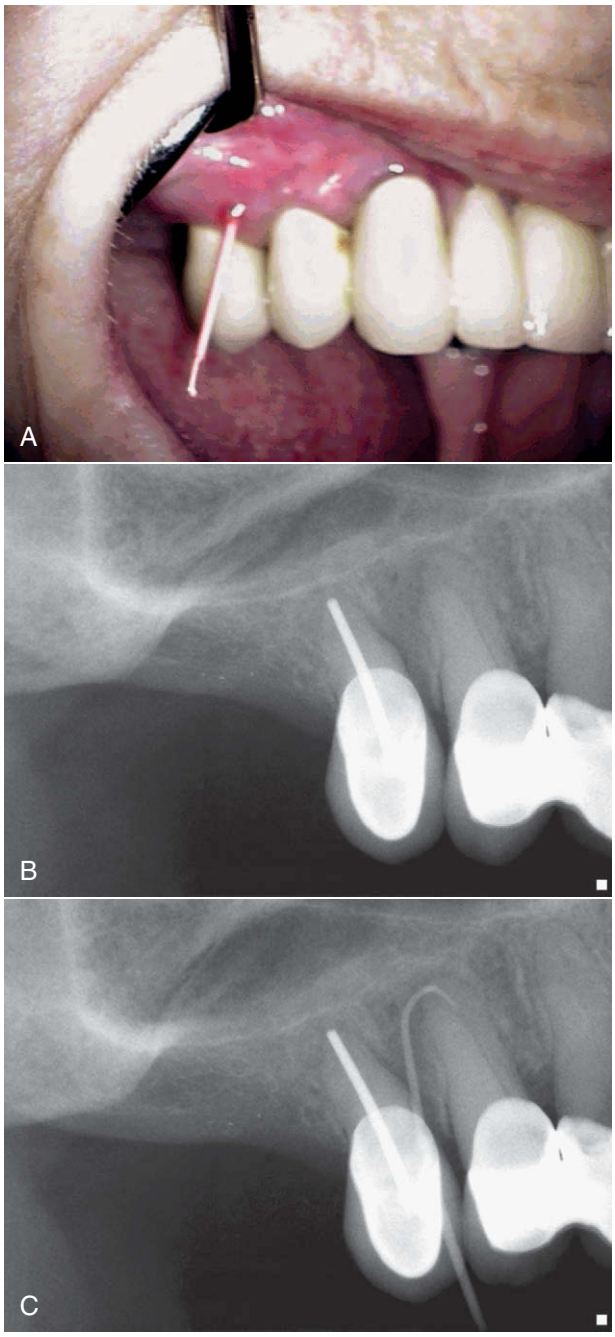

FIG. 1-15 A, To locate the source of an infection, the sinus tract can be traced by threading the stoma with a gutta-percha point. **B,** The radiograph of the area shows an old root canal in tooth #4, and a questionable radiolucent area associated with tooth #5, with no indication of the etiology of the sinus tract. **C,** After tracing the sinus tract, the gutta-percha is seen to be directed to the source of pathosis, the apex of tooth #5.

type of sinus tract can be differentiated from a primary periodontal lesion because the latter generally presents as a pocket with a broad coronal opening and more generalized alveolar bone loss around the root. Other pulp testing methods will assist in verifying the etiology.[39,90,93]

Palpation

In the course of the soft tissue examination, the alveolar hard tissues should also be palpated. Emphasis should be placed on detecting any soft tissue swelling or boney expansion, especially noting how it compares with and relates to the adjacent and contralateral tissues. In addition to objective findings, the clinician should question the patient about any areas that feel unusually sensitive during this palpation part of the examination.

Percussion

Referring back to the patient's chief complaint may indicate the importance of percussion testing for this particular case. If the patient is experiencing acute sensitivity or pain on mastication, this response can typically be duplicated by individually percussing the teeth, which often isolates the symptoms to a particular tooth. Pain to percussion does not indicate that the tooth is vital or nonvital, but is rather an indication of inflammation in the periodontal ligament (i.e., symptomatic apical periodontitis). This inflammation may be secondary to physical trauma, occlusal prematurities, periodontal disease, or the extension of pulpal disease into the periodontal ligament space. The indication of where the pain is coming from is interpreted by the mesencephalic nucleus, receiving its information from proprioceptive nerve receptors. Although subject to debate, the general belief is that there are few, if any, proprioceptors in the dental pulp; however, they are prevalent in the periodontal ligament spaces.[16] This is why it may be difficult for the patient to discriminate the location of dental pain in the earlier stages of pathosis, when only the C fibers are stimulated. Once the disease state extends into the periodontal ligament space, the pain may become more localized for the patient; therefore the affected tooth will be more identifiable with percussion and mastication testing.

Before percussing any teeth, the clinician should tell the patient what will transpire during this test. Because the presence of acute symptoms may create anxiety and possibly alter the patient's response, properly preparing the patient will give more accurate results. The contralateral tooth should first be tested as a control, as well as several adjacent teeth that are certain to respond normally. The clinician should advise the patient that the sensation from this tooth is normal and ask to be advised of any tenderness or pain from subsequent teeth. The testing should initially be done gently, with light pressure being applied digitally with a gloved finger-tapping. If the patient cannot detect any significant difference between any of the teeth, the test should be repeated using the blunt end of an instrument, like the back end of a mirror handle (Fig. 1-16). The teeth should first be percussed occlusally, and if the patient discerns no difference, the test should be repeated, percussing the buccal and lingual aspects of the teeth. For any heightened responses, the test should be repeated as necessary to determine that it is accurate and reproducible, and the information should be documented.

FIG. 1-16 Percussion testing of a tooth, using the back end of a mirror handle.

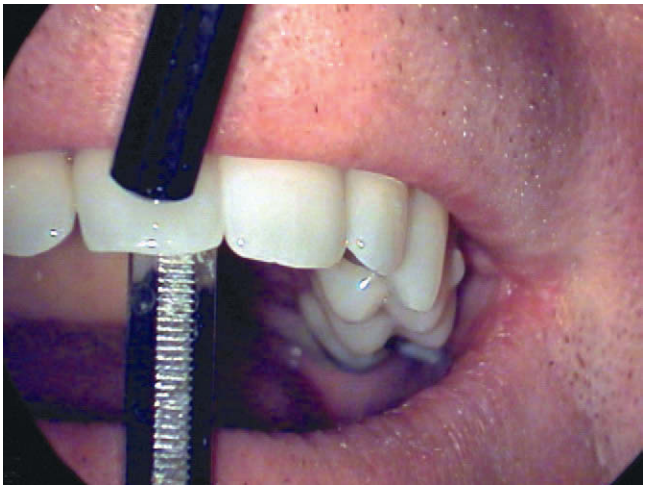

FIG. 1-17 Mobility testing of a tooth, using the back ends of two mirror handles.

Mobility

Like percussion testing, an increase in tooth mobility is not an indication of pulp vitality. It is merely an indication of a compromised periodontal attachment apparatus. This compromise could be the result of acute or chronic physical trauma, occlusal trauma, parafunctional habits, periodontal disease, root fractures, rapid orthodontic movement, or the extension of pulpal disease, specifically an infection, into the periodontal ligament space. Often the mobility reverses to normal after the initiating factors are repaired or eliminated. Because determining mobility by simple finger pressure can be visually subjective, the back ends of two mirror handles should be used, one on the buccal aspect of the tooth, and one on the lingual aspect of the tooth (Fig. 1-17). Any mobility over +1 mobility should be considered abnormal (Box 1-2). However, the teeth should be evaluated on the basis of how mobile they are relative to the adjacent and contralateral teeth.

BOX 1-2

Recording Tooth Mobility

+1 mobility: The first distinguishable sign of movement greater than normal
+2 mobility: Horizontal tooth movement no greater than 1 mm
+3 mobility: Horizontal tooth movement greater than 1 mm, with or without the visualization of rotation or vertical depressability

BOX 1-3

Recording Furcation Defects

Class I furcation defect: The furcation can be probed but not to a significant depth.
Class II furcation defect: The furcation can be entered into but cannot be probed completely through to the opposite side.
Class III furcation defect: The furcation can be probed completely through to the opposite side.

Periodontal Examination

Periodontal probing is an important part of any intraoral diagnosis. The measurement of periodontal pocket depth is an indication of the depth of the gingival sulcus, which corresponds to the distance between the height of the free gingival margin and the height of the attachment apparatus below. Using a calibrated periodontal probe, the clinician should record the periodontal pocket depths on the mesial, middle, and distal aspects of both the buccal and lingual sides of the tooth, noting the depths in millimeters. The periodontal probe is "stepped" around the long axis of the tooth, progressing in 1-mm increments. Periodontal bone loss that is wide, as determined by a wide span of deep periodontal probings, is generally considered to be of periodontal etiology and is typically more generalized in other areas of the mouth. However, isolated areas of vertical bone loss may be of an endodontic etiology, specifically from a nonvital tooth whose infection has extended from the periapex to the gingival sulcus. Again, proper pulp testing is imperative, not just for the determination of a diagnosis but also for the development of an accurate prognosis assessment. For example, a periodontal pocket of endodontic origin may resolve after endodontic treatment, but if the tooth was originally vital with an associated deep periodontal pocket, endodontic treatment will not improve the periodontal condition. In addition, as discussed elsewhere in this chapter, a vertical root fracture may often cause a localized narrow periodontal pocket that extends deep down the root surface. Characteristically, the adjacent periodontium is usually within normal limits.

Furcation bone loss can be secondary to periodontal or pulpal disease. The amount of furcation bone loss, as observed both clinically and radiographically, should be documented (Box 1-3).

Pulp Tests

Pulp testing involves attempting to make a determination of the responsiveness of pulpal sensory neurons. The tests involve thermal or electrical stimulation of a tooth in order to obtain a subjective response from the patient (i.e., to determine whether the pulpal nerves are functional), or the tests may involve a more objective approach using devices that objectively detect the integrity of the pulpal vasculature. Unfortunately, the quantitative evaluation of the status of pulp tissue can only be determined histologically, as it has been shown that there is not necessarily a good correlation between the objective clinical signs and symptoms and the pulpal histology.[91,92]

Thermal

Various methods and materials have been used to test the pulp's response to thermal stimuli. The baseline or normal response to either hot or cold is a patient's report that a sensation is felt but disappears immediately on removal of the thermal stimulus. Abnormal responses include a lack of response to the stimulus, the lingering or intensification of a painful sensation after the stimulus is removed, or an immediate, excruciatingly painful sensation as soon as the stimulus is placed on the tooth.

Heat testing is most useful when a patient's chief complaint is intense dental pain on contact with any hot liquid or food. When a patient is unable to identify which tooth is sensitive, a heat test is appropriate. Starting with the most posterior tooth in that area of the mouth, each tooth is individually isolated with a rubber dam. An irrigating syringe is filled with a liquid (most commonly plain water) that has a temperature similar to that which would cause the painful sensation. The liquid is then expressed from the syringe onto the isolated tooth to determine whether the response is normal or abnormal. The clinician moves forward in the quadrant, isolating each individual tooth until the offending tooth is located. That tooth will exhibit an immediate, intense painful response to the heat. With heat testing a delayed response may occur, so waiting 10 seconds between each heat test will allow sufficient time for any onset of symptoms.

Another method for heat testing is to apply heated gutta-percha or compound stick to the surface of the tooth. If this method is used, a light layer of lubricant should be placed onto the tooth surface before applying the heated material to prevent the hot gutta-percha or compound from adhering to the dry tooth surface. Heat can also be generated by the friction created when a dry rubber-polishing wheel is run at a high speed against the dry surface of a tooth. However, this latter method is seldom used today.

If the heat test confirms the results of other pulp testing procedures, emergency care can then be provided. Often a tooth that is sensitive to heat may also be responsible for some spontaneous pain. In these cases the patient may present with cold liquids in hand just to minimize the pain (Fig. 1-18). In these cases, the application of cold to a specific tooth may eliminate the pain and greatly assist in the diagnosis. Typically, a tooth that responds to heat and then is relieved by cold is found to be necrotic.

Cold is the primary pulp testing method for many clinicians today. To be most reliable, cold testing should be used in conjunction with an electric pulp tester so that the results

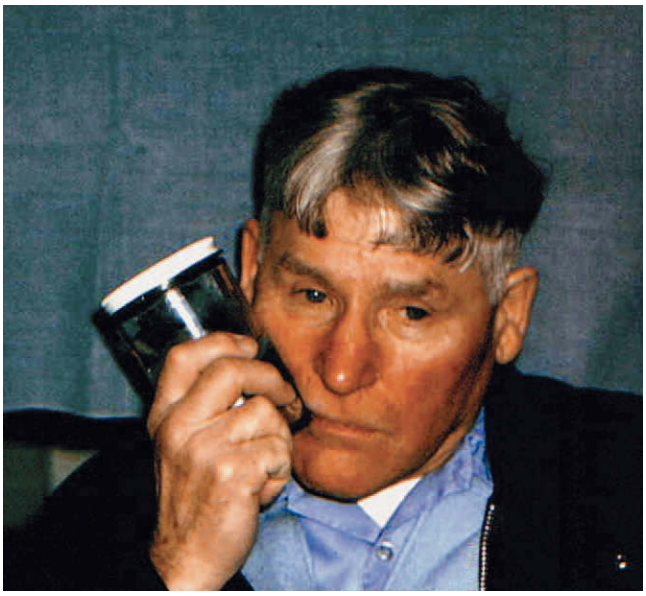

FIG. 1-18 Patient has irreversible pulpitis associated with the mandibular right second molar and has found that the only way to alleviate the pain is to place a jar filled with ice water against the right side of his face.

from one test will verify the findings of the other test. If a mature, untraumatized tooth does not respond to both electric pulp test and cold test, then the pulp should be considered necrotic.[71] However, a multirooted tooth, with at least one root containing vital pulp tissue, may respond to a cold test even if one or more of the roots contain necrotic pulp tissue.[71] Cold testing can be accomplished similarly to heat testing, by individually isolating teeth with a rubber dam. This technique for cold testing is especially useful for patients presenting with porcelain jacket crowns or porcelain-fused-to-metal crowns where there is no natural tooth surface (or much metal) accessible. Another benefit of this technique for cold testing is that it requires no armamentarium except for a rubber dam. If a clinician chooses to perform this test with sticks of ice, then the use of the rubber dam is recommended because melting ice will run onto adjacent teeth and gingiva, yielding potentially false-positive responses.

Frozen carbon dioxide (CO_2), also known as *dry ice* or *carbon dioxide snow,* has been found to be reliable in eliciting a positive response if vital pulp tissue is present in the tooth.[32,71,72] One study found that vital teeth would respond to both CO_2 and skin refrigerant, with skin refrigerant producing a slightly quicker response.[48] Carbon dioxide has also been found to be effective in evaluating the pulpal response in teeth with full coverage crowns for which electric pulp testing is not possible.[6] For testing purposes a solid stick of CO_2 is prepared by delivering CO_2 gas into a specially designed plastic cylinder (Fig. 1-19). The resulting CO_2 stick is applied to the facial surface of either the natural tooth structure or crown. Several teeth can be tested with a single CO_2 stick. The teeth should be isolated and the oral soft tissues should be protected with a 2 × 2-in. gauze or cotton roll so the CO_2 will not come into contact with these structures. Because of the extremely cold temperature of the CO_2 (−69° F to −119° F; −56° C to −98° C) burns of the soft tissues can occur. Investigators[6] have demonstrated on extracted teeth that CO_2 application resulted in a significantly greater intrapulpal temperature decrease than either skin refrigerant or ice. Studies[45,77] have also shown that the application of CO_2 to teeth does not result in any irreversible damage to the pulp tissues or cause any significant enamel crazing.

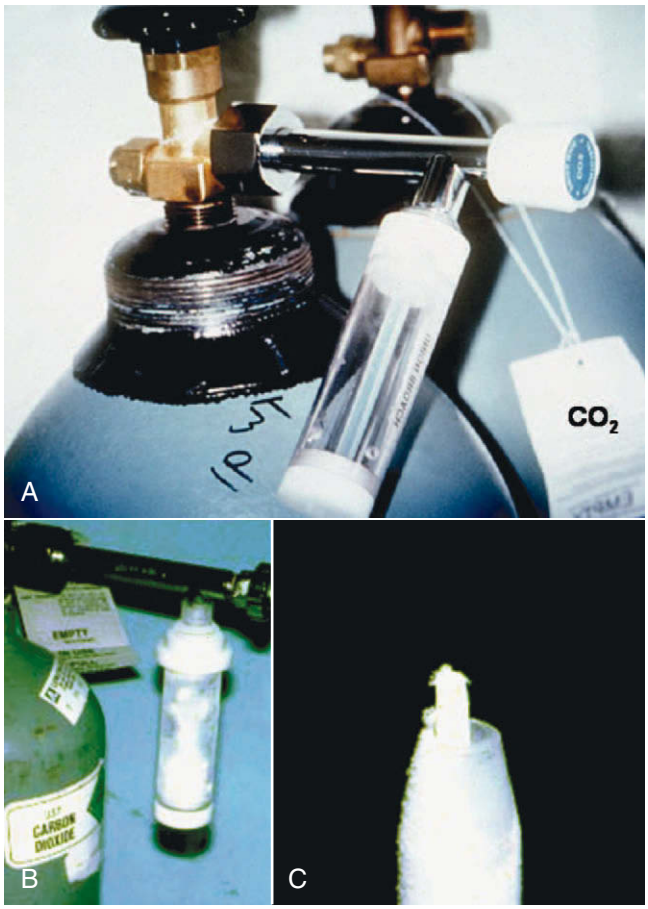

FIG. 1-19 A, Carbon dioxide tank with apparatus attached to form solid CO_2 stick/pencil. **B,** CO_2 gas being formed into a solid stick/pencil. **C,** CO_2 stick/pencil being extruded from the end of the plastic carrier.

The most popular method of performing cold testing is with a refrigerant spray. It is readily available, easy to use, and provides test results that are reproducible, reliable, and equivalent to that of CO_2.[32,48] One of the current product contains 1,1,1,2-tetrafluoroethane, which has zero ozone depletion potential and is environmentally safe. It has a temperature of −26.2° C.[48] The spray is most effective for testing purposes when it is applied to the tooth on a large #2 cotton pellet (Fig. 1-20). In one study[47] a significantly lower intrapulpal temperature was achieved when a #2 cotton pellet was dipped or sprayed with the refrigerant compared with the result when a small #4 cotton pellet or cotton applicator was used. The sprayed cotton pellet should be applied to the midfacial area of the tooth or crown. As with any other pulp testing method, adjacent or contralateral "normal" teeth should be tested to establish a baseline response. It appears that CO_2 and refrigerant spray are superior to other cold testing methods and equivalent or superior to the electric pulp tester for assessing pulp vitality.[6,32]

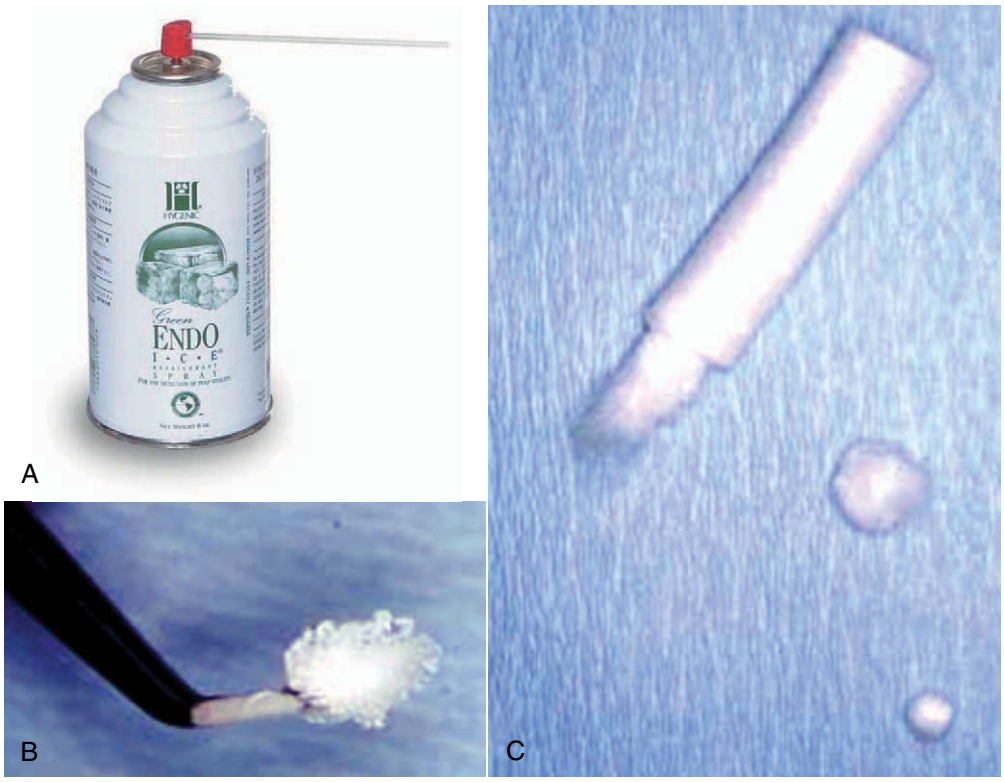

FIG. 1-20 A, Refrigerant spray container. **B,** A cotton roll can be used to form a large cotton pellet, or a size #2 (large) cotton pellet can be used to apply the refrigerant spray to the tooth surface. The small #4 cotton pellet does not provide as much surface area as the #2 cotton pellet, and therefore it should not be used to deliver the refrigerant to the tooth surface. **C,** A large cotton pellet that has been sprayed with the refrigerant and is ready to be applied to the tooth surface. One study[72] compared the ability of thermal and electric pulp testing methods to register the presence of vital pulp tissue. The *sensitivity,* which is the ability of a test to identify teeth that are diseased, was 0.83 for the cold test, 0.86 for heat test, and 0.72 for the electric test. This means the cold test correctly identified 83% of the teeth that had a necrotic pulp, whereas heat tests were correct 86% of the time and electric pulp tests were correct only 72% of the time. This same study evaluated the *specificity* of these three tests. Specificity relates to the ability of a test to identify teeth without disease. Ninety-three percent of teeth with healthy pulps were correctly identified by both the cold and electric pulp tests, whereas only 41% of the teeth with healthy pulps were identified correctly by the heat test. From the results of the testing it was found that the cold test had an accuracy of 86%, the electric pulp test 81%, and the heat test 71%.

Electric

Assessment of pulp vitality is most frequently accomplished by electric pulp testing and/or cold testing. The vitality of the pulp is determined by the intactness and health of the vascular supply, not the status of the pulpal nerve fibers. Even though advances are being made with regard to determining the vitality of the pulp on the basis of the blood supply, this technology is not accurate enough at this time to be used on a routine basis in a clinical setting.

The electric pulp tester has limitations in providing information about the vitality of the pulp. The response of the pulp to electric testing does not reflect the histologic health or disease status of the pulp.[91,92] A response by the pulp to the electric current only denotes that some viable nerve fibers are present in the pulp and are capable of responding. Numerical readings on the pulp tester have significance only if the number differs significantly from the readings obtained from a control tooth tested on the same patient with the electrode positioned at a similar area on both teeth. However, in most cases, the response is scored as either present or absent. Studies[91,92] have shown that electric pulp test results are most accurate when no response is obtained to any amount of electric current. This lack of response has been found most frequently when a necrotic pulp is present. The electric pulp tester will not work unless the probe can be placed in contact with or be bridged[69] to the natural tooth structure. With the advent of universal precautions for infection control, the patient may be required to place a finger or fingers on the tester probe to complete the electric circuit for some models; however, lip clips are an alternative to having patients hold the tester. The use of rubber gloves prevents the clinician from completing the circuit.[3] Proper use of the electric pulp tester requires that the teeth to be evaluated be isolated and dried. A control tooth of similar tooth type and location in the arch should be tested first in order to establish a baseline response and to inform the patient what a "normal" sensation is. The suspected tooth should be tested at least twice to confirm the results. The tip of the testing probe that will be placed in contact with the tooth structure must be coated with a water- or petroleum-based medium.[62] The most commonly used medium is toothpaste. The coated probe tip is placed in the incisal third of the facial or buccal area of the tooth to be tested.[10] Once the probe is in contact with the tooth, the patient is asked to touch or grasp the tester probe (Fig. 1-21, *A*).[3] This completes the circuit and initiates the delivery of electric current to the tooth. The patient is instructed to remove his or her finger(s) from the probe when a "tingling" or "warming" sensation is felt in the tooth. The

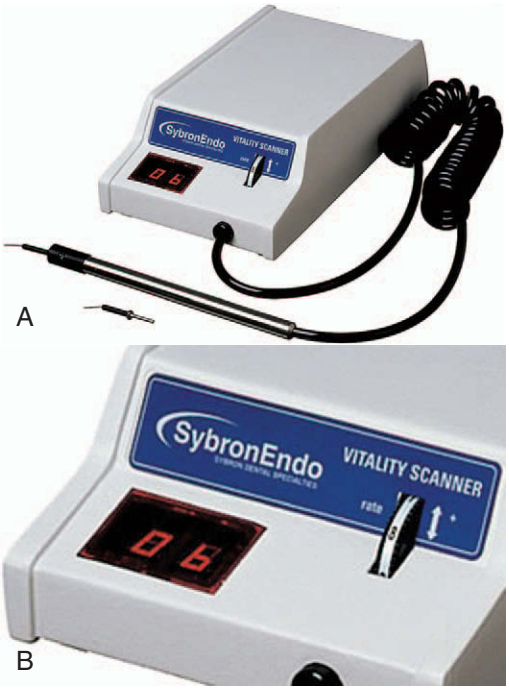

FIG. 1-21 A, View of an electric pulp tester with probe. The probe tip will be coated with a medium such as toothpaste and placed in contact with the tooth surface. The patient will activate the unit by placing a finger on the metal shaft of the probe. **B,** View of the electric pulp tester control panel: The knob on the right front of the unit controls the rate at which the electric current is delivered to the tooth. The plastic panel on the left front displays the digital numerical reading obtained from the pulp test. The digital scale runs from 0 to 80. *(Courtesy SybronEndo, Orange, Calif.)*

readings from the pulp tester are recorded (Fig. 1-21, B) and will be evaluated once all the appropriate teeth have been tested and the results obtained from other pulp testing methods.

If a complete coverage crown or extensive restoration is present, a bridging technique can be attempted to deliver the electric current to any exposed natural tooth structure.[69] The tip of an endodontic explorer is coated with toothpaste or other appropriate medium and placed in contact with the natural tooth structure. The tip of the electric pulp tester probe is coated with a small amount of toothpaste and placed in contact with the side of the explorer. The patient completes the circuit and the testing proceeds as described previously. If no natural tooth structure is available then an alternative pulp testing method, such as cold, should be used.

As noted previously, studies[32,71,72] have shown that there does not appear to be any significant difference between the pulp testing results obtained with the electric pulp tester and those obtained by the thermal methods, although cold tests have been shown to be more reliable than electric pulp tests in younger patients with less developed root apices.[71] However, unlike electric pulp testing, cold testing can reveal the health and integrity of pulp tissue (i.e., no response, a momentary response, or a prolonged, painful response after the thermal stimulus is removed). This is why it is a good rationale to verify the results obtained by one testing method by comparing them with the results obtained by the other method. Until such time that the testing methods used to assess the vascular supply of the pulp become less time-consuming and technique-sensitive, thermal and electric pulp testing will continue to be the primary methods for determining pulp vitality.

Laser Doppler Flowmetry

Laser Doppler flowmetry (LDF) is a method used to assess blood flow in microvascular systems. Attempts are being made to adapt this technology to assess pulpal blood flow. A diode is used to project an infrared light beam through the crown and pulp chamber of a tooth. The infrared light beam is scattered as it passes through the pulp tissue. The Doppler principle states that the light beam will be frequency-shifted by moving red blood cells but will remain unshifted as it passes through static tissue. The average Doppler frequency shift will measure the velocity at which the red blood cells are moving.[81]

Several studies[25,44,61,81-83] have found LDF to be an accurate, reliable, and reproducible method of assessing pulpal blood flow. Even with these positive findings, the technology is not advanced enough for this method to be used on a routine basis in a dental practice. In one clinical trial[25] fabricating the individualized stabilization jig, making the LDF recordings took approximately 1 hour, a finding not unique to this study. If technology can be developed whereby testing by LDF can be accomplished in minutes, it will likely replace the thermal and electric pulp testing methods.

As is discussed in Chapter 16, certain luxation injuries will cause inaccuracies in the results of electric and thermal pulp testing. LDF has been shown to be a great indicator for pulpal vitality in these cases.[96]

Pulse Oximetry

One of the great advantages of pulp testing with devices such as the laser Doppler flowmeter is that the collected data are based on objective findings rather than subjective patient responses. The pulse oximeter is another such noninvasive device (Fig. 1-22). Widely used in medicine, it is designed to measure the oxygen concentration in the blood and the pulse rate. A pulse oximeter works by transmitting two wavelengths of light, red and infrared, through a translucent portion of a patient's body (e.g., a finger, earlobe, or tooth). Some of the light is absorbed as it passes through the tissue; how much is absorbed depends on the ratio of oxygenated to deoxygenated hemoglobin in the blood. On the opposite side of the targeted tissue, a sensor detects the absorbed light, and on the basis of

the difference between the light emitted and the light received, a microprocessor calculates the pulse rate and oxygen concentration in the blood.[84] The transmission of light to the sensor requires that there be no obstruction from restorations, which can sometimes limit the usefulness of pulse oximetry to test pulp vitality.

Attempts to use the pulse oximeter to diagnosis pulp vitality have met with mixed results. Some studies[84,103] have reported that pulse oximetry is a reliable method for assessing pulp vitality. Others[103] have stated that in its present form the pulse oximeter is not of predictive diagnostic value for diagnosing pulp vitality. Most of the problems appear to be related to the currently available technology. Some investigators have concluded that these devices used for pulp testing are too cumbersome and complicated to be used on a routine basis in a dental practice.[50,84,103] However, Gopikrishna and colleagues[37] developed a sensor that can be directly applied to a tooth for assessing human pulp vitality and found it more accurate than electric and thermal pulp tests. This device has been especially useful in evaluating teeth that have been subjected to traumatic injuries,[38] because these teeth tend to present, especially in the short term, with questionable vitality using conventional pulp testing methods.[4]

Special Tests

Bite Test

Percussion and bite tests are indicated when a patient presents with pain while biting. On occasion, the patient may not know which tooth is sensitive to biting pressure, and percussion and bite tests may help to localize the tooth involved. The tooth may be sensitive to biting when the pulpal pathosis has extended into the periodontal ligament space, creating a *periradicular periodontitis,* or the sensitivity may be present secondary to a crack in the tooth. The clinician can often differentiate between periradicular periodontitis and a cracked tooth or fractured cusp. If periradicular periodontitis is present, the tooth will respond with pain to percussion and biting tests regardless of where the pressure is applied to the coronal part of the tooth. A cracked tooth or fractured cusp will elicit pain only when the percussion or bite test is applied in a certain direction to one cusp or section of the tooth.[15,80]

For the bite test to be meaningful a device should be used that will allow the clinician to apply pressure to individual cusps or areas of the tooth. A variety of devices have been used for bite tests, including cotton applicators, toothpicks, orangewood sticks, and rubber polishing wheels. Today several devices are specifically designed to perform this test. The Tooth Slooth (Professional Results, Laguna Niguel, CA) (Fig. 1-23) and FracFinder (Hu-Friedy, Oakbrook, IL) are just two of the commercially available devices used for the bite test. As with all pulp tests, adjacent teeth should be used as controls so that the patient is aware of the "normal" response to these tests. The small cupped-out area on these instruments is placed in contact with the cusp to be tested. The patient is then asked to apply biting pressure with the opposing teeth to the flat surface on the opposite side of the device. The biting pressure should be applied slowly until full closure is achieved. The firm pressure should be applied for a few seconds; the patient is then asked to release the pressure quickly. Each individual cusp on a tooth can be tested in a like manner. The clinician should note whether the pain is elicited during the pressure phase or on quick release of the pressure. A common finding with a fractured cusp or cracked tooth is the frequent presence of pain on release of biting pressure.

FIG. 1-23 To determine which tooth is sensitive to mastication and which part of that tooth is sensitive, having the patient bite on a specially designed bite stick is often helpful.

Test Cavity

The test cavity method for assessing pulp vitality is seldom used today. This method is used only when all other test methods are deemed impossible or the results of the other tests are inconclusive. An example of a situation in which this method might be used is when the tooth suspected of having pulpal disease has a full coverage crown. If no sound tooth structure is available to use a bridging technique with the electric pulp tester and cold test results are inconclusive, a small class I cavity preparation is made through the occlusal surface of the crown. This is accomplished with a high-speed #1 or #2 round bur with proper air and water coolant. The patient is not anesthetized while this procedure is performed, and the patient is asked to respond if any painful sensation is felt during the drilling procedure. If the patient feels pain once the bur contacts sound dentin, the procedure is terminated and the class I cavity preparation is restored. This sensation signifies only that there is some viable nerve tissue remaining in the pulp, not that the pulp is totally healthy. If the patient fails to feel any sensation when the bur reaches the dentin, it is a good indication that the pulp is necrotic and root canal therapy is indicated.

Staining and Transillumination

To determine the presence of a crack in the surface of the tooth, the application of a stain to the area is often of great assistance. Applying a bright fiberoptic light probe to the surface of the tooth is also helpful. This will be elaborated on later in this chapter in the discussion of the detection of cracks and fractures.

Selective Anesthesia

When symptoms are not localized or referred, the diagnosis may be challenging. Sometimes the patient may not even be

able to specify whether the symptoms are emanating from the maxillary or mandibular arch. In these instances, when pulp testing is inconclusive, *selective anesthesia* may be helpful.

If the patient cannot determine which arch the pain is coming from, then the clinician should first selectively anesthetize the maxillary arch. This should be accomplished by using a periodontal ligament (intraligamentary) injection. The injection is administered to the most posterior tooth in the quadrant of the arch that may be suspected, starting from the distal sulcus. The anesthesia is subsequently administered in an anterior direction, one tooth at a time, until the pain is eliminated. If, after an appropriate period of time, the pain is not eliminated, the clinician should similarly repeat this technique on the mandibular teeth below. It should be understood that periodontal ligament injections may inadvertently anesthetize an adjacent tooth, and thus are more useful for identifying the arch rather than the specific tooth.

Radiographic Examination and Interpretation

Intraoral Radiographs

Few diagnostic tests provide as much useful information as dental radiography. For this reason, the clinician is sometimes tempted to prematurely make a definitive diagnosis based solely on radiographic interpretation. However, the image should be used only as one sign, providing important clues in the diagnostic investigation. When not coupled with a proper history and clinical examination and testing, the radiograph alone can lead to a misinterpretation of normality and pathosis (Fig. 1-24). Because treatment planning will ultimately be based on this diagnosis, the potential for inappropriate treatment may be great if the radiograph alone is used for making this diagnosis. The clinician should not subject the patient to unnecessary multiple radiation exposures; often two pretreatment images from different angulations are sufficient. But in extenuating circumstances, especially when the diagnosis is difficult, multiple exposures may be necessary in order to determine the presence of multiple roots, multiple canals, resorptive defects, caries, restoration defects, root fractures, and the extent of root maturation and apical development.

The radiographic appearance of endodontic pathosis can sometimes be highly subjective. In a study by Goldman and colleagues,[34] there was agreement for the presence of pathosis in only 50% of the radiographically evaluated cases, as interpreted by two endodontists, three second-year residents, and an associate professor in radiology. In addition, when the cases were evaluated several months later, the evaluators agreed with their own original diagnosis only 75% to 83% of the time. Again, this emphasizes the necessity for other objective diagnostic tests, as well as the importance of obtaining and comparing older radiographs.

For standard two-dimensional radiography, clinicians basically project x-radiation through an object and capture the image on a recording medium—either x-ray film or a digital sensor. Much like casting a shadow from a light source, the image appearance may vary greatly depending on how the radiographic source is directed. Therefore, the three-dimensional interpretation of the resulting two-dimensional image requires not only knowledge of normality and pathosis but also advanced knowledge of how the radiograph was exposed. By virtue of "casting a shadow," the anatomic features

FIG. 1-24 Radiograph of what appears to be a periapical lesion associated with a nonvital tooth; however, the tooth is vital. The appearance of apical bone loss is actually secondary to a cementoma.

that are closest to the film (or sensor) will move the least when there is a change in the horizontal or vertical angulation of the radiation source (Fig. 1-25). This may be helpful in determining the existence of additional roots, the location of pathosis, and the unmasking of anatomic structures. Changes in the horizontal or vertical angulation may help elucidate valuable anatomic and pathologic information; it also has the potential to hide important information. An incorrect vertical angulation may cause the buccal roots of a maxillary molar to be masked by the zygomatic arch. An incorrect horizontal angulation may cause roots to overlap with the roots of adjacent teeth, or it may incorrectly create the appearance of a one-rooted tooth, when two roots are actually present.

In general, when endodontic pathosis appears radiographically, it appears as bone loss in the area of the periapex. The infection in the pulpal space transgresses through the pulp canal space and into the adjacent alveolar bone. The pathosis may present merely as a widening or break in the lamina dura—the most consistent radiographic finding when a tooth is nonvital[49]—or it may present as a radiolucent area at the apex of the root or in the alveolar bone adjacent to the exit of a lateral or furcation canal. On occasion there may be no radiographic change at all, even in the presence of an acute periradicular abscess.

Variability in the radiographic expression of an osseous pathosis has much to do with the relative location of the root of the tooth and how it is oriented with respect to the cortical and cancellous bone. Radiographic changes from bone loss will

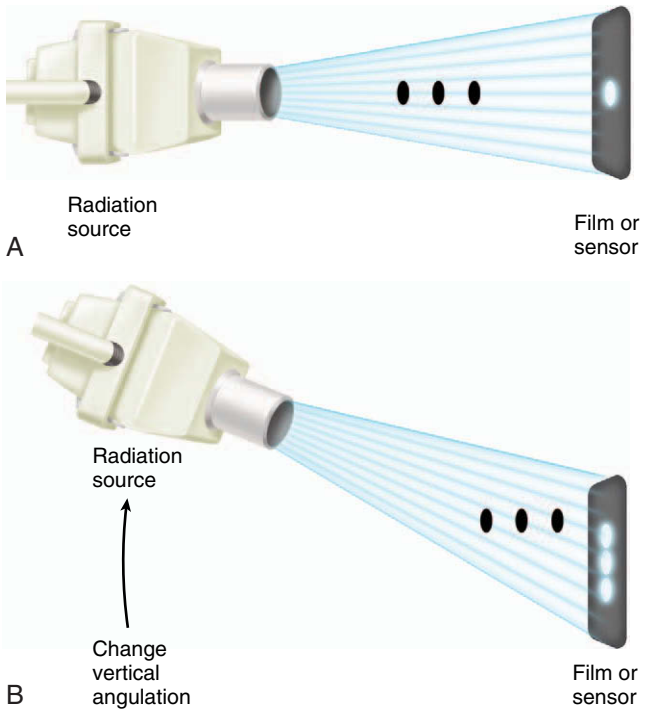

FIG. 1-25 Radiographic images are only two-dimensional, and often it is difficult to discriminate the relative location of overlapping objects. **A,** When the source of the radiation is directly perpendicular to overlapping objects, the image is captured without much separation of the objects. However, when the radiation source is at an angle to offset the overlapping objects, the image is captured with the objects being viewed as separated. **B,** The object that is closest to the film (or sensor) will move the least, with the object closest to the radiation source appearing farthest away.

not be detected if the bone loss is only in cancellous bone. However, radiographic evidence of pathosis will be observed once this bone loss extends to the junction of the cortical and cancellous bone, as was illustrated by Bender and Seltzer,[11] who created artificial lesions in cadaver bone and evaluated them radiographically. As a follow-up to this study, the authors reported why certain teeth are more prone to exhibit radiographic changes than others, depending on their anatomic location.[12] Their findings revealed that the radiographic appearance of endodontic pathosis is correlated with the relationship of the periapex of the tooth and its juxtaposition to the cortical–cancellous bone junction. Most anterior and premolar teeth are located close to the cortical–cancellous bone junction. For this reason, periapical pathosis from these teeth is exhibited sooner. By comparison, the distal roots of mandibular first molars and both roots of mandibular second molars are generally positioned more centrally within the cancellous bone, as are maxillary molars, especially the palatal roots. Periapical lesions from these roots must expand more before they reach the cortical–cancellous bone junction and are recognized as radiographic pathosis. For these reasons, it is important not to exclude the possibility of pulpal pathosis in situations in which there are no radiographic changes.

Many factors can influence the quality of the radiographic interpretation, including the ability of the person exposing the radiograph, the quality of the radiographic film, the quality of the exposure source, the quality of the film processing, and the skill with which the film is viewed. Controlling all of these variables can be a difficult challenge but is paramount for obtaining an accurate radiographic interpretation.

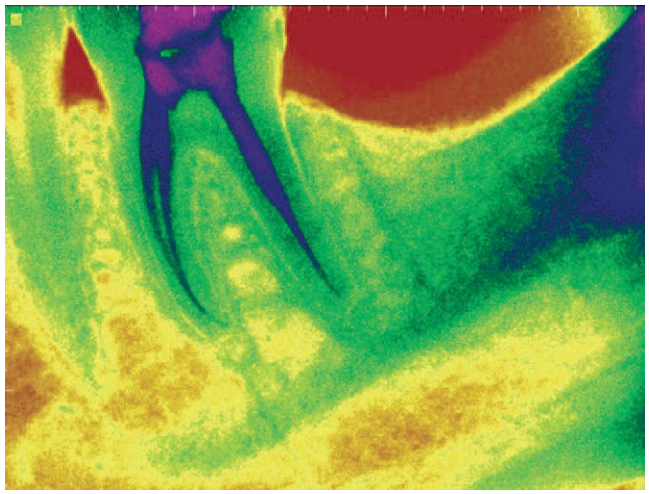

FIG. 1-26 Digital radiography has an advantage over conventional film in that the image can be enhanced and colorized, a useful tool for patient education.

Digital Radiography

One technique for controlling many of the variables in the diagnostic quality of conventional radiography has been the advent of *digital radiography*. This technology has been available for approximately 20 years but has more recently been refined with better hardware and more user-friendly software. Digital radiography has the ability to capture, view, magnify, enhance, and store radiographic images in an easily reproducible format that does not degrade over time.

Digital radiography uses no x-ray film and requires no chemical processing. Instead, a *sensor* is used to capture the image created by the radiation source. This sensor is either directly or remotely attached to a local computer, which interprets this signal and, using specialized software, translates the signal into a two-dimensional digital image that can be displayed and enhanced. The image is stored in the patient's file, typically in a dedicated network server, and can be recalled as needed. Further information about digital radiography may be found in Chapter 5 and online Chapters 28 and 29.

The viewing of a digital radiographic image on a high-resolution monitor allows for rapid and easy interpretation for both the clinician and the patient. The image appears almost instantly, with no potential for image distortion from improper chemical processing, because there is none. The clinician can zoom in to different areas on the x-ray image, digitally enhance the image in order to better visualize certain anatomic structures, and in some cases the image can even be colorized, a useful tool for patient education (Fig. 1-26).

Until recently, x-ray film has had a slightly better resolution than most digital radiography images, at about 16 line pairs per millimeter (lp/mm).[63] However, some sensor manufacturers are now claiming to have resolutions beyond that of film and up to 22 lp/mm. Under the best of circumstances, the human eye can see only about 10 lp/mm, which is the lowest

resolution for most dental digital radiography systems. The digital sensors are much more sensitive to radiation than conventional x-ray film and thus require 50% to 90% less radiation in order to acquire an image, an important feature for generating greater patient acceptability of dental radiographs.

The diagnostic quality of this expensive technology has been shown to be comparable to, but not necessarily superior to, perfectly exposed and perfectly processed conventional film-based radiography.[24,52,70] However, digital radiography has the advantage over conventional film in that there is no diminution in diagnostic quality caused by developing and processing errors, and it has the ability to enhance, magnify, store, and electronically send the images, as well the ability to duplicate the original radiograph as a perfect copy. In 1998, the American Association of Endodontists (Chicago, IL) predicted that "digital radiography will rapidly replace conventional dental X-rays."[2] The reader is referred to Chapters 28 and 29 for more information about digital radiography.

Cone-Beam Volumetric Tomography

The radiographic interpretation of a potential endodontic pathosis is an integral part of endodontic diagnosis and prognosis assessment. Until about 10 years ago, routine dental radiography consisted of only two-dimensional imaging. But limitations in conventional radiography promulgated a need for three-dimensional imaging, known as *cone-beam volumetric tomography* (CBVT) (also known as *cone-beam volumetric imaging* [CBVI] or cone-beam computerized tomography [CBCT]). Although a form of this technology has existed since the early 1980s,[79] these devices first appeared specifically for use in dentistry in 1998.[65] Most of these machines are similar to a dental panoramic radiographic device, whereby the patient stands or sits as a cone-shaped radiographic beam is directed to the target area with a reciprocating capturing sensor on the opposite side (Fig. 1-27). The resulting information is digitally reconstructed and interpreted to create an interface whereby the clinician can three-dimensionally interpret "slices" of the patient's tissues in a multitude of planes (Figs. 1-28 and 1-29). The survey of the scans can be directly interpreted immediately after the scan. Various software applications have been used to enable the images to be sent to other clinicians. This is accomplished either in printed format or with portable and transferable software that can be interactively used by another clinician.

In general, the dental clinician will desire a limited field of vision, confining the study to the maxilla and mandible. However, many devices have the ability to provide a full field of vision for viewing more regional structures. Clinicians should thoroughly understand the ethical and medical–legal ramifications of doing scans with full fields of view. Incidental nondental findings have been seen from these scans, such as

FIG. 1-27 Cone-beam volumetric tomography, using the 3D Accuitomo 80. *(Courtesy J. Morita USA, Irvine, Calif.)*

FIG. 1-28 Cone-beam volumetric tomography has the ability to capture, store, and present radiographic images in various horizontal and vertical planes. *(Courtesy J. Morita USA, Irvine, Calif.)*

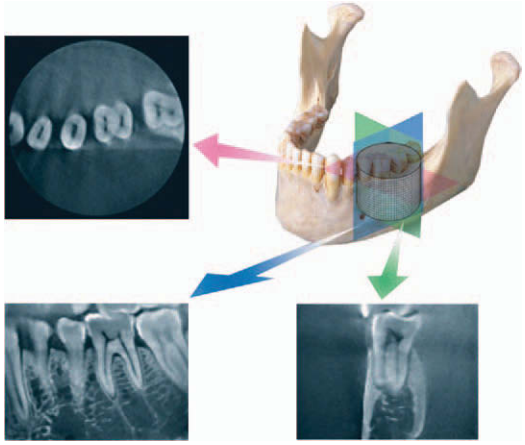

FIG. 1-29 Cone-beam volumetric tomography has the advantage of being able to detect pathosis in the bone or associated with the teeth without the obstruction of anatomic structures. The planes of vision may be axial, sagittal, or coronal. *(Courtesy J. Morita USA, Irvine, Calif.)*

intracranial aneurysms, that when undetected could be life-threatening.[66] The radiation source of CBVT is different from that of conventional two-dimensional dental imaging in that the radiation beam created is conical in shape. Also, conventional digital dental radiography is captured and interpreted as "pixels," a series of "dots" that collectively produces an image of the scanned structure. For CBVT, the image is instead captured as a series of three-dimensional pixels, known as *voxels*. Combining these voxels gives a three-dimensional image that can be "sliced" into various planes, allowing for specific evaluations never before possible without a necropsy (Fig. 1-30). One of the advantages of using a device that has a limited field of vision is that the voxel size can be less than half that of a device using a full field of vision, thereby increasing the resolution of the resulting image, providing for a more accurate interpretation of anatomic structures. The development of limited field of vision devices has also contributed to decreasing the costs of these relatively expensive machines, making them more practical for dental office use.[27]

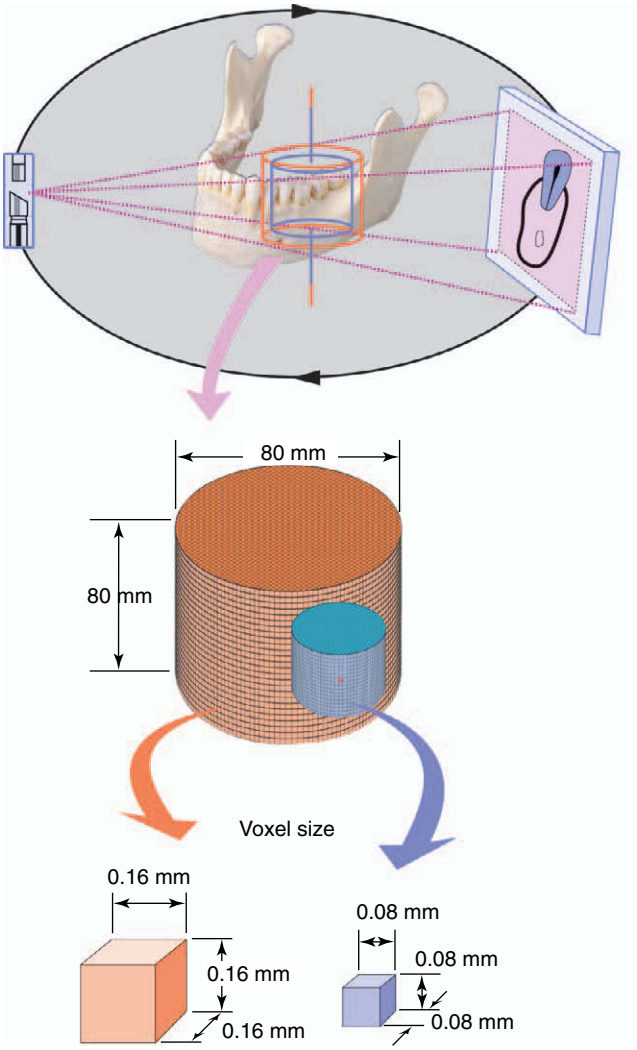

FIG. 1-30 The radiation source in cone-beam volumetric tomography is conical. The receiving sensor captures the image as "voxels," or three-dimensional pixels of information, allowing digital interpretation.

Two-dimensional dental radiography has two basic shortcomings: the lack of early detection of pathosis in the cancellous bone because of the density of the cortical plates, and the influence of the superimposition of anatomic structures. In 1961, Bender and Seltzer[11,12] showed that artificially created "lesions" in cancellous bone were radiographically undetected unless the bone loss extended to the junction between the cancellous and cortical bone. Therefore, an infection that is present only in the cancellous bone will typically not be radiographically visible. Consistent with this finding, if the root of a nonvital infected tooth is closer to the cortical bone (e.g., the *mesial* root of a mandibular first molar), the pathosis will be detected sooner than if the infected root is more centered within the cancellous bone (e.g., the *distal* root of a mandibular first molar). Because CBVT can clearly visualize the interior of the cancellous bone without the superimposition of the cortical bone, these boney defects may be more easily detected. In 2007, Lofthag-Hansen and colleagues[57] studied 48 teeth with "endodontic problems," using both standard periapical radiographs and CBVT. Three different oral radiologists reviewed the scans. They found demonstrable lesions associated with 32 of these teeth, using standard periapical radiographs, but found pathosis associated with 42 teeth when using CBVT. In addition, 53 roots from these teeth were found to have pathosis associated with them, using standard periapical radiographs, whereas when using CBVT, 86 roots were found to have associated pathosis. Nakata and colleagues[67] showed how periapical bone loss associated with a palatal root was detected by CBVT when it was not visible in conventional periapical radiographs. The superimposition of anatomic structures can also mask the interpretation of alveolar defects. Specifically, the maxillary sinus, zygoma, incisive canal and foramen, nasal bone, orbit, mandibular oblique ridge, mental foramen, mandibular mentalis, sublingual salivary glands, tori, and the overlap of adjacent roots may either obscure bone loss or mimic bone loss, making an accurate radiographic interpretation sometimes difficult or impossible. Cotton and colleagues[19] presented seven case reports in which CBVT was invaluable in ascertaining information essential for making a diagnosis related to alveolar pathoses. These scans revealed an incomplete root canal, a large incisive foramen suspicious of being a lesion of endodontic origin, a root fracture, internal resorption, cervical resorption, root canal cement extruded with symptoms associated with the mental nerve, and a lesion associated with a failed implant that was originally thought to have been of endodontic origin from an adjacent tooth. In 2001, Velvart and colleagues[102] found 100% accuracy with CBVT scans predicting 78 periapical lesions that were then confirmed by surgical biopsy. However, when applying conventional radiographic imaging to these same cases, they found that only 78% of these lesions could be detected.

Cone-beam volumetric tomography should not be seen as a replacement for conventional dental radiography, but rather as a diagnostic adjunct. The advantage of conventional dental radiography is that it can visualize most of the structures in one image. CBVT, although it can show great detail in many planes of vision, can also leave out important details if the "slice" is not in the area of existing pathosis (Fig. 1-31). There is a promising future for the use of CBVT for endodontic diagnosis. It has already proven invaluable in the detection of dental and nondental pathoses (Fig. 1-32).

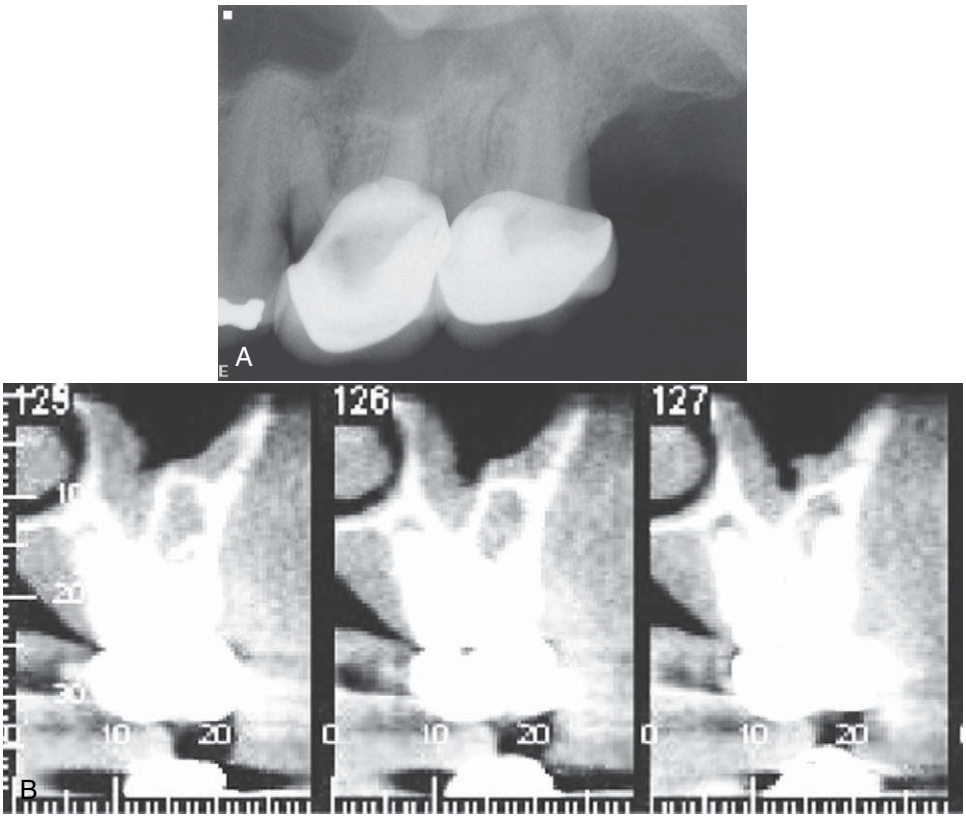

FIG. 1-31 A, This standard two-dimensional radiographic image reveals recurrent caries under the mesial margin of the maxillary first molar. However, the patient localized pain to mastication on the maxillary second molar. **B,** Cone-beam volumetric tomography revealed an apical abscess associated with the maxillary second molar. The bone loss was obscured on the two-dimensional radiograph by the maxillary sinus, zygoma, and cortical bone.

Root Fractures and Cracks

Because of the wide variety of different types of cracks in teeth, there may be a myriad of symptoms and presentations, often making the diagnosis of a crack difficult. The extensiveness of a crack may directly alter the prognosis assessment for a given tooth. Therefore, any possible crack should be examined before dental treatment. These cracks may be as innocent as a superficial enamel craze line, or they may be as prominent as a fractured cusp. The crack may progress into the root system to involve the pulp, or it may even split the entire tooth into two separate pieces. The crack may be oblique, extending cervically, such that once the coronal segment is removed the tooth may or may not be restorable. Any of these situations may present with mild, moderate, or severe symptoms or possibly no symptoms at all. Because of the high prevalence of fractures and cracks in teeth and how they can directly alter the prognosis for a tooth, an extensive review is presented.

Crack Types

There have been many attempts in the literature to classify cracks in teeth, trying to differentiate the extent to which the crack has progressed into the tooth structure. By defining the type of crack present, an assessment of the prognosis may be determined and treatment alternatives may be planned as fully described in Chapter 17. Unfortunately, it is often impossible to determine how extensive a crack is until the tooth is extracted. Therefore, the determination of a crack is often more of a prediction, rather than a definitive diagnosis.

Cracks in teeth can be divided into three basic categories:

- Craze lines
- Fractures (also referred to as *cracks*)
- Split roots

Craze lines are merely cracks in the enamel that do not extend into the dentin and either occur naturally or develop after trauma. They are more prevalent in adult teeth and usually occur more in the posterior teeth. If light is transilluminated through the crown of such a tooth, these craze lines may show up as fine lines in the enamel with light being able to transmit through them, indicating that the crack is only superficial. Craze lines typically will not manifest with symptoms. No treatment is necessary for craze lines unless they create a cosmetic issue.

Fractures extend deeper into the dentin than superficial craze lines and primarily extend mesially to distally, involving the marginal ridges. Dyes and transillumination are helpful in visualizing potential root fractures.

Symptoms from a fractured tooth range from none to severe pain. A fracture in the tooth does not necessarily dictate that the tooth has split into two pieces, but left alone, especially with provocations such as occlusal prematurities, the fracture may progress to a split root. A fractured tooth may be treated by a simple restoration, endodontics, or even extraction, depending on the extent and orientation of the fracture, the degree of symptoms, and whether or not the symptoms can be eliminated. This makes the clinical management of fractured teeth difficult and sometimes unpredictable.

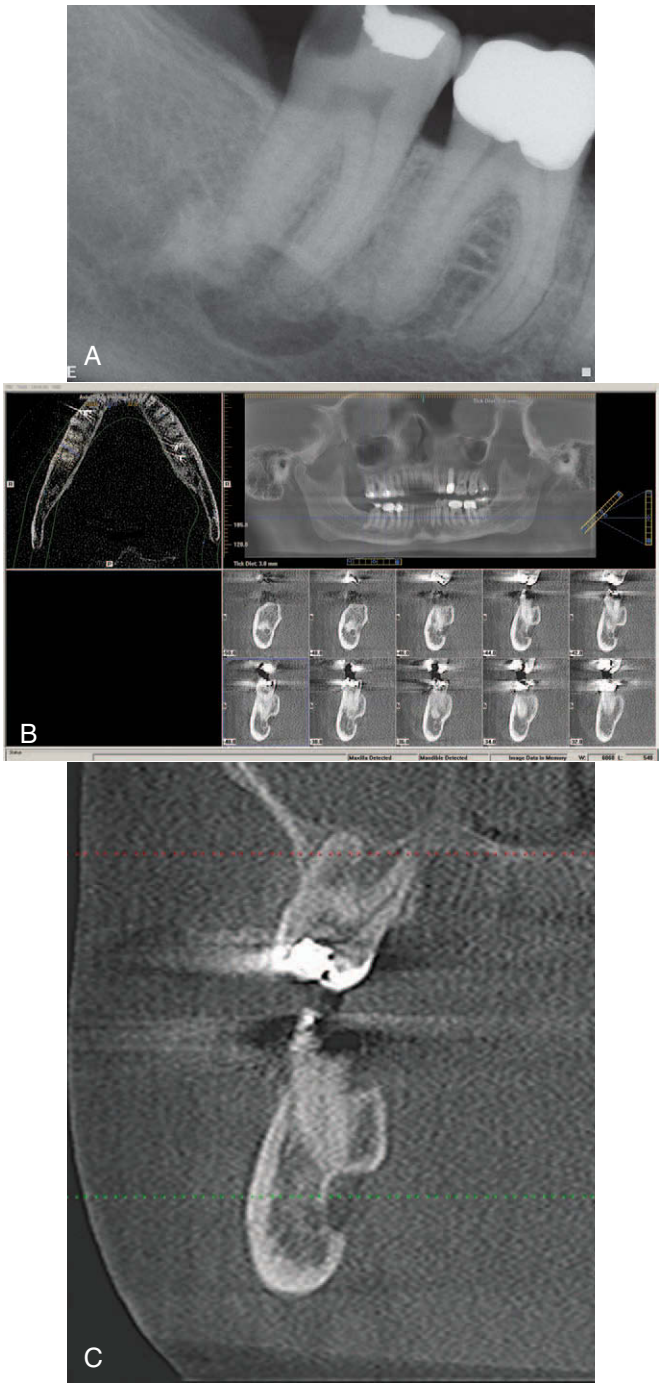

FIG. 1-32 A, Periapical radiograph revealed apical bone loss on this mandibular second molar, suspicious of apical pathosis. **B,** Cone-beam volumetric tomography revealed salivary indentation of the mandible in the area apical and lingual to the mandibular second molar, consistent with a Stafne defect. **C,** Enlargement of coronal section in the area of the mandibular second molar and the Stafne defect located on the lingual aspect of the mandible.

A definitive combination of factors, signs, and symptoms that, when collectively observed, allows the clinician to conclude the existence of a specific disease state is termed a *syndrome*. However, given the multitude of signs and symptoms that fractured roots can present with, it is often difficult to achieve an objective definitive diagnosis. For this reason, the terminology of *cracked tooth syndrome*[14] should be avoided.[1] The subjective and objective factors seen in cases of fractured teeth will generally be diverse; therefore a tentative diagnosis of a fractured tooth will most likely be more of a prediction. Once this prediction is made, the patients must be properly informed as to any potential decrease in the prognosis of the pending dental treatment. Because treatment options for repairing fractured teeth have only a limited degree of success, early detection and prevention, and proper informed consent, are crucial.[5,20,51,68,85,88,97]

Split roots occur when a fracture extends from one surface of the tooth to another surface of the tooth, with the tooth separating into two segments. If the split is more oblique, it is possible that once the smaller separated segment is removed, the tooth might still be restorable, for example, a fractured cusp. However, if the split extends below the osseous level or involves the pulp, the tooth may not be restorable and endodontic treatment may not result in a favorable prognosis.

Proper prognosis assessment before any dental treatment is imperative, but is often difficult in cases of cracked teeth. Because of the questionable long-term success from treating cases of suspected or known fractures, the clinician should be cautious in the decision to continue with treatment and should avoid treating cases of definitive split roots.

Vertical Root Fractures

Certainly, of the previous three categories, fractured teeth are the most variable in presentation, in that the extent of the fracture is often difficult to determine. One of the more common reasons for recurrent endodontic pathosis is the *vertical root fracture,* a severe crack in the tooth that extends longitudinally down the long axis of the root. Often it extends through the pulp and to the periodontium. It tends to be more centrally located within the tooth, as opposed to being more oblique, and typically traverses through the marginal ridges. These fractures may be present before endodontic treatment, secondary to endodontic treatment, or they may develop after endodontic treatment has been completed. Because diagnosing these vertical root fractures may be difficult, they often go unrecognized. Typically, these cracks lead to a split root, leaving the tooth with a poor prognosis. Therefore, diagnosing the existence and extent of a vertical root fracture is imperative before any restorative or endodontic treatment because these cracks can dramatically affect the overall success of treatment. Because the presence of vertical root fractures plays such an important role in the prognosis assessment of teeth, a detailed analysis of vertical root fractures is presented here.

ETIOLOGY OF A VERTICAL ROOT FRACTURE

Vertical root fractures may arise from a physical traumatic injury, occlusal prematurities,[14] repetitive parafunctional habits of heavy stressful chewing,[104] or resorption-induced pathologic root fractures.[8] However, the most common cause of vertical root fractures may be iatrogenic dental treatment.[8,14,74] Dental procedures such as the placement of posts and pins[31,60] or the tapping into place of a tightly fitting post or intracoronal restoration may induce a vertical root fracture (Fig. 1-33). The most common dental procedure contributing to vertical root fractures is endodontic treatment.[8] Before treatment, teeth that are about to undergo endodontic treatment may be predisposed

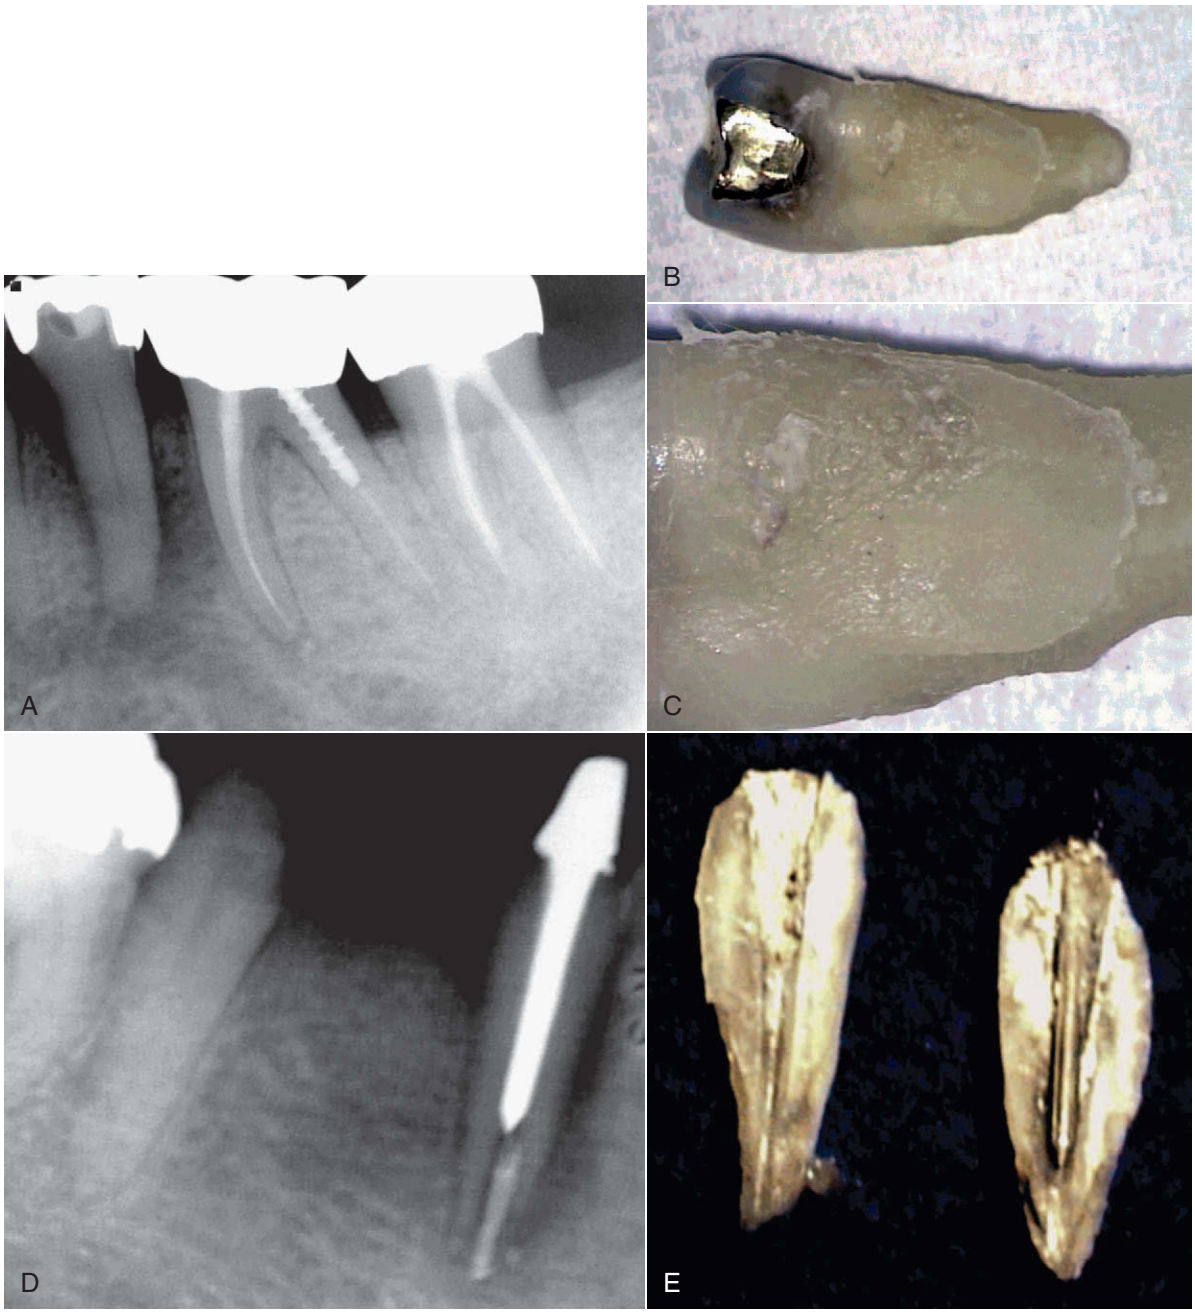

FIG. 1-33 Poorly fitting intracoronal restorations can place stresses within the tooth that can cause a vertical root fracture. **A,** This radiograph of a mandibular second premolar (with a gold inlay) reveals extensive periapical and periradicular bone loss, especially on the distal aspect. **B,** The tooth pulp tested nonvital, and there was an associated 12-mm-deep, narrow, isolated periodontal pocket on the buccal aspect of the tooth. After the tooth was extracted, the distal aspect was examined. **C,** On magnification (×16) the distal aspect of the root revealed an oblique vertical root fracture. Similarly, the placement of an ill-fitting post may exert intraradicular stresses on a root that can cause a fracture to occur vertically. **D,** This radiograph depicts a symmetrical space between the obturation and the canal wall, suggesting a vertical root fracture. **E,** After the tooth is extracted, the root fracture can be easily observed.

to vertical root fractures because quite often the tooth is already compromised from extensive coronal restorations, caries, resorption, or trauma. Teeth were once thought to be more susceptible to fracturing after endodontic treatment because of a decrease in hydration.[41] However, later studies found no difference in the dentin properties after endodontic procedures.[43,87] Although the physical characteristics of the dentin may not be compromised by endodontic treatment, the overenlarging of an endodontic access and excessive canal shaping will result in an increased amount of dentin removal. Consequently, the root may become weaker and may be more predisposed to vertical root fractures. Intracanal forces from excessive compaction pressure during obturation may also contribute to an increased incidence of vertical root fractures.[8,60]

DETERMINATION OF A VERTICAL ROOT FRACTURE

The assessment of a potential vertical root fracture may be based more on subjective than on objective findings, making the diagnosis more like an art than a science, but early detection is crucial. Many subtle findings can lead the clinician to suspect a vertical root fracture.[18] Medical and dental histories are important. Clinical, periodontal, and radiographic examinations may be at best only suggestive of a vertical root fracture. The tooth is typically painful, with symptoms ranging from mild to severe in intensity. When the tooth is painful, patients will typically complain of symptoms when they occlude or release on the tooth in a specific direction. Also noteworthy is the anatomic location of the tooth in question. Mandibular second molars have a higher incidence of vertical root fractures, followed by maxillary first molars and maxillary premolars.[14] Prominent cusps, balancing interferences, and occlusal prematurities may all be factors in this predisposition to fracturing.

MEDICAL HISTORY

The patient's medical history may seem like an unlikely place to discover any suggestion of a vertical root fracture. But a history of facial trauma may add information to help in the creation of a differential diagnosis. For example, patients with seizure disorders may be prone to dental trauma, either from severe seizure-induced clenching, or from physical injuries sustained secondary to a grand mal seizure (Fig. 1-34). In addition, a patient who has had a stroke, heart attack, or any other ailment that might have resulted in lack of consciousness could have traumatized a tooth. This could result in a vertical root fracture if the trauma is directed accordingly.

FIG. 1-34 Physical trauma from sports-related injuries or seizure-induced trauma, if directed accordingly, may cause a vertical root fracture in a tooth. This fracture occurred in a 7-year-old child secondary to trauma from a grand mal seizure.

DENTAL HISTORY

Various comments made by a patient when a dental history is taken may direct the clinician to suspect a vertical root fracture. A patient might report ice chewing or other parafunctional habits. A patient might also describe a symptom by stating "the tooth only hurts when I bite a certain way." Comments like "it only started hurting after I accidentally bit down on a cherry pit" might also be suggestive of a vertical root fracture. Other comments concerning recent dental treatment may also be significant. Localized pain in tooth after the placement of a cast post or cast intracoronal restoration could also implicate a vertical root fracture. The repeated falling out of a coronal restoration could be due to a fracture between the axial walls of the preparations; as the fractured segments flex or move apart, the restoration between these segments may lose its resistance form, become loose, and dislodge. Similarly, a retrograde restoration that has become dislodged could be secondary to a vertical root fracture apically.[26,74] As the apical fracture opens up, the retrograde restoration may come out (Fig. 1-35). An endodontic procedure that was performed well but does not result in healing may also be suggestive of a vertical root fracture, especially if the tooth does not heal after retreatment or apical surgery.

CLINICAL EVALUATION OF A VERTICAL ROOT FRACTURE

Crack Probing A vertical root fracture can occasionally be observed on clinical examination. The use of a dental operating microscope may be invaluable in detecting cracks and fractures in the clinical crown and root surfaces. Probing the crack may elicit pain or even reveal moving segments on either side of the crack line, indicating a split tooth. To determine the extent of the fracture, it is important to apply some pressure to the cusps that are adjacent to any visible crack (Fig. 1-36). On occasion, pressure to the cusp or actual probing of the crack will reveal a split tooth that would not have otherwise been found.

Selective Sensitivity Vertical root fractures may manifest as a selective sensitivity when the tooth is percussed in a particular direction. The back end of a dental mirror handle is a useful instrument. There are also specially designed bite sticks that when applied to a certain part of the tooth may elicit pain that would not be present when biting on another location of the tooth's occlusal surface (see Fig. 1-20).

Restorative Treatment Highly suspect of a vertical root fracture is a tooth with minimal or no restoration or caries that is nonvital. Except for luxation injuries, systemic disease (e.g., intraoral herpes zoster),[36] or surgical procedures that may accidentally devitalize a tooth (e.g., sinus surgery, orthognathic surgery, accidental extraction of a tooth with subsequent replantation), a vertical root fracture is one of the few reasons for such a tooth to become nonvital (Fig. 1-37). A tooth with recurrent endodontic pathosis and a post that is an abutment to a cantilever bridge should also be suspected of having a

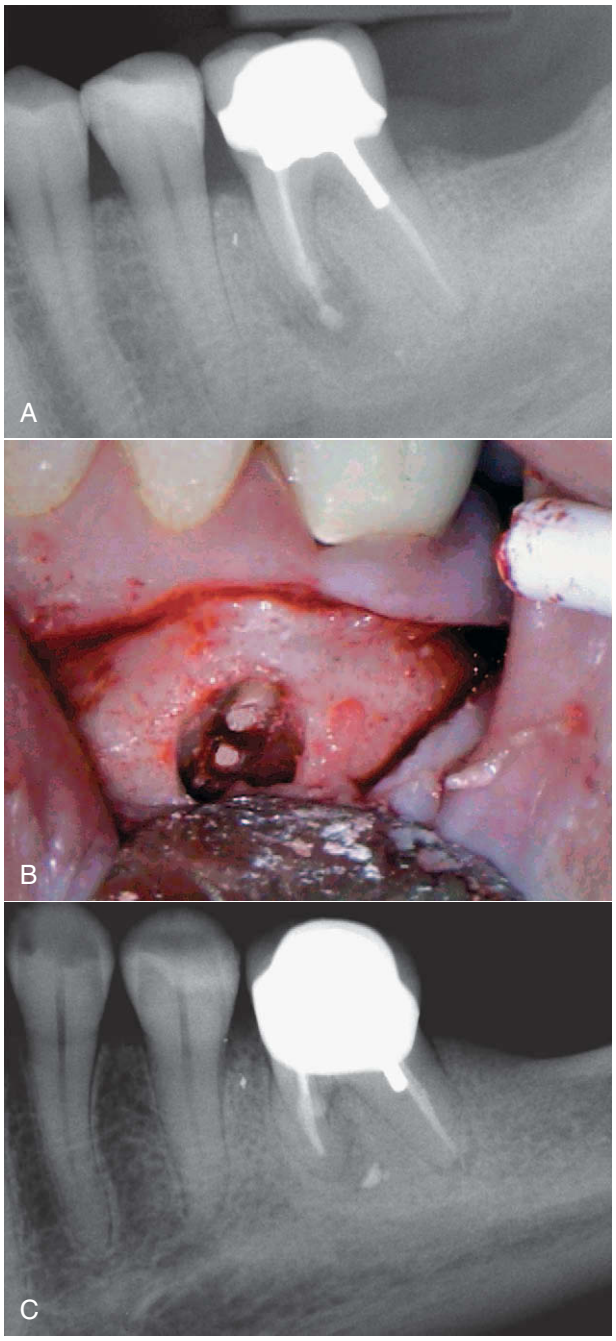

FIG. 1-35 Pulp infections that are refractory to endodontic treatment may often result from vertical root fractures. **A,** This radiograph shows the placement of retrograde restorations in the apex of the mesial roots of this lower left first molar. **B,** This photograph shows that the restorations are directly in the root's apex. **C,** After a little more than 1 year, the retrograde restorations are observed to have been dislodged, suggesting the possibility of a vertical root fracture.

vertical root fracture (Fig. 1-38). The torque created during mastication on the cantilevered pontic and the subsequent flexing of the bridge can cause stresses in the root that lead to vertical root fracture. Persistent symptoms from a tooth with a conservative cast intracoronal restoration should also make the clinician suspicious of a vertical root fracture. Generally speaking, there must be a reason for a tooth becoming nonvital and/or causing pain. The clinician should evaluate the restorative treatment, or lack thereof, and try to make an assessment as to whether or not there is sufficient cause for necrosis or symptoms; differential diagnosis should always include *vertical root fracture* under these circumstances.

Multiple Sinus Tracts Also indicative of a vertical root fracture is the presence of multiple sinus tracts adjacent to the tooth in question. Because the fracture may be present on at least two surfaces of the tooth, the infected area may drain to multiple sites, creating multiple sinus tracts.[26]

Dental Operating Microscope Used in medicine for years, the dental operating microscope (DOM) has become an invaluable tool when doing endodontic treatment. With magnification capabilities exceeding ×25, and with superb illumination, the clinician is now capable of observing intracoronal and extracoronal details with great precision. Sometimes a fracture may be observed extracoronally before endodontic treatment; its depth can be visualized intracoronally with the DOM after an endodontic access has been created (Fig. 1-39).

Surgical Exposure Often the only definitive way to determine whether there is a vertical root fracture or split tooth is by direct surgical exposure. For optimal visualization of a potential fracture, a full-thickness mucoperiosteal flap incision should be created at the level of the sulcus and reflected apically. Typically, only a small flap is necessary, because once the flap is reflected, if there is a vertical root fracture, it can usually be seen after the overlying granulation tissue is removed. Many times there is an associated boney dehiscence directly over the fracture. The use of a DOM is especially helpful in maximizing the illumination and visualization of these defects (Fig. 1-40).

Transillumination and Dyes Often it may be necessary to remove the restoration in the tooth to better visualize the fracture. Methylene blue dye, when painted on the tooth surface with a cotton tip applicator, will penetrate into cracked areas. The excess dye may be removed with a moist application of 70% isopropyl alcohol. The dye will indicate the possible location of a crack. Transillumination may be more helpful (Fig. 1-41). Directing a high-intensity light directly on the exterior surface of the tooth at the cementum–enamel junction (CEJ) may indicate the extent of the fracture. Teeth with fractures block transilluminated light. The part of the tooth that is proximal to the light source will absorb this light and glow, whereas the area beyond this fracture will not have light transmitted to it and will be gray by comparison.[74] Although the presence of a fracture may be evident using dyes and transillumination, the depth of the fracture cannot always be determined.

RADIOGRAPHIC EVALUATION OF A VERTICAL ROOT FRACTURE

On occasion, a vertical root fracture or a split tooth may be an obvious diagnosis based on radiographic findings (Fig. 1-42). However, most of the time the fracture is in a plane that is not perceptible from a periapical radiograph. In one study[82] using extracted teeth, investigators determined that a fracture

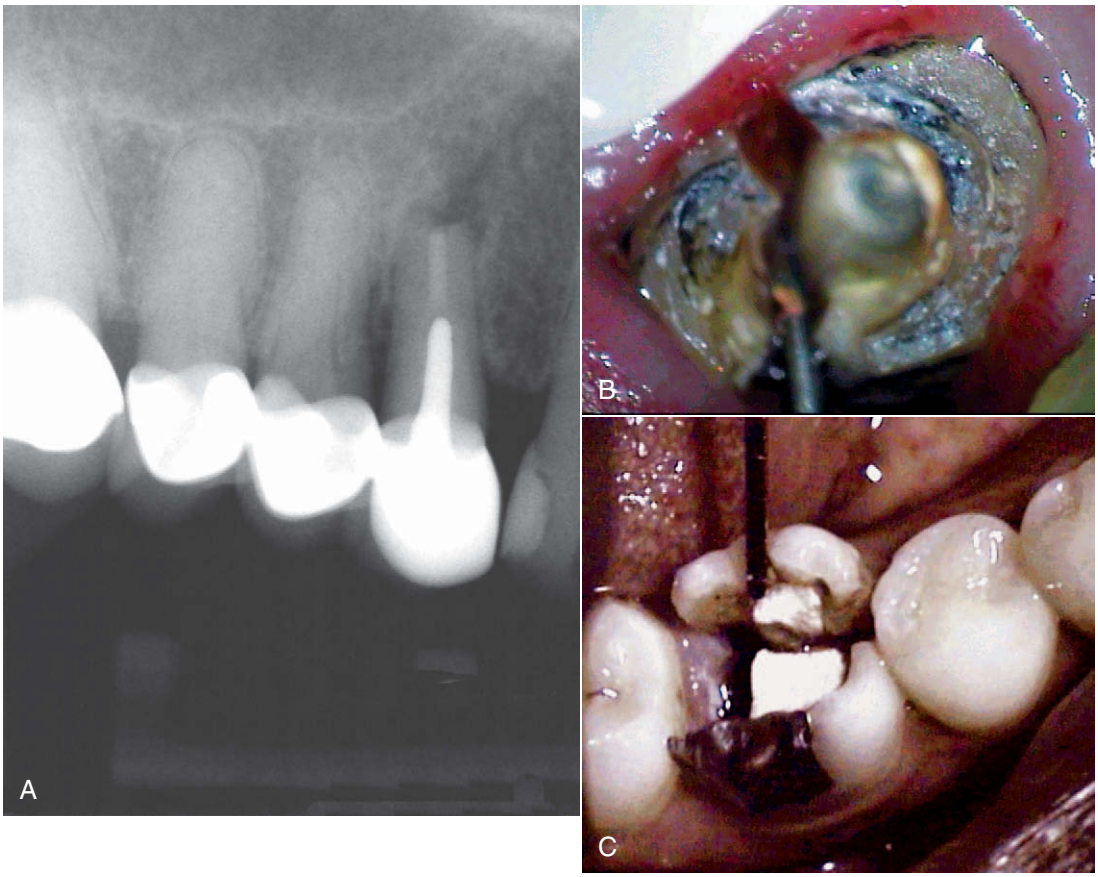

FIG. 1-36 Often it is difficult to diagnose a root fracture unless the coronal restoration is removed. **A,** This radiograph shows no evidence of a fracture. **B,** However, once the crown and post are removed, the fracture is easily visualized. **C,** Sometimes it is helpful to physically push on the axial walls of the clinical crown in order to observe the existence of a fracture.

becomes visible when the x-ray beam is directed within 4 degrees of the fracture plane. Outside of this horizontal angulation, a fracture may not be discernible. They also found that when a vertical root fracture is present, it is observed in a radiograph only 35.7% of the time (Fig. 1-43).

Another interesting way to detect vertical root fractures or split teeth is from a CAT scan or by cone-beam volumetric tomography. This technique has been shown to be superior to dental radiography in the detection of vertical root fractures.[105] However, this type of imaging is typically not available in dental offices, other than certain specialty practices.

To assist the clinician, other radiographic signs may be helpful in the detection of vertical root fractures.

Cement Trail When the vertical root fracture or split root extends from the mesial surface to the distal surface of the tooth, often this crack can be "interpreted" after endodontic treatment has been performed. Sometimes a "cement trail" can be seen up or across the root. This is the cement extruded through and out of the fracture site, after which it becomes visible radiographically. It can be confused with the obturation passing through accessory canals, but the appearance is more diffuse in cases of vertical root fractures, with no observation of a symmetrical lateral canal passing from a main canal (Fig. 1-44).

Halo-like Bone Loss Typically, when a nonvital tooth causes radiographic changes, the bone loss occurs apically. However, often when there is a vertical root fracture or split root, the bone loss has a tendency to give a "halo-like" appearance, traversing circumferentially around the root. The radiolucent area may also travel almost completely up one side of the root, with this pattern of bone loss often termed a "J-type" lesion[98] (Fig. 1-45).

Isolated Bone Loss The clinician should be aware of unusual radiographic changes revealing extensive bone loss that is isolated to just one tooth in the absence of advanced periodontal disease (Fig. 1-46). This could be suggestive of a vertical root fracture or split tooth.

When attempting to make a diagnosis of a vertical root fracture or split tooth, the clinician should also look for the following:

- A widened canal space that is inconsistent with the canal spaces of the adjacent roots (Fig. 1-47)
- A radiolucent space presenting between the long axis of the obturation material (or post) and the canal wall (Fig. 1-48)
- An associated bone loss mesial and distal to the root. When a vertical root fracture or split root extends from the mesial surface to the distal surface of the tooth, there is often an atypical widening of the entire periodontal ligament space

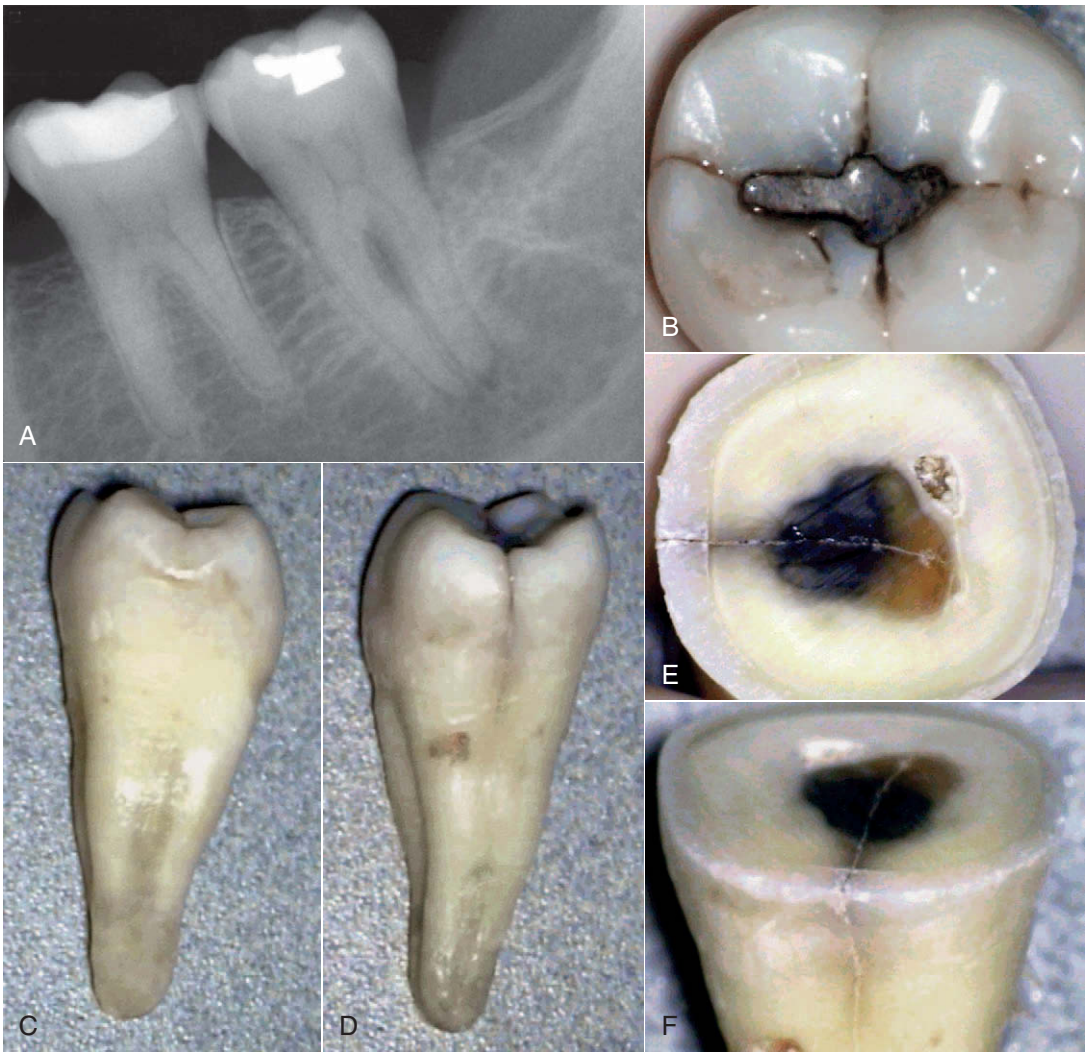

FIG. 1-37 A tooth with minimal or no restoration or caries is unlikely to become nonvital. **A,** This radiograph of a mandibular second molar shows a restoration that is distant from the pulp chamber, yet the tooth is nonvital and symptomatic. **B,** On occlusal examination, a slight crack is observed on the distal marginal ridge. **C,** After extraction, the mesial aspect of the crown and root shows no indication of a fracture. **D,** However, the distal aspect of the crown and coronal root shows the fracture. **E** and **F,** When the crown is sectioned, the crack can be observed to extend well into the pulp chamber.

When these features are visualized on the radiograph, a vertical root fracture or split tooth should be strongly suspected.

PERIODONTAL EVALUATION OF A VERTICAL ROOT FRACTURE

Typically, a vertical root fracture or split tooth has associated bone loss contiguous with the fracture line. Left undetected, this creates a dehiscence in the bone and a V-type pattern of bone loss extending apically. The periodontal pocket associated with this bone loss is generally isolated, narrow, and deep (Fig. 1-49); a similar defect may occur 180 degrees opposite to the defect (i.e., the other side of the fracture on the other side of the root). When the periodontal probe is inserted into this type of periodontal pocket, it is *tight* within the pocket, and the periodontal probe's movement from side to side is restricted. This is a classic periodontal presentation and is practically pathognomonic for a vertical root fracture or split tooth.

PROGNOSIS OF A VERTICAL ROOT FRACTURE

A patient who consents to endodontic treatment must be informed if the tooth has a questionable prognosis. The clinician must be able to interpret the subjective and objective findings that suggest a vertical root fracture or split tooth, be able to make a prediction as to the eventual potential of healing, and must convey these suspicions to the patient. The prognosis assessment should be described as follows.

Good Prognosis If a coronal crack is observed with nonmovable segments and the patient does not have symptoms, notwithstanding any other adverse parameters the tooth has a good prognosis.

Fair Prognosis If the tooth is sensitive on probing the occlusal crack, with the opposing segments nonmovable, then the prognosis is more guarded. The patient should understand that the pending endodontic treatment may not resolve the symptoms

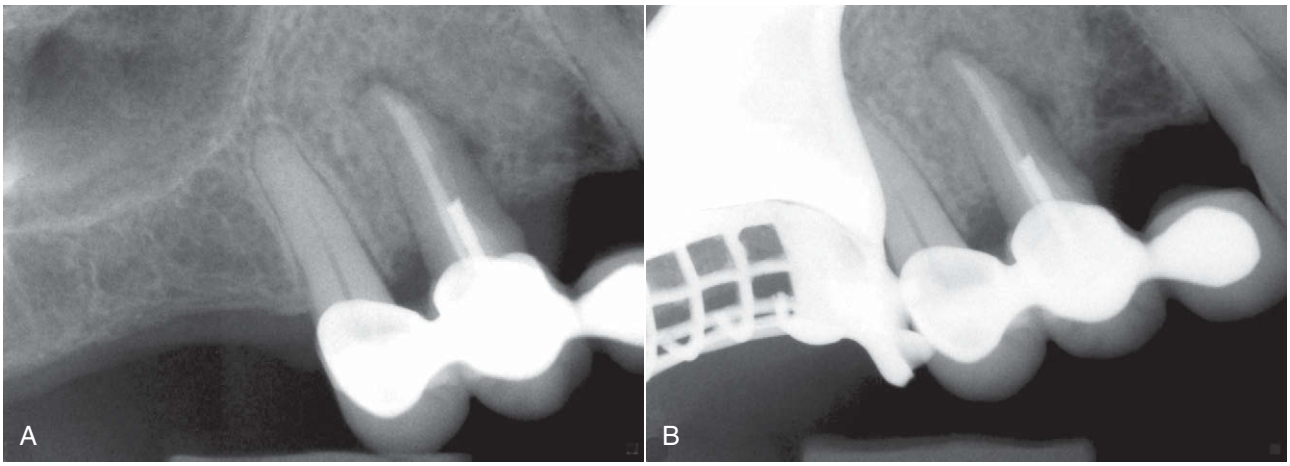

FIG. 1-38 A, Cantilever bridges can create oblique forces on an abutment tooth, especially if that tooth has endodontic treatment with a post. **B,** A distal-extension removable partial denture can compound the stresses on the abutment tooth, setting up a situation that can predispose that tooth to a vertical root fracture.

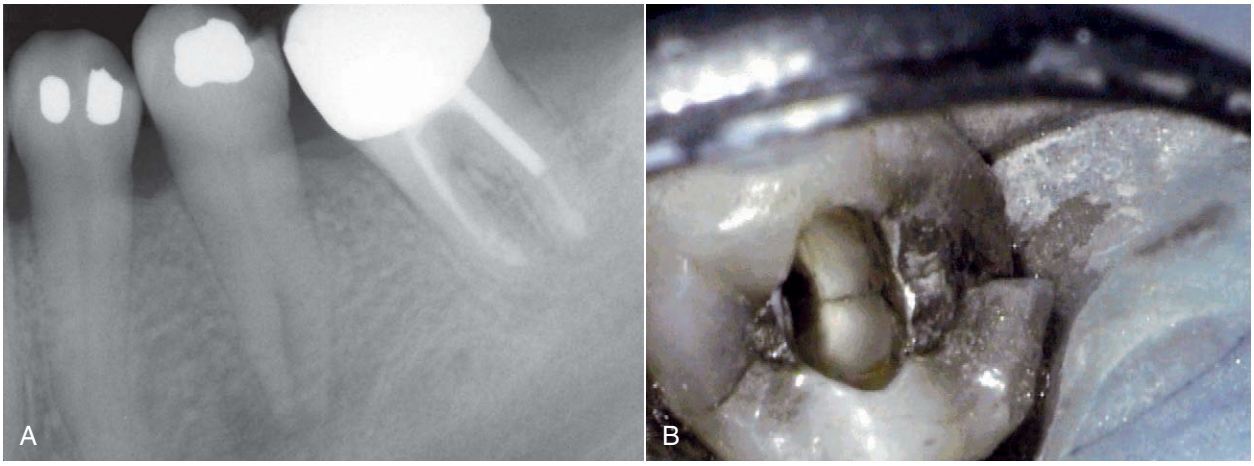

FIG. 1-39 Often a radiograph does not give a good indication of a vertical root fracture. **A,** This mandibular second premolar is nonvital, with a restoration that is not significantly close to the pulp chamber. **B,** The interior walls of the pulp chamber are examined under high magnification (×12) to reveal a vertical root fracture.

and that the prognosis is only fair. If endodontic treatment is performed, the interior walls of the access should be carefully examined, preferably with the use of a DOM along with transillumination, to determine whether the crack has traversed into the canal space (see Fig. 1-39). If this is observed, the patient should again be advised of the potential for a more compromised prognosis. The tooth should be restored with a bonded intracoronal core in the access, the use of a post should be avoided, and a full-coverage restoration with cuspal reinforcement should be placed.[86,100]

Poor Prognosis If there are movable segments on either side of the occlusal crack, then the prognosis is poor. Often the movement of the segments is difficult to visualize, so magnification is essential. If the pulp of this tooth is diagnosed as being necrotic, with a minimal caries and restorative history, and has a deep, narrow, isolated periodontal pocket with normal periodontium otherwise, then a vertical root fracture or a split root should be highly suspected, and extraction should be considered.

Referred Pain

The perception of pain in one part of the body that is distant from the actual source of the pain is known as *referred pain*. Whereas pain of nonodontogenic origin can refer pain to the teeth, teeth may also refer pain to other teeth as well as to other anatomic areas of the head and neck (see Chapter 3). This may create a diagnostic challenge, in that the patient may insist that the pain is from a certain tooth or even from an earache when, in fact, it is originating from a distant tooth with pulpal pathosis. Using electronic pulp testers, investigators found that patients could localize *which* tooth was being stimulated only 37.2% of the time and could narrow the location to three teeth only 79.5% of the time, illustrating that patients may have a difficult time discriminating the location of pulpal pain.[30]

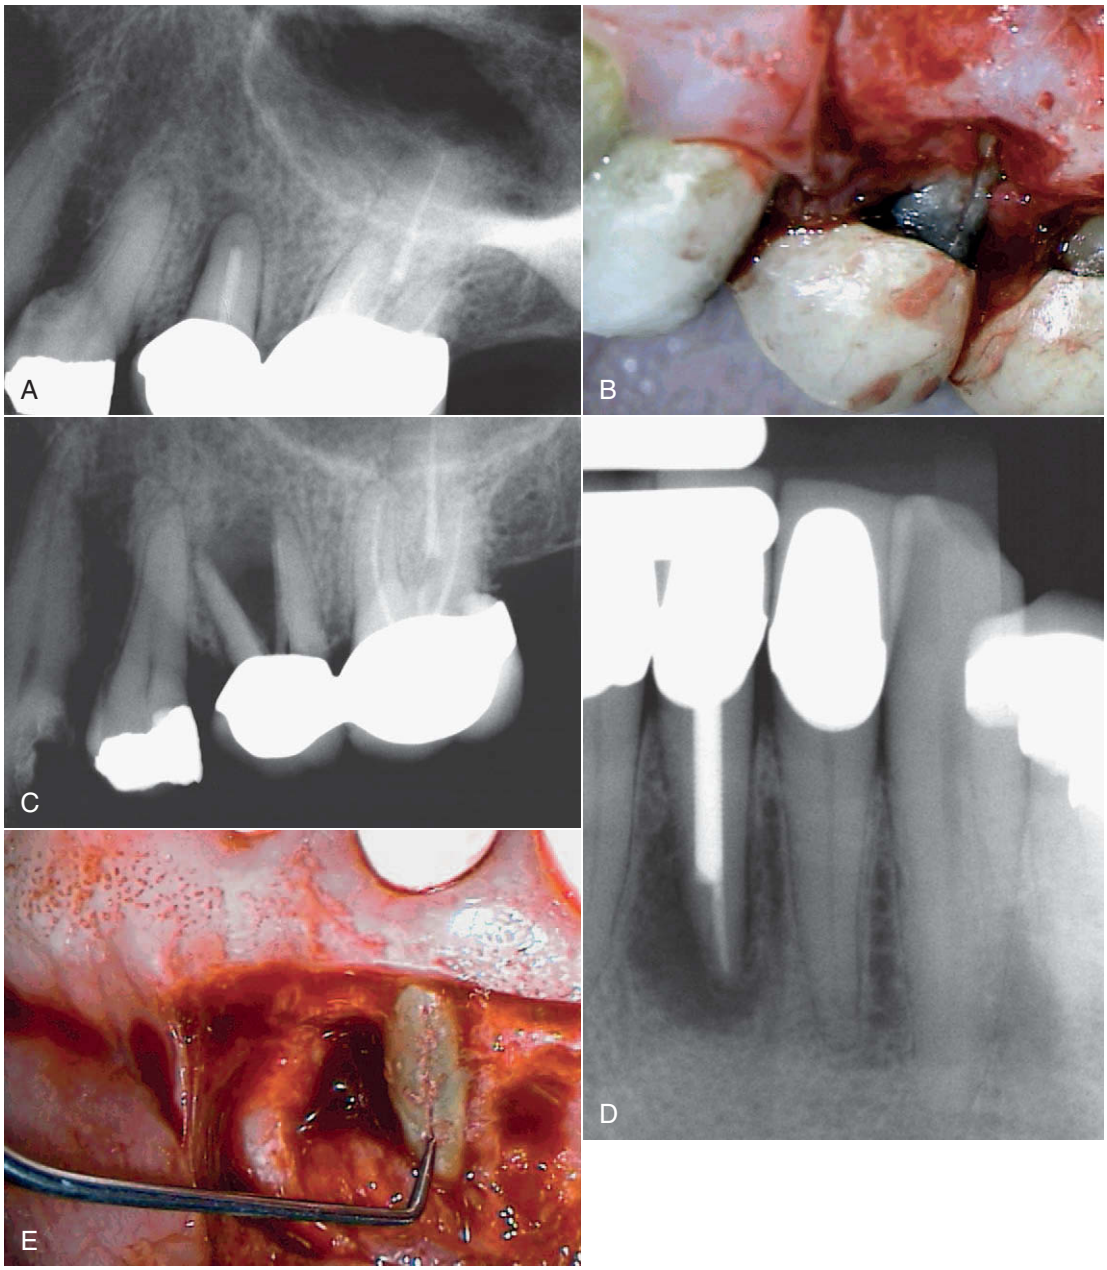

FIG. 1-40 When a vertical root fracture is suspected, sometimes the reflection of a surgical flap over the root may allow better visualization. **A,** The radiograph here shows no indication of a root fracture. **B,** However, after surgical exposure, the fracture can be seen. **C,** Unfortunately, this tooth was never extracted and is observed with a prominent split root 1 year later. **D,** Similarly, the radiograph of this mandibular anterior tooth shows no indication of a root fracture. **E,** However, when the root is surgically exposed, the fracture is easily seen.

Referred pain from a tooth is usually provoked by an intense stimulation of pulpal C fibers, the slow conducting nerves that when stimulated cause an intense, slow, dull pain. Anterior teeth seldom refer pain to other teeth or to opposite arches, whereas posterior teeth may refer pain to the opposite arch or to the periauricular area but seldom to the anterior teeth.[9,89] Mandibular posterior teeth tend to transmit referred pain to the periauricular area more often than maxillary posterior teeth. One study showed that when second molars were stimulated with an electric pulp tester, patients could discriminate accurately which arch the sensation was coming from only 85% of the time, compared with an accuracy level of 95% with first molars and 100% with anterior teeth.[101] The authors also pointed out that when patients first feel the sensation of pain, they are more likely to accurately discriminate the origin of the pain. With higher levels of discomfort, patients have less ability to accurately determine the source of the pain. Therefore, in cases of diffuse or referred pain, the history of where the patient first felt the pain may be significant.

Because referred pain can complicate a dental diagnosis, the clinician must be sure to make an accurate diagnosis to protect the patient from unnecessary dental or medical treatment.

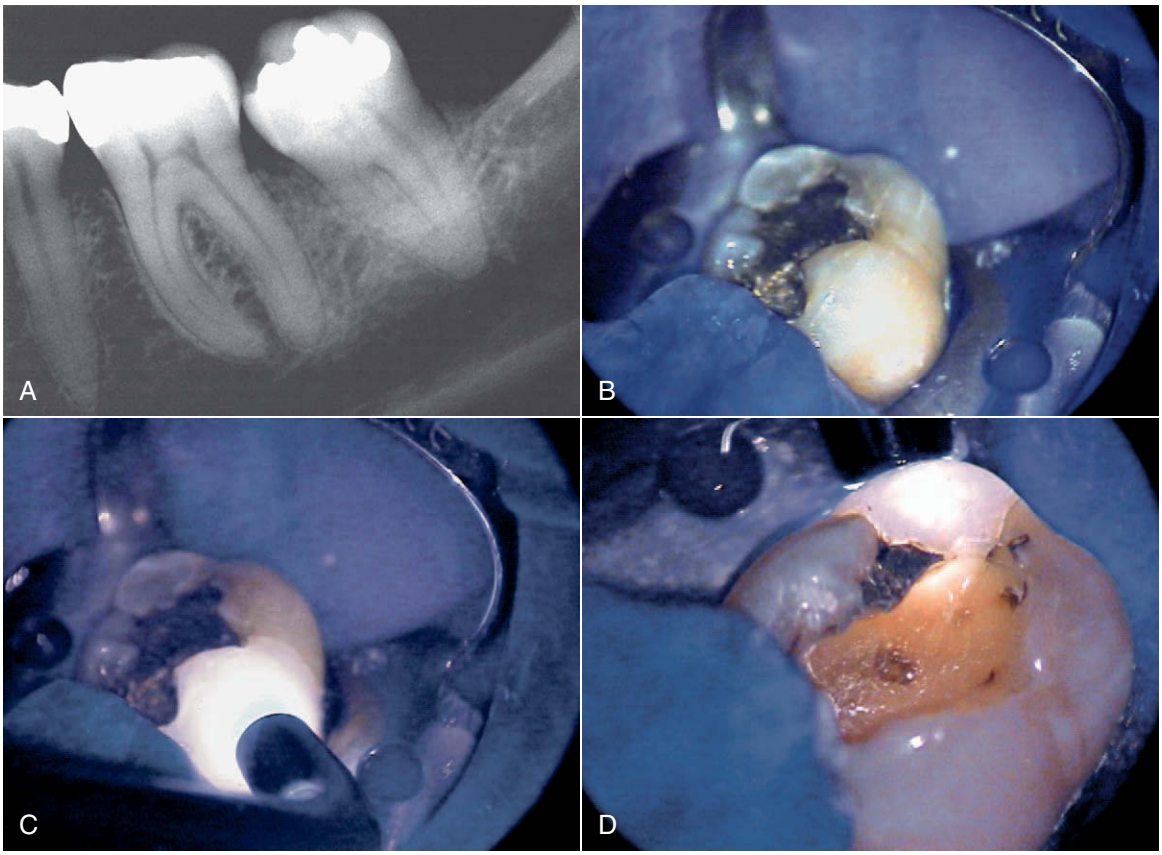

FIG. 1-41 Sometimes there is no clear indication of why a tooth is symptomatic. This radiograph shows a mandibular second molar with a moderately deep restoration **(A);** the pulp tests nonvital. Without any transillumination a fracture cannot be detected **(B).** However, by placing a high-intensity light source on the tooth surface, a root fracture can be observed on the buccal surface **(C)** and the distal-lingual surface **(D).**

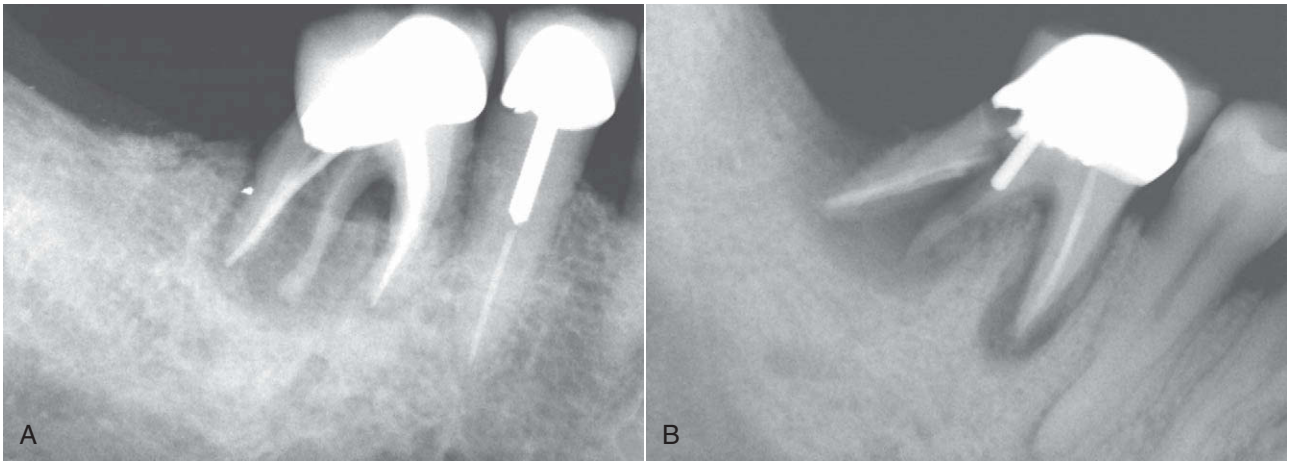

FIG. 1-42 Vertical root fractures that develop into split roots are sometimes easy to diagnose from a radiograph.

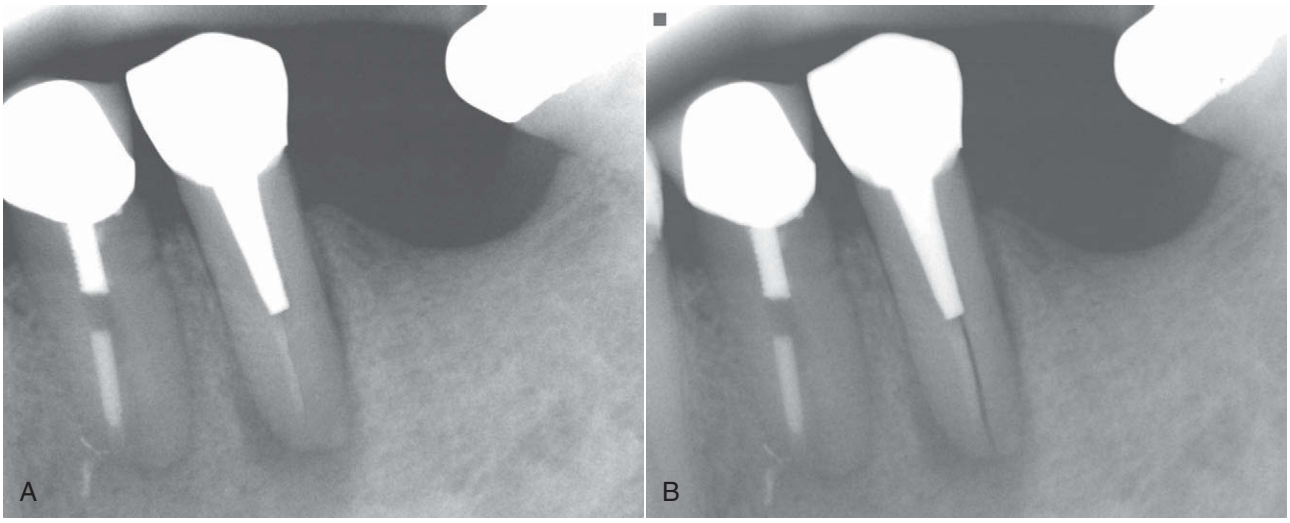

FIG. 1-43 Although split roots are not always radiographically visible, the precise angulation of the radiation source is necessary in order to observe them. **A,** A root fracture is not visible in the radiograph of this mandibular first premolar. **B,** However, if exposed with only a small change in the horizontal angulation, the fracture becomes visible.

FIG. 1-44 After obturation, obturating material may extrude through accessory canals. However, sometimes an extensive "cement trail" of material up the side of the root extrudes through a fracture space, with no demarcation of accessory canals. This is suggestive of a vertical root fracture.

FIG. 1-45 Often the radiographic presentation of a vertical root fracture is the pattern of bone loss occurring in a "J-shaped" radiolucency, with the bone loss originating apically and progressing coronally up one side of the root.

FIG. 1-46 Extensive periodontal bone loss around an isolated tooth, with the adjacent teeth within normal limits, is suggestive of a vertical root fracture.

FIG. 1-47 When there is a disproportionate widening of a canal space compared with the canals in the same tooth or adjacent teeth, as seen in this mandibular second molar, a vertical root fracture should be suspected.

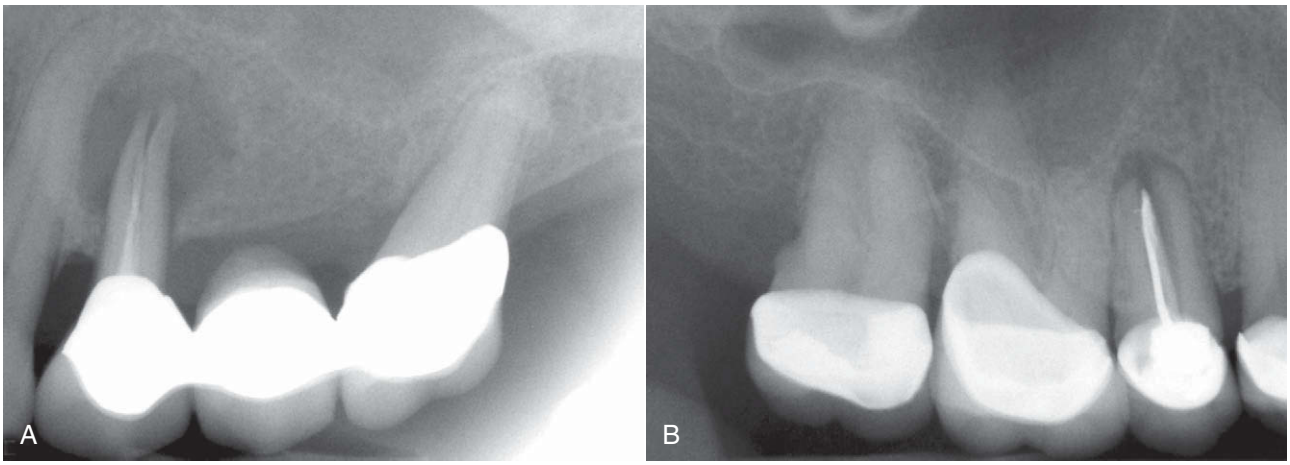

FIG. 1-48 A space between the obturation and the canal wall is highly suggestive of a split tooth.

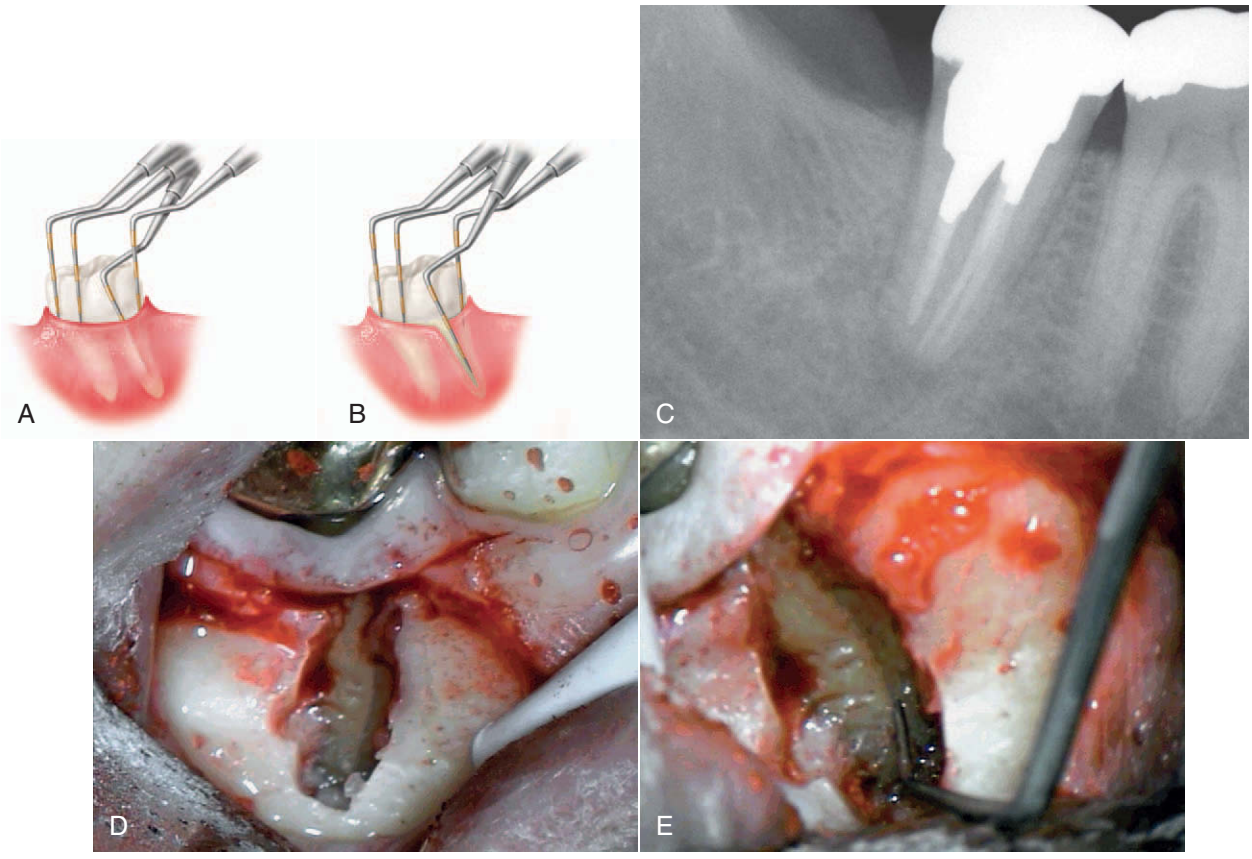

FIG. 1-49 When a narrow, isolated periodontal defect is present, with the adjacent periodontal structures within normal limits, there is typically an associated boney dehiscence with an underlying vertical root fracture beneath **(A-B).** This mandibular second molar showed this type of defect, as observed on surgical exploration **(C-E).**

CLINICAL CLASSIFICATION OF PULPAL AND PERIAPICAL DISEASES

Many attempts have been made over the years to develop classifications of pulpal and periapical disease. However, many studies have shown that there is not a great correlation between clinical signs and symptoms and the histopathology of a given clinical condition.[91,92] The terminology that has been historically used are biologic terms that may not accurately depict the actual histologic condition of the pulp and supporting periodontal tissues. Because removal of the questionable pulpal tissue for histologic examination is not practical, *clinical* classifications have been developed in order to formulate treatment plan options. In the most general terms, the objective and subjective findings are used to classify the suspected pathosis, with the assigned designations merely representing the presence of healthy or diseased tissue.

On October 3, 2008, the American Association of Endodontists convened a *Consensus Conference on Diagnostic Terminology* in an attempt to standardize the terminology used for classification of pulpal and periapical disease conditions. Terms such as acute and chronic, symptomatic and asymptomatic, reversible and irreversible, nonvital and necrotic, and apical, periapical, and periradicular are all used to describe similar clinical presentations. The conference was organized to establish uniformity in diagnostic terminology for textbook authors, practicing clinicians, and dental school faculty teaching endodontic diagnostic classifications. Although standardized diagnostic classifications remain a topic of active research, it is hoped that this first step in reaching a consensus will result in uniform diagnostic terminology in the near future. Until such a time that a consensus is reached, histologic terms such as "pulpal inflammation" or "infected pulp" should be avoided. These terms only describe the histopathology of these tissues subjectively because it is not possible to objectively determine their true status without the removal and direct microscopic examination of the affected tissues. The terminology and classification that follows are based on those suggested by the American Board of Endodontics (ABE) in 2007.

Pulpal Disease

Normal Pulp

Teeth with normal pulp do not exhibit any spontaneous symptoms. The pulp will respond to pulp tests, and the symptoms produced from such tests are mild, do not cause the patient distress, and result in a transient sensation that disappears in seconds. Radiographically, there may be varying degrees of pulpal calcification but no evidence of resorption, caries, or mechanical pulp exposure. No endodontic treatment is indicated for these teeth.

Reversible Pulpitis

When the pulp within the tooth is irritated so that the stimulation is uncomfortable to the patient but reverses quickly after irritation, it is classified as *reversible pulpitis*. Causative factors include caries, exposed dentin, recent dental treatment, and defective restorations. Conservative removal of the irritant will resolve the symptoms. Confusion can occur when there is exposed dentin, without evidence of pulp pathosis, which can sometimes respond with sharp, quickly reversible pain when subjected to thermal, evaporative, tactile, mechanical, osmotic, or chemical stimuli. This is known as *dentin* (or *dentinal*) *sensitivity* (or *hypersensitivity*). Exposed dentin in the cervical area of the tooth accounts for most of the cases diagnosed as dentin sensitivity.[76]

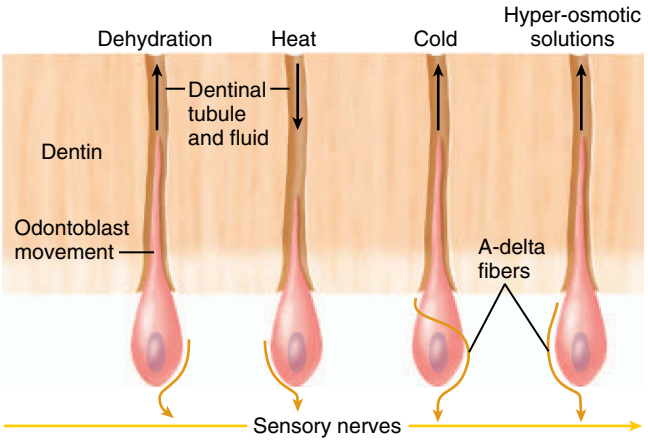

FIG. 1-50 Dentinal tubules are filled with fluid that, when stimulated, will cause sensation. Temperature changes, air, and osmotic changes can provoke the odontoblastic process to induce the stimulation of underlying A-delta fibers.

As is described in later chapters, the fluid movement within dentinal tubules stimulates the odontoblasts and associated fast-conducting A-delta nerve fibers in the pulp, which in turn produce sharp, quickly reversible dental pain (Fig. 1-50). The more open these tubules are (e.g., from a newly exposed preparation, dentin decalcification, periodontal scaling, tooth-bleaching materials, or coronal tooth fractures), the more the tubule fluid will move and, subsequently, the more the tooth will display dentin sensitivity when stimulated. When making a diagnosis, it is important to discriminate this dentin sensitivity sensation from that of reversible pulpitis, which would be secondary to caries, trauma, or new or defective restorations. Detailed questioning about recent dental treatment, not to mention a thorough clinical and radiographic examination, will help to separate dentin sensitivity from other pulpal pathosis, as the treatment modalities for each are completely different.[13]

Irreversible Pulpitis

As the disease state of the pulp progresses into the classification of *irreversible pulpitis,* treatment to remove the diseased tissue will be necessary. The ABE has suggested dividing this classification into the subcategories of symptomatic and asymptomatic irreversible pulpitis.

SYMPTOMATIC IRREVERSIBLE PULPITIS

Teeth that are classified as having *symptomatic irreversible pulpitis* exhibit intermittent or spontaneous pain. Rapid exposure of teeth in this category to dramatic temperature changes (especially to cold stimuli) will elicit heightened and prolonged episodes of pain even after the thermal stimulus has been removed. The pain in these cases may be sharp or dull, localized, diffuse, or referred. Typically there are minimal or no changes in the radiographic appearance of the periradicular

bone. With advanced irreversible pulpitis a thickening of the periodontal ligament may become evident on the radiograph, and there may be some suggestion of pulpal irritation by virtue of extensive pulp chamber and root canal space calcification. Deep restorations, caries, pulp exposure, or any other direct or indirect insult to the pulp, recently or historically, may be present, may be seen radiographically or clinically, or may be suggested from a complete dental history. Typically, when symptomatic irreversible pulpitis remains untreated, the pulp will eventually become necrotic.

ASYMPTOMATIC IRREVERSIBLE PULPITIS

On occasion, deep caries will not produce any symptoms, even though clinically or radiographically the caries may extend well into the pulp. Left untreated, the tooth may become symptomatic or the pulp will become necrotic. In cases of *asymptomatic irreversible pulpitis,* endodontic treatment should be performed as soon as possible so that symptomatic irreversible pulpitis does not take place and result in severe pain and patient distress.

Pulp Necrosis

When pulpal *necrosis* (or *nonvital pulp*) occurs, the pulpal blood supply is nonexistent and the pulpal nerves are nonfunctional. It is the only clinical classification that directly attempts to describe the histologic status of the pulp (or lack thereof). This condition is subsequent to symptomatic or asymptomatic irreversible pulpitis. After the pulp becomes completely necrotic, the tooth will typically become asymptomatic until such time that symptoms develop as a result of extension of the disease process into the periradicular tissues. With pulp necrosis, the tooth will not respond to electric pulp tests or to cold stimulation. However, if heat is applied for an extended period of time, the tooth may respond to this stimulus. This response could possibly be related to remnants of fluid or gases in the pulp canal space expanding and extending into the periapical tissues. As previously discussed, a traumatic injury to a tooth may prevent the lack of a response to pulp tests and mimic that of pulpal necrosis; therefore, a good dental history is imperative. Pulpal necrosis may be partial or complete and it may not involve all of the canals in a multirooted tooth. For this reason, the tooth may present with confusing symptoms and where pulp testing over one root may give no response and over another root may give a vital response. The tooth may also exhibit symptoms of symptomatic irreversible pulpitis.

After the pulp becomes necrotic, bacterial growth can be sustained within the canal. When this infection (or the bacterial toxins from this infection) extends into the periodontal ligament space, the tooth may become symptomatic to percussion or exhibit spontaneous pain. Radiographic changes may occur, ranging from a thickening of the periodontal ligament space to the appearance of a periapical radiolucent lesion. The tooth may become hypersensitive to heat, even to the warmth of the oral cavity, and is often relieved by applications of cold. As previously discussed, this may be helpful in attempting to localize a necrotic tooth when the pain is referred or not localized.

Previously Treated

The ABE has suggested a clinical diagnostic category for those cases that present where the tooth has already had nonsurgical root canal therapy performed and the root canal system has been filled with some type of root canal obturating material. In this situation the tooth may or may not present with signs or symptoms but will require additional nonsurgical or surgical endodontic procedures to retain the tooth. In most of these situations there will no longer be any vital or necrotic pulp tissue present to respond to pulp testing procedures.

Previously Initiated Therapy

The ABE has also suggested another clinical diagnostic category for those cases that present with partial endodontic therapy has been performed. Teeth in this category would include cases where only a pulpotomy or pulpectomy had been performed before presenting for root canal therapy. In most instances the pulpotomy or pulpectomy was performed as an emergency procedure for symptomatic or asymptomatic irreversible pulpitis cases. In other situations these procedures may have been performed as part of vital pulp therapy procedures, traumatic tooth injuries, apexification or apexogenesis therapy. At the time these cases present for the root canal therapy it would not be possible to make an accurate pulpal diagnosis since all or part of the pulp tissue has already been removed.

Apical (Periapical) Disease

Normal Apical Tissues

This classification is the standard against which all of the other apical disease processes are compared. In this category the patient is asymptomatic and the tooth responds normally to percussion and palpation testing. The radiograph reveals an intact lamina dura and periodontal ligament space around all the root apices.

Symptomatic Apical Periodontitis

A tooth with *symptomatic apical periodontitis* will have an acutely painful response to biting pressure or percussion. This tooth may or may not respond to pulp vitality tests, and the radiograph or image of this tooth will generally exhibit at least a widened periodontal ligament space and may or may not have an apical radiolucency associated with one or all of the roots.

Asymptomatic Apical Periodontitis

A tooth with *asymptomatic apical periodontitis* generally presents with no clinical symptoms. This tooth does not respond to pulp vitality tests, and the radiograph or image will exhibit an apical radiolucency. This tooth is generally not sensitive to biting pressure but may "feel different" to the patient on percussion.

Acute Apical Abscess

A tooth with an *acute apical abscess* will be acutely painful to biting pressure, percussion, and palpation. This tooth will not respond to any pulp vitality tests and will exhibit varying degrees of mobility. The radiograph or image can exhibit anything from a widened periodontal ligament space to an apical radiolucency. Swelling will be present intraorally and the facial tissues adjacent to the tooth will almost always present with some degree of swelling. The patient will frequently be febrile, and the cervical and submandibular lymph nodes will exhibit tenderness to palpation.

Chronic Apical Abscess

A tooth with a *chronic apical abscess* will not generally present with clinical symptoms. This tooth will not respond to pulp vitality tests and the radiograph or image will exhibit an apical radiolucency. The tooth is generally not sensitive to biting pressure but can "feel different" to the patient on percussion. This entity is distinguished from asymptomatic apical periodontitis because it will exhibit intermittent drainage through an associated sinus tract.

Pain of Nonodontogenic Origin

If after all of the testing procedures are completed and the decision is reached that the pain is not of odontogenic origin, then the patient should be referred to an orofacial pain clinic for further testing. This diagnostic classification is covered in detail in Chapter 3.

SUMMARY

Endodontics is a multifaceted specialty, with much emphasis on how cases are clinically treated. Clinicians have increased their ability to more accurately perform endodontic procedures by way of increased visualization using DOMs, precise apical foramen detection using electronic apex locators, enhanced imaging techniques using digital radiography, and more. Practices have incorporated more refined canal cleaning and shaping techniques by using ultrasonics and rotary-driven nickel titanium files facilitated with computer-assisted electronic handpieces. Many other recent advancements have also been introduced with the objective of achieving an optimal result during endodontic treatment. However, these advancements are useless if an incorrect diagnosis is made. Before the clinician ever considers performing any endodontic treatment, the following questions must be answered:

- Is the existing problem of dental origin?
- Are the pulpal tissues within the tooth pathologically involved?
- Why is the pulpal pathosis present?
- What is the appropriate form of treatment?

Testing, questioning, and reasoning are combined in order to achieve an accurate diagnosis and to ultimately form an appropriate treatment plan. The art and science of making this diagnosis are the first steps that must be taken before initiating any treatment.

CRACKED AND FRACTURED TEETH

EMERGENCY CLASSIFICATIONS

The proper diagnosis and effective management of acute dental pain is possibly one of the most rewarding and satisfying aspects of providing dental care. An endodontic emergency is defined as pain and/or swelling, caused by various stages of inflammation or infection of the pulpal and/or periapical tissues. The cause of dental pain is generally from caries, deep or defective restorations, or trauma. Bender[9] stated that patients who manifest severe or referred pain almost always had a previous history of pain with the offending tooth. Approximately 85% of all dental emergencies arise as a result of pulpal or periapical disease, which would necessitate either extraction or endodontic treatment to relieve the symptoms.[32,47] It has also been estimated that about 12% of the U.S. population experienced a toothache in the preceding 6 months.[44]

Determining a definitive diagnosis can sometimes be challenging and even frustrating for the clinician; but a methodical, objective, and subjective evaluation, as described in Chapter 1, is imperative before developing a proper treatment plan. Unfortunately, on the basis of the diagnosis, there are conflicting opinions on how to best clinically manage various endodontic emergencies. According to surveys taken among endodontists in 1977,[18,19] 1990,[25] and 2009[43] there are seven clinical presentations that are considered endodontic emergencies:

1. Irreversible pulpitis and normal periapex
2. Irreversible pulpitis and acute apical periodontitis
3. Necrotic pulp with acute apical periodontitis, with no swelling
4. Necrotic pulp, fluctuant swelling, with drainage
5. Necrotic pulp, fluctuant swelling, with no drainage
6. Necrotic pulp, diffuse facial swelling, with drainage through canals
7. Necrotic pulp, diffuse facial swelling, with no drainage

There are other endodontic emergencies that were not discussed in these surveys. These emergencies pertain to traumatic dental injuries, as discussed in Chapter 17, to teeth that have had previous endodontic treatment, as discussed in Chapters 16 and 25, and endodontic flare-ups that may occur between treatment sessions. Of course, there are also many types of facial pain that have a nonodontogenic origin; these are described in detail in Chapter 3.

In the decades between the previously cited surveys, there have been several changes as to the preferred clinical management of endodontic emergencies. Many of these treatment modifications have occurred because of the more contemporary armamentarium and materials as well as new evidence-based research and the presumption of empirical clinical success.

EMERGENCY ENDODONTIC MANAGEMENT

Because pain is both a psychologic and biologic entity, as discussed in Chapters 19 and online Chapter 26, the management of acute dental pain must take into consideration both the physical symptoms as well as the emotional state of the patient. The patient's needs, fears, and coping mechanisms must be compassionately understood. This assessment and the clinician's ability to build rapport with the patient are key factors in the comprehensive success of the patient's management.[9,24,35,64]

The methodical steps for determining an accurate diagnosis, based on evaluation of the patient's chief complaint, review of the medical history, and the protocols used for an objective and subjective diagnosis, are described in detail in Chapter 1. Once it has been determined that endodontic treatment is necessary, it is incumbent on the clinician to take the proper steps necessary to manage the acute dental emergency.

As described in Chapters 11 and 27, the clinician has a responsibility to inform the patient of the recommended treatment plan, and to advise the patient of the treatment alternatives, the risks and benefits that pertain, and the expected prognosis under the present circumstances. Given this information, the patient may elect extraction over endodontics, or possibly request a second opinion. The treatment plan should never be forced on a patient. The informed course of treatment is made jointly between the patient and the clinician.

In the event of an endodontic emergency, the clinician must determine the optimal mode of endodontic treatment pursuant to the diagnosis. Treatment may vary depending on the pulpal or periapical status, the intensity and duration of pain, and whether there is diffuse or fluctuant swelling. Paradoxically, as discussed later, the mode of therapy that we tend to choose has been directed more from surveys of practicing endodontists rather than from controlled clinical studies or research investigations.

Vital Teeth

As described in Chapter 1, vital teeth can have one of the following presentations:

- *Normal:* The teeth are asymptomatic with no objective pathoses.
- *Reversible pulpitis:* There is a reversible sensitivity to cold and/or osmotic changes (i.e., sweet, salty, and sour).
- *Irreversible pulpitis:* The sensitivity to temperature changes is more intense and with a longer duration.

Reversible Pulpitis

Reversible pulpitis can be induced by caries, exposed dentin, recent dental treatment, and defective restorations. Conservative removal of the irritant and a proper restoration will typically resolve the symptoms. However, the symptoms from exposed dentin, specifically from gingival recession and cervically exposed roots, can often be difficult to alleviate. Topical applications of desensitizing agents and the use of certain dentifrices have been helpful in the management of dentin hypersensitivity; the etiology, physiology, and management of this are discussed in Chapter 19.

Irreversible Pulpitis

The diagnosis of irreversible pulpitis can be subcategorized as asymptomatic or symptomatic. *Asymptomatic* irreversible pulpitis pertains to a tooth that has no symptoms, but with deep caries or tooth structure loss that, if left untreated, will cause the tooth to become symptomatic or nonvital. On the other hand, the pain from *symptomatic* irreversible pulpitis is often an emergency condition that requires immediate treatment. These teeth exhibit intermittent or spontaneous pain, whereby exposure to extreme temperatures, especially cold, will elicit intense and prolonged episodes of pain, even after the source of the stimulus is removed.

In 1977,[18,19] 187 board-certified endodontists were surveyed to determine how they would manage various endodontic emergencies. Ten years later, 314 board-certified endodontists responded to the same questionnaire in order to determine whether there have been any procedural changes in how these emergencies are managed.[25] The emergency treatment of a tooth with irreversible pulpitis with or without a normal periapex seemed to be managed fairly similarly. In the same survey conducted in 2009,[43] most respondents stated that they cleaned to the level of the "apex," as confirmed with an electronic apex locator; this suggests a change in the management of endodontic cases based on the advent of a more contemporary armamentarium. In general, the most current survey indicates that there is a trend toward more cleaning and shaping of the canal when irreversible pulpitis presents with a normal periapex, compared with performing just pulpectomies as described in the 1977 survey. None of the individuals surveyed in the 1990 or 2009 poll stated that they would manage these emergencies by establishing any type of drainage by trephinating the apex, making an incision, or leaving the tooth open for an extended period of time. In addition, for vital teeth, the 1977 survey did not even broach the concept of completing the endodontics in one visit, whereas in the 1988 study about one third of the respondents indicated that they would complete these vital cases in a single visit. Since the early 1980s, there seems to have been an increase in the acceptability of providing endodontic therapy in one visit, especially in cases of vital pulps, with most studies revealing an equal number, or fewer, flare-ups after single-visit endodontic treatment.[20,54,56,61,63,69] However, this has not come without controversy, with some studies showing otherwise,[23,77] contending that there is more posttreatment pain after single-visit endodontics, and possibly a lower long-term success rate. Unfortunately, time constraints at the emergency visit often make the single-visit treatment option difficult.[3] If root canal therapy is to be completed at a later date, medicating the canal with calcium hydroxide probably is indicated to reduce the chances of bacterial growth in the canal between appointments[13]; however, controlled studies have not substantiated this concept.[10,13,31] One randomized clinical study showed that a dry cotton pellet was as effective in relieving pain as a pellet moistened with camphorated monochlorophenol (CMCP), metacresylacetate (Cresatin), eugenol, or saline.[31] Sources of infection, such as caries and defective restorations, should be completely removed to prevent recontamination of the root canal system between appointments.[31] The concept of single- versus multiple-visit endodontics is described in greater detail in Chapter 4.

For emergency endodontic treatment of vital teeth that are not initially sensitive to percussion, occlusal reduction has not been shown to be beneficial.[15,25] However, the clinician should be cognizant of the possibility of occlusal interferences and prematurities that might cause tooth fracture under heavy mastication. In vital teeth in which the inflammation has extended periapically, which will present with pretreatment pain to percussion, occlusal reduction has been reported to reduce posttreatment pain.[25,53,62]

Antibiotics are not recommended for the emergency management of irreversible pulpitis[40] (see Chapter 19). Moreover, placebo-controlled clinical trials have demonstrated that antibiotics have no effect on pain levels in patients with irreversible pulpitis.[51]

On the basis of several surveys of board-certified endodontists as well as other recommendations in the literature,[13,25,30,43,71] the emergency management of a symptomatic irreversible pulpitis involves initiating root canal treatment, with complete pulp removal and total cleaning of the root canal system. Unfortunately, in an emergency situation, the allotted time necessary for this treatment is often an issue.

Given the potential time constraints and inevitable differences in skill level between clinicians, it may not be feasible to complete the total canal cleaning at the initial emergency visit. Subsequently, especially with multirooted teeth, a pulpotomy (removal of the coronal pulp or tissue from the widest canal) has been advocated for emergency treatment of irreversible pulpitis.[30,71]

To assist the clinician in assessing the level of difficulty of a given endodontic case, the American Association of Endodontists (Chicago, IL) has developed the "AAE Endodontic Case Difficulty Assessment Form and Guidelines" (Fig. 2-1). This form is intended to make case selection more efficient, more consistent, and easier to document, as well as to provide a more objective ability to determine when it may be necessary to refer the patient to another clinician, who may be better able to manage the complexities of the case.

Pulpal Necrosis With Acute Apical Abscess

No Swelling

Over the years, the proper methodology for the emergency endodontic management of necrotic teeth has been controversial. In a 1977 survey of board-certified endodontists,[18,19] it was reported that, in the absence of swelling, most respondents would completely instrument the canals, keeping the file short of the radiographic apex. However, when swelling was present, the majority of those polled in 1977 preferred to leave the tooth open, with instrumentation extending beyond the apex to help facilitate drainage through the canals. Ten years later and again validated in a 2009 study, most respondents favored complete instrumentation regardless of the presence of swelling. Also, it was the decision of 25.2% to 38.5% of the clinicians to leave these teeth open in the event of diffuse swelling; 17.5% to 31.5% left the teeth open in the presence of a fluctuant swelling. However, as discussed later, there is currently a trend toward not leaving teeth open for drainage. There is also another trend: when treatment is done in more than one visit, most endodontists will use calcium hydroxide as an intracanal medicament.[43]

Care should be taken not to allow necrotic debris to be pushed beyond the apex, because this has been shown to promote more posttreatment discomfort.[10,25,59,67] Improvements in technology, such as electronic apex locators, have facilitated increased accuracy in determining working length measurements, which in turn may allow for a more thorough canal debridement. These devices are now used by an increased number of clinicians.[17,43]

TREPHINATION

In the absence of swelling, trephination is the surgical perforation of the alveolar cortical plate to release from between the cortical plates the accumulated tissue exudate that causes pain. Its use has been historically advocated to provide pain relief in patients with severe and recalcitrant periradicular pain.[18,19] The technique involves an engine-driven perforator entering through the cortical bone and into the cancellous bone, often without the need for an incision.[12] This provides a pathway for drainage from the periradicular tissues. Although more recent studies have failed to show the benefit of trephination in patients with irreversible pulpitis with acute periapical periodontitis[48] or symptomatic necrotic teeth with radiolucencies,[53] there are still some advocates who recommend trephination for managing acute and intractable periapical pain.[33] The clinician should understand that local anesthesia may be difficult.[36] Also, extreme care must be taken to guard against inadvertent and possibly irreversible injury to the tooth root or surrounding structures, such as the mental foramen, intraalveolar nerve, or maxillary sinus.

NECROSIS AND SINGLE-VISIT ENDODONTICS

Although single-visit endodontic treatment for teeth diagnosed with irreversible pulpitis is not contraindicated,[1,56,58,63,78] performing single-visit endodontics on necrotic and previously treated teeth is not without controversy. In cases of necrotic teeth, research[20] has indicated that there may be no difference in posttreatment pain if the canals are filled at the time of the emergency versus a later date. Although some more recent studies[68,72] have questioned the long-term prognosis of such treatment, especially in cases of acute periodontitis, several studies,[21,42] including a CONSORT (Consolidated Standards of Reporting Trials) clinical trial,[57] have shown no difference in outcome between single-visit and two-visit treatments. The concept of single- versus multivisit endodontics is further discussed in Chapter 4.

Swelling

Tissue swelling may be associated with an acute periradicular abscess at the time of the initial emergency visit, or may occur as an interappointment flare-up or as a postendodontic complication. Swellings may be localized or diffuse, fluctuant or firm. Localized swellings are confined within the oral cavity whereas a diffuse swelling, or cellulitis, is more extensive, spreading through adjacent soft tissues, dissecting tissue spaces along fascial planes.[37]

Swelling may be controlled by establishing drainage through the root canal or by incising the fluctuant swelling. As discussed later, and in Chapter 15, antibiotics are also an integral part of the management of swelling. The principal modality for managing swelling secondary to endodontic infections is to achieve drainage and remove the source of the infection.[27,37] When the swelling is localized, the preferred avenue is drainage through the root canal. Complete canal debridement and disinfection[29,74] are paramount to success regardless of observable drainage, because the presence of any bacteria remaining within the root canal system will compromise the resolution of the acute infection.[45] In the presence of persistent swelling, gentle finger pressure to the mucosa overlying the swelling may help facilitate drainage. Once the canals have been cleaned and allowed to dry, the access should be closed.[13,25,30] In these cases, there has been a trend to use calcium hydroxide as the intracanal medicament.[43]

INCISION FOR DRAINAGE

Often it becomes necessary to establish drainage from a localized soft tissue swelling. This can be accomplished through the *incision for drainage* of the area.[52] Incision for drainage is indicated whether the cellulitis is indurated or fluctuant.[37] A pathway for drainage is needed to prevent further spread of infection. An incision for drainage allows decompression of the increased tissue pressure associated with edema and can provide significant pain relief for the patient. The incision

Guidelines for Using the AAE Endodontic Case Difficulty Assessment Form

The AAE designed the Endodontic Case Difficulty Assessment Form for use in endodontic curricula. The Assessment Form makes case selection more efficient, more consistent and easier to document. Dentists may also choose to use the Assessment Form to help with referral decision making and record keeping.

Conditions listed in this form should be considered potential risk factors that may complicate treatment and adversely affect the outcome. Levels of difficulty are sets of conditions that may not be controllable by the dentist. Risk factors can influence the ability to provide care at a consistently predictable level and impact the appropriate provision of care and quality assurance.

The Assessment Form enables a practitioner to assign a level of difficulty to a particular case.

LEVELS OF DIFFICULTY

MINIMAL DIFFICULTY	Preoperative condition indicates routine complexity (uncomplicated). These types of cases would exhibit only those factors listed in the MINIMAL DIFFICULTY category. Achieving a predictable treatment outcome should be attainable by a competent practitioner with limited experience.
MODERATE DIFFICULTY	Preoperative condition is complicated, exhibiting one or more patient or treatment factors listed in the MODERATE DIFFICULTY category. Achieving a predictable treatment outcome will be challenging for a competent, experienced practitioner.
HIGH DIFFICULTY	Preoperative condition is exceptionally complicated, exhibiting several factors listed in the MODERATE DIFFICULTY category or at least one in the HIGH DIFFICULTY category. Achieving a predictable treatment outcome will be challenging for even the most experienced practitioner with an extensive history of favorable outcomes.

Review your assessment of each case to determine the level of difficulty. If the level of difficulty exceeds your experience and comfort, you might consider referral to an endodontist.

The AAE Endodontic Case Difficulty Assessment Form is designed to aid the practitioner in determining appropriate case disposition. The American Association of Endodontists neither expressly nor implicitly warrants any positive results associated with the use of this form. This form may be reproduced but may not be amended or altered in any way.

FIG. 2-1 The American Association of Endodontists (AAE) Endodontic Case Difficulty Assessment Form and Guidelines, developed to assist the clinician in assessing the level of difficulty of a given endodontic case and to help determine when referral may be necessary.

Continued

AAE Endodontic Case Difficulty Assessment Form

Criteria and Subcriteria	Minimal Difficulty	Moderate Difficulty	High Difficulty
A. PATIENT CONSIDERATIONS			
Medical history	☐ No medical problem (ASA Class 1*)	☐ One or more medical problems (ASA Class 2*)	☐ Complex medical history/serious illness/disability (ASA Classes 3-5*)
Anesthesia	☐ No history of anesthesia problems	☐ Vasoconstrictor intolerance	☐ Difficulty achieving anesthesia
Patient disposition	☐ Cooperative and compliant	☐ Anxious but cooperative	☐ Uncooperative
Ability to open mouth	☐ No limitation	☐ Slight limitation in opening	☐ Significant limitation in opening
Gag reflex	☐ None	☐ Gags occasionally with radiographs/treatment	☐ Extreme gag reflex which has compromised past dental care
Emergency condition	☐ Minimum pain or swelling	☐ Moderate pain or swelling	☐ Severe pain or swelling
B. DIAGNOSTIC AND TREATMENT CONSIDERATIONS			
Diagnosis	☐ Signs and symptoms consistent with recognized pulpal and periapical conditions	☐ Extensive differential diagnosis of usual signs and symptoms required	☐ Confusing and complex signs and symptoms: difficult diagnosis ☐ History of chronic oral/facial pain
Radiographic difficulties	☐ Minimal difficulty obtaining/interpreting radiographs	☐ Moderate difficulty obtaining/interpreting radiographs (*e.g.*, high floor of mouth, narrow or low palatal vault, presence of tori)	☐ Extreme difficulty obtaining/interpreting radiographs (*e.g.*, superimposed anatomical structures)
Position in the arch	☐ Anterior/premolar ☐ Slight inclination (<10°) ☐ Slight rotation (<10°)	☐ 1st molar ☐ Moderate inclination (10-30°) ☐ Moderate rotation (10-30°)	☐ 2nd or 3rd molar ☐ Extreme inclination (>30°) ☐ Extreme rotation (>30°)
Tooth isolation	☐ Routine rubber dam placement	☐ Simple pretreatment modification required for rubber dam isolation	☐ Extensive pretreatment modification required for rubber dam isolation
Morphologic aberrations of crown	☐ Normal original crown morphology	☐ Full coverage restoration ☐ Porcelain restoration ☐ Bridge abutment ☐ Moderate deviation from normal tooth/root form (*e.g.*, taurodontism, microdens) ☐ Teeth with extensive coronal destruction	☐ Restoration does not reflect original anatomy/alignment ☐ Significant deviation from normal tooth/root form (*e.g.*, fusion, dens in dente)
Canal and root morphology	☐ Slight or no curvature (<10°) ☐ Closed apex <1 mm diameter	☐ Moderate curvature (10-30°) ☐ Crown axis differs moderately from root axis. Apical opening 1-1.5 mm in diameter	☐ Extreme curvature (>30°) or S-shaped curve ☐ Mandibular premolar or anterior with 2 roots ☐ Maxillary premolar with 3 roots ☐ Canal divides in the middle or apical third ☐ Very long tooth (>25 mm) ☐ Open apex (>1.5 mm in diameter)
Radiographic appearance of canal(s)	☐ Canal(s) visible and not reduced in size	☐ Canal(s) and chamber visible but reduced in size ☐ Pulp stones	☐ Indistinct canal path ☐ Canal(s) not visible
Resorption	☐ No resorption evident	☐ Minimal apical resorption	☐ Extensive apical resorption ☐ Internal resorption ☐ External resorption
C. ADDITIONAL CONSIDERATIONS			
Trauma history	☐ Uncomplicated crown fracture of mature or immature teeth	☐ Complicated crown fracture of mature teeth ☐ Subluxation	☐ Complicated crown fracture of immature teeth ☐ Horizontal root fracture ☐ Alveolar fracture ☐ Intrusive, extrusive or lateral luxation ☐ Avulsion
Endodontic treatment history	☐ No previous treatment	☐ Previous access without complications	☐ Previous access with complications (*e.g.*, perforation, non-negotiated canal, ledge, separated instrument) ☐ Previous surgical or nonsurgical endodontic treatment completed
Periodontal-endodontic condition	☐ None or mild periodontal disease	☐ Concurrent moderate periodontal disease	☐ Concurrent severe periodontal disease ☐ Cracked teeth with periodontal complications ☐ Combined endodontic/periodontic lesion ☐ Root amputation prior to endodontic treatment

*American Society of Anesthesiologists (ASA) Classification System

Class 1: No systemic illness. Patient healthy.
Class 2: Patient with mild degree of systemic illness, but without functional restrictions, *e.g.*, well-controlled hypertension.
Class 3: Patient with severe degree of systemic illness which limits activities, but does not immobilize the patient.
Class 4: Patient with severe systemic illness that immobilizes and is sometimes life threatening.
Class 5: Patient will not survive more than 24 hours whether or not surgical intervention takes place.

www.asahq.org/clinical/physicalstatus.htm

FIG. 2-1, cont'd

also provides a pathway not only for bacteria and bacterial by-products but also for the inflammatory mediators that are associated with the spread of cellulitis.

The basic principles of incision for drainage are as follows:

- Make the incision at the site of greatest fluctuant swelling.
- Dissect gently, through the deeper tissues, and thoroughly explore all parts of the abscess cavity, eventually extending to the offending roots that are responsible for the pathosis. This will allow compartmentalized areas of inflammatory exudates and infection to be disrupted and evacuated.
- To promote drainage, the wound should be kept clean with very warm saltwater mouth rinses. Intraoral heat application to infected tissues results in a dilation of small vessels, which subsequently intensifies host defenses through increased vascular flow.[27,37]

A diffuse swelling may develop into a life-threatening medical emergency. Because the spread of infection can traverse between the fascial planes and muscle attachments, vital structures can be compromised and breathing may be impeded. It is imperative that the clinician be in constant communication with the patient to ensure that the infection does not worsen and that medical attention is provided as necessary. Antibiotics and analgesics should be prescribed, and the patient should be monitored closely for the next several days or until there is improvement. Individuals who show signs of toxicity, elevated body temperature, lethargy, central nervous system (CNS) changes, or airway compromise should be referred to an oral surgeon or medical facility for immediate care and intervention.

Symptomatic Teeth With Previous Endodontic Treatment

The emergency management of teeth with previous endodontic treatment may be technically challenging and time-consuming. This is especially true in the presence of extensive restorations, including posts and cores, crowns, and bridgework. However, the goal remains the same as for the management of necrotic teeth: Remove contaminants from the root canal system and establish patency to achieve drainage.[31,58] Gaining access to the periapical tissues through the root canals may require removal of posts and obturation, as well as negotiating blocked or ledged canals. Failure to complete root canal debridement and achieve periapical drainage may result in continued painful symptoms. The ability, practicality, and feasibility to adequately re-treat the root canal system must be carefully assessed before the initiation of treatment, as conventional retreatment might not be the optimal treatment plan. This is further discussed in Chapter 254.

Leaving Teeth Open

On rare occasions, canal drainage may continue from the periapical spaces (Fig. 2-2). In these cases, the clinician may opt to step away from the patient for some time to allow for the drainage to continue and hopefully resolve on the same treatment visit.[71]

Historically, in the presence of acutely painful necrotic teeth with no swelling to diffuse swelling, 19.4% to 71.2% of surveyed endodontists would leave the tooth open between visits.[18,19] However, the more current literature makes it clear that this form of treatment would impair uneventful resolution and create more complicated treatment.[6,8,79] For this reason, *leaving teeth open between appointments is not recommended.* There has even been a documented case report of a foreign object being found to enter the periapical tissues through a tooth that had been left open for drainage.[66] However, leaving teeth open between visits to allow for drainage or to manage intractable pain is not without controversy. August in 1977[4] and again in 1982[5] suggested that the problem with leaving teeth open had more to do with how they are later closed. He found that total instrumentation before the closing of open teeth had a 96.7% success rate.

ANTIBIOTICS

The prescription of antibiotics should be adjunctive to appropriate clinical treatment (see Chapters 15 and 19 for details). Because of potential risk factors such as allergies, drug interactions, and systemic complications, antibiotics should be prescribed judicially. They are indicated when signs and symptoms suggest systemic involvement such as high fever, malaise, cellulitis, unexplained trismus, and persistent and progressive infections, and for patients who are immunologically compromised.[7,22,28,34,74] The objective is to aid in the elimination of infection from the tissue spaces. The use of antibiotics alone, without properly addressing the source of the endodontic infection, is not appropriate treatment.[27,37]

ANALGESICS

Because a more thorough description of pain medications can be found in Chapter 19, the following information is merely a summary of pain control using analgesics. Because pulpal and periapical pain involves inflammatory processes, the first choice of analgesics is nonsteroidal antiinflammatory drugs (NSAIDs).[43] However, no pain medication can replace the efficacy of thoroughly cleaning the root canal to rid the tooth of the source of infection.[26]

Aspirin has been used as an analgesic for more than 100 years. In some cases, it may be more effective than 60 mg of codeine[14]; its analgesic and antipyretic effects are equal to those of acetaminophen, and its antiinflammatory effect is more potent.[16] However, aspirin's side effects include epigastric distress, nausea, and gastrointestinal ulceration. In addition, its analgesic effect is inferior to that of ibuprofen, 400 mg. When NSAIDs and aspirin are contraindicated, such as in patients for whom gastrointestinal problems are a concern, acetaminophen is the preferred nonprescription analgesic. The maximal dose of 4 g in a 24-hour period should not be exceeded.

For moderate to severe pain relief, ibuprofen, an NSAID, has been found to be superior to aspirin (650 mg) and acetaminophen (600 mg) with or without codeine (60 mg). Also, ibuprofen has fewer side effects than the combinations with opioid.[14,39] The maximal dose of 3.2 g in a 24-hour period should not be exceeded. Patients who take daily doses of aspirin for its cardioprotective benefit can take occasional doses of ibuprofen; however, it would be prudent to advise such patients to avoid regular doses of ibruprofen.[46] These patients would gain more relief by taking a selective cyclooxygenase (COX)-2 inhibitor, such as diclofenac or celecoxib.

Because of their antiinflammatory effect, NSAIDs can suppress swelling to a certain degree after surgical procedures. The good analgesic effect combined with the additional

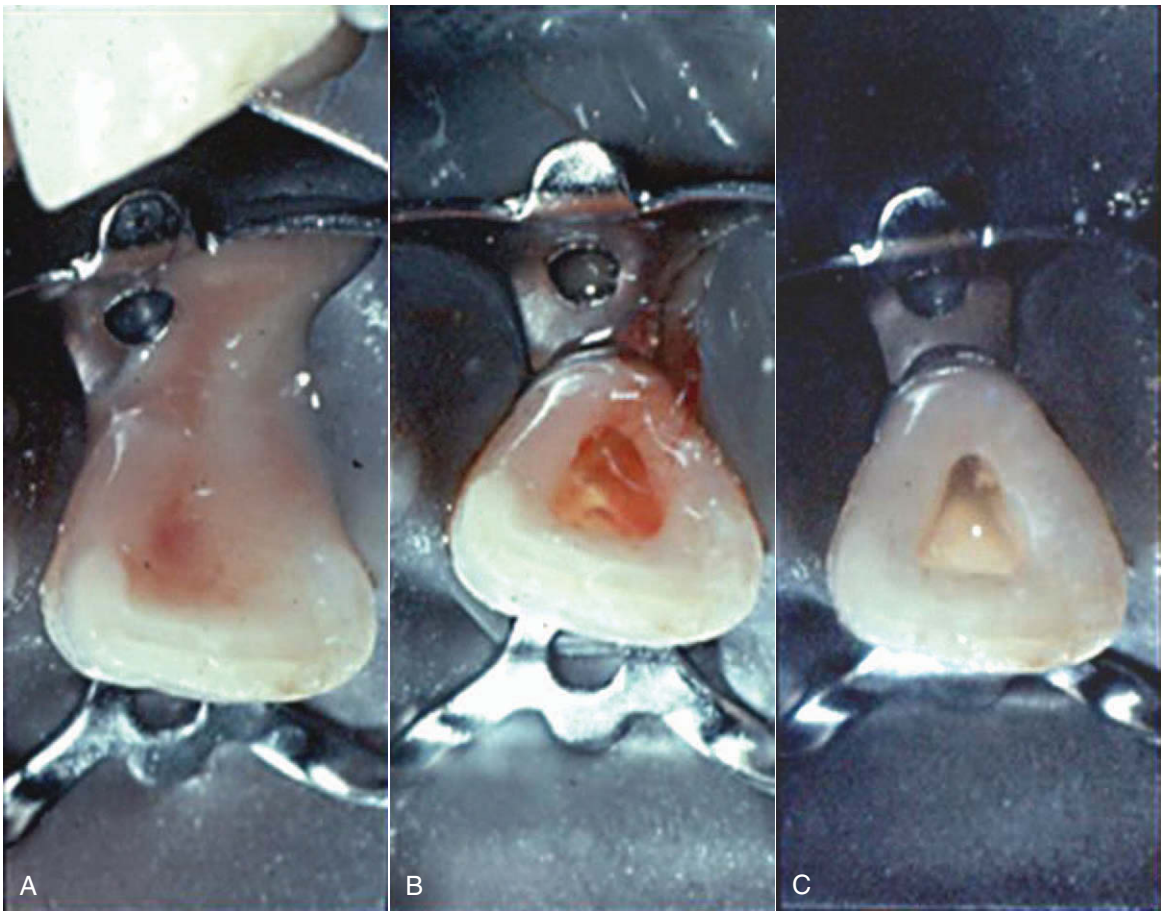

FIG. 2-2 Nonvital infected tooth with active drainage from the periapical area through the canal. **A,** Access opened and draining for 1 minute. **B,** Drainage after 2 minutes. **C,** Canal space dried after 3 minutes.

antiinflammatory benefit make NSAIDs, especially ibuprofen, the drug of choice for acute dental pain in the absence of any contraindication to their use. Ibuprofen has been used for more than 30 years and has been thoroughly evaluated.[16] If the NSAID alone does not have a satisfactory effect in controlling pain, then the addition of an opioid may provide additional analgesia. However, in addition to other possible side effects, opioids may cause nausea, constipation, lethargy, dizziness, and disorientation.

LABORATORY DIAGNOSTIC ADJUNCTS

Chapter 15 discusses culturing techniques and indications. Because the results of culturing for anaerobic bacteria usually require at least 1 to 2 weeks, it is not considered routine in the management of an acute endodontic emergency. Thus, in an endodontic emergency, antibiotic treatment, *when indicated* (see Chapter 15), should begin immediately, because oral infections can progress rapidly.

FLARE-UPS

An endodontic flare-up is defined as an acute exacerbation of a periradicular pathosis after the initiation or continuation of nonsurgical root canal treatment.[2] The incidence may be from 2% to 20% of cases.[38,49,55,76] A meta-analysis of the literature, using strict criteria, showed the flare-up frequency to be 8.4%.[73] Endodontic flare-ups seem to be more prevalent among females under the age of 20 years, and may occur more in maxillary lateral incisors; mandibular first molars, when there are large periapical lesions; and in the re-treatment of previous root canals.[70] The presence of pretreatment pain may also be a predictor of potential posttreatment flare-ups.[38,70,76] Fortunately, there does not seem to be a decrease in the successful conclusion of cases that had a treatment flare-up.[41]

Endodontic flare-ups may occur because of a variety of reasons, including preparation beyond the apical terminus, overinstrumentation, pushing dentinal and pulpal debris into the periapical area,[27] incomplete removal of pulp tissue, overextension of root canal filling material, chemical irritants (such as irrigants, intracanal medicaments, and sealers), hyperocclusion, root fractures, and microbiologic factors.[65] Although many of these cases can be pharmacologically managed (see Chapter 19), recalcitrant cases may require reentry into the tooth, the establishment of drainage either through the tooth or via trephination, or, at a minimum, adjustment of the occlusion.[15,62,65] The prophylactic use of antibiotics to decrease the incidence of flare-ups has been met with some controversy. Whereas earlier investigators[50] found that antibiotic administration before treatment of necrotic teeth decreased the incidence of flare-ups, a more recent study[70] found antibiotic use less effective than analgesics in reducing interappointment

emergencies, and other, more current studies[60,75] concluded that the prophylactic use of antibiotics had no effect on post-treatment symptoms.

CRACKED AND FRACTURED TEETH

Described in detail in Chapter 1, cracks and fractures can be difficult to locate and diagnose, but their detection can be an important component in the management of an acute dental emergency. In the early stages, cracks are small and difficult to discern. Removal of filling materials, applications of dye solutions, selective loading of cusps, transillumination, and magnification are helpful in their detection. As the crack or fracture becomes more extensive, it can become easier to visualize. Because cracks are difficult to find and their symptoms can be so variable, the name *cracked tooth syndrome* has been suggested[11] even though it is not truly a syndrome. Cracks in vital teeth often exhibit a sudden and sharp pain, especially during mastication. Cracks in nonvital or obturated teeth tend to have more of a "dull ache," but can still be sensitive to mastication.

The determination of the presence of a crack or fracture is paramount because the prognosis for the tooth may be directly dependent on the extent of the crack or fracture. Management of cracks in vital teeth may be as simple as a bonded restoration or a full coverage crown. However, even the best efforts to manage a crack may be unsuccessful, often requiring endodontic treatment or extraction. Fractures in nonvital or obturated teeth may be more challenging. In addition, it must be determined whether the crack or fracture was the cause of the necrosis. If so, the prognosis for the tooth is generally poor; thus extraction is recommended.

SUMMARY

The management of endodontic emergencies is an important part of a dental practice. It can often be a disruptive part of the day for the clinician and staff, but it is an invaluable solution for the distressed patient. Methodical diagnosis and prognostic assessment are imperative, with the patient being informed of the various treatment alternatives.

ACKNOWLEDGMENT

The editors acknowledge Dr. Louis Berman for his extraordinary contribution to preparing this chapter for publication.

A nonodontogenic toothache is, of course, an oxymoron. How can one have a toothache that is not odontogenic in etiology? The answer lies in the differentiation of the person's perception of where they sense their pain, termed the site of the pain, from the location of a pathophysiologic process giving rise to the pain that may or may not be in the same region, termed the source of the pain. This concept of the attribution of pain to an anatomic region that is different from the location of the etiologic process is generically known as "referred pain phenomenon" and is known to occur in multiple areas of the body. Thus, a nonodontogenic toothache has a source of pain that is not the tooth indicated by the patient, thereby clearly demonstrating the diagnostic challenge being presented.

Pain is common. It causes human suffering and has significant socioeconomic effects. Pain is a motivator that provokes individuals to seek care. But protracted chronic pain debilitates and can significantly impair the quality and productivity of a

person's life. One survey revealed that 66% of respondents reported experiencing pain or discomfort over a 6-month period. Significantly, 40% of respondents reported that this pain affected them to a "high degree."[16] A study published in 2003 estimated the lost productive work time attributed to common pain conditions among active workers to cost $61.2 billion per year.[104] One investigator reported that over a 6-month period of time, 22% of Americans experienced at least one of five types of facial pain. Of these pains, the most common type (12.2%) was toothache.[71]

Although toothache is the most common pain entity occurring in the facial region,[71] it is clear that many other types of pain can occur in the same general area. A primary responsibility of a dental practitioner is to diagnose pathologic entities associated with the oral cavity and masticatory apparatus. Many of these pathologic entities have pain as a primary component of their presentation. Because dental practitioners are sought out daily for the alleviation of odontogenic pain, it is imperative for them to have a basic working knowledge of other types of facial pain in order to make an accurate diagnosis and properly select care for patients. It is paramount to realize that not all pain entities presenting as toothache are of odontogenic origin. The presenting toothache may be a heterotopic symptom of another disorder. A heterotopic symptom is perceived to originate from a site that is different from the tissue that is actually the source of the pain. This is in contrast to primary pain, in which the perceived site of pain is the actual tissue from which the pain originates. Before discussing pain entities that mimic toothache it is helpful to have an understanding of the neurobiologic mechanisms of orofacial pain.

REVIEW OF NEUROANATOMY

Somatic Structures

To understand the pathways by which orofacial pain occurs, one must first gain a basic understanding of the structures involved in its transmission to higher brain centers. Structures of the orofacial region can be divided into two broad categories: somatic and neural structures. Somatic structures are those that make up the different nonneural tissues and organs. The somatic structures can be further anatomically divided into superficial and deep structures. Superficial structures include the skin, mucosa, and gingiva; pain that arises from these superficial structures is usually well localized (e.g., a sharp explorer penetrating the gingiva results in well-localized pain). Deep structures include musculoskeletal and visceral tissues. Pain from these deep structures is typically poorly localized and diffuse.

Neural Structures

Neural structures involved in the perception of pain include the afferent (toward the brain) and efferent (away from the brain) regulation of somatic structures. Transmission of nerve impulses from orofacial structures to the brain is via the peripheral nervous system, whereas modulation and interpretation of these impulses into what we feel as pain occur in the central nervous system. Pain can arise solely from either central or peripheral nervous tissue but heterotopic pain, which is often involved with nonodontogenic toothache, likely requires central modulation to occur.

Peripheral Nervous System

Pain arises as a result of tissue damage, or the potential for tissue damage, and is transmitted via terminal nerve fibers known as primary afferent nerve fibers. Two major classes of nociceptive (or pain-sensing) primary afferent nerve fibers can detect potentially damaging noxious stimuli: the A-delta and C fibers. Both fiber types have a wide distribution throughout the skin, oral mucosa, and tooth pulp. In addition, separate classes of nerve fibers exist that are involved in detecting nonnoxious stimuli such as vibration and proprioception. Such fibers can be found in the periodontal ligament, skin, and oral mucosa and include the A-beta fibers.

PRIMARY AFFERENT NEURONS

Detection and encoding of noxious stimuli for the orofacial region are performed primarily by the trigeminal, or fifth cranial, nerve. The majority of cell bodies of the trigeminal sensory fibers are in the trigeminal ganglion located on the floor of the middle cranial fossa. The peripheral axons of the trigeminal ganglion run in three divisions—the ophthalmic (V1), maxillary (V2), and mandibular (V3)—which innervate most of the oral mucosa, the temporomandibular joint, the anterior two thirds of the tongue, the dura of the anterior and middle cranial fossae, the tooth pulp, gingiva, and periodontal membrane.

In the peripheral nervous system, these neurons or nerves are referred to as primary afferent (i.e., sensory) fibers. The primary afferent fibers can broadly be divided into A-beta fibers, which transmit light touch or proprioceptive information, and A-delta and C fibers, which encode pain. The tooth is densely innervated by afferent nerve fibers, which are believed to transmit mainly pain in response to thermal, mechanical, or chemical stimuli. The vast majority of dental nerves are C fibers that innervate the central pulp, and most of which terminate beneath the odontoblasts.[20]

A-beta Fibers The rapidly conducting myelinated neurons that respond to light touch are called A-beta fibers. Under normal conditions, activation of the A-beta fibers by high-intensity stimulation results in low-frequency output in the central nervous system. Activation of A-beta fibers normally is interpreted as nonpainful mechanical stimulation[109] or "prepain."[20] A-beta fibers have been shown to undergo phenotypic changes that allow them to encode painful stimuli under inflammatory conditions.[84]

A-delta Fibers The A-delta fibers are lightly myelinated, have a faster conduction velocity than C fibers, and are believed to transmit a sharp or pricking sensation. A-delta fibers respond primarily to noxious mechanical stimuli rather than to chemical or thermal stimuli. Other A-delta fibers may be polymodal (responding to mechanical, chemical, and thermal stimuli)[10] or respond only to cold/mechanical[68] or hot/mechanical noxious stimuli.[34]

In the tooth pulp, A-delta fibers traverse the odontoblastic layer and terminate in the dentinal tubules.[22] Because of their location and their sensitivity to mechanical stimulation, A-delta fibers are believed to respond to stimuli that result in movement of fluid within the dentinal tubules (e.g., osmotic, mechanical probing or thermal stimuli applied to the external surface of the tooth).[15] Consistent with the hypothesized

mechanism of dentinal pain is the fact that the stimuli that cause dentinal fluid movement result in a sharp pain associated with A-delta fiber activation.[81] When intense noxious stimuli activate the A-delta fibers, the input to the central nervous system consists of high-frequency action potentials.

C Fibers The C fibers are unmyelinated, have slower conduction velocity, and are associated with a dull, aching, or burning sensation. Most C fibers are polymodal, responding to mechanical, thermal, and chemical stimuli. Because of the difference in conduction velocities, A-delta fibers are believed to transmit early, shooting pain, whereas C fibers would transmit late, dull pain. Noxious stimuli that exceed the receptor threshold of these nociceptive primary afferent terminals result in action potentials that travel centrally, signaling tissue damage. In the pulp tissue, the more centrally located C fibers respond to thermal, mechanical, and chemical stimuli, and are believed to be sensitized by inflammation.[34] All visceral structures are innervated primarily by afferent fibers conducting nociceptive information such as that carried by A-delta and C fibers.

Central Nervous System

The primary afferent fibers are responsible for the transduction and transmission of sensory information to higher brain centers and they do so by synapsing on neurons located within the trigeminal nucleus, which spans the midbrain and cervical spinal cord. This point marks the beginning of the central nervous system and is the point at which processing of pain information begins (Fig. 3-2).

Just as there are different types of sensory neurons in the periphery, in the trigeminal nucleus there are also different types of neurons that receive nociceptive input from the periphery. The ascending neurons located in the trigeminal nucleus are known collectively as *second-order* or *projection neurons* and can be subdivided into three distinct groups of neurons based on the type of information they receive: (1) low-threshold mechanoreceptors, (2) nociceptive-specific and (3) wide dynamic range neurons.

The primary central site of termination for nociceptive fibers is the subnucleus caudalis located in the most caudal region of the trigeminal nucleus,[34,50,120] which anatomically and functionally resembles the dorsal horn of the spinal cord and has been referred to as the medullary dorsal horn.[50] Four major components of nociceptive processing are located in the dorsal horn of the subnucleus caudalis: central terminals of afferents, local circuit neurons (interneurons), projection neurons, and descending neurons.[62] Within the subnucleus caudalis, the A-delta and C fibers terminate primarily in the outer laminae

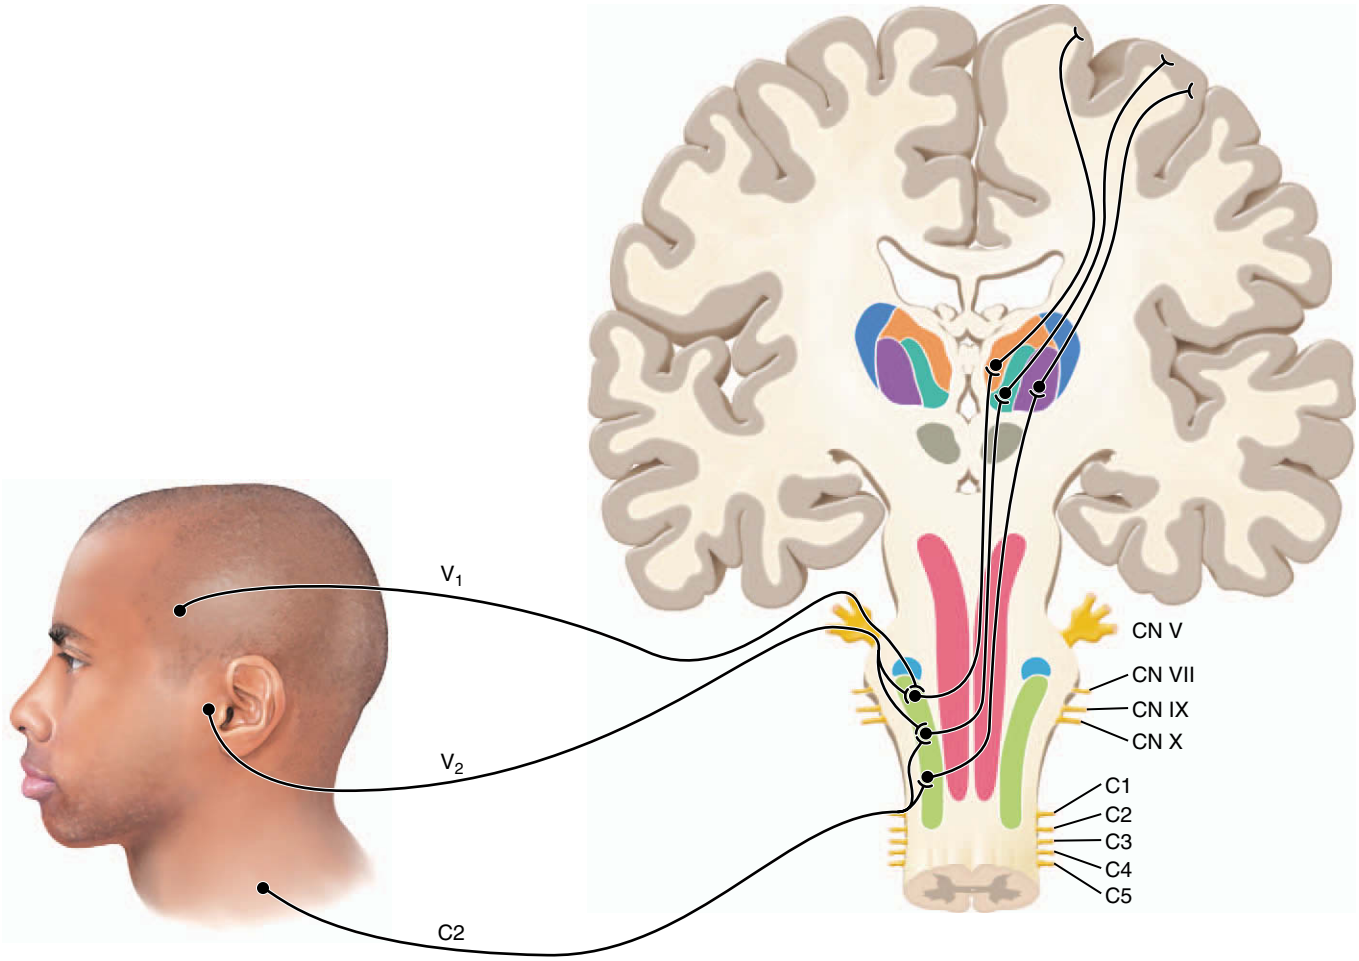

FIG. 3-2 A graphic depiction of the trigeminal nerve entering the brainstem. The primary afferent neuron synapses with a second-order neuron in the trigeminal nucleus. The second-order neuron carries pain information to the thalamus from which it is sent to the cerebral cortex for interpretation. (*Redrawn from Okeson JP*: Bell's orofacial pains, *ed 5, Chicago, 1995, Quintessence Publishing.*)

(I and IIa) and lamina V. Local circuit neurons are composed of islet cells (which are thought to be inhibitory) and stalked cells (which are believed to be excitatory).[33] Combined, the local circuit neurons may modulate nociceptive transmission from the primary afferents to the projection neurons.

The fourth component of the dorsal horn is the terminal endings of descending neurons. The descending neurons originate in the nucleus raphe magnus (NRM), the medullary reticular nuclei, and the locus ceruleus (LC). Descending brainstem neurons release serotonin (from the NRM) and/or norepinephrine (from the LC), which may inhibit the activity of projection neurons directly or by activating local opioid interneurons. These neurons are responsible for the endogenous abatement of pain; blockade of their activity results in increased pain transmission and reduced pain thresholds.

SECOND-ORDER NEURONS

Projection neurons have axons that cross to the contralateral medulla to ascend in the trigeminothalamic tract and project to the ventral posterior medial and intralaminar nuclei of the thalamus, where additional neurons project to the cortex. Projection neurons involved in the transmission of painful stimuli can be divided into two classes: wide dynamic range and nociceptive-specific neurons. Wide dynamic range neurons receive input from mechanoreceptors, thermoreceptors, and nociceptors, whereas nociceptive-specific neurons are excited solely by nociceptors. These two types of projection neurons may be responsible for signaling the severity and location of pain, respectively.[69]

Multiple primary afferent neurons may synapse on a single projection (i.e., convergence). This occurs to a much greater degree in deep tissues as opposed to cutaneous tissues. Primary afferent fibers of nontrigeminal origin such as those derived from vagus, glossopharyngeal, facial, and cervical spinal ganglia have been shown to converge and synapse onto trigeminal projection neurons located as far caudal as spinal level C4.[64] This phenomenon of convergence may result in the clinical finding of pain that radiates beyond an area of tissue injury. Convergence may also explain why pain appears to be associated with a site other than the injured area. Interestingly, when projection neurons receive input from superficial and deep structures, the more superficial inputs usually predominate.[99] Thus, pain originating from deep structures would typically be referred to superficial areas (e.g., pain originating from the jaw muscles would typically be referred to the face rather than deeper structures).

Autonomic Nervous System

The entire sympathetic innervation of the orofacial region is supplied by the stellate ganglia, which is located bilaterally at the level of the seventh cervical vertebra. Under normal conditions sympathetic stimulation has no influence on sensory function. However, afferent sympathetic fibers in an area of trauma may become involved in the response to pain and may also play a role in chronic pain states. Specifically, C fibers in the area of partial nerve injury may become responsive to sympathetic nerve stimulation. The modulation of nociception by the sympathetic nervous system has been shown such that release of pain neurotransmitters may be altered in the presence of sympathetic agonists and by blockade of the sympathetic nervous system, using antagonists.[61] Whether the effects of sympathetic nerve fibers on pain transmission are direct (via homeostatic regulation) or indirect remain unclear. The parasympathetic division of the autonomic nervous system has not been shown to be involved in the development or modulation of pain.

REVIEW OF NEUROPHYSIOLOGY

Peripheral Sensitization

After tissue insult there is an inflammatory reaction that often produces pain. The severity of pain that follows is related to several conditions of the injury, such as the type, extent, and location; the innervation of the tissue; and the phase of the inflammation. In the nociceptive system, tissue injury can manifest itself as increased responsiveness and/or reduced thresholds to a noxious stimulus, referred to as hyperalgesia. Hyperalgesia can be partially accounted for by sensitization of nociceptors (primary hyperalgesia), and by central nervous system mechanisms (secondary hyperalgesia).

In the absence of tissue damage, activation of C or A-delta fibers produces a transient pain. This pain is believed to serve as a physiologic warning. When there is tissue injury, afferent fibers may be activated by lower intensity stimuli than usual, and the quality of pain may be more persistent and intense. This phenomenon is due, in part, to sensitization of nociceptors, including an increase in spontaneous activity.

At the site of tissue injury there are a number of inflammatory mediators that can directly or indirectly sensitize primary afferent nociceptors (see Chapter 19 for more details). These inflammatory mediators may be released from the local tissue cells, circulating and resident immune cells, vasculature and endothelial smooth muscle cells, and peripheral nervous system cells.

Central Sensitization

After peripheral tissue injury there is an afferent barrage from C fibers resulting from peripheral tissue inflammation, decreased afferent thresholds, and spontaneous firing of afferent fibers. When a second-order neuron receives a prolonged barrage of nociceptive input, the second-order neuron may also become sensitized. This results in a phenomenon referred to as central sensitization.[13] The result of central sensitization is enhanced processing (i.e., amplification) of neural impulses that are being transmitted to higher brain centers. Two effects of central sensitization are secondary hyperalgesia and referred pain.

Secondary hyperalgesia is an increased response to painful stimulation at the site of pain resulting from central nervous system changes. This is in contrast to primary hyperalgesia, which is a lowered pain threshold resulting from sensitization of peripheral neurons. Secondary hyperalgesia might be felt in superficial (e.g., gingiva or skin) or deep structures (e.g., muscles or teeth).

Terminology

In general, as research progresses and uncovers new ways we look at pain, the terminology changes. This can introduce some confusion, especially when older terms are used. Therefore, it may be helpful to present contemporary definitions of some of the basic terms and review some of the previously mentioned terms (Box 3-1).

BOX 3-1

Types of Pain

Pain
An unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in term of such damage[73]

Nociceptive Pain
Pain arising from activation of nociceptors[73]

Neuropathic Pain
Pain arising as a direct consequence of a lesion or disease affecting the somatosensory system[73,111]

Peripheral Sensitization
Increased responsiveness and reduced thresholds of nociceptors to stimulations of their receptive fields[73]

Central Sensitization
Increased responsiveness of nociceptive neurons in the central nervous system to their normal or subthreshold afferent input[73]

Heterotopic Pain
Any pain that is felt in an area other than its true source is heterotopic pain. There are three types of heterotopic pain: referred, central, and projected.[87] Referred pain is pain felt in an area innervated by a nerve different from the one that mediates the primary pain. Referred pain cannot be provoked by stimulation of the area where the pain is felt; rather, it is brought on by manipulation of the primary source of pain (Fig. 3-3). In addition, referred pain cannot be arrested unless the primary source of pain is anesthetized. The referral of pain tends to occur in a laminated fashion (Fig. 3-4). This is because peripheral nociceptors enter the spinal trigeminal tract in a laminated fashion. As a result there are general referral patterns in the face. In addition, the referral of pain is usually in a cephalad or upward direction. This is evidenced clinically in that pain from mandibular molars typically is referred to maxillary molars, as opposed to premolars or incisors

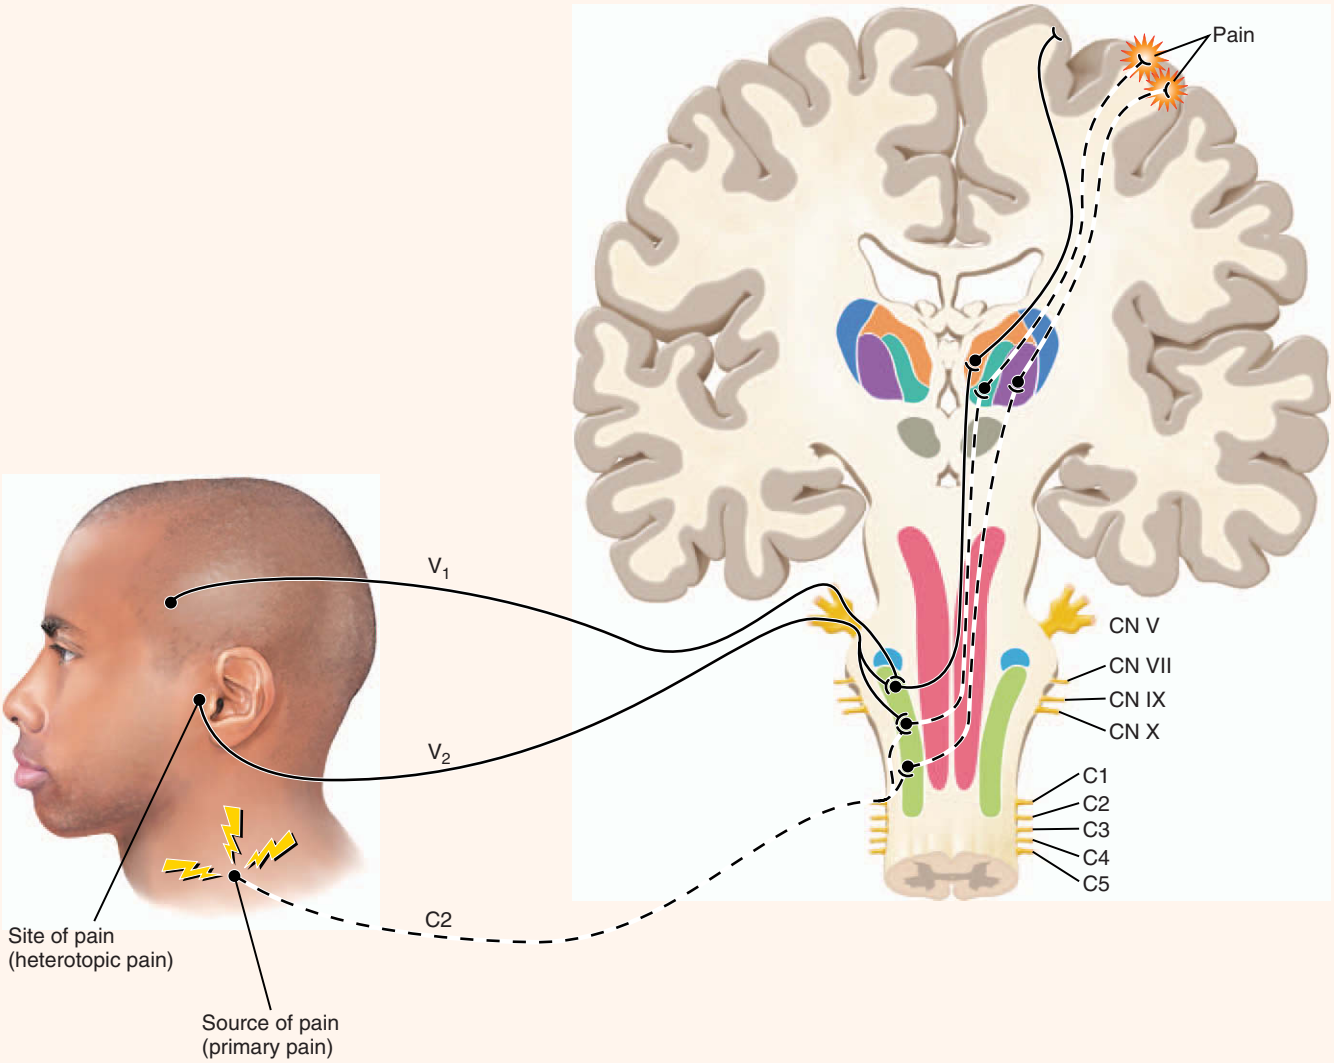

FIG. 3-3 Illustration of pain that is referred from an area innervated by one nerve *(C2)* to an area innervated by a different nerve *(V2)*. Note that this phenomenon occurs secondary to the convergence of different neurons onto the same second-order neuron in the trigeminal nucleus. The sensory cortex perceives two locations of pain. One area is the trapezius region that represents the source of pain. The second area of perceived pain is felt in the temporomandibular joint area, which is only a site of pain, not a source of pain. This pain is heterotopic (referred). *(Redrawn from Okeson JP:* Bell's orofacial pains, *ed 5, Chicago, 1995, Quintessence Publishing.)*

These laminated patterns commonly reflect the patterns of referred pains felt in the orofacial structures. *(Redrawn from Okeson JP:* Bell's orofacial pains*, ed 5, Chicago, 1995, Quintessence Publishing.)*

CLINICAL ENTITIES THAT CAN PRESENT AS TOOTHACHE

Sources of Odontogenic Toothache

Before considering heterotopic pains that may present as toothache, it is important to fully understand odontogenic pain as a primary source for toothache. There are only two structures that serve as sources for primary odontogenic pain. These structures are the pulp–dentin complex and the periradicular tissues. The innervation of the pulp is similar to that of other deep visceral tissues and in various states of pathosis will have pain characteristics similar to deep visceral tissues. The primary nociceptors of the pulp that respond to inflammation are the slow-conducting, high-threshold C fibers. Because their threshold is high, C fibers do not respond to normal or nonpathologic dentinal stimulation. C fibers typically conduct pain that is associated with tissue damage. In addition, C fibers respond in a threshold manner that can be termed "all or nothing." For example, a slightly cold stimulus that is below the C fiber threshold will fail to produce any sensation. Only when a stimulus is intense enough to reach the threshold will the C fiber fire, resulting in the sensation of pain.

Pulpal pain is mediated by C fibers and is dull, aching, or throbbing in nature. This is in contrast to the quick short sharp sensation produced by A-delta fibers that mediate dentinal pain. Therefore, when pulp testing, it is meaningful to note not only whether the patient perceived the stimulus but also the nature of the stimulus perceived. A simple notation of "s" (short) to indicate a response more typical of an A-delta fiber (dentinal pain), or a "p" (prolonged) to indicate the response was more indicative of a C fiber response (pulpal pain).

Tissue inflammation can result in sensitization of nerve fibers. When peripheral nociceptors (e.g., pulpal C fibers) are sensitized, the threshold of firing in response to a given stimulus (e.g., temperature and pressure) is lowered. In states of sensitization these nociceptors can be provoked with a less intense stimulus. The threshold for excitation is still "all or nothing" but the required level of stimulation has decreased.

These fibers can become so sensitized that they may fire at as low a temperature threshold as body temperature,[81] normally not sufficient to stimulate a C fiber. In fact, they can become so sensitized that they will fire in response to the normal pulse pressure of cardiac contraction, eliciting a complaint of "I can feel my heartbeat in my tooth" or "my tooth is throbbing." Sensitized C fibers can even fire without provocation, resulting in spontaneous pain.

Typical of deep visceral tissues, the pulpal nociceptors demonstrate a high degree of convergence in the central nervous system. In a study of cat brain, 74% of the neurons tested in the subnucleus caudalis showed convergence from multiple tooth pulps.[19] In addition, the dental pulp lacks proprioceptive neurons. The high degree of convergence from pulp tissue and the lack of proprioceptive information provided are the key factors in why purely pulpal pain can be so difficult for patients to localize. In addition to reducing localization of pain, convergence increases the referral of pain to tissues not actually affected by the inflammation. The fact that there is convergence of neurons from the pulps of mandibular teeth with those of maxillary teeth can result in pain from a mandibular pulpitis being referred to the maxillary arch. Because pulpal pain may be poorly localized by the patient, it is important for the clinician to localize the source of the pain. This is often accomplished through the use of tests that are employed in an attempt either to reproduce the eliciting stimulus of a patient's pain or to eliminate the pain. For example, pulpal pain should be aggravated with hot or cold stimulation and should be eliminated or significantly reduced with local anesthetic.

Unlike pulpal pain, pain of periradicular origin is easier to localize. Mechanoreceptors are numerous in the periodontal ligament (PDL) and are most densely concentrated in the apical one third.[74] Once inflammation from pulpal disease extends into the periodontal ligament patients are able to locate the source of the pain much more readily. As a musculoskeletal structure the PDL responds to noxious stimulation in a graded fashion. That is, the degree of discomfort a patient feels in relation to their periradicular pain is dependent on the degree of peripheral sensitization and the amount of provocation to this structure. A sensitized PDL will be uncomfortable to a patient if percussed lightly but more uncomfortable if percussed heavily. This is known as a graded response. It is, therefore, appropriate to record periradicular testing such as percussion and palpation in terms of degrees of tenderness (vs. "all or nothing"). As with pulpal pain, pain of periradicular origin should also have an identifiable etiology. Periradicular pain tends to be dull, aching, or throbbing and should resolve completely with local anesthesia. If pain of suspected periradicular origin is nonresponsive to local anesthetic, it is a strong indication that the pain may be nonodontogenic in origin.

The tooth is unique in the human body in that it has a visceral-like component, the pulp, and a musculoskeletal component, the periodontal ligament. Therefore, odontogenic pain can have a wide variety of presentations. Tooth pain can be diffuse or well localized, mild or intense, spontaneous or provoked with various stimuli applied at various intensities. The quality can vary between sharp and dull, aching or throbbing. This potential for extreme variability makes it possible for toothaches to mimic or be mimicked by many other types of pain that occur in the head and neck. In addition, because both the pulp tissue and periodontal ligament can be categorized as deep somatic tissue, continued nociceptive input from odontogenic pain has a great propensity to produce central excitatory effects such as secondary hyperalgesia, referred pain, secondary co-contraction of muscles, myofascial trigger points, and autonomic changes. These effects play a large role in adding to the complexity of diagnosing odontogenic pain and differentiating tooth pain from other sources in the region.

Sources of Nonodontogenic Toothache

This chapter provides information for the dental clinician to aid in the identification of toothaches with a nonodontogenic etiology. The clinician must have a thorough knowledge of all possible causes of orofacial pain, which includes both odontogenic and nonodontogenic conditions. This knowledge will prevent misdiagnosis and allow for proper treatment selection and referral if necessary. For information about treatment of these disorders other references should be used.

Consensus on the exact taxonomy with diagnostic criteria and their interrelationships among various orofacial pain disorders has not been established. Various health care professions involved in the diagnosis and treatment of such pains have used different terms in the literature. This of course can, and has, led to confusion, especially within what we refer to as neuropathic pain. The terms used in the literature are diverse, and overlap in meaning to an unknown degree; for example, phantom tooth pain and atypical odontalgia are used interchangeably. At other times the literature uses the same terms to describe seemingly different disorders; for example, trigeminal neuralgia has the connotation of an idiopathic pain disorder characterized either as intense, intermittent lightning bolt–type pain within one or more distributions of the trigeminal nerve, or as continuous pain that is often mild to moderate in intensity that arises in association with injury to a specific branch of the trigeminal nerve. Efforts have resulted in a working diagnostic framework for neuropathic pains.[111] Our classification scheme uses this framework to enhance clarity of communication and follow consensus, even though the application of these criteria to pains that present in the orofacial region is known to be associated with misclassification.[30]

Overall, one can classify the nonodontogenic reasons for toothache into five broad groups of pain disorders:

1. Musculoskeletal and other nonprogressive pains arising from somatic structures
2. Neurovascular pain, otherwise known as headache disorders
3. Neuropathic pains
4. Pain of purely psychologic origin, otherwise known as psychogenic toothache
5. Pain associated with a pathologic process

Musculoskeletal and Somatic Pain

MYOFASCIAL PAIN

Although any deep somatic tissue type in the head and neck has the propensity to induce central excitatory effects and therefore cause referral of pains to teeth, pains of muscular origin appear to be the most common.[40] Myofascial pain (MFP) emanates from small foci of hyperexcitable muscle tissue. Clinically these areas feel like taut bands or knots and are termed trigger points.[110] Typically the pain is described as a diffuse, constant, dull, aching sensation; this may lead the

clinician to a misdiagnosis of pulpal pain. Another potentially misleading characteristic of masticatory muscle pain is that patients may report pain when chewing. This feature is similar to pain that is periradicular, not pulpal in origin. On further investigation, it should become clear that the pain is triggered by contraction of masticatory muscles rather than loading of periodontal ligaments. Palpation of the muscles of mastication should reproduce the pain whereas percussion of the teeth should not. The intensity of the pain will increase and can be perceived in a distant site. Myofascial pain that is perceived to emanate from a tooth is a referred type of heterotopic pain. That is, the pain is felt in an area other than the nerve branch that innervates the trigger point. Typically muscles that refer pain to teeth are the masseter, temporalis, and lateral pterygoid; muscles of the neck and nonmuscular deep structures of the face can also be a source for this type of pain.[118]

Although the definitive pathogenesis of MFP is unknown, authors have theorized that muscles may become disturbed through injury or sustained contraction such as clenching.[39,88] Clinically this muscular contraction might occur as a parafunctional habit or as a protective response by localized muscle to an ongoing deep noxious input such as dental pain. Considering this theory and what is witnessed clinically, trigger points appear to be induced or aggravated by toothache. It also appears that trigger points can persist after the toothache has been resolved. This can be confusing for the clinician and frustrating for the patient. It is important to realize the relationship of these two entities. MFP can mimic toothache and toothaches may induce the development of MFP.

Toothaches of myofascial origin may arise with or without evidence of pulpal or periapical pathosis. Definitive diagnosis is based on lack of symptoms after pulp testing and percussion and/or palpation sensitivity, and/or failure to resolve symptoms with local anesthetic blockade. In contrast, jaw function and palpation of the masticatory muscle(s) will elicit toothaches of myofascial origin. Typically, local anesthetic infiltration into the trigger point(s) will lead to resolution of symptoms.

Some common therapeutic modalities used to treat myofascial pain include deep massage, relaxation techniques, "spray and stretch," muscle relaxants, and trigger point injections. Deep massage and relaxation techniques have the advantage of being noninvasive and easily administered. Spray and stretch involves application of a vapor coolant spray to the skin overlying the trigger point followed by a gentle stretching of the muscle. Trigger point injections are used for both the diagnosis and treatment of myofascial pain. Specifically, if the pain complaint is diminished on injection of the trigger point(s) then the source of the pain has been confirmed. The therapeutic efficacy of a trigger point injection varies. Some patients might experience lasting relief with one injection or several, whereas others may not. See the later section Additional Tests for further information about trigger point injections.

PAIN OF SINUS AND/OR NASAL MUCOSAL ORIGIN

Sinus/nasal mucosal pain is another source of pain that can mimic toothache.[2,3,25,114] Sinus pain can exhibit symptoms of fullness or pressure below the eyes, but is generally not particularly painful unless the nasal mucosa is also affected.[32] Pain from the nasal mucosa tends to be dull and aching and can also have a burning quality typical of visceral mucosal pain. In general, these pains are of viral, bacterial, or allergic etiology. Other symptoms consistent with these types of disease (e.g., congestion and/or nasal drainage) should be noted in the patient history.

Typical of deep visceral tissues, sinus/nasal mucosal pain can induce central excitatory effects such as secondary hyperalgesia, referral of pain, and autonomic changes. It is this tendency that gives sinus/nasal pain the ability to masquerade as toothache. Secondary hyperalgesia, seen clinically as a concentric spread of pain beyond the area of tissue injury, will result in tenderness of the mucosa in the area of the maxillary sinuses as well as tenderness to percussion of several maxillary teeth. Teeth tender to percussion and palpation suggest periradicular inflammation. Autonomic sequelae might present as edema and/or erythema in the area, which could be suggestive of a dental abscess. However, when an etiology for pulpal and therefore periradicular pathosis is absent, sinus/nasal mucosal disease should be suspected. Other symptoms of sinus disease include sensitivity to palpation of structures overlying sinuses (i.e., paranasal tenderness) and a throbbing or increased pain sensation when the head is placed lower than the heart. Dental local anesthetic blockade will not abate sinus/nasal mucosa pain although topical nasal anesthetic will.

Patients with suspected sinus/nasal mucosal disease should be referred to an otolaryngologist for further diagnosis and treatment. Physical examination as well as adjunctive tests may be necessary for definitive diagnosis. Tests may include nasal cytologic and ultrasound studies and the use of nasal endoscopes, in addition to imaging tests such as radiology and computed tomographic imaging.[31] Treatment of sinus/nasal mucosa pain is dependent on the etiology (e.g., bacterial, viral, allergic, or obstructive),

SALIVARY GLAND PAIN

Pain referred from one or more of the salivary glands may be perceived as tooth pain; this has not been encountered in clinical practice by the authors, but has been reported to present as a nonodontogenic toothache.[70,94] Because the primary somatosensory innervation of the salivary glands comes from the mandibular branch, it is conceivable that such a presentation will occur most often in mandibular teeth.

Neurovascular Pain

Neurovascular pains, otherwise and interchangeably referred to as headache disorders, have qualities similar to pulpal pain. These types of pain can be intense, often pulsatile, and are known to occur only in the head. The International Headache Society (Oxford, UK) has developed a classification system that is widely accepted even though validation studies of these criteria have yet to be published. The interested reader should consult the classification system for more details on this topic.[49] Primary neurovascular pain disorders are thought to be a referred pain phenomenon, meaning that intracranial branches of the trigeminal nerve become sensitized via incompletely understood mechanisms and the associated pain and symptoms are perceived in the somatic structures of the head. Most commonly people report pain presenting in the forehead, back of the head, and temples but also in the sinuses, jaws, and teeth. The current understanding of the pathophysiology of headaches implies that dental disease and treatments are not

likely to be a cause of a person developing a headache disorder, but rather, because the same neuroanatomic circuitry is involved, these aspects of dentistry can be thought of as an inciting event, similar to the analogy that exercise producing increased demands on the cardiovascular system can be an inciting event for an acute myocardial infarction. For this reason, the dental clinician should be aware of the diagnostic status of their patients, because patients with headache disorders are likely to experience more peritreatment pain complications that are related to the innate hyperexcitability of the trigeminal nervous system in these people.

Of most interest to the dental clinician are the primary headache disorders, which comprise the bulk of the headache disorders that occur within the population and have been reported to present as nonodontogenic toothache. To simplify thinking, these primary headache disorders can be grouped into three major subdivisions: (1) migraine, (2) tension-type headache, and (3) cluster headache and other trigeminal autonomic cephalalgias (TACs).

Migraine is a common headache, with about 18% of females and 6% of males experiencing this type of headache.[72,105] It is associated with significant amounts of disability, which is the motivating factor that brings the patient to seek care and the reason why this type of headache is the one most often seen in medical clinics.[107] Migraine has been reported to present as toothache[4,23,29,46,82,86] and is likely the most common neurovascular disorder to do so. In addition to this, people with migraine headaches are thought of as having increased regional pain sensitivity that has diagnostic and treatment implications for the clinician.[85]

Migraine headaches typically last between 4 and 72 hours. They tend to be unilateral in presentation and pulsatile in quality, with a moderate to severe intensity to the pain. Patients may also experience nausea and/or vomiting, as well as photophobia or phonophobia, which are different from toothache. The headache is usually aggravated with routine physical activity, such as walking up stairs. Caffeine/ergotamine compounds have been used widely in the past as abortive agents for migraine headaches, but in contemporary times they have been replaced with triptans, such as sumatriptan and rizatriptan.[79] Of note: Migraine headaches may partially or fully abate with the use of nonsteroidal antiinflammatory medications in a similar fashion as toothaches.

Tension-type headache is the most frequent headache disorder experienced, with a wide range of reported prevalence (41% to 96%).[96,100] The concept of tension-type headache pain presenting as toothache has not been reported in the literature, to our knowledge, likely because the construct of what a tension-type headache is has not been clearly defined. Some research supports the notion that a tension-type headache has a significant musculoskeletal component to the pain,[106] whereas other research suggests otherwise. Tension-type headaches are likely a heterogeneous group of similarly presenting head pains that have overlapping pathophysiologic mechanisms, which has led some researchers to consider aspects of tension-type headache to be the same as musculoskeletal orofacial pain, otherwise known as temporomandibular disorders (TMDs).[48]

Cluster headaches and other TACs are rare neurovascular disorders that are strictly unilateral pains defined by the concurrent presentation of at least one ipsilateral autonomic symptom, such as nasal congestion, rhinorrhea, lacrimation, eyelid edema, periorbital swelling, facial erythema, ptosis, or miosis, that occurs with the pain. The major distinguishing features between these headache disorders are the duration and frequency of the pain episodes, as well as the gender most often afflicted. Cluster headache is the most common of the group, occurring in men three to four times more often than in women, with pain episodes lasting between 15 minutes and 2 hours that occur at a frequency of eight episodes per day to one every other day. These headaches come in clusters, with active periods of 2 weeks to 3 months,[49] thus the name. Elimination of pain after 10 minutes' inhalation of 100% oxygen is diagnostic for cluster headache[43]; sublingual ergotamine and sumatriptan are also effective acute treatment for cluster headache.[36] Paroxysmal hemicrania, which has a 3:1 female predilection, presents with characteristics similar to those of cluster headache but with a frequency of more than five per day lasting 2 to 30 minutes.[49] This headache disorder has a 100% response to indomethacin but is refractory to other treatments,[56] which underscores the need for obtaining an accurate diagnosis from an experienced clinician.

From a nonodontogenic perspective, cluster headache[4,11,18,45] and almost all the other TACs have been reported in the literature to present as nonodontogenic toothache.[4,8,9,27,77,91,98] The concurrent autonomic features, such as discoloration or swelling in the anterior maxilla, might compound the diagnostic problem by suggesting tooth abscess. It is important to note that neurovascular headaches tend to be episodic with complete remission between episodes, whereas toothache pain usually has at least some background pain that stays between any exacerbations. Provocation of the tooth should not result in a clear increase in pain, but cause a slight alteration because this tissue has become hypersensitized. Local anesthetic is unpredictable in these cases and can mislead the clinician. Management by the typical clinician is to determine that the pain is not of odontogenic origin and then to refer the patient to an appropriate care provider. Other neurovascular disorders not classified as primary headaches have been reported to present as nonodontogenic toothache, such as cough headache.[78] One would not expect a dental clinician who does not have a specific focus on orofacial pain to arrive at such a specific diagnosis, but rather to be aware of and sensitive to the fact that more obscure headache disorders exist and should be considered in the differential diagnosis of a nonodontogenic toothache that is not easily classified.

Neuropathic Pain

All previously described pain entities can be classified as somatic pain. That is, they are a result of noxious stimulation of somatic structures. These impulses are transmitted by normal neural structures and their clinical characteristics are related to stimulation of normal neural structures. Neuropathic pain actually arises from abnormalities in the neural structures themselves. The clinical examination generally reveals no somatic tissue damage and the response to stimulation of the tissue is disproportionate to the stimulus. For this reason, neuropathic pains can be misdiagnosed as psychogenic pain simply because a local cause cannot be visualized. There are many ways to categorize neuropathic pain in the orofacial region. For the purposes of this chapter and ease of discussion, neuropathic pain is divided into four subcategories: neuralgia, neuroma, neuritis, and neuropathy. It should be acknowledged

that these subcategories are arbitrary and that the different subcategories are not mutually exclusive.

NEURALGIA

As alluded to previously, not all uses of the term "neuralgia" refer to what is often thought of as the classic trigeminal neuralgia or tic douloureux. Sometimes the term "neuralgia" is used to describe pain felt along a specific peripheral nerve distribution, such as with postherpetic neuralgia and occipital neuralgia, as opposed to a focus of pain disorders that have similar characteristics and are thought to have common underlying pathophysiologic mechanisms. When used in the generic sense to describe pains that present intraorally, it can lead to a great deal of confusion.

Although deviations are not uncommon, trigeminal neuralgia is characteristically an intense, sharp shooting pain that is most often unilateral. Ipsilateral to the perceived location of the symptoms is an area that, on stimulation such as light touch, elicits sharp shooting pain. The area that elicits the pain is referred to as a trigger zone, and it can be in the distribution of the resultant pain or in a different distribution—but is always ipsilateral. While most patients present with a characteristic trigger zone, not all patients will present with this finding. An important characteristic of trigger zones is that the response to the stimulus is not proportional to the intensity of the stimulus. That is, slight pressure on a trigger zone results in severe pain. In addition, once triggered, pain typically subsides within a few minutes until triggered again. This is in contrast to odontogenic pain, which may come and go but does not do so in such a predictable and repeatable manner. Finally, the trigger for odontogenic pain is an area that has no sensory abnormalities (e.g., dysesthesia or paresthesia).

Trigger zones for trigeminal neuralgia tend to be related to areas of dense somatosensory innervation, such as the lips and teeth. For this reason, triggers that elicit this type of pain may include chewing and may lead both the patient and clinician to think of a diagnosis of odontogenic pain. In addition, because the trigger involves peripheral input, anesthetizing the trigger zone may result in a diminution of symptoms. This can be very misleading to the clinician if the assumption is that local anesthetic blocks only odontogenic pain.

Because symptoms can be quite severe, patients may consent to or even insist on treatment even though the clinical findings do not definitively support an odontogenic etiology. The possibly misleading symptoms, along with the willingness of the patient to consent to what may seem to be desperate measures, emphasize the importance of a thorough history and clinical evaluation. The absence of a dental etiology for the symptoms (e.g., large restorations, dental trauma, or recent dental treatment) in the presence of the characteristic sharp shooting pain should alert the clinician to consider trigeminal neuralgia in the differential diagnosis. In general, these individuals should be referred to a neurologist or orofacial pain/oral medicine clinician for a complete diagnostic workup and treatment, because case series have suggested 15% to 30% of patients have secondary reasons related to their pain,[51,119] such as brain tumors and multiple sclerosis.

Trigeminal neuralgia typically presents in individuals more than 50 years of age. The etiology is thought to be inflammation in one of the trunks of the gasserian ganglion, possibly as a result of carotid artery pressure. Individuals with multiple sclerosis will develop trigeminal neuralgia more frequently than the general population. For this reason, a person less than 40 years of age who develops trigeminal neuralgia should also be screened for multiple sclerosis[122] or other intracranial pathosis.[51] The two general treatment options for trigeminal neuralgia are pharmacologic and surgical procedures. Because of the possible complications associated with surgery, this form of treatment is usually considered only after attempting pharmacologic therapies. Several medications, including carbamazepine, baclofen, gabapentin, and more recently pregabalin and oxcarbazepine, have been used to treat trigeminal neuralgia. Drugs aimed at relieving nociception, such as nonsteroidal antiinflammatory agents, have no significant benefit in these patients; nor do opioid-based analgesics. Clinical trials support carbamazepine as a first-line drug for treating trigeminal neuralgia.[6] In patients who experience pain relief from carbamazepine, the effect is usually rapid; most will report a decrease in severity of symptoms within the first couple of days.

What is thought to be a variation of trigeminal neuralgia, and may also mimic toothache, is pretrigeminal neuralgia. Pretrigeminal neuralgia, as suggested by the name, has been described as symptoms that are different from those of classic trigeminal neuralgia but that respond to pharmacotherapy like classic trigeminal neuralgia and, over time (usually weeks to 3 yr), take on the classical characteristics of trigeminal neuralgia. The definitive features include the presence of a dull aching or burning pain that is less paroxysmal in nature but still triggered by a light touch within the orofacial region, with variable periods of remission.[42] The subsequent onset of true neuralgic pain may be quite sudden or may appear several years later,[88] which emphasizes the need for long-term follow-up of these patients to obtain an accurate final diagnosis.

NEUROMA

The term "neuroma" has been around for many years and is often overused in an attempt to describe other types of neuropathic pain. A traumatic neuroma, also known as an amputation neuroma, is a proliferative mass of disorganized neural tissue at the site of a traumatically or surgically transected nerve. A part of the diagnosis, therefore, is confirmation of a significant event that would account for the damage to the nerve. Symptoms will not develop until the neural tissue on the proximal stump has had time to proliferate, typically about 10 days after the event. Tapping over the area of a neuroma elicits volleys of sharp electrical pain (i.e., Tinel's sign) similar to trigeminal neuralgia. In contrast to trigeminal neuralgia, there should be a zone of anesthesia peripheral to the area of the neuroma[92] that can be identified by checking for loss of pinprick sensibility, such as with the use of an explorer. Treatment involves pharmacologic management, often via local measures, and surgical coaptation of the nerve with prognosis being variable and dependent on adequate distal nerve tissue and time interval between injury and reconstruction.[123] Therefore, early recognition and referral are of key importance to prevent significant distal nerve degeneration.[66] Although neuromas most commonly develop in the area of the mental foramen, lower lip, and tongue, there is some evidence that they can also form in extraction sites and after pulpal extirpation. Neuromas were found to form in extraction sites between 4 and 6 months after removal of the tooth in an experimental

animal model.[60] Although not all neuromas that form are painful, this could be a potential explanation for ongoing pain in extraction sites after healing has appeared to occur.[92] It is interesting to ponder the possibility of neuroma formation in deafferentation injuries such as pulpectomy and the implications this might have on continued PDL sensitivity after adequate root canal treatment. For treatment of neuromas that are not amenable to surgical correction, see the later section Neuropathy.

NEURITIS

Neuritis is a condition caused by inflammation of a nerve or nerves secondary to injury or infection of viral or bacterial etiology. In general, pain from a virally induced neuritis, such as recurrent herpes simplex or herpes zoster, will be associated with skin or mucosal lesions (Fig. 3-5). This presentation does not result in much of a diagnostic challenge, but pain can precede the vesicular outbreak by many days or even weeks.[41] Because neuritic disorders are caused by reactivation of a virus that has been dormant in the trigeminal ganglion, they are considered projected pain with distribution within the dermatomes innervated by the affected peripheral nerves. The nerves affected by the virus may solely supply deeper tissues and therefore may not produce any cutaneous lesions. In the absence of skin or mucosal lesions a viral neuritis can be difficult to diagnose[41,53,58] and should be considered in the differential diagnosis of a patient with a history of primary herpes zoster infection. Bacterial infection of the sinuses or dental abscess can also cause neural inflammation that may result in pain. This pain occurs simultaneously with pain of the infected tissues and usually dissipates once the etiology is addressed. In susceptible individuals, virally or bacterially induced neuritis may produce a postinfection neuropathy of the infected nerve. The pain is fairly constant and can be dull, aching, and burning. Also, the pain may be accompanied by allodynia, a painful response to normally nonnoxious stimulation such as light brushing of the skin. Oral acyclovir has become the most common treatment for acute herpetic outbreaks and been shown to be efficacious in decreasing the duration and severity of pain after herpes zoster infection. Efficacy is based only on administration in the prevesicular, not the vesicular, stage.[103] Addition of prednisolone to acyclovir produces only slight benefits over acyclovir alone. Neither acyclovir alone nor its combination with prednisolone appears to reduce the frequency of postherpetic neuralgia.[116]

Localized traumatic injury can also induce neuritis. This injury can be chemical, thermal, or mechanical in nature. A classic endodontic example of a chemical injury to a nerve is the overextension of a highly neurotoxic paraformaldehyde-containing paste (e.g., Sargenti paste) onto the inferior alveolar nerve. Chemical trauma can be due to certain toxic components of the endodontic filling materials such as eugenol, irrigating solutions such as sodium hypochlorite, or intracanal medicaments such as formocresol (Fig. 3-6).[80] Mechanical compression in addition to thermal trauma may be a factor when thermoplasticized material is overextended, using an injectable[44] or carrier-based technique. Mechanical nerve trauma is more commonly associated with oral surgical procedures such as orthognathic surgery and third molar extraction.

Neuropathic complications have also been documented after mandibular implant surgery at a rate of 5% to 15% with permanent neuropathies resulting in approximately 8% of these cases.[57] It is unfortunate that traumatic neuritis is often misdiagnosed as a posttreatment chronic infection and that the area is re-entered and debrided. Additional surgical insult further traumatizes the nerve, prolonging the already present nociceptive barrage, which puts the patient at an increased risk of developing central hyperalgesia. Undiagnosed and mistreated cases of acute neuritis not only lead to unnecessary dental procedures but may also aggravate the neuritis and, therefore, the neuritic pain has a greater chance of becoming chronic.

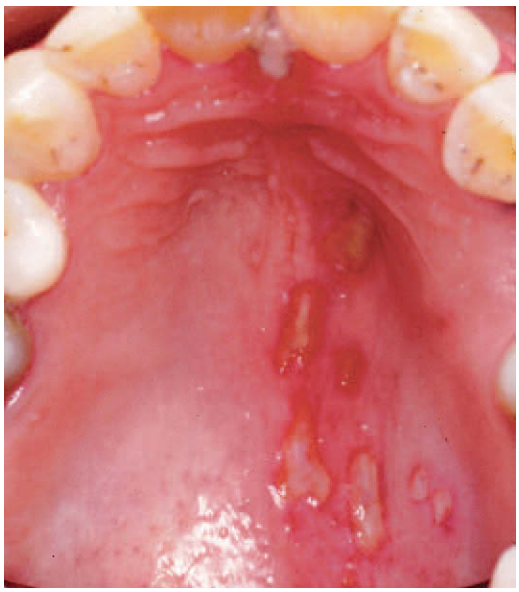

FIG. 3-5 Herpes zoster involving the maxillary division of the left trigeminal nerve of the palate of a 45-year-old male. He complained of a deep, diffuse dull ache of his maxillary left quadrant for 1 week before this vesicular outbreak.

FIG. 3-6 Extrusion of the filling material from the distal canal of tooth #30 of a 36-year-old female. Her complaint was of extreme pain after completion of the root canal treatment followed by sharp, burning continuous pain that could be made worse by a light touch of the tooth.

Neuritic pain typically is a persistent, nonpulsatile burning and is often associated with sensory aberrations such as paresthesia, dysesthesia, or anesthesia. The pain can vary in intensity, but when stimulated, the pain provoked is disproportionate to the stimulus.

Treatment of acute neuritis is based on its etiology. In instances of chemical trauma (e.g., Sargenti paste) where there is obvious irritant present, surgical debridement of the nerve to remove any substance that can continue to irritate the nerve is an important aspect of treatment. With a neuritis secondary to mechanical compression (e.g., implant placement) of a nerve, nerve decompression by removal of the implant fixture is indicated. Such localized, acute, traumatically induced neuritis is inflammatory in nature and, therefore, can also benefit from supportive pharmacotherapies such as steroids. For management of neuritis that is not responsive to the previously cited treatments, medications used to treat neuropathic pain may be used (see Neuropathy).

NEUROPATHY

In this chapter we use the word *neuropathy* as the preferred term for localized, sustained nonepisodic pain secondary to an injury or change in a neural structure. Historically, other terms have been used including *atypical facial pain*. This term suggests pain that is felt in a branch of the trigeminal nerve and that does not fit any other pain category. If pain of an unknown source is perceived in a tooth it may be labeled *atypical odontalgia*. If the pain persists after the tooth has been extracted it is referred to as *phantom tooth pain*. The major limitation in the use of all these terms is that they merely suggest an area where a pain of unknown etiology exists and completely lack any information regarding their pathophysiology. Although each of these terms has been extensively described in the literature,[75,76] probably none of them actually represents one discrete condition but rather a collection of various conditions. At present, a subcommittee of the International Association for the Study of Pain (IASP, Seattle, WA) has put on hold the development of diagnostic criteria and terminology for orofacial pain because the research evidence does not clearly indicate preferred terminology based on presumed mechanisms. Until these criteria are published the use of old terms, and the confusion they bring, will persist.

Once a nerve has been sensitized via injury or disease it may remain so and present as a peripherally sensitized nerve. This peripheral sensitization and the ongoing pain (nociceptive barrage) that accompanies it can induce changes in the central or sympathetic nervous systems. *Peripheral* sensitization, *central* sensitization, and *sympathetic* enhancement all can potentially impact the clinical presentation of a neuropathy. A typical clinical course of someone with an undiagnosed neuropathy might consist of treatment for a toothache. When the pain does not resolve with nonsurgical root canal treatment, it might then be followed by apical surgery and then perhaps an extraction. The extraction site might then be explored and debrided in a misguided attempt to remove any potential source of the patient's ongoing pain. After each treatment, there tends to be a reduction of the pain for a short time and then a return to its original, or even increased, intensity level. It is likely that this is a result of a new neural injury consisting of reorganization and resprouting that increases the inhibition of nerve firing for a time. Surgical approaches to neuropathies are not effective because they do not desensitize the nerve. On the contrary, surgical intervention may aggravate the situation by inflicting an additional neural injury in the periphery and contributing to the already present nociceptive input. This intervention therefore puts the patient at increased risk of developing worse peripheral sensitization, a new-onset central sensitization, or a sympathetic component to their pain. This statement is not meant to refer to situations with concurrent nerve trunk compression or other type of physical or chemical irritation present.

A diagnosis of neuropathy is based primarily on history and examination. The history should reveal some inflammation-inducing event (see the earlier sections Neuritis and Neuroma) although the nature of the initial insult is not always identified. Typically, the examination is grossly unremarkable with no evidence of local tissue damage. However, constant pain of varying degrees of intensity will be reported in a focal area. This area may be hyperalgesic or allodynic. That is, noxious stimulation to the area will be perceived as more painful or nonnoxious stimulation will now be perceived as painful. Neuropathic disorders have a predilection for women rather than men but can affect both genders. These patients are usually more than 30 years of age and may have a history of migraine.[102] In the orofacial region neuropathies are most commonly seen in the maxillary premolar area and molar region.[54]

Neuropathies can be classified on the basis of their clinical presentation and response to therapies. *Peripheral neuropathy* may develop after sensitization of a peripheral nerve and presents clinically as described previously. Diagnosis of peripheral neuropathy is based on its favorable response to peripheral neural blockade. Treatment is directed at decreasing the sensitization of peripheral nerves and reducing ectopic neuronal firing. Topical as well as systemic medications can be used to treat cutaneous peripheral neuropathies. Some topical medications include topical anesthetics and capsaicin-containing compounds as well as transdermal preparations of nonsteroidal antiinflammatory drugs (NSAIDs), sympathomimetic agents, and *N*-methyl-D-aspartate (NMDA) receptor-blocking agents.[90]

The clinical presentation of a *central neuropathy* is similar to that of a peripheral neuropathy. After sensitization of peripheral nerves and the accompanying nociceptive barrage, the pain is nonremitting and lacks evidence of tissue insult. Unlike its peripheral counterpart, allodynia and secondary hyperalgesia are clearly present. That is, the area of pain is significantly larger than the initial site of injury. The most telling sign that a neuropathy has taken on a more central component is that local anesthetics are no longer effective. Therefore, the treatment must be directed toward the central processing of pain. This is done with medications such as NMDA receptor agonists (ketamine), gabapentin, tricyclic antidepressants, and opioids. The prognosis for a central neuropathy is not as good as for a peripheral neuropathy, as central neuropathic pain tends to become more refractory with time. Treatment is often based on the management of pain rather than its cure.

The last variation of neuropathic pain is sympathetically enhanced or maintained pain. In cases of sympathetically maintained pain (SMP), peripheral nerve fibers upregulate the expression of adrenergic receptors, making them responsive and sensitive to sympathetic input. SMP may also have a

central component, whereby constant sympathetic drive alters neuronal excitability. Neuronal injury may induce sprouting of sympathetic axons into the trigeminal spinal nucleus because basket-like formations of sympathetic fibers have been reported around the cell bodies of sensory neurons in the dorsal root ganglia.[117] Increases in sympathetic drive, such as with stress and fever, may aggravate SMP. Diagnosis of sympathetically maintained pain is based on blocking sympathetic outflow to the affected region via sympathetic nerve blocks. In the orofacial region this would require a stellate ganglion block. The block is considered diagnostic for SMP if the block is effective in decreasing the patient's pain. Multiple blocks can also be used as a form of therapy. Other therapies include drugs that target peripheral α_2-adrenoceptors (agonists) or α_1-adrenoceptors (antagonists), such as guanethidine, phentolamine, and clonidine.

Psychogenic Toothache

Psychogenic toothache falls within a group of mental disorders known as somatoform. The name is derived from the fact that the patient has somatic complaints, yet lacks a physical cause. Because these patients lack a physical cause for pain they will also present without local tissue changes. Patients with somatoform disorder are not fabricating the symptoms, nor are they seeking conscious benefit. It is important to make a distinction between somatoform disorders and factitious or malingering disorders.[5] In factitious disorders there are physical and/or psychologic symptoms that are produced by the individual and are under voluntary control. Malingering is similar to factitious disorder with the added characteristic that the symptoms are presented for obvious and recognizable benefit. This diagnostic category poses a significant diagnostic challenge. Lacking evidence of local tissue damage is typical of heterotopic pain entities previously discussed in this chapter. It is important to emphasize that psychogenic pain is rare. When arriving at this diagnosis it is critical that all other potential diagnoses have been ruled out. The diagnosis of psychogenic toothache is one of exclusion and is based on the clinician's awareness of other heterotopic pain characteristics and behavior. Of particular note are centrally emanating pains, cardiac pain, and neurovascular and neuropathic pain.

Psychogenic pain is known to be precipitated by severe psychologic stress. These pains present a general departure from the characteristics of any other pain condition. That is, they may not fit normal anatomic distributions or physiologic patterns. The pain may be felt in multiple teeth and the pain may jump around from one tooth to another. The intensity of pain reported tends to be more severe than is reflected by the patient's level of concern about their condition. Their response to therapy is variable, including a lack a response or an unusual or expected response. Early identification of psychogenic pain and referral to a psychologist or psychiatrist is necessary to avoid irreversible and unnecessary dental treatment.

Toothache Referred From a Distant Organic Source

A variety of different pathologies that seem to be unrelated have been reported to present as nonodontogenic toothache.[89,94] The only common link that can be identified is that the involved tissues are innervated by branches of cranial nerves, and hence nociceptive input is processed in the trigeminal nucleus. Therefore, conceivably, any somatic structure with cranial nerve innervation has the potential to cause pain that is perceived by the patient as a toothache. For this reason, once dentoalveolar etiologies for such pain have been ruled out, all possible sources of nonodontogenic pain including distant pathology should be considered in the differential diagnosis. Several of these types of organic pathologies that have been reported to present as toothache are described in the following sections.

CARDIAC AND THORACIC STRUCTURES

Cardiac pain has been cited as the cause of nonodontogenic toothache in a number of case reports.[7,35,55,67,83,112] Classically, cardiac pain presents as a crushing substernal pain that most commonly radiates to the left arm, shoulder, neck, and face. Although not as common, anginal pain may present solely as dental pain, generally felt in the lower left jaw.[14] Similar to pain of pulpal origin, cardiac pain can be spontaneous and diffuse with a cyclic pattern that fluctuates in intensity from mild to severe. The pain can also be intermittent and the patient may be completely asymptomatic at times. The quality of cardiac pain when referred to the mandible is chiefly aching and sometimes pulsatile. Cardiac pain may be spontaneous or increased with physical exertion, emotional upset, or even the ingestion of food.[7] Cardiac pain cannot be aggravated by local provocation of teeth. Anesthetizing the lower jaw or providing dental treatment will not reduce the pain. It can be decreased with rest or a dose of sublingual nitroglycerin. Diagnosis of cardiac pain, along with immediate referral, is mandatory to avoid impending myocardial infarction.

Besides pain of cardiac origin, other chest structures have been reported to produce nonodontogenic toothache pain. Various cancerous lesions of the lungs have been described to present a mandibular pain, on both the ipsilateral and contralateral sides of the tumor,[21,52] as well as diaphragmatic pain mediated via the phrenic nerve.[12]

INTRACRANIAL STRUCTURES

Space-occupying lesions within and around the brain are known to impinge on structures innervated with somatosensory fibers, such as the dural and perivascular tissues, causing pain. These pains are highly variable, with a common complaint being headache or head pain. Just as intracranially derived pain may be referred to the face and jaws in neurovascular disorders, it may also present as a toothache.[1,113] To outline the vast differences in clinical features of such pain, intracranial lesions have also been reported to cause trigeminal neuralgic pain in response to treatment of what was first thought to be toothache.[26] This extreme variability has been observed by one of the authors, which leads to the recommendation that if local etiologic factors are not readily identified in a patient with toothache symptoms, magnetic resonance brain imaging should be considered.

THROAT AND NECK STRUCTURES

Nonodontogenic toothache has been reported to arise from various structures of the neck, but these reports are sparse and hence it is not possible to draw conclusions regarding how patients with these pain-provoking disorders may present. Squamous cell carcinoma of the lateral pharyngeal surface presenting as ipsilateral mandibular molar pain has been

observed by one of the authors; this finding is consistent with previous reports of non-odontogenic pain being associated with smooth muscle tumors of a similar location.[115] Vascular structures of the neck have also been implicated in the production of toothache symptoms, with a report of a patient initially presenting for dental care when pain was from the result of a life-threatening carotid artery dissection.[97]

CRANIOFACIAL STRUCTURES

Clinically, pain from other craniofacial structures has been observed as being the most common reason for organic pathologies presenting as nonodontogenic toothache, likely because these structures are innervated by branches of the trigeminal nerve. Tumors in the maxillary sinus[24,37,121] and jaw,[108] as well as metastatic disease, particularly within the mandible,[28,47,93,101] have been reported. The clinical presentation of symptoms is highly variable, but a common feature is sensory loss along the distribution of the nerve, the result of pain arising from nerve impingement. This underscores the need for regional imaging techniques, such as pantomography or computed tomography (CT) (as opposed to just periapical radiographs), especially in patients who have a history of cancer. One must also not forget that nerve impingement anywhere along the distribution of the trigeminal nerve, even within the cranial vault itself,[17] can elicit nonodontogenic tooth pain.

Vascular structures within the craniofacial region have also been reported to present as nonodontogenic toothache, with arteritis being the pain-provoking pathology.[59,63] These pains have been described as a continuous dull pain that can sometimes be made worse with jaw function. The stereotypical presentation include a history of eyesight changes, such as blurred vision, and the examination feature of pulseless, indurated temporal arteries that are painful to palpation. A laboratory finding of an elevated erythrocyte sedimentation rate (ESR) is suggestive of the disorder, and diagnosis is confirmed by temporal artery biopsy. Treatment includes administration of corticosteroids and, because permanent blindness is a possible sequela if cranial arteries are left unmanaged, immediate referral to the appropriate medical colleague.

TAKING A PATIENT'S HISTORY

Pain diagnosis is largely based on the patient's subjective history; however, it is rare that patients will give all pertinent diagnostic information about their pain of their own accord. Often it is necessary to carefully extract the details of the patient's pain complaint through systematic and thorough questioning. This is known as "taking a history" and it involves both careful listening and astute questioning. Figure 3-7 is an example of a basic diagnostic workup for odontogenic pain. It can be easily used to obtain histories of typical odontogenic pain by circling all descriptors that apply and then filling in the remaining blanks. As the details of a patient's pain complaint are gathered, the clinician should be mentally progressing though an algorithm of possible diagnoses, as each detail should lend itself to one type of pain over another. After completing a thorough and accurate history of the complaint(s) (Fig. 3-8), often the diagnosis has already been narrowed down to one particular pain entity. This is particularly true with odontogenic pain. The only question that will remain is "which tooth is it?" It is critical to keep in mind that whereas patients will provide information about the perceived site of pain, it is the clinician's examination that will reveal the true source of their pain. With more complicated pain complaints the clinician may have a list of possible diagnoses. This is known as a differential diagnosis. This differential will serve to guide the examination and testing in an effort to confirm one diagnosis while ruling out all others. If after completing the subjective examination all items on the differential are outside the clinician's scope of practice, then the clinician should continue the examination until he or she has a firm idea of the possible diagnosis so that a proper referral can be made. In addition, it is paramount that all odontogenic sources have been ruled out and that this information is communicated to the health care provider to which the patient is referred. If no differential can be formulated after the history has been taken, then the history should be redirected to the patient to confirm that the information is complete and accurate. If the patient is unable to provide sufficient information regarding their pain complaint then it may be helpful to have them keep a pain history, detailing the aspects of their pain on a daily basis. Of utmost importance is to avoid treatment when the diagnosis is uncertain. Diagnostic therapy (i.e., "let's do a root canal treatment and see if it helps") may result in costly treatment that does not improve the patient's condition, and could be a factor in aggravating and perpetuating a patient's pain. Treatment should always specifically address a diagnosis.

Sufficient for pain of odontogenic origin.

Subjective

Pain: (Circle all appropriate)		Level (0-10)_____
Well-localized	Diffuse	Intermittent
Spontaneous	Elicited (cold, hot, chewing)	Throbbing
Constant	Fluctuant	
Dull ache	Sharp shooting	

Onset_____

Progression (F/I/D)_____

Aggravating factors:_____

Relieving factors:_____

FIG. 3-7 Example of a form to evaluate odontogenic pain.

A complete medical history along with current medications and drug allergies should always be ascertained. It is also important to make note of demographic information, as patients of certain genders and ages are more at risk for some disorders compared with others.

Recording a patient's *chief complaint* in their own words is a medical legal necessity but falls short of comprising a thorough pain history. A complete history begins with a patient's general pain complaint, for example, "My tooth hurts." Patients may have more than one pain complaint, for example, "My tooth hurts and it is starting to make my jaw hurt." All pain complaints should be noted and investigated separately.

Chief complaint

Prioritize complaints _____

Specify location _____

VAS 0-10 _____

Initial onset

When did you first notice this? _____

Progression

Frequency _____

Intensity _____

Duration _____

Previous similar complaints

Have you ever had this type of pain before? _____

Characterize complaint

Daily, not daily _____

Constant, fluctuant, intermittent _____

Duration _____

Temporal pattern _____

Quality _____

Aggravating factors

What makes this pain worse? Be specific! _____

Alleviating factors

What makes this pain better? _____

How much better? _____

Associated factors

Swelling _____

Discoloration _____

Numbness _____

Relationship to other complaints

Would your jaw hurt if your tooth didn't hurt? _____

Prior consults/treatment

Who? _____

When? _____

What was the diagnosis? _____

What was done? _____

How did it affect the pain? _____

FIG. 3-8 Example of a form to evaluate pain history.

Understanding the specific components of the complaints makes it possible to discern the relationship between the complaints. That is, either the complaints are wholly separate and there are two types of pathosis present, or one source of pain is merely creating a heterotopic pain that is wholly secondary to the first.

Begin with determining the *location* at which the patient perceives the pain. Aspects of the location involve localization and migration. Pain should be definable as either well localized or diffuse and either superficial or deep. Easily localized superficial pain tends to be cutaneous or neurogenic. Musculoskeletal pain is felt deeply and is more localizable once it is provoked. Deep, diffuse pain is suggestive of deep somatic pain, be it visceral or musculoskeletal. Both tissue types are involved in a high degree of nociceptor convergence in the trigeminal nucleus and, therefore, much more likely to be involved in creating heterotopic pain. Typical referral patterns of deep somatic pain tend to follow peripheral dermatomes that reflect the laminations in the trigeminal nucleus. Referred pain also tends to occur in a cephalad direction. Therefore, referred pain from a deep somatic tissue such as tooth pulp, cardiac tissue, or skeletal muscle will respect this pattern. Pain that spreads distally along a nerve branch is much more indicative of a projected type of heterotopic pain. Projected pains

imply a neurogenic source and possibly one that is secondary to impingement from intracranial pathosis. Recall that superficial sources of pain are not likely to be involved in referral, so if a patient is indicating that the pain is superficial and spreading this is highly suggestive of a neurogenic rather than a cutaneous source.

Assessment of the *intensity* of pain is easily accomplished using a verbal analog scale. This question is best phrased, "On a scale of one to ten, zero being no pain and ten being the worst pain you can imagine, how bad is your pain?" Not only can intensity provide insight about pain type; it can also help guide posttreatment pain management as well as provide a baseline for response to therapies.

Identifying the *onset* of pain may provide information regarding etiology. Question if the onset followed a particular event such as a dental appointment or a traumatic injury. Beware of these relationships, as they can also be misleading. Having a temporal correlation does not necessarily ensure a cause-and-effect relationship. The onset of pain may be either gradual or sudden. Severe pain of sudden onset can signal a more serious problem. Pain that has been present over a protracted period to time, particularly if the pain has been unchanging, is highly suggestive of a nonodontogenic pain source.

Other *temporal* aspects of pain include frequency and duration. The question should be asked: How often does the pain occur and how long does it last? These temporal aspects may establish patterns that point more clearly to one condition over another.

Progression of the patient's pain over time should be noted. Whether pain is better, worse, or unchanging since its onset should be broken down into three factors: frequency, intensity, and duration. Static pain that does not change over time is typically not odontogenic in origin.

The *quality* of pain, that is, "what it feels like," is a critical aspect of a pain history. Knowledge of pain characteristics as they relate to tissue types is essential. Pain quality can be difficult for patients to describe and it is often necessary to provide them with a list of descriptors from which to choose. In instances of odontogenic pain the list is fairly short. The deep visceral and musculoskeletal components of a tooth limit true odontogenic pain to having qualities that are either dull, aching, or throbbing. If there is an aspect of sharpness to the pain it is helpful to understand whether the sharpness is stabbing in nature, which would be more indicative of A-delta fiber-mediated dentinal pain, or whether it is electrical in nature, which would be more indicative of a neuralgia. Some common examples of pain descriptors and their respective pain types are listed in Table 3-1.

Factors that precipitate or aggravate the patient's pain complaint are of key importance in diagnosis. Not only do aggravating factors suggest the tissue types that may be involved, but they also aid in directing the objective tests. When gathering information, it is important to be specific. If a patient reports pain while eating, keep in mind that many structures are stimulated during mastication, such as muscles, temporomandibular joints (TMJs), mucosa, PDLs, and potentially pulps. Be specific as to the aggravating factor. The lack of any aggravating factors is an indication that the pain is not of odontogenic origin.

Alleviating factors can provide insight as to the nature of the pain. If the pain is relieved by a medication it is critical to know the specific medication, its dosage, and the degree to which the pain was attenuated. It is equally important to know what has no effect on the intensity of the pain. For example, a pain that is mid-level in intensity yet completely unresponsive to antiinflammatory drugs suggests a pain that is not inflammatory in origin.

TABLE 3-1

Examples of Pain Descriptors

Origin	Quality of Pain
Muscular	Dull, aching
Neurogenic	Shocking, burning
Vascular	Throbbing, pulsatile

Associated factors such as swelling, discoloration, and numbness must be ascertained, as well as their correlation with symptoms. Swelling of acute onset is suggestive of an infection, and its concurrent pain would be of inflammatory origin. Swelling that comes and goes with the intensity of pain suggests an autonomic component. The same can be said for discoloration, such as redness. Numbness or any other type of sensory aberrations should be recorded. If the altered sensation is a major component of the pain complaint then it should be investigated separately and its relationship to the pain determined. Pains that occur with sensory aberrations tend to have a strong neurogenic component.

If there is more than one pain complaint present, an effort should be made during the subjective history to determine the *relationship of the complaints*. One pain might serve as an aggravating factor to the other. There may be a correlation as to the onset, intensity, or progression of the complaints. Also, keep in mind that patients may actually have more than one type of pathosis occurring concurrently and there may be no relationship whatsoever. Ask whether there have been any *previous similar complaints* and, if so, what happened. Recurrence of similar pains might reveal a pattern that lends itself to a particular pain diagnosis.

It is critical to gain knowledge of any prior consultations that have occurred. Details regarding the type of clinician, actual workup performed, and diagnosis rendered will be helpful in narrowing down a differential. Any treatment that was performed should be ascertained and its effect on the chief complaint.

PATIENT EXAMINATION

As stated previously, the purpose of the history is to gather information about a patient's pain complaint in order to formulate a list of possible diagnoses based on specific pain characteristics. Poor or improper symptom analysis will lead to a false differential and any testing will therefore have limited meaning. Performing a general examination including extraoral, intraoral, and hard and soft tissue assessment is requisite to confirm the health of various structures and to identify possible pain-producing etiologies. When a patient presents with a toothache, the pain is usually of odontogenic origin. Diagnostic procedures are often limited to confirming a suspect

tooth rather than identifying a nonodontogenic source of pain. Standard pulpal and periradicular tests serve to aid in both ruling in odontogenic pain and therefore ruling out nonodontogenic pain as a diagnosis. Remember that the site of pain is determined by patient history, but the true source of the pain should be revealed with testing. If the chief complaint cannot be reproduced with standard tests then additional tests may be necessary to narrow down a differential diagnosis. For detail on general examinations and standard tests, please refer to Chapter 1.

Additional Tests

Further tests should be chosen with forethought in an effort to develop a workable differential that can guide the clinician toward a meaningful consultation or an appropriate referral for the patient. These tests may consist of palpation or provocation of various structures, sensory testing, or diagnostic blocks. The application of these tests is not covered in detail in this chapter. For more information about the application and interpretation of these tests, please consult other sources.

Palpation and percussion are common tests to differentiate odontogenic pain from pain of sinus origin. Palpation of the sinuses consists of firm pressure placed over the involved sinus (usually maxillary). In addition, pain of sinus origin may be provoked with a lowering of the patient's head.

If pain of muscular origin is suspected then an attempt to reproduce this pain can be done by palpation of the muscles of mastication or provocation via functional manipulation. The temporalis, deep and superficial masseter, medial pterygoid, and digastric muscles should be palpated in an effort to discover tenderness or trigger points that reproduce the pain complaint. The medial pterygoid is only partially accessible to palpation and may need to be functionally tested by stretching the muscle (opening wide) or contracting the muscle (biting firmly). The lateral pterygoid may be difficult if not impossible to palpate intraorally and therefore is more appropriately assessed by functional manipulation. Pain emanating from this muscle may be increased by protruding the jaw against resistance. Exacerbating the chief complaint by muscular function provides a strong indication of a myofascial source of pain.

Because of the complexity of innervation and the occurrence of heterotopic pain in the orofacial region it may be difficult to definitively determine the origin of pain by testing alone. It cannot be stressed enough that primary pain should not only be provoked by local manipulation but also be relieved by anesthetic blocking. In diagnostic anesthesia the relief of pain has a typical onset and duration, depending on the particular anesthetic used. In addition, the pain should be completely diminished or else suspicion of a central component or a coexisting disorder should arise. The use of diagnostic anesthesia may be necessary and useful in augmenting the diagnostic workup (see Fig. 3-9, *A* and *B*). Topical anesthetic can be helpful in the investigation of cutaneous pain and peripheral neuropathies. Anesthetic injection including peripheral nerve blocks can be used to determine whether the etiology of the pathosis is peripheral to the area of the block. Pain that persists after the onset of usual signs of anesthesia suggests a central component to the patient's pain. The patient's history and general examination are of key importance in differentiating between the pain of a central neuropathy and the central pain emanating from an intracranial mass.

Pain that is primarily muscular, as suggested by trigger points discovered on examination, can be further investigated by local anesthetic injection into the trigger point. Trigger point injections are typically performed with either a 27- or 25-gauge needle and a minimally myotoxic anesthetic such as 2% lidocaine or 3% mepivacaine without a vasoconstrictor. Myofascial trigger point injections may result in temporary relief from pain at the trigger point as well as at the site of referral.

Sympathetic efferent activity can play a role in the enhancement or maintenance of chronic pain. In the head and neck, sympathetic activity flows through the stellate ganglion located bilaterally near the first rib. In patients in whom there is suspicion of a sympathetic component to their pain, a stellate ganglion block can be used to provide diagnostic insight. This is usually done by a trained anesthesiologist. An effective block delivered to the stellate ganglion will interrupt sympathetic outflow to the ipsilateral side of the face, resulting in a partial Horner's syndrome. This is evidenced by flushing, congestion, lacrimation, miosis of the pupil, ptosis, and anhidrosis.[65] A sympathetic blockade that diminishes or eliminates a pain state may serve to guide future treatment such as repeated blocks or systemic treatment with sympathetically active drugs (e.g., clonidine and prazosin).[95]

Neurologic conditions, both peripheral and central, can present as pain in the orofacial region. A role of the clinician is to help rule out gross neurologic conditions secondary to intracranial pathosis. Patients with systemic complaints such as nausea, dizziness, or changes in one of the special senses should raise suspicion of intracranial pathosis. A neurologic screening examination including a gross sensory and motor evaluation of cranial nerves ii–xii should be performed. For details on cranial nerve examination, please refer to other sources.[38] Investigation of sharp/dull differentiation as well as light touch discrimination between the different branches of the trigeminal nerve can provide insight as to location and etiology of pathosis.

Case Studies

Case 1

A 56-year-old male presents with a chief complaint of "This tooth still hurts and it's getting worse. It even hurts when I smile." His medical history reveals a history of angina secondary to 70% occlusion of his right coronary artery. He also reports a history of hypercholesterolemia. He has no history of myocardial infarction and denies any other significant medical history. The patient is taking lovastatin (Mevacor, 400 mg/day), nifedipine (Procardia, 60 mg once per day), and atenolol (50 mg once per day). He has no known drug allergy.

The patient was referred by a periodontist for evaluation of continued pain associated with tooth #3. He had been receiving periodontal maintenance therapy for generalized moderate adult periodontitis for more than 5 years. He had root canal treatment and a mesial buccal root amputation of tooth #3 as treatment for a localized area of advanced periodontitis 6 months ago.

SUBJECTIVE HISTORY

After careful questioning, it becomes apparent that the patient is experiencing pain having two different qualities: an

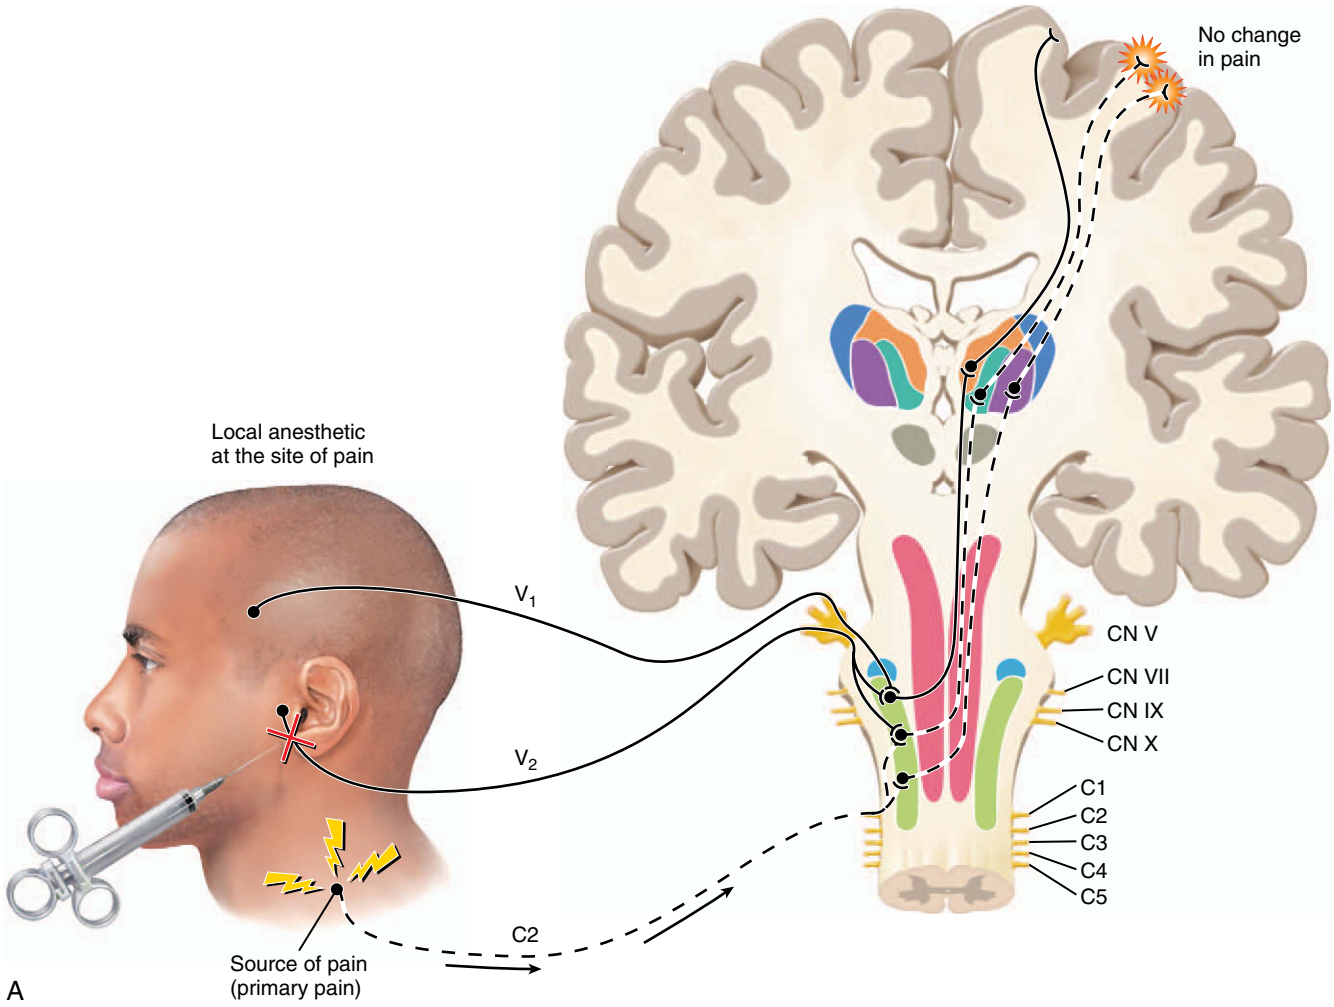

FIG. 3-9 A, Local anesthesia at the site of pain fails to reduce the pain.

intermittent ache associated with tooth #3 and an intermittent sharp shooting pain also associated with tooth #3. The intermittent dull ache was of gradual onset 9 months ago. This pain was unaffected by the nonsurgical root canal treatment and root amputation. This pain has increased in frequency, intensity, and duration over the last 3 months. There is no temporal component. The dull ache is aggravated by biting and by the occurrence of the sharp shooting pain. The sharp shooting pain had a sudden onset 6 months ago. It has also increased in frequency, intensity, and duration without a temporal component. It can occur spontaneously or when "smiling big." The patient reports that the sharp shooting pain can also be aggravated by pressing lightly on his face in the area overlying #3, but not by pressing intraorally on #3.

EXAMINATION

The coronal portion of the amputated mesiobuccal root had been restored with IRM (Intermediate Restorative Material; DENTSPLY Caulk, Milford, DE). No cracks, fractures, sinus tracts, or swelling is detected. There are generalized probing depths of 4 mm throughout the upper right sextant. Tooth #3 has an 8-mm-broad probing defect mesially with bleeding on probing. For the results of clinical testing, see Table 3-2.

*Endo Ice (Coltène/Whaledent, Cuyahoga Falls, Ohio) is used to detect pulp vitality.

†*s*, Pain of short duration.

A periapical radiograph (Fig. 3-10) shows evidence of prior nonsurgical root canal treatment and mesiobuccal root amputation of tooth #3. Mild to moderate horizontal bone loss is evident in the quadrant. No radiographic evidence of caries or apical radiolucencies is noted.

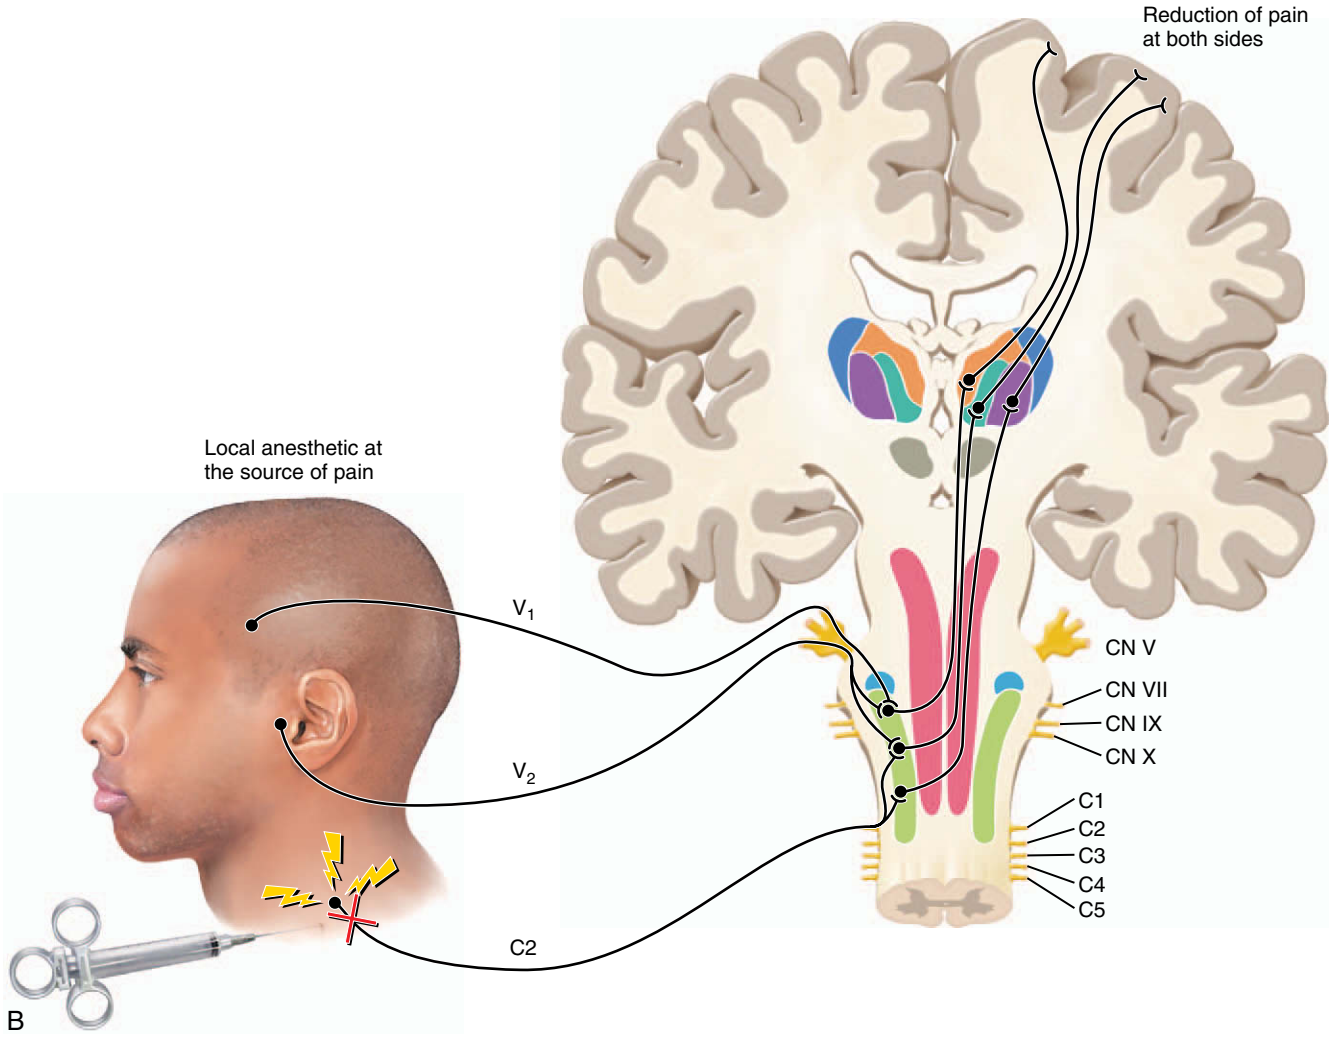

FIG. 3-9, cont'd B, Local anesthesia at the source of pain reduces the pain at the source as well as at the site. *(Redrawn from Okeson JP:* Bell's orofacial pains, *ed 5, Chicago, 1995, Quintessence Publishing.)*

FIG. 3-10 Periapical radiograph showing prior nonsurgical root canal treatment and mesiobuccal root amputation of tooth #3.

Additional tests: In the absence of a clear etiology, a more extensive extraoral examination is performed. Cranial nerves ii–xii are intact. The sharp shooting pain is predictably produced with light brushing of the skin over the area of tooth #3. This examination increases the patient's subjective complaint of a dull ache associated with tooth #3. With the likelihood of two possible sources of pain existing, a diagnostic anesthetic block of tooth #3 is performed: buccal infiltration of tooth #3 with 27 mg of 3% mepivacaine without epinephrine. After 3 minutes the patient no longer reports a dull ache at tooth #3 and he is nontender to percussion. His sharp shooting pain can still be initiated with light brushing of the skin over the area of tooth #3 and continues to cause a dull ache in the area of tooth #3. Diagnoses of trigeminal neuralgia and advanced localized adult periodontitis of tooth #3 are made. The patient is referred to a neurologist for evaluation and treatment. The diagnosis of trigeminal neuralgia is confirmed and he is placed on carbamazepine at 100 mg/day.

Case 2

A 28-year-old male presents with a chief complaint of "My teeth on the right side hurt." His past medical history is not significant. He denies any systemic disease and has no known drug allergies. He is currently taking 600 mg of ibuprofen as needed for pain. He is taking no other medications. The patient was referred by his general clinician for evaluation of pain associated with his teeth on the right side.

SUBJECTIVE HISTORY

After careful questioning, it is determined that the patient is experiencing pain of two different types. The most distressing pain to the patient is a diffuse, right-sided, constant low-grade dull ache (3/10 on a verbal analog scale [VAS]). The onset was gradual, beginning 2 years ago. The pain has recently increased in intensity and duration. This pain is aggravated by opening wide and increases in intensity after the occurrence of a sharp pain that is induced by biting down. There is no notable temporal component and no attempts have been made by the patient to obtund the pain.

His other pain type had a sudden onset approximately 4 months ago. This pain is localized to the area of the right first molars. It is an intermittent sharp shooting pain (8/10 on VAS) that occurs when biting.

EXAMINATION

Tooth #3 has an occlusal amalgam with cracks evident on the mesial marginal ridge and the buccal groove. Tooth #30 has an occlusal amalgam and cracks are noted on the mesial and distal marginal ridges of the tooth. There are no swellings or sinus tracts and no probing greater than 4 mm on the right side. A periapical radiograph demonstrates no evidence of caries or apical radiolucencies. The patient's sharp pain is reproduced with a bite test applied to the ML cusp of tooth #30. After the bite test he reports an intensifying of his dull ache. For the results of clinical testing see Table 3-3.

Thirty seconds after pulp testing has been completed the patient again reports an intensifying of his dull ache.

Additional tests: In consideration of an uncertain diagnosis a more extensive examination is performed. Palpation and provocation tests of the muscles of mastication reveal a trigger point in his right deep masseter. Palpation of this trigger point results in immediate intensifying of his "toothache." A trigger point injection of 3% mepivacaine without epinephrine is done in an effort to clarify a diagnosis. After a trigger point injection, all tests are repeated. Palpation of the trigger point no longer produces pain. The bite test and cold test still produce a short sharp pain but are no longer followed by a dull ache.

Diagnosis of reversible pulpitis secondary to a cracked tooth #31, and myofascial pain of the right masseter, are made. The patient is given home care instructions for treatment of his myofascial pain and he is referred to his general clinician for cuspal coverage of both teeth #3 and #30.

SUMMARY

As clinicians who are frequently called on to diagnose and treat complaints of orofacial pain, it is important to have a thorough knowledge of odontogenic and nonodontogenic causes of orofacial pain. The basis for this knowledge begins with an understanding of the anatomy and physiology of the pain system, and how alterations in this system can result in pain that is poorly localized and therefore misdiagnosed. A realization that pain does not always originate in the structures in which they are felt, along with an understanding of the neurobiologic basis of heterotopic pain, is necessary to ensure accurate diagnosis of orofacial pain.

There are several indicators that a toothache may be nonodontogenic in origin. Red flags for nonodontogenic pain include toothaches that have no apparent etiology for pulpal or periradicular pathosis; pain that is spontaneous, poorly localized, or migratory; and pain that is constant and nonvariable. In addition, pain that is described as burning, pricking, or "shocklike" is less likely to be pulpal or periradicular in origin.

A thorough pain history and examination of dental and nondental structures are essential to differentiate between odontogenic and nonodontogenic sources of pain. Examples of key components of the pain history and examination are included in this chapter for reference. In addition, the chapter has focused on the more common nonodontogenic sources of orofacial pain. As stated previously, the role of the dental clinician is to diagnose and treat disorders of the oral cavity and masticatory structures. In the event that a nondental pathosis is suspected, a differential diagnosis of probable disorders is essential as part of a referral to a more appropriate health care provider. In addition, an understanding of any potential role or interaction of dental structures in the patient's pain complaint should be communicated as part of the referral.

CHAPTER

4

Case Selection and Treatment Planning

PAUL A. ROSENBERG and JARED C. FRISBIE

CHAPTER OUTLINE

COMMON MEDICAL FINDINGS THAT MAY INFLUENCE ENDODONTIC TREATMENT PLANNING
- Cardiovascular Disease
- Diabetes
- Pregnancy
- Malignancy
- Bisphosphonate Therapy
- Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome
- End-Stage Renal Disease and Dialysis
- Prosthetic Implants
- Behavioral and Psychiatric Disorders
- Psychosocial Evaluation

DENTAL EVALUATION AND DEVELOPMENT OF THE ENDODONTIC TREATMENT PLAN
- Periodontal Considerations
- Surgical Considerations
- Restorative Considerations
- Endodontic Therapy or Dental Implant
- Vital Case
- Nonvital Case
- Single-Visit versus Multiple-Visit Treatment
- Retreatment Case
- Immature teeth
- Other Factors That May Influence Endodontic Case Selection

The process of case selection and treatment planning begins after a clinician has diagnosed an endodontic problem. The clinician must determine whether the patient's oral health needs are best met by providing endodontic treatment and maintaining the tooth or by advising extraction. The use of rotary instruments, ultrasonics, and microscopy as well as new materials has made it possible to predictably retain teeth that previously could not have been treated. Even teeth that have failed initial endodontic treatment can often be successfully retreated using nonsurgical or surgical procedures.

Increased knowledge concerning the importance of anxiety control, nonsteroidal antiinflammatory drug (NSAID) premedication, profound local anesthesia, appropriate occlusal adjustment, and biologically based clinical procedures enables clinicians to complete endodontic procedures without intra- or posttreatment pain.

Questions concerning tooth retention and possible referral can be answered only after a complete patient evaluation. The evaluation must include assessment of medical, psychosocial, and dental factors as well as consideration of the relative complexity of the endodontic procedure. Although most medical conditions do not contraindicate endodontic treatment, some can influence the course of treatment and require specific modifications. A number of valuable texts are available that review the subject of dental care for the medically compromised patient.[32,40,78] The American Academy of Oral Medicine (Edmonds, WA) has an excellent website (http://www.aaom.com/) that can be used to elicit information about medically compromised patients.

Perhaps the most important advice for a clinician who plans to treat a medically compromised patient is to be prepared to communicate with the patient's physician. The proposed treatment can be reviewed, and medical recommendations should be documented. Figure 4-1 depicts a sample medical consultation letter that can be modified as necessary.

The American Society of Anesthesiologists (ASA; Park Ridge, IL) Physical Status Classification system is commonly used to express medical risk (Box 4-1).

The ASA classification system remains the most widely used assessment method for preanesthetic patients despite some inherent limitations to its use as a peritreatment risk predictor. This classification system is a generally accepted and useful guide for pretreatment assessment of relative risk but does not advise appropriate treatment modifications. The clinician needs to go beyond the classification system and gather more information from the patient and physician, including the patient's compliance with suggested medication, frequency of physician visits, and most recent visit. Typical questions include the following: *Do you take medication as prescribed by your physician?* Or, *When was the last time you were examined by your physician?* Other systems have been proposed that would better reflect the increasing number of medically complex patients treated by clinicians as Americans live longer.[31] Regardless of the classification system used, these

Michael White, MD
1 Walker Street
Brown City, OK

Dear Dr. White,

Your patient, Ms. Mary Smith, presented for consultation on August 10, 2009, concerning tooth #19. The tooth is asymptomatic at this time, but a small (4 mm x 3 mm), well-circumscribed periradicular radiolucency associated with the palatal root was noted on radiographic examination. The tooth was tested for vitality using thermal and electrical modalities and found to be nonvital, indicating an odontogenic cause for the lesion. The tooth will require endodontic treatment in order to be maintained. The prognosis for nonsurgical endodontic treatment in this case is good. I anticipate that her dental medication plan would include lidocaine with epinephrine for anesthesia and ibuprofen for postoperative pain control.

In a review of the patient's medical history she noted that she is being treated for a malignancy of the thyroid gland and is undergoing radiation therapy. She was unable to provide more specific information about her treatment.

I would appreciate information regarding her ability to undergo endodontic treatment at this time. Please call me if there is further information that you would require concerning the dental treatment to be provided. Thank you.

Yours truly,

Peter Jones, DDS

FIG. 4-1 Sample medical consultation letter.

BOX 4-1

American Society of Anesthesiologists Physical Status Classification System

P1: Normal, healthy patient; no dental management alterations required
P2: Patient with mild systemic disease that does not interfere with daily activity or who has a significant health risk factor (e.g., smoking, alcohol abuse, gross obesity)
P3: Patient with moderate to severe systemic disease that is not incapacitating but may alter daily activity
P4: Patient with severe systemic disease that is incapacitating and a constant threat to life

From: http://www.asahq.org/clinical/physicalstatus.htm

generalized guidelines need to be individualized for the patient under care.

An alternative means of considering risk assessment is to review the following issues:

- History of allergies
- History of drug interactions, adverse effects
- Anxiety (past experiences and management strategy)
- Presence of prosthetic valves, joints, stents, pacemakers, and so on
- Antibiotics required (prophylactic or therapeutic)
- Hemostasis (normal expected, modification to treatment)
- Patient position in chair
- Infiltration or block anesthesia with or without vasoconstrictor
- Significant equipment concerns (radiographs, ultrasonics, electrosurgery)
- Emergencies (potential for occurrence, preparedness)

A review of these areas provides the clinician with essential background data before initiating treatment.

COMMON MEDICAL FINDINGS THAT MAY INFLUENCE ENDODONTIC TREATMENT PLANNING

Cardiovascular Disease

Patients with some forms of cardiovascular disease are vulnerable to physical or emotional stress that may be encountered during dental treatment, including endodontics. Patients may be confused or ill informed concerning the specifics of their particular cardiovascular problem. In these situations, consultation with the patient's physician is mandatory before the initiation of endodontic treatment. Patients who have had a myocardial infarction (i.e., "heart attack") within the past 6 months should not have elective dental care. Such patients have increased susceptibility to repeat infarctions and other cardiovascular complications and may be taking medications that could potentially interact with the vasoconstrictor in the local anesthetic. In addition, a vasoconstrictor should not be administered to patients with unstable angina pectoris or to patients with uncontrolled hypertension, refractory arrhythmias, recent myocardial infarctions (less than 6 mo), recent stroke (less than 6 mo), recent coronary bypass graft (less than 3 mo), uncontrolled congestive heart failure, and uncontrolled hyperthyroidism. Vasoconstrictors may interact with some antihypertensive medications and should be used only after consultation with the patient's physician. For example, vasoconstrictors should be used with caution in patients taking digitalis glycosides (e.g., digoxin) because the combination of these drugs could precipitate arrhythmias. Local

anesthetic agents with minimal or no vasoconstrictors are usually adequate for nonsurgical endodontic procedures (see also Chapter 20).[40] A systematic review of the cardiovascular effects of epinephrine concluded that, although the quantity and quality of pertinent articles were problematic, the increased risk for adverse events among uncontrolled hypertensive patients was low, and the reported adverse events associated with epinephrine use in local anesthetics was minimal.[6] Another review highlighted the advantages of including a vasoconstrictor in the local anesthesia, and stated that "pain control was significantly impaired in those patients receiving the local anesthetic without the vasoconstrictor as compared to those patients receiving the local anesthetic with vasoconstrictor."[12]

A patient who has specific heart conditions may be susceptible to an infection of the heart valves, induced by a bacteremia. This infection is called *infective* or *bacterial endocarditis* and is potentially fatal. The American Heart Association (AHA; Dallas, TX) amended their recommendations in 2007 and recommends antibiotic prophylaxis in patients with prosthetic heart valves, a history of infective endocarditis, and a number of congenital heart abnormalities.[77] The specific recommendations are summarized in a reference guide by the American Association of Endodontists (AAE; Chicago, IL) found online at http://www.aae.org/dentalpro/guidelines.htm. Because the AHA periodically revises its recommended antibiotic prophylactic regimen for dental procedures, it is essential that the clinician stay current concerning this important issue. A low compliance rate exists among at-risk patients regarding their use of the suggested antibiotic coverage before dental procedures. Therefore the clinician must question patients concerning their compliance with the prescribed prophylactic antibiotic coverage before endodontic therapy. If a patient has not taken the antibiotic as recommended, it may be administered up to 2 hours after the procedure.[77]

Patients with artificial heart valves are considered highly susceptible to bacterial endocarditis. Consulting the patient's physician in such cases regarding antibiotic premedication is essential. Some physicians elect to administer parenteral antibiotics in addition to or in place of the oral regimen. The coronary artery bypass graft is a common form of cardiac surgery. Ideally, vasoconstrictors should be minimized during the first 3 months after surgery to avoid the possibility of precipitating arrhythmias. Ordinarily these patients do not require antibiotic prophylaxis after the first few months of recovery unless there are other complications.[77]

A clinician may be the first to detect elevated blood pressure if he/she routinely evaluates blood pressure before treatment. Furthermore, patients receiving treatment for hypertension may not be controlled adequately because of poor compliance or inappropriate drug therapy. Abnormal blood pressure readings may be the basis for physician referral.

Few conditions exist in which there is a possibility that dental treatment could seriously injure the patient or result in death. However, acute heart failure during a stressful dental procedure in a patient with significant valvular disease and heart failure or the development of infectious endocarditis represent two such life-threatening disorders.[67] Careful evaluation of patients' medical histories including the cardiac status of patients, the use of appropriate prophylactic antibiotics, and stress reduction strategies will minimize the risk of serious cardiac sequelae.

There is a widespread belief among dental clinicians and physicians that oral anticoagulation therapy in which patients receive drugs such as warfarin (Coumadin) must be discontinued before dental treatment to prevent serious hemorrhagic complications, especially during and after surgical procedures. Aspirin is a drug commonly used as an anticoagulant on a daily basis without the supervision of a physician. Clinical studies do not support the routine withdrawal of anticoagulant therapy before dental treatment for patients who are taking such medications.[35,40] When patients report they are receiving an anticoagulant medication, they can benefit from the clinician using the following guidelines:

- Identify the reason why the patient is receiving anticoagulant therapy.
- Assess the potential risk versus benefit of altering the drug regimen.
- Know the laboratory tests used to assess anticoagulation levels (i.e., international normalized ratio [INR] values for patients receiving warfarin therapy).
- Be familiar with methods used to obtain hemostasis both intra- and posttreatment.
- Be familiar with the potential complications associated with prolonged or uncontrolled bleeding.
- Consult the patient's physician to discuss the proposed dental treatment and to determine the need to alter the anticoagulant regimen.

Another cardiac complication may occur in patients with Hodgkin's disease or breast cancer, who often receive irradiation to the chest as an element of treatment. Although the therapy often cures the malignancy, it has been implicated in causing late-onset heart disease that may influence the development of a treatment plan and subsequent treatment. Therapeutic irradiation of the chest results in the inadvertent inclusion of the heart within the irradiation field. Some patients may experience pathologic changes of the heart valves that could predispose them to endocarditis, accelerated atherosclerosis of the coronary artery that increases their risk of experiencing a fatal myocardial infarction, or both. Clinicians must identify patients who have received irradiation to the chest and consult with patients' physicians in order to determine whether that therapy has damaged the heart valves or coronary arteries. Patients with radiation-induced valvular disease may require prophylactic antibiotics when undergoing specific dental procedures that are known to cause a bacteremia and a heightened risk of developing endocarditis. Patients with radiation-induced coronary artery disease should be administered only limited amounts of local anesthetic agents containing a vasoconstrictor. They may require the administration of sedative agents and cardiac medications to preclude ischemic episodes. Consultation with the patient's physician is an appropriate response when a patient presents with a history that includes prior radiation to the chest.[27]

Diabetes

The Centers for Disease Control and Prevention (CDC, Atlanta, GA) in 2006 reported a 6% increase in the incidence of diabetes mellitus in the United States in 1 year.[30] This dramatic change has been linked to a remarkable increase in obesity among Americans during the last 10 years. Diabetes is the third leading

cause of death in the United States, and it is estimated that nearly 20 million Americans, representing 6.5% of the population, have diabetes.[45] Even more alarming is the fact that approximately 6 million of those cases have not been diagnosed. It is likely that diabetic patients requiring endodontic treatment will be increasingly common.

Diabetes mellitus appears to have multiple causes and several mechanisms of pathophysiology.[40] It can be thought of as a combination of diseases that share the key clinical feature of glucose intolerance. Patients with diabetes, even those who are well controlled, require special consideration during endodontic treatment. The patient with diabetes who is well controlled medically and free of serious complications such as renal disease, hypertension, or coronary atherosclerotic disease, is a candidate for endodontic treatment. However, special considerations exist in the presence of acute infections. The non–insulin-controlled patient may require insulin, or the insulin dose of some insulin-dependent patients may have to be increased.[57] When surgery is required, consultation with the patient's physician is advisable in order to consider adjustment of the patient's insulin dosage, antibiotic prophylaxis, and dietary needs during the posttreatment period.

The clinician should ask diabetic patients who self-monitor their glucose levels to bring a glucometer to each visit. If pretreatment glucose levels are below normal fasting range (80-120 mg/dl), it may be appropriate to take in a carbohydrate source.[72] A source of glucose (e.g., glucose tablets, orange juice, or soda) should be available if signs of insulin shock (hypoglycemic reaction caused by overcontrol of glucose levels) occur.[40] Signs and symptoms of hypoglycemia include confusion, tremors, agitation, diaphoresis, and tachycardia.[72] The clinician can avoid a hypoglycemic emergency by taking a complete, accurate history of time and amount of the patient's insulin and meals.

Appointments should be scheduled with consideration given to the patient's normal meal and insulin schedule.[57] Usually, a patient with diabetes who is well managed medically and is under good glycemic control without serious complications such as renal disease, hypertension, or coronary atherosclerotic heart disease can receive any indicated dental treatment.[45] However, patients with diabetes who have serious medical complications may need a modified dental treatment plan.[32] Moreover, studies suggest that diabetes is associated with a decrease in the success of endodontic treatment in cases with pretreatment periradicular lesions.[11,26] These patients may require referral to an endodontist for alternative treatment considerations.

Pregnancy

Although pregnancy is not a contraindication to endodontics, it does modify treatment planning. Protection of the fetus is a primary concern when administration of ionizing radiation or drugs is considered. Of all the safety aids associated with dental radiography, such as high-speed film, digital imaging, filtration, and collimation, the most important is the protective lead apron with thyroid collar.[7,76] Although drug administration during pregnancy is a controversial subject, Box 4-2 presents commonly used dental drugs usually compatible with both pregnancy and breast-feeding.[40] A major concern is that a drug may cross the placenta and be toxic or teratogenic to the fetus. In addition, any drug that is a respiratory depressant can cause maternal hypoxia, resulting in fetal hypoxia, injury, or death. Ideally, no drug should be administered during pregnancy, especially during the first trimester. If a specific situation makes adherence to this rule difficult, then the clinician should review the appropriate current literature and discuss the case with the physician and patient.[10,43,47]

BOX 4-2

Partial List of Drugs Usually Compatible With Both Pregnancy and Breast-Feeding

- Local anesthetics including lidocaine, etidocaine, and prilocaine
- Many antibiotics including penicillins, clindamycin, and azithromycin
- Acetaminophen
- Acyclovir
- Prednisone
- Antifungals including fluconazole and nystatin

Further considerations exist during the postpartum period if the mother breast-feeds her infant. A clinician should consult the responsible physician before using any medications for the nursing mother. Alternative considerations include using minimal dosages of drugs, having the mother bank her milk before treatment, having her feed the child before treatment, or suggesting the use of a formula for the infant until the drug regimen is completed. There are limited data available on drug dosages and the effects on breast milk.[40]

In terms of treatment planning, elective dental care is best avoided during the first trimester because of the potential vulnerability of the fetus. The second trimester is the safest period in which to provide routine dental care. Complex surgical procedures are best postponed until after delivery.

Malignancy

Some malignancies may metastasize to the jaws and mimic endodontic pathosis, whereas others can be primary lesions (Fig. 4-2). A panoramic radiograph is useful in providing an overall view of all dental structures. When a clinician begins an endodontic procedure on a tooth with a well-defined apical radiolucency, it might be assumed to result from a nonvital pulp. Pulp testing is essential to confirm a lack of pulp vitality in such cases. A vital response in such cases is indicative of a nonodontogenic lesion.

Careful examination of pretreatment radiographs from different angulations is important because lesions of endodontic origin would not be expected to be shifted away from the radiographic apex in the various images.

A useful website for the differential diagnosis of radiographic lesions (Oral Radiographic Differential Diagnosis [ORAD] II) was created by Dr. Stuart White and is available online at http://www.orad.org/index.html. A definitive diagnosis of a periradicular osteitis can be made only after biopsy. When a discrepancy exists between the initial diagnosis and clinical findings, consultation with an endodontist is advisable.

Patients undergoing chemotherapy or radiation to the head and neck may have impaired healing responses. Treatment should be initiated only after the patient's physician has been consulted. Resolving the question of endodontic treatment or

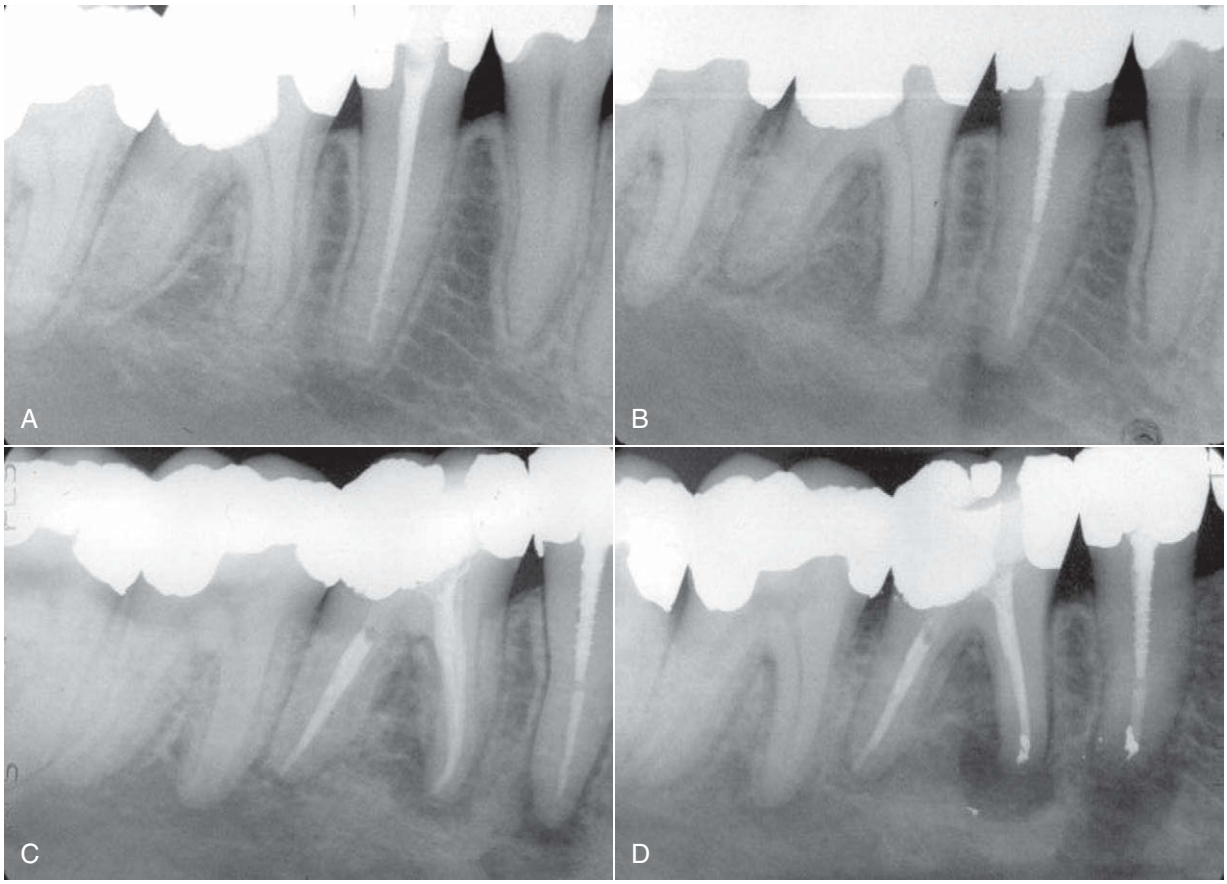

FIG. 4-2 A, Periapical view of tooth #29 after endodontic treatment by a general dental clinician. The diagnosis was irreversible pulpitis. **B,** Patient was referred to an endodontist 4 months later to evaluate radiolucencies of teeth #29 and #30. Symptoms indicated irreversible pulpitis of tooth #30, with concurrent lower right lip and chin paresthesia. Past medical history revealed breast cancer in remission. **C,** Nonsurgical endodontics was performed on tooth #30. Immediate referral was made to an oncologist/oral surgeon for biopsy to rule out nonodontogenic origin of symptoms. **D,** Surgical posttreatment radiograph of teeth #29 and #30. The biopsy report confirmed metastatic breast cancer. *(Courtesy Dr. R. Sadowsky, Dr. L. Adamo, and Dr. J. Burkes.)*

extraction for preradiation patients often requires a dialogue between the dental clinician and the physician.

The effect of the external beam of radiation therapy on normal bone is to decrease the number of osteocytes, osteoblasts, and endothelial cells, thus decreasing blood flow. Pulps may become necrotic from this impaired condition.[40] Toxic reactions during and after radiation and chemotherapy are directly proportional to the amount of radiation or dosage of cytotoxic drug to which the tissues are exposed. Delayed toxicities can occur several months to years after radiation therapy. Oral infections and any potential problems should be addressed before initiating radiation. It is advised that symptomatic nonvital teeth be endodontically treated at least 1 week before initiating radiation or chemotherapy, whereas treatment of asymptomatic nonvital teeth may be delayed.[40] The outcome of endodontic treatment should be evaluated within the framework of the toxic results of radiation and drug therapy. The white blood cell (WBC) count and platelet status of a patient undergoing chemotherapy should also be reviewed before endodontic treatment. In general, routine dental procedures can be performed if the granulocyte count is greater than 2000/mm^3 and the platelet count is greater than 50,000/mm^3. If urgent care is needed and the platelet count is below 50,000/mm^3, consultation with the patient's physician is required.[59]

Bisphosphonate Therapy

Bisphosphonates offer great benefits to patients at risk of bone metastases and in the prevention and treatment of osteoporosis. A patient's risk of developing osteonecrosis of the jaw while receiving oral bisphosphonates appears to be low, but there are factors known to increase the risk for bisphosphonate-associated osteonecrosis (BON) (Box 4-3).[3,4]

Because there are no studies that appropriately present the incidence of BON and treatment is unpredictable, prevention strategies are extremely important.[3,4] For patients at higher risk of BON, surgical procedures such as extractions, endodontic surgery, or placement of dental implants should be avoided, if possible. Sound oral hygiene and regular dental care may be the best approach to lowering the risk of BON.[3] Patients taking bisphosphonates and undergoing endodontic therapy should sign an informed consent form, inclusive of the risks, benefits, and alternative treatment plans.[4] In case of any infection in a patient taking bisphosphonates, aggressive use of systemic antibiotics is indicated.[40] Discontinuing bisphosphonate therapy may not eliminate any risk of developing BON.[41,42,44]

BOX 4-3

Risk Factors for Development of Bisphosphonate-Associated Osteonecrosis

- History of taking bisphosphonates for more than 2-3 years, especially with intravenous therapy
- History of cancer, osteoporosis, or Paget's disease
- History of traumatic dental procedure
- Patient more than 65 years of age
- History of periodontitis
- History of chronic corticosteroid use
- History of smoking
- History of diabetes

There is currently no valid diagnostic technique available to determine whether a patient is at risk of BON,[3] although some clinicians have proposed use of the CTX (C-terminal telopeptide of type I collagen α_1 chain) test (Quest Diagnostics, Madison, NJ) for assessing the risk of developing BON. For patients who have developed BON, close coordination with an oral maxillofacial surgeon or dental oncologist is highly recommended.

An astute awareness of the potential risk of BON in patients receiving bisphosphonate therapy is critical. Increased attentiveness to the prevention, recognition, and management of BON will allow the clinician to make the best treatment decisions. Our knowledge of BON is developing rapidly and it is essential that the clinician monitor published recommendation changes.[3,4,41,42,44]

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

It is important, when treating patients with acquired immunodeficiency syndrome (AIDS), that the clinician understand the patient's level of immunosuppression, drug therapies, and potential for opportunistic infections. Although the effect of human immunodeficiency virus (HIV) infection on long-term prognosis of endodontic therapy is unknown, it has been demonstrated that clinicians may not have to alter their short-term expectations for periapical healing in patients infected with HIV.[56] The clinical team must also minimize the possibility of transmission of HIV from an infected patient, and this is accomplished by adherence to universal precautions (for details see Universal Precautions for Prevention of Transmission of HIV and Other Bloodborne Infections, available at http://www.cdc.gov/ncidod/dhqp/bp_universal_precautions.html). Although saliva has not been demonstrated to transmit the virus in a dental situation, the potential for it to do so exists.[14,40] Infected blood can transmit HIV, and during some procedures it may become mixed with saliva. Latex gloves and eye protection are essential for the clinician and staff. HIV can be transmitted by needlestick or via an instrument wound, but the frequency of such transmission is low, especially with small-gauge needles.[40]

A vital aspect of treatment planning for the patient with HIV/AIDS is to determine the current $CD4^+$ lymphocyte count and level of immunosuppression. In general, patients having a $CD4^+$ cell count exceeding 400 mm^3 may receive all indicated dental treatment. Patients with a $CD4^+$ cell count less than 200 mm^3 will have increased susceptibility to opportunistic infections and may be effectively medicated with prophylactic drugs. Consultation with the patient's physician is advisable before performing surgical procedures and before initiating complex treatment plans.[40,65]

End-Stage Renal Disease and Dialysis

Consultation with the patient's physician is suggested before dental care is initiated for patients being treated for end-stage renal disease. Depending on the patient's status and the presence of other diseases common to renal failure (e.g., diabetes mellitus, hypertension, and systemic lupus erythematosus), dental treatment may be best provided in a hospital setting. The goal of dental care for patients being treated for end-stage renal disease is to slow the progression of disease and preserve the patient's quality of life.[40,55]

The most recent American Heart Association guidelines do not include a recommendation for prophylactic antibiotics before invasive dental procedures for patients receiving dialysis with intravascular access devices.[5] Although controversy exists, antibiotic prophylaxis should be provided for patients receiving hemodialysis and who have known cardiac risk factors. When prophylaxis is used, the standard regimen of the American Heart Association is recommended.[5]

Some drugs frequently used during endodontic treatment are affected by dialysis. Drugs metabolized by the kidneys and nephrotoxic drugs should be avoided. Both aspirin and acetaminophen are removed by dialysis and require a dosage adjustment in patients with renal failure. Amoxicillin and penicillin also require dosage adjustment as well as a supplemental dosage subsequent to hemodialysis.[55] It is advisable to consult the patient's physician concerning specific drug requirements during endodontic treatment. Endodontic treatment is best scheduled on the day after dialysis, because on the day of dialysis patients are generally fatigued and could have a bleeding tendency.[40]

Prosthetic Implants

Patients with prosthetic implants are frequently treated in dental practices. The question concerning the need for antibiotic prophylaxis to prevent infection of the prosthesis has been debated for many years. A statement was issued jointly in 2003 by the American Dental Association (Chicago, IL) and the American Academy of Orthopaedic Surgeons (Rosemont, IL) in an attempt to clarify the issue.[1] The statement concluded that scientific evidence does not support the need for antibiotic prophylaxis for dental procedures to prevent prosthetic joint infections. It went on to state that antibiotic prophylaxis is not indicated for dental patients with pins, plates, and screws, nor is it routinely indicated for most patients with total joint replacements. However, the statement indicated that some "high-risk patients" who are at increased risk for infection and undergoing dental procedures likely to cause significant bleeding should receive antibiotic prophylactic treatment. Such patients would include those who are immunocompromised or immunosuppressed, who have insulin-dependent (type I) diabetes, who are in the first 2 years following joint replacement, or who have previous joint infections, malnourishment, or hemophilia.[1] The advisory statement concludes that the final decision on whether to provide antibiotic prophylaxis is the responsibility of the clinician, who must consider potential benefits and risks. It should be noted that

although endodontics has been shown to be a possible cause of bacteremia,[17,66] the risk is minimal in comparison with extractions, periodontal surgery, scaling, and prophylaxis.[52] Consultation with the patient's physician on a case-by-case basis is advisable to establish the need for prophylaxis.

Behavioral and Psychiatric Disorders

Stress reduction is an important factor in the treatment of patients with behavioral and psychiatric disorders. Sensitivity to the patient's needs must be part of the dental team's approach. Significant drug interactions and side effects are associated with tricyclic antidepressants, monoamine oxidase inhibitors, and antianxiety medications.[40] Consultation with physicians in such cases is essential before using sedatives, hypnotics, antihistamines, or opioids.

Psychosocial Evaluation

The initial visit, during which medical and dental histories are gathered, provides an opportunity to consider the patient's psychosocial status. Although some patients may want to maintain a tooth with a questionable prognosis, others may lack the necessary sophistication to comprehend the potential risks and benefits. It would be a mistake to lead patients beyond what they can appreciate, and patients should not be allowed to dictate treatment that has a poor prognosis.

The clinician should also assess the patient's level of anxiety as an important part of preparation for the procedure to follow. It is reasonable to assume that most patients are anxious to some degree, especially when they are about to undergo endodontic treatment. A conversation describing the procedure and what the patient can expect is an important part of an anxiety reduction protocol. It is well documented that a high level of anxiety is a predictor of poor anesthesia and posttreatment pain.[13,48] More than 200 studies indicate that behavioral intervention for the highly anxious patient before treatment decreases anxiety before and after surgery, reduces posttreatment pain, and accelerates recovery.[13]

DENTAL EVALUATION AND DEVELOPMENT OF THE ENDODONTIC TREATMENT PLAN

The strategic value of a tooth in question should be considered before presenting alternative treatment plans to the patient. Although some decisions may be straightforward, considering alternative treatment options can be challenging as the clinician weighs multiple factors that will play a role in determining the ultimate success or failure of the case. Referral of the patient to a specialist should be considered when the complexity of a procedure is beyond the ability of a clinician. Factors that affect endodontic prognosis, including periodontal and restorative, must be considered. The alternative of a dental implant offers another choice when the endodontic prognosis is poor.

Periodontal Considerations

Extensive periodontal lesions frequently complicate the endodontic procedure being considered. Such lesions may necessitate consultation with an endodontist and/or periodontist in order to gather more information about the tooth's prognosis. A tooth with a poor periodontal prognosis may have to be sacrificed, despite a favorable endodontic prognosis.

When establishing the prognosis of a tooth with an endodontic/periodontal lesion, there are essential factors to be considered. Determination of pulp vitality and the extent of the periodontal defect are central to establishing the prognosis and developing a treatment plan for a tooth with an endodontic/periodontal lesion (see also Chapter 18).

In primary endodontic disease the pulp is nonvital (Figs. 4-3 and 4-4), whereas in primary periodontal disease the pulp retains vitality. True combined endodontic–periodontal disease occurs less frequently. The combined lesion is found when the endodontic disease process advances coronally and joins with a periodontal pocket progressing apically. There is significant attachment loss with this type of lesion and the prognosis is guarded.[61] The radiographic appearance of combined endodontic–periodontal lesions may be similar to that of a vertically fractured tooth. Therapy for true combined lesions requires both endodontic and periodontal therapy. Sequencing of treatment is based on addressing the initial chief complaint.

The prognosis for and treatment of each type of endodontic–periodontal disease vary. Primary endodontic disease should be treated solely by endodontic therapy and the prognosis is usually good. Primary periodontal disease should be treated only by periodontal therapy and the prognosis varies depending on the seventy of the disease and patient's response to treatment.[61]

Pathogenesis of the lesion can be better understood after vitality testing, periodontal probing, radiographic assessment, and evaluation of dental history. When extensive prostheses are planned, the potential risk of including a tooth with a questionable prognosis must be considered. It is not prudent to incorporate a chronic problem into a new complex prosthesis (Fig. 4-5).

Surgical Considerations

Surgical evaluation is particularly valuable in the diagnosis of lesions that may be nonodontogenic. Biopsy is the definitive means of diagnosing osseous pathosis, which may mimic a lesion of endodontic origin. When retreatment is being considered, the clinician must determine whether nonsurgical, surgical, or combined treatment is appropriate. This decision is influenced by the presence of complex restorations, posts, and the radiographic assessment of prior endodontic therapy.

Endodontic surgery is most often performed in an attempt to correct failure of nonsurgical therapy. Before surgery, it is essential that the clinician attempt to determine the cause of failure. For example, a deficient restoration or recurrent decay will result in microleakage into the root canal space. Unless that issue is addressed, apical surgery will not be successful (Fig. 4-6).

Endodontic surgery (see Chapter 21) may also be performed as a primary procedure when there are complications such as calcific metamorphosis. In those cases, by using surgery as primary therapy, an apical seal can be established while preserving the crown of the tooth. The treatment plan for these cases is determined after reviewing multiple radiographs and considering the possibility of completing nonsurgical therapy without destroying an otherwise functional crown or natural tooth. Endodontic surgery without prior nonsurgical therapy should be a treatment of last resort and only when nonsurgical treatment is not possible.

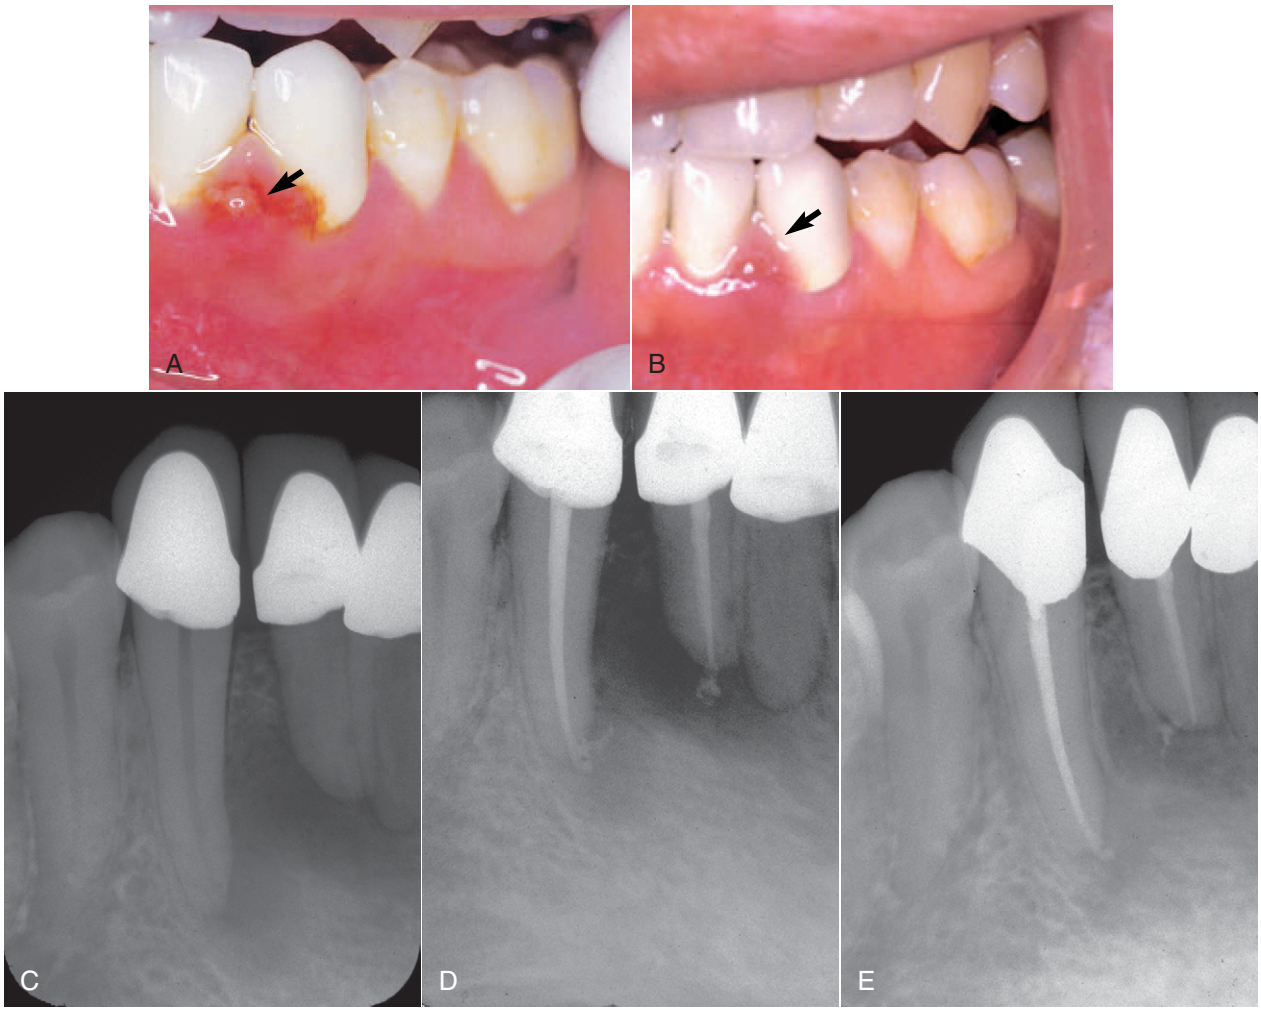

FIG. 4-3 A, Inflamed, edematous interproximal tissue *(arrow)* caused by acute endodontic pathosis. **B,** Soft tissue healing *(arrow)* 3 days after initiation of endodontic treatment. **C,** Periradicular pathosis. **D,** Completed endodontic therapy. **E,** Periradicular healing at 1-year recall.

The primary reason for apical surgery is to improve the quality of the apical seal. Dramatic changes in surgical technique and materials have occurred: The advent of microscopy, endoscopy, and ultrasonics, as well as of new retrograde materials such as mineral trioxide aggregate, represent important modifications of surgical technique.

Reviewing the best available evidence for alternative treatments is an important aspect of treatment planning for a tooth with failed endodontics. Evidence concerning healing potential after endodontic surgery is an important consideration in the management of posttreatment disease.[28] Numerous studies have examined the outcome of apical surgery and the results vary considerably.[73,74,80] This variability may reflect actual outcome differences or reflect variations in case selection techniques, recall periods, and methodology.

A study prospectively[74] assessed the 4- to 8-year outcome of apical surgery on 155 teeth in 138 patients. The recall rate was 85% and the overall healed rate was 74%. The healed rate was significantly higher for teeth with small (≤5 mm) than larger pretreatment lesions (χ^2, $P = 0.02$). Analysis indicated an increased odds ratio for disease persistence for teeth with larger pretreatment lesions and pretreatment root canal filling of adequate length. Pretreatment lesion size and root-filling length were significant predictors of the outcome of apical surgery.

One study assessed various predictors for healing 1 year after periapical surgery.[73] The study evaluated pretreatment, surgical, and posttreatment variables as possible predictors for a 1-year healing outcome in periapical surgery. Only one parameter, pain at initial examination, reached a 0.05 level of significance in a logistic regression analysis, indicating that patients presenting with pain at the initial examination before surgery had a significantly lower rate of healing at the 1-year follow-up compared with patients having no pain at the initial examination.[73]

Restorative Considerations

A satisfactory restoration may be jeopardized by a number of factors. Subosseous root caries (perhaps requiring crown lengthening), poor crown-to-root ratio, and extensive periodontal defects or misalignment of teeth may have serious effects on the final restoration. These problems must be recognized before endodontic treatment is initiated. For complex cases, a restorative treatment plan should be in place before

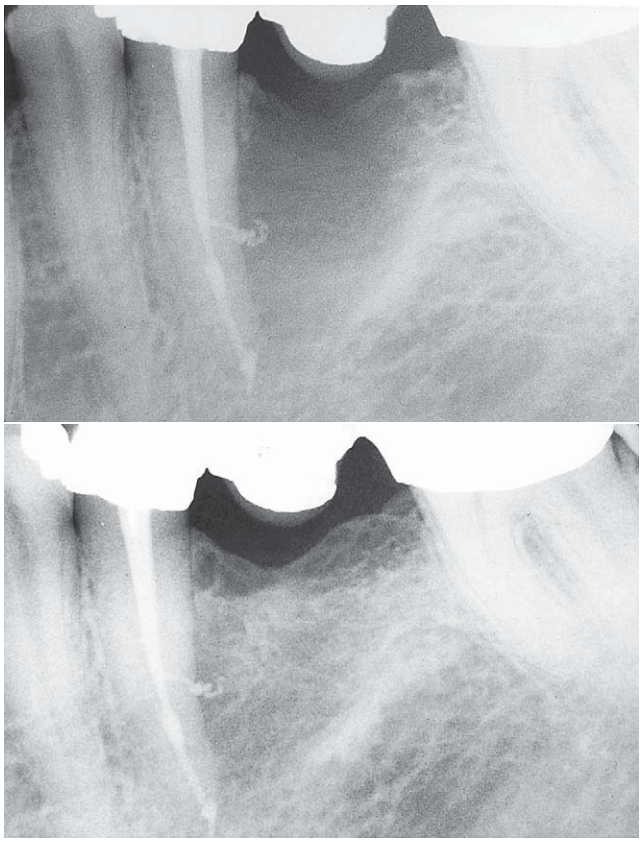

FIG. 4-4 A large, bony defect associated with tooth #20 healed after endodontic therapy. The tooth was nonvital, and no significant periodontal probing depth indicated pulpal disease.

initiating endodontic treatment. Some teeth may be endodontically treatable but nonrestorable, or they may represent a potential restorative complication because of a large prosthesis. Reduced coronal tooth structure under a full-coverage restoration makes endodontic access more difficult because of reduced visibility and lack of radiographic information about the anatomy of the chamber. It is not unusual for restorations to be compromised during endodontic access (see Fig. 4-6). Whenever possible, restorations should be removed before endodontic treatment.

FIG. 4-5 Tooth #30 has a poor prognosis. Periodontal probing reached the apex of the distal root. Extraction is indicated and should be done as soon as possible to prevent further damage to the mesial bone associated with tooth #31. Implant site preservation is another consideration in treatment planning for this case.

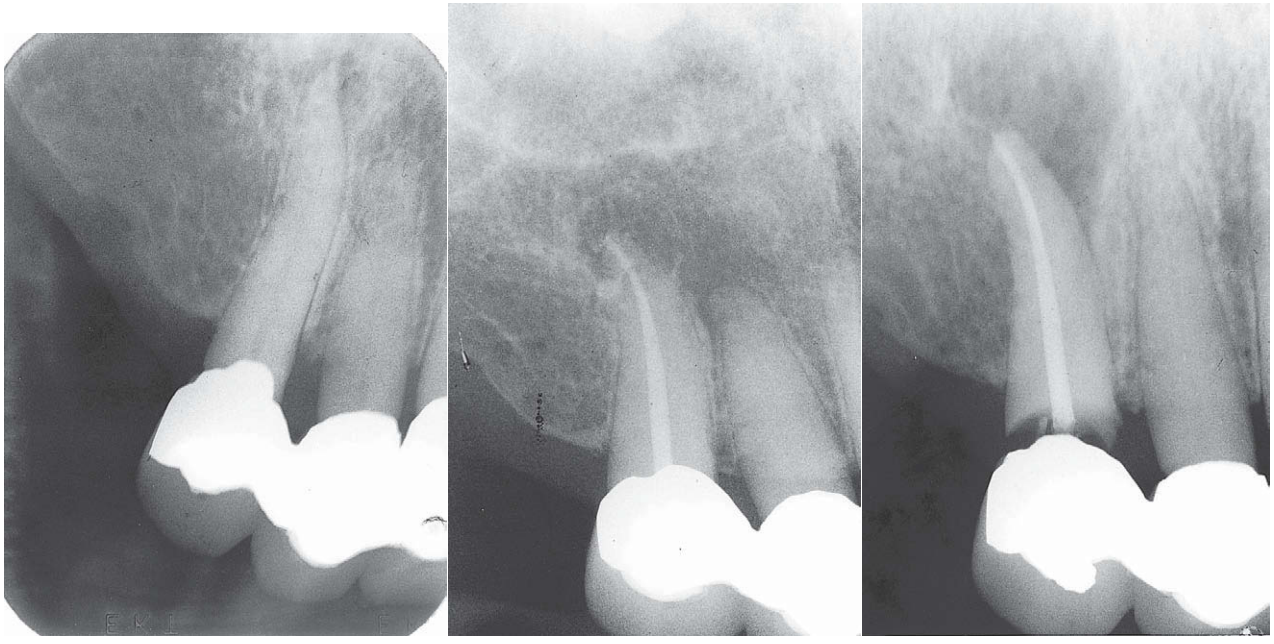

FIG. 4-6 Four years after endodontic therapy, the patient complained of pain and swelling associated with tooth #6. The initial impression was that apical surgery was indicated. However, further radiographs revealed the true cause of the endodontic failure. The initial endodontic access through the crown or caries damaged the coronal seal and recurrent decay followed.

Endodontic Therapy or Dental Implant

The successful evolution of dental implants as a predictable replacement for missing teeth has had a positive impact on patient care. A clinician now has an additional possibility to consider when developing a treatment plan for a patient with a missing tooth or teeth. More challenging is the decision concerning whether or not to pursue endodontics for a tooth with a questionable prognosis or extract and use a single-tooth implant as a replacement. At this time, there are no randomized controlled outcome studies comparing endodontic therapy with single-tooth implants. Numerous studies have evaluated both nonsurgical endodontic therapy[16,50,51,62,70,71] and endosseous dental implants.[2,15,34,39]

It is not possible to compare outcome studies because of variations in research methodologies, follow-up periods, and criteria associated with determining success or failure. A review of outcome studies points to the need for randomized controlled trials with standardized or similar methodologies that could provide a higher level of evidence to use in answering important clinical prognostic questions. A synthesis of available evidence indicates that both primary root canal treatment and single-tooth implants are highly predictable procedures when treatment is appropriately planned and implemented.

A systematic review of the literature examined the success and failure of nonsurgical endodontic therapy. The authors concluded that four conditions (pretreatment absence of a periapical radiolucency, root filling with no voids, root filling extending to 2 mm within the radiographic apex, and satisfactory coronal restoration) were found to improve the outcome of primary root canal treatment. They went on to note that the results of the review "should be interpreted with caution and cannot be considered to give definitive conclusions because of the retrospective and heterogeneous nature of the data. It does, however, provide strong clues about the factors likely to dominate outcomes and inform the design of future randomized trials."[50]

Another study[16] assessed clinical and radiographic success of initial endodontic therapy of 510 teeth over a 4- to 6-year period. It was found that 86% of teeth healed and 95% remained asymptomatic and functional. Absence of pretreatment apical periodontitis, single-rooted teeth, and the absence of intratreatment complications were significant predictors of better outcome in initial endodontic treatment.[1] In 2004, a study considered the outcomes of endodontic treatment on 1,462,936 teeth. More than 97% of teeth were retained after 8 years. It should be noted that most of these cases were completed by general dental clinicians.[62]

The American Dental Association's Council on Scientific Affairs has reported high survival rates for endosseous implants. An evaluation of 10 studies with more than 1400 implants demonstrated survival rates ranging from 94.4% to 99% with a mean survival rate of 96.7%.[2] With such high survival rates reported for endodontics and single-tooth implants a clinician must consider a multiplicity of factors within the context of the best available evidence. Most current studies indicate no significant difference in the long-term prognosis between restored endodontically treated teeth and single-tooth implants.[34]

A retrospective cross-sectional comparison of initial nonsurgical endodontic treatment and single-tooth implants compared 196 implant restorations and 196 matched initial nonsurgical root canal–treated teeth. The results suggested that restored endodontically treated teeth and single-tooth implant restorations have similar failure rates, although the implant group showed a longer average and median time to function and a higher incidence of posttreatment complications requiring subsequent treatment intervention.[19]

A review summarized the best available evidence concerning factors influencing treatment planning involving preservation of a tooth with endodontic therapy or replacement by a single-tooth implant. Factors considered included prosthetic restorability of the natural tooth, quality of bone, esthetic concerns, cost-to-benefit ratio, systemic factors, potential for adverse effects, and patient preferences. The authors concluded that "endodontic treatment of teeth represents a feasible, practical and economical way to preserve function in a vast array of cases and that dental implants serve as a good alternative in selected indications in which prognosis is poor."[34]

It seems clear that the patient is best served by retaining their natural dentition as long as the prognosis for long-term retention is positive. It is not reasonable to extract a tooth if endodontics with a good prognosis can be completed. It is also not reasonable for a patient to invest in root canal therapy, a post and crown if the prognosis is highly questionable and an implant with a good prognosis can be placed. An important advantage of providing endodontic therapy is to allow rapid return of the patient's compromised dentition to full function and aesthetics. This rapid return is in marked contrast to the use of provisional restorations associated with dental implants while waiting for osseous integration.

Interestingly, some endodontic advanced education programs are now including implant training in their curriculum. This training will enable the endodontist to provide more value to the patient and referring dental clinician as treatment plans are determined. Such dually trained endodontists will be well positioned to provide endodontic therapy or place an implant as best serves the patient.

The scope of modern endodontics has been enhanced by the use of ultrasonics and microscopy as well as improved instruments and new materials. Teeth can be retained today that could not have been treated in the past. Biologically, it is clear that elimination of intraradicular infection is the key to endodontic success.

Vital Case

The acute vital case is best managed by a biologically based approach. Pain in such cases may be due to increased intrapulpal pressure and/or the release of inflammatory mediators and extension of the pathogenic process into the periodontal membrane. The challenge for the clinician is to treat inflamed and well-innervated tissue without causing additional pain. Performing a complete pulpotomy or, if time permits, establishing measurement control and completing a pulpectomy has a high degree of predictability in alleviating pain.[8,33] If a canal has been entered, the clinician should be committed to removing all tissue. Partial instrumentation (i.e., leaving tissue remnants in the canal) may result in increased posttreatment pain.[8,24,58] Teeth should be closed with a temporary filling at the conclusion of the visit in order to prevent bacterial contamination from saliva. After instrumentation of vital teeth with a history of pain and percussion sensitivity, occlusal

reduction has been shown to be important in preventing posttreatment pain.[60]

Nonvital Case

The acute nonvital case represents a microbiologic challenge for the clinician (see also Chapters 9 and 15). A tooth that has had an asymptomatic nonvital pulp for some time may suddenly become acutely symptomatic. The cause of this dramatic change is due to an imbalance in the host–parasite relationship. This can be due to an increase in the virulence of bacteria, a change in the flora, or reduced host defense mechanisms.[8] These changes can be initiated simply by opening the tooth and changing the environment of the bacterial flora. The therapeutic goals in such cases are to reduce the bacterial content in the root canal system and to promote decompression of the periradicular tissues by instrumentation and irrigation of the canal. Calcium hydroxide should be delivered into the root canal system as an intervisit dressing. Teeth should be closed with a cotton pledget in the chamber covered by a temporary seal. Endodontic treatment should be completed as soon as possible in order to prevent continued bacterial penetration into the canal. When a fluctuant swelling exists, incision and drainage may be performed in conjunction with canal instrumentation (Figs. 4-7 and 4-8).

Single-Visit versus Multiple-Visit Treatment

Vital cases are often suitable for single-visit treatment. The number of roots, time available, and the clinician's skills are factors to be considered. Severity of the patient's symptoms is another important consideration. For example, a patient in severe pain, with or without swelling, should not experience a long visit including access, instrumentation, and obturation. Treatment in such cases should be directed at alleviating pain, with filling of the canal postponed until a later visit. The clinician's judgment of what the patient can comfortably tolerate (regarding duration of the visit) is made on a case-by-case basis.

There are advantages in having a patient return for a second visit, after initially presenting with an endodontic emergency due to pain and/or swelling. The second visit allows the clinician to determine the effect of the therapy on the inflamed tissues. Deferring the filling of the canal(s) also leads to a shorter initial visit for the emergency patient. Although some researchers have reported less posttreatment pain in single-visit cases,[24,58] a systematic review found that there was no detectable difference in the effectiveness of root canal treatment in terms of radiologic success between single and multiple visits.[25] Neither single-visit nor multiple-visit root canal treatment can prevent 100% of short-term and long-term complications.[25] The review found that the incidence of postobturation discomfort was similar in the single- and multiple-visit approaches although analgesic use was significantly less

FIG. 4-7 Incision and drainage should be performed on this fluctuant swelling *(arrow)* in conjunction with canal instrumentation.

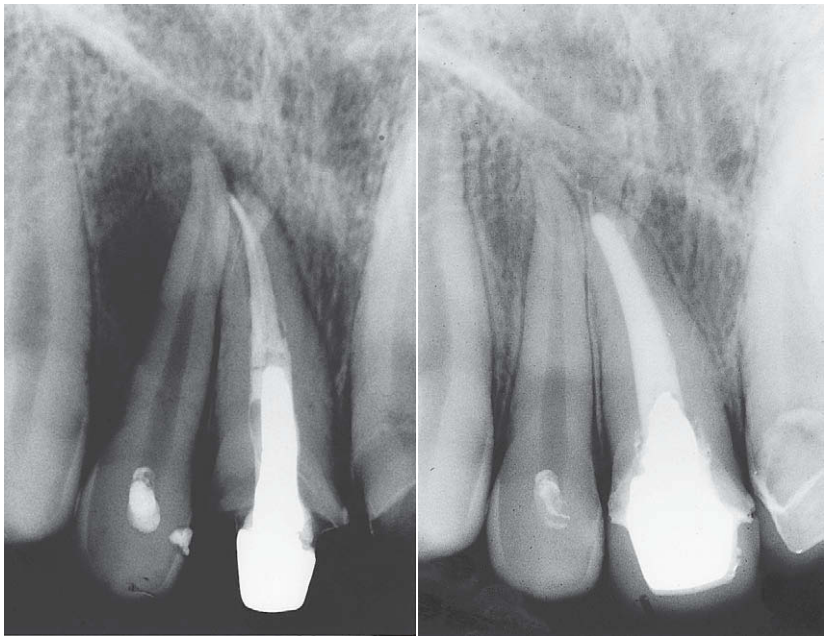

FIG. 4-8 Two years after endodontic therapy of tooth #8, the patient returned with pain and swelling. A clinician mistakenly began endodontic access on tooth #7, without confirming the apparent radiographic diagnosis by vitality testing. Tooth #7 was vital, and tooth #8 was successfully retreated after removal of the post. *(Courtesy Dr. Leon Schertzer.)*

common in patients undergoing multiple-visit root canal treatment.

A systematic review examined the prevalence of posttreatment pain and flare-up among patients undergoing single- and multiple-visit endodontic treatment.[63] The heterogeneity among the included studies was far too great to conduct a meta-analysis and yield meaningful results. The authors concluded that there was a lack of compelling evidence indicating a significantly different prevalence of posttreatment pain/flare-up with either single- or multiple-visit root canal treatment.

Teeth with nonvital pulps and apical periodontitis are often more complex than vital cases. Agreement is lacking concerning the appropriateness of single-visit endodontics for treating these patients. Some have postulated that the intervisit use of an antimicrobial dressing is essential to thoroughly disinfect the root canal system.[68,69] In contrast, other researchers have found no statistically significant difference in success when using the single-visit or multivisit approach to the nonvital tooth with apical periodontitis.[25,29,46,53,54,75] Two randomized controlled trials compared radiographic evidence of periapical healing after root canal treatment of necrotic teeth completed in one or two visits. The authors found no statistically significant difference in healing between the two groups.[46,53]

Treatment planning for an endodontic case should be based on biologic considerations. Patients who present with acute symptoms present a different set of biologic issues than those with an asymptomatic tooth. A swelling associated with an abscess, cellulitis, or presence of a stoma represent signs of biologic processes. The biologic significance of these conditions should be considered before determining specific goals for each visit. Although in most cases the clinical procedures required to complete endodontic treatment can be accomplished in a single visit, that does not mean it is the better course of treatment. What can be done and what should be done represent two very different approaches to endodontic treatment planning. The patient's systemic health, level of anxiety, and symptoms, as well as the complexity of the root canal system, are factors that must be considered.

Agreement is lacking concerning long-term success rates associated with single-visit and multivisit procedures. Sjögren and associates[68] investigated the influence of infection at the time of root filling on the outcome of endodontic treatment of teeth with apical periodontitis. Periapical healing was observed 5 years after completion of treatment. They concluded that "Complete periapical healing occurred in 94% of cases that yielded a negative culture. When the samples were positive before root filling, the success rate of treatment was just 68%—a statistically significant difference." They concluded that the objective of eliminating bacteria from the root canal system "cannot be reliably achieved in a one-visit treatment because it is not possible to eradicate all infection from the root canal without the support of an interappointment antimicrobial dressing." However, the findings of Friedman,[29] Weiger and colleagues,[75] and Peters and Wesselink[54] contrast with those of Sjögren and colleagues.[68] Those studies found no statistically significant differences in healing between teeth, with apical periodontitis, treated in one visit and two visits with the inclusion of calcium hydroxide as an intravisit medication.[54,75] Sathorn and colleagues completed a systematic review of single- versus multiple-visit endodontic treatment of teeth with apical periodontitis.[64] They found that, on the basis of current best available evidence, single-visit root canal treatment appeared to be slightly more effective than multiple-visit treatment (6.3% higher healing rate). However, the difference between these two treatment regimens was not statistically significant.[64] This is a complicated issue because the inability to detect differences between groups might also be due to variations in research methodology, including sample size, duration of follow-up, and treatment methods.

It is possible that total elimination of bacteria may not be absolutely necessary for healing. Perhaps maximal reduction of bacteria, effective root canal filling, and a timely satisfactory coronal restoration can result in a high level of clinical success. However, regardless of the number of appointments, effective bacteriologic disinfection of the root canal system is critical.[38]

A study concerning the outcome of initial treatment noted the complexity of treating apical periodontitis.[29] The author commented that "… treatment of this disease cannot be improved merely by changing treatment techniques. Because apical periodontitis results from interactions between microorganisms, their environment and the host immune system, only use of effective modifiers of any of these three factors might significantly improve the outcome of treatment."

Retreatment Case

Retreatment cases offer a particular set of challenges to the clinician, and this topic is covered extensively in Chapter 26. Important questions to be considered before retreatment include the following:

- Why did the treatment fail?
- Are prior radiographs available for review?
- Is there an obvious procedural problem that can be corrected?
- Is the canal system readily accessible for reentry?
- Are there additional factors (other than endodontic) that may have contributed to the failure?
- Is the tooth critical to the treatment plan?
- Does the patient understand the prognosis for the tooth and want to attempt retreatment?

A retreatment plan should be developed after the clinician has determined the cause of failure and weighed other factors that may affect the prognosis (e.g., root fracture, defective restoration) (Figs. 4-9 to 4-12). Retreatment cases may require surgical endodontics in combination with nonsurgical retreatment. Referral to a specialist is often helpful when planning treatment for complex cases.

Immature Teeth

Primary and immature permanent teeth may have pulpal pathosis caused by caries or trauma; preserving these young teeth is essential. Premature loss of an anterior tooth can lead to malocclusion, predispose the patient to tongue habits, impair aesthetics, and damage the self-esteem of the patient. See Chapters 16 and 24 for further information.

Other Factors That May Influence Endodontic Case Selection

A variety of factors may complicate proposed endodontic therapy. Calcifications, dilacerations, or resorptive defects may compromise endodontic treatment of a tooth with potentially strategic value (Fig. 4-13). The inability to isolate a tooth is

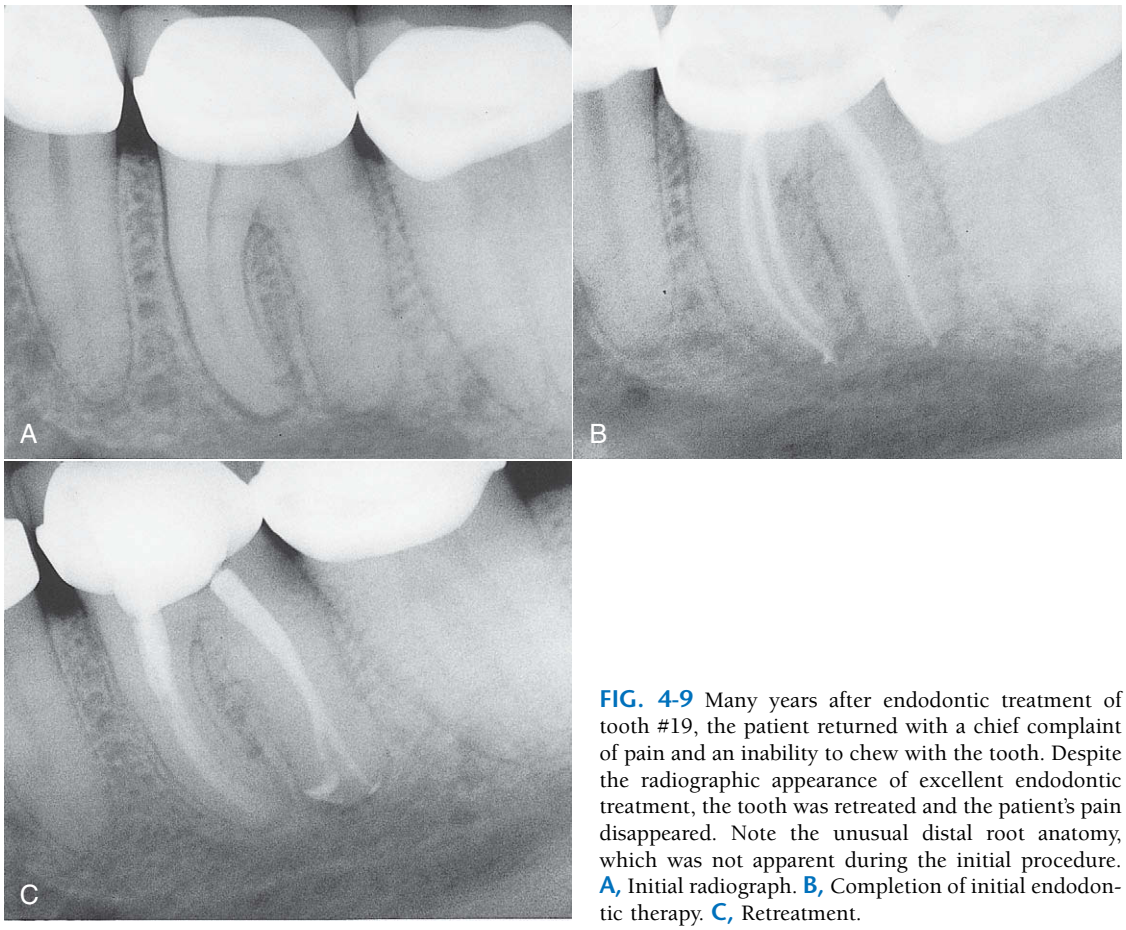

FIG. 4-9 Many years after endodontic treatment of tooth #19, the patient returned with a chief complaint of pain and an inability to chew with the tooth. Despite the radiographic appearance of excellent endodontic treatment, the tooth was retreated and the patient's pain disappeared. Note the unusual distal root anatomy, which was not apparent during the initial procedure. **A,** Initial radiograph. **B,** Completion of initial endodontic therapy. **C,** Retreatment.

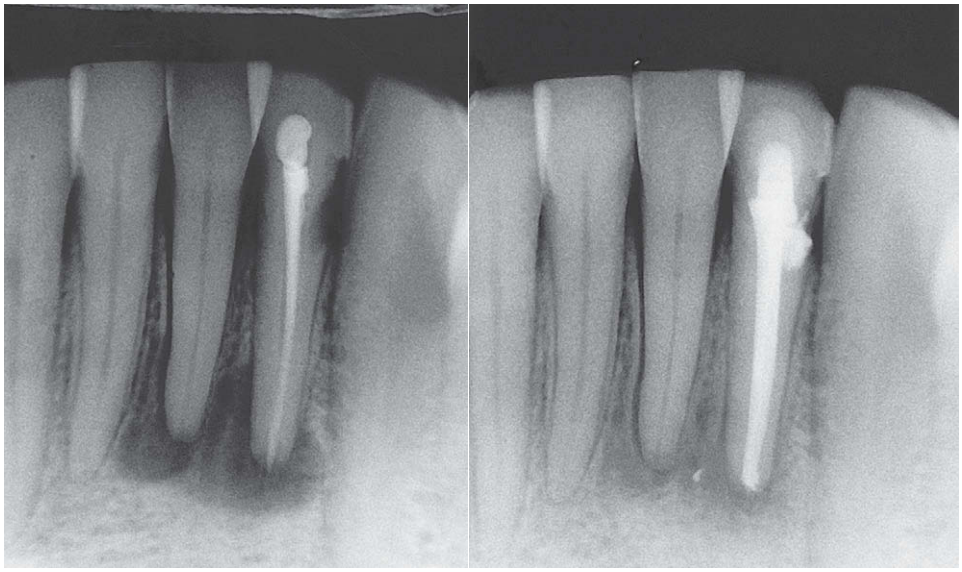

FIG. 4-10 Initial radiograph was misleading and implicated tooth #23 and tooth #24. Pulp testing indicated a vital pulp in tooth #24, and it was not treated. Retreatment of #23 resulted in healing of the periradicular lesion. *(Courtesy Dr. Leon Schertzer.)*

also a problem and may result in bacterial contamination of the root canal system. Extra roots and canals pose a particular anatomic challenge that radiographs do not always reveal (Fig. 4-14). A bite wing radiograph is useful in providing an accurate image of the pulp chambers of posterior teeth. Retreatment cases offer particular mechanical challenges and are discussed in detail in Chapter 25. Ledges, perforations, or a post may be present, all of which complicate treatment and alter the prognosis. The clinician should recognize these potential problems and be able to manage and factor them into the decision concerning the tooth's prognosis, including the possibility that the patient should be referred to a specialist.

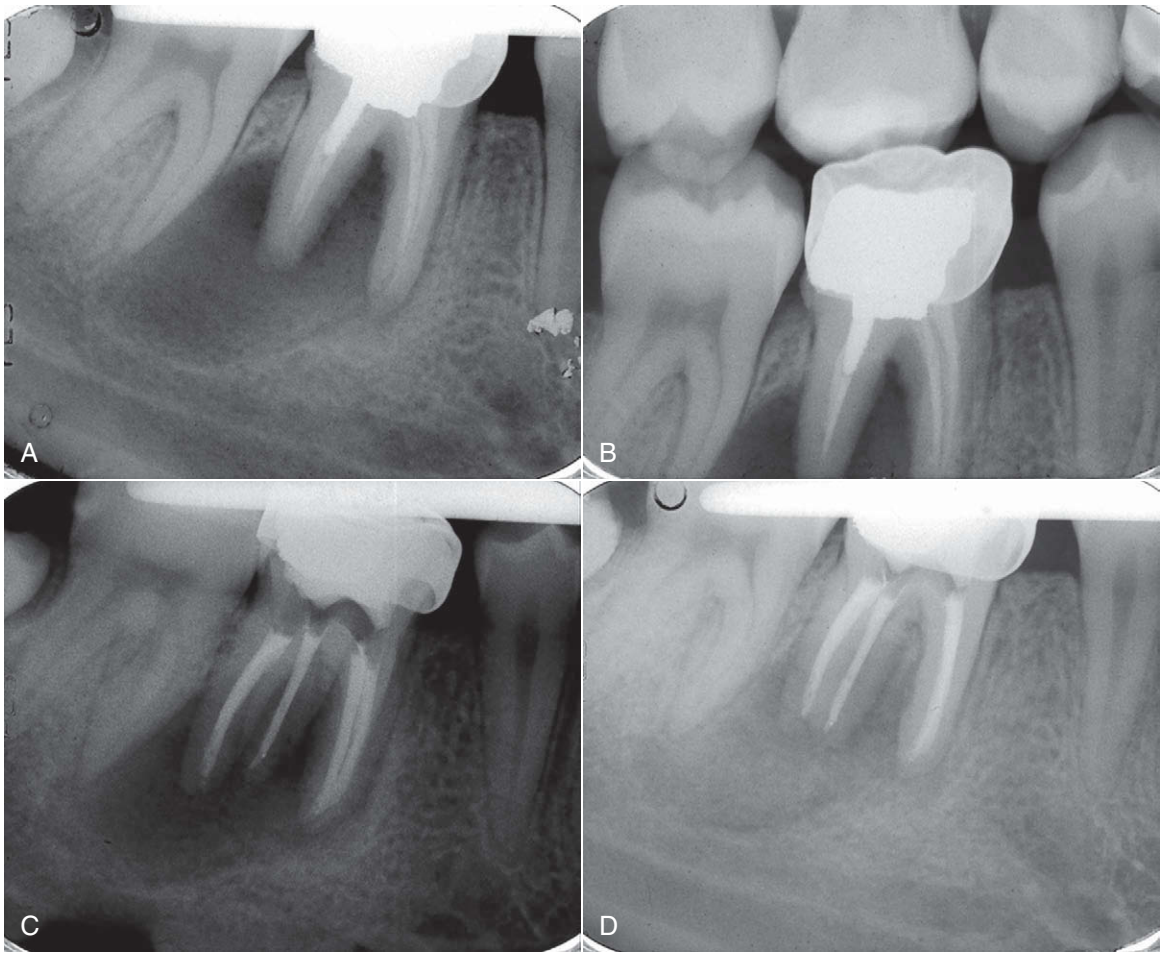

FIG. 4-11 Nonsurgical retreatment of tooth #30. An additional root was located and treated. **A,** Note inadequate endodontic treatment and large periapical lesion. **B,** Bite wing radiograph. **C,** Retreatment after post removal. **D,** Eighteen-month recall radiograph indicates periapical healing.

Some clinicians use a simple formula for determining which endodontic cases they treat and which they refer to a specialist. The number of roots may be the determining factor in a decision concerning referral, or the key factor may be the chronic or acute status of the case. Others consider the complexity of the ultimate prosthesis as a factor in considering an endodontic referral. The most important variables in determining whether to refer a patient to a specialist are the skills of the clinician and the complexity of the case.

The American Association of Endodontists (AAE) developed guidelines for assessing endodontic case difficulty (available at http://www.aae.org/dentalpro/CaseAssmtReferral.html) (see Fig. 2-1). The AAE Endodontic Case Difficulty Assessment Form enables a clinician to assign a level of difficulty to a particular case. The form describes cases of minimal, moderate, and high degrees of difficulty. This form lists criteria that can be used to identify cases that should be referred to a specialist. The use of surgical operating microscopes, endoscopes, and ultrasonics enables the specialist to predictably treat teeth that would not previously have been treatable.

Developing specific goals at each visit helps to organize the treatment. For example, for an uncomplicated molar or premolar, some clinicians will set a specific goal for the first visit that includes access and thorough instrumentation, while deferring the obturation to a second visit. Uncomplicated single-rooted, vital teeth may be planned for a single-visit approach. It is important that ample time be allowed so that the procedure can be adequately completed without undue stress. These recommendations have a biologic basis. Biologically, it is not reasonable to partially instrument root canal systems, thereby leaving residual inflamed pulpal remnants or necrotic debris in the canal, because such remnants may cause pain and be susceptible to infection. The clinician would be well advised to begin canal instrumentation only if time permits the extirpation of all pulp tissue.

Anxiety

Anxiety presents a problem at many levels of dental care (see also online Chapter 26). Avoidance of dental treatment due to anxiety appears to be associated with significant deterioration of oral and dental health.[79] Even at the diagnostic stage, severe anxiety may confuse the process.[21] Several studies support the hypothesis that pain or fear of pain is a primary source of anxiety as well as an obstacle to seeking dental care.[37,79] Also,

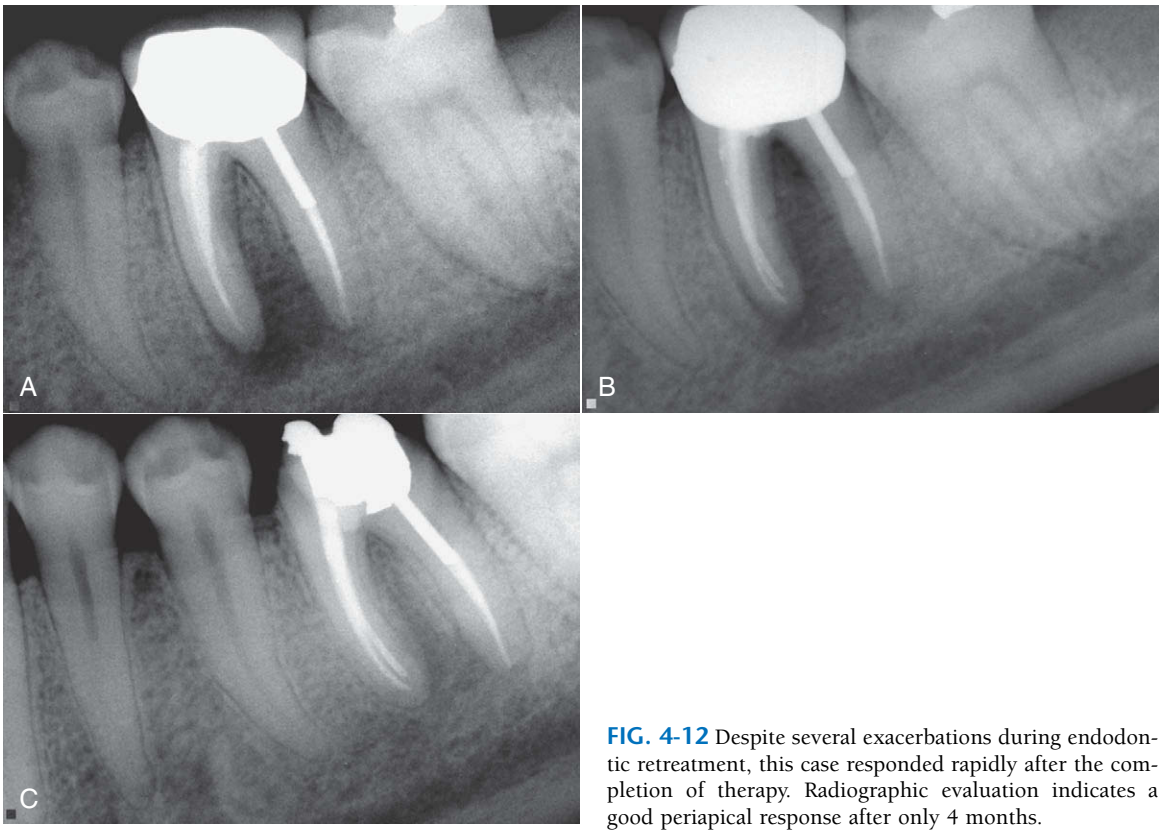

FIG. 4-12 Despite several exacerbations during endodontic retreatment, this case responded rapidly after the completion of therapy. Radiographic evaluation indicates a good periapical response after only 4 months.

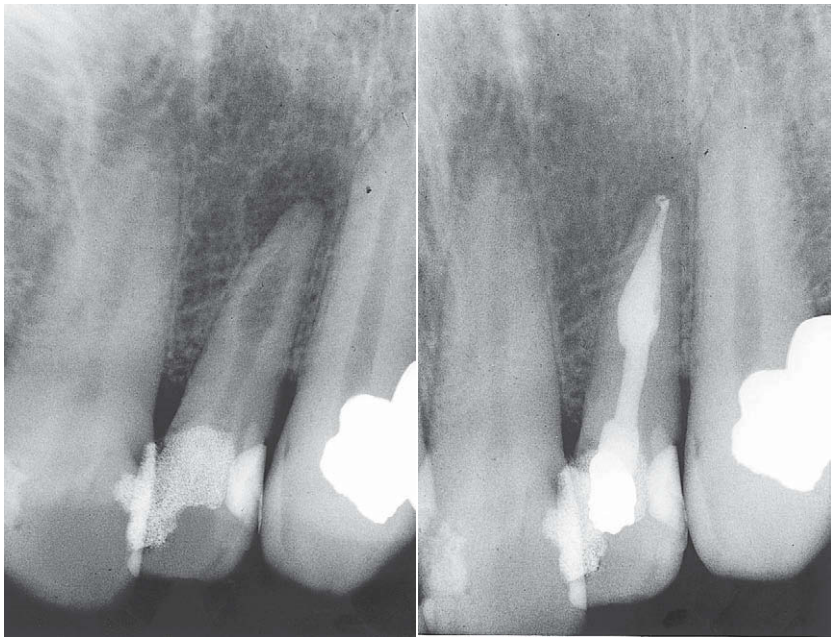

FIG. 4-13 Resorptive defects can be successfully treated. Early intervention, before there is perforation of the root, increases the chance of success. *(Courtesy Dr. Leon Schertzer.)*

highly anxious patients appear to be more sensitive to pain.[22,36] High levels of anxiety have been found to negatively affect clinical procedures including local anesthesia.[48]

It has been demonstrated that dental anxiety and expectation of pain had a profound effect on a patient's ability to understand information provided.[23] A person's cognitive ability to process information is significantly affected by stress.[23] A study found that 40% of patients who had minor oral surgery did not remember receiving both written and verbal instructions, contributing to 67% noncompliance with antibiotic prescriptions.[9] Patients' anxiety can compromise their understanding of complex treatment plans. Decisions made by a patient concerning options involving tooth retention or loss may be markedly affected by anxiety.

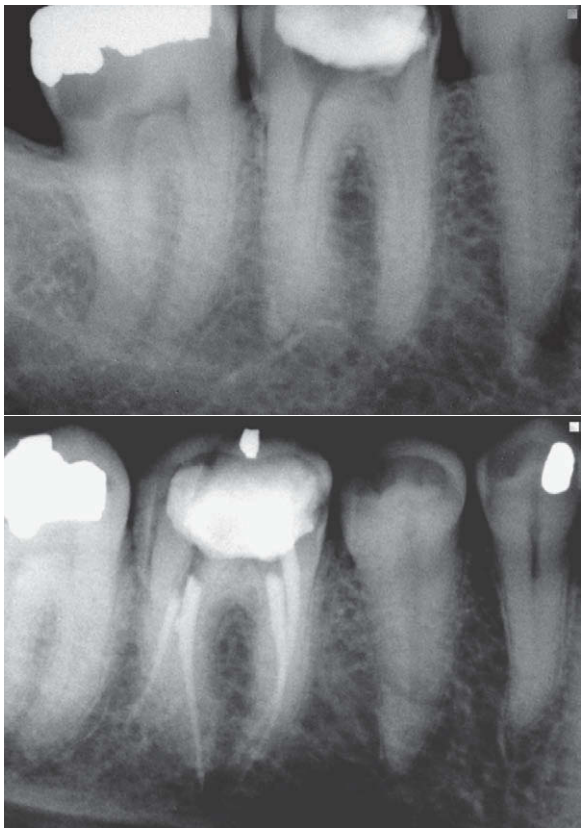

FIG. 4-14 The presence of curved roots and multiple canals is a complicating factor.

Unfortunately, the impact that a high level of anxiety can have on patient's cognition, local anesthesia, and intra- and posttreatment experiences is not always recognized. Existing research has focused primarily on the effect of pretreatment information on reducing anxiety and stress during surgery.[23] It was determined, using an anxiety virtual analog scale (AVAS), that higher AVAS scores were correlated with a greater number of injections needed to eliminate pain and that the higher the score, the less likely it was that pain would be eliminated during endodontic treatment.[18]

In a landmark medical study it was found that pretreatment discussion of surgical treatments and associated discomfort reduced by 50% the need for posttreatment morphine and reduced the time to discharge.[20] More than 200 studies indicate that pre-emptive behavioral intervention decreases anxiety before and after surgery, reduces posttreatment pain intensity and intake of analgesics, and accelerates recovery.[13] A calm setting, reassurance by the clinician and explanation of the treatment plan, as well as a discussion about pain prevention strategies are all important steps even before treatment starts.[49] Written as well as a verbal description of the proposed treatment are helpful. It may also be of value to have a family member or friend accompany the patient for a discussion of the treatment plan.

Scheduling Considerations

If a vital case is to be treated by a multivisit approach, it is suggested that the clinician allow 5 to 7 days between canal instrumentation and obturation in order to allow periradicular tissues to recover. When a vital case is to be treated in a single visit, adequate time must be scheduled so that the clinician can comfortably complete the procedure. It is wise to schedule patients who require mandibular block anesthesia to arrive 15 to 20 minutes before their treatment visit. This avoids the frustration of "losing treatment time" while the anesthetic agent becomes fully effective (see also Chapter 20).

Appointments to fill nonvital cases should be scheduled approximately 1 week after instrumentation in order to maximize the antimicrobial effect of the intracanal dressing when calcium hydroxide is used.[8,68,69] Acute (pain and/or swelling) nonvital cases should be seen every 24 to 48 hours in order to monitor the patient's progress and bring the acute symptoms under control. Further cleaning and shaping are important components of the treatment as the clinician seeks to eliminate persistent microbes in the canal system. Long delays between visits contribute to the development of resistant microbial strains and should be avoided.

CHAPTER

5

Preparation for Treatment

GERALD N. GLICKMAN and MERLYN W. VOGT

CHAPTER OUTLINE

PREPARATION OF THE OPERATORY
- Infection Control
- Health Insurance Portability and Accountability Act

PATIENT PREPARATION
- Treatment Planning
- Case Presentation
- Informed Consent
- Radiation Safety
- Principles of ALARA
- Premedication With Antibiotics
- Bisphosphonate-Associated Osteonecrosis of the Jaws
- Antianxiety Regimens
- Pain Control by Pretreatment Administration of NSAIDs
- Pain Control by Local Anesthesia

PREPARATION OF RADIOGRAPHS
- Function, Requirements, and Limitations of the Radiograph in Endodontics
- Principles of Endodontic Radiography
- Orascopy and Endoscopy

PREPARATION FOR ACCESS: TOOTH ISOLATION
- Armamentarium
- Methods of Rubber Dam Placement
- Aids in Rubber Dam Placement
- Problem Solving in Tooth Isolation

Before nonsurgical root canal treatment can begin, a number of issues related to treatment considerations, along with clinician and patient needs, must be addressed. These include proper infection control and occupational safety procedures for the entire health care team and treatment environment; appropriate communication with the patient, including case presentation and informed consent; premedication, if necessary, followed by effective administration of local anesthesia; a quality radiographic or digital image survey; and thorough isolation of the treatment site.

PREPARATION OF THE OPERATORY

Infection Control

Because all dental health care personnel (DHCP), including those not directly involved in patient care, are at risk for exposure to a host of infectious organisms (e.g., influenza; upper respiratory disease; tuberculosis [TB]; herpes; hepatitis B, C, and D; and acquired immunodeficiency syndrome [AIDS]), effective infection control procedures must be used to minimize the risk of cross-contamination in the work environment.[21-23,25,54,71,73] These infection control procedures must not only protect patients and the dental team from contracting infections during dental procedures, but also reduce the number of microorganisms in the immediate dental environment to the lowest level possible.

As the AIDS epidemic continues to expand, it has been established that the potential for occupational transmission of human immunodeficiency virus (HIV) and other fluid-borne pathogens can be minimized by enforcing infection control policies specifically designed to reduce exposure to blood and other infected body fluids.[12,13,16,54,73] Because HIV has been shown to be fragile and easily destroyed by heat or chemical disinfectants, the highly resistant nature of the hepatitis B virus, along with its high blood titers, makes it a good model to evaluate infection control practices in order to prevent transmission of a large number of other pathogens via blood or saliva. Because all infected patients are not readily identifiable through the routine medical history and many are asymptomatic, the American Dental Association (ADA, Chicago, IL) recommends that each patient be considered potentially infectious; this means that the same strict infection control policies or universal precautions apply to all patients.[22,73] In addition, the Occupational Safety and Health Administration (OSHA) of the U.S. Department of Labor, in conjunction with both the ADA and the Centers for Disease Control and Prevention (CDC, Atlanta, GA), has issued detailed guidelines on hazard and safety control in the dental setting.[2,3,11-14,41,73] In 1992, laws specifically regulating exposure to blood-borne disease became effective through the OSHA standard 29 CFR 1910.1030, Occupational Exposure to Bloodborne Pathogens.[25] Primarily designed to protect any employee who could be "reasonably anticipated" to have contact with blood or any other potentially infectious materials, the standard encompasses a combination of engineering and work practice controls, as well as recommendations for the use of equipment and protective clothing, training, signs and labels, and hepatitis B vaccinations. It also authorizes OSHA to conduct inspections and impose financial penalties for failure to comply with specific regulations.[25]

In 1993 the ADA, CDC, and OSHA recommended or mandated specific infection control guidelines for dental practice.

In 2003 the CDC updated these guidelines to help further reduce the potential for disease transmission from patient to DHCP, from DHCP to patient, and from patient to patient. The document now emphasizes the use of standard precautions rather than universal precautions for the prevention of exposure to and transmission of not only blood-borne pathogens but also other pathogens encountered in oral health settings.[15] The major recommendations including updates are as follows:

1. The ADA and CDC recommend that all DHCP with potential occupational exposure to blood or other potentially infectious material be vaccinated against hepatitis B. The OSHA standard requires that employers make the hepatitis B vaccine available to occupationally exposed employees, at the employer's expense, within 10 working days of assignment to tasks that may result in exposure. An employee who refuses the vaccine must sign a declination form that uses specific language approved by OSHA. In addition, postexposure follow-up and evaluation must be made available to all employees who have had an exposure incident. In addition, all DHCP must be educated about tuberculosis; baseline tuberculin skin tests (TSTs) must be done for all DHCP who might have contact with persons suspected or confirmed to have active TB.[15]
2. A thorough patient medical history, which includes specific questions about hepatitis, AIDS, current illnesses, unintentional weight loss, lymphadenopathy, and oral soft-tissue lesions, must be taken and updated at subsequent appointments. All patents should be screened for latex allergies, and they should be referred if an allergy is suspected.[15]
3. Dental personnel must wear protective attire and use proper barrier techniques. The standard requires the employer to ensure that employees use personal protective equipment (PPE) and that such protection is provided at no cost to the employee.
   a. Disposable latex or vinyl gloves must be worn when contact with body fluids or mucous membranes is anticipated or when touching potentially contaminated surfaces; they may not be washed for reuse. OSHA requires that gloves be replaced after each patient contact, when torn, or when punctured. If their integrity is not compromised, sturdy, unlined utility gloves for cleaning instruments and surfaces may be decontaminated for reuse. Polyethylene gloves may be worn over treatment gloves to prevent contamination of objects, such as drawers, light handles, or charts.
   b. Hands, wrists, and lower forearms must be washed with either a nonantimicrobial soap or antimicrobial soap and water when hands are visibly soiled, after bare-handed touching of inanimate objects likely to be contaminated, before and after treating each patient, before donning gloves, and immediately after removing gloves.[15] An antimicrobial surgical hand scrub should be used for surgical procedures before donning sterile gloves. The standard requires that any body area that has contact with a potentially infectious material, including saliva, must be washed immediately after contact. It is strongly recommended that hand lotions that do not affect glove integrity be used to prevent dryness associated with hand-washing.[15] Sinks should have electronic, elbow-, foot-, or knee-action faucet controls for asepsis and ease of function. Employers must provide washing facilities (including an eye wash) that are readily accessible to employees.
   c. Masks and protective eyewear with solid side shields or chin-length face shields are required when splashes or sprays of potentially infectious materials are anticipated and during all instrument and environmental cleanup activities. When a face mask is removed, it should be handled by the elastic or cloth strings, not by the mask itself. It is further suggested that the patient wear protective eyewear.
   d. Protective clothing, either reusable or disposable, must be worn when clothing or skin is likely to be exposed to body fluids, and it should be changed when visibly soiled or penetrated by fluids. OSHA's requirements for protective clothing (i.e., gowns, aprons, laboratory coats, and clinic jackets) are difficult to interpret, because the "type and characteristics [thereof] will depend upon the task and degree of exposure anticipated." The ADA and CDC recommend long-sleeved uniforms. However, according to OSHA, long sleeves are required only if significant splashing of blood or body fluids to the arms or forearms is expected. Thus endodontic surgery would likely warrant long-sleeved garments. OSHA requires that the protective garments not be worn outside the work area. The standard prohibits employees from taking contaminated laundry home to be washed; it must be washed at the office or by an outside laundry service. Contaminated laundry must be placed in an impervious laundry bag that is colored red and labeled "BIOHAZARD." Although OSHA does not regulate nonprotective clothing (e.g., scrubs), such clothing should be handled like protective clothing once fluids have penetrated it.
   e. Patients' clothing should be protected from splatter and caustic materials, such as sodium hypochlorite, with waist-length plastic coverings overlaid with disposable patient bibs.
   f. High-volume evacuation greatly reduces the number of bacteria in dental aerosols and should be employed when using the high-speed handpiece, water spray, or ultrasonics.
   g. Use of the dental dam as a protective barrier is mandatory for nonsurgical root canal treatment, and failure to use this barrier is considered to be below standard care.[16,17,29]
4. OSHA regulates only contaminated sharps. Contaminated *disposable* sharps (e.g., syringes, needles, and scalpel blades) and contaminated *reusable* sharps (e.g., endodontic files) must be placed into separate, leak-proof, closable, puncture-resistant containers. These containers should be colored red or labeled "BIOHAZARD," and they should be marked with the biohazard symbol. The standard states that before decontamination (i.e., sterilization), contaminated reusable sharps must not be stored or processed in a way that requires employees to use their hands to reach into the containers to retrieve the instruments. The OSHA ruling allows picking up sharp instruments by hand only after they are decontaminated.[21,41,54]
   a. The clinician should take the following steps when handling contaminated endodontic files: With tweezers, place used files in glass beaker containing a nonphenolic

disinfectant and detergent holding solution. At the end of the day, discard the solution and rinse with tap water. Add ultrasonic cleaning solution, and place the beaker in the ultrasonic bath until thoroughly clean (i.e., 5 to 15 min). Discard the ultrasonic solution, and rinse with tap water. Pour the contents of the beaker onto a clean towel, and use tweezers to place the clean files into a metal box for sterilization. Files with any visible debris should be separately sterilized. Once sterilized, these files can be picked up by hand and debrided, using 2 × 2 inch sponges. Once cleaned, files should be returned to the metal box for sterilization. (As indicated in Chapter 8, all files should be regarded as disposable.)

b. In general, the standard prohibits bending or recapping of anesthesia needles. However, during endodontic treatment, reinjection of the same patient is often necessary, so recapping is essential. Recapping with a one-handed scoop method and using a mechanical device are the only permissible techniques; needles must not be recapped by using both hands or directing the needle point toward any part of the body.[15] Shearing or breaking of contaminated needles should never be permitted.

5. Countertops and operatory surfaces, such as light handles, radiograph unit heads, chair switches, and any other surface likely to become contaminated with potentially infectious materials, can be either covered or disinfected. Protective coverings (e.g., clear plastic wrap, special plastic sleeves, and aluminum foil) can be used. These coverings should be changed between patients and when they become contaminated. OSHA mandates, however, that work surfaces be decontaminated or recovered or both at the end of each work shift and immediately after overt contamination. The coverings should be removed by gloved personnel, discarded, and then replaced with clean coverings after gloves are removed. Alternatively, countertops and operatory surfaces can be wiped with absorbent toweling to remove extraneous organic material and then sprayed with an Environmental Protection Agency (EPA)–registered and ADA-accepted tuberculocidal disinfectant (e.g., a 1 : 10 dilution of sodium hypochlorite, iodophor, or synthetic phenol). With the advent of endodontic microscopy, appropriate barriers should be placed on the handles and controls of the microscope, or the entire unit can be draped to prevent cross-contamination. If the system becomes contaminated, disinfection should be performed according to the microscope manufacturer's guidelines.
6. Contaminated radiographic film packets must be handled in a way that prevents cross-contamination. Contamination of the film (when it is removed from the packet) and subsequent contamination of the processing equipment can be prevented either by properly handling the film as it is removed from the contaminated packet or by preventing the contamination of the packet during use.[70] After exposure, "overgloves" should be placed over contaminated gloves to prevent cross-contamination of processing equipment or darkroom surfaces.[40] For darkroom procedures, films should be carefully manipulated out of their holders and dropped onto a disinfected surface or into a clean cup without being touched. Once the film has been removed, gloves should be removed and discarded; the film can then be processed. All contaminated film envelopes must be accumulated (after film removal) in a strategically positioned impervious bag and disposed of properly. For daylight loaders, exposed film packets should be placed into a paper cup; gloves should be discarded and hands washed. Next, a new pair of gloves should be donned, and the paper cup with films and an empty cup should be placed into the chamber. Using gloved hands, the chamber should be entered and packets should be carefully opened, allowing the film to drop onto a clean surface in the chamber. Empty film packets should then be placed into an empty cup and gloves removed and discarded in the cup; films can then be processed.[41] Plastic envelopes, such as the ClinAsept barriers (Kodak Dental Systems/Carestream Health, Rochester, NY), have simplified the handling of contaminated, exposed films by protecting films from contact with saliva and blood during exposure. Once a film is exposed, the barrier envelope is easily opened and the film can be dropped into a paper cup or onto a clean area before processing. The barrier-protected film, however, should be wiped with an EPA-approved disinfectant as an added precaution against contamination during opening.[70] For digital radiography sensors, U.S. Food and Drug Administration (FDA)–cleared barriers should be used.
7. In conjunction with the previously mentioned guidelines for infection control, a mouth rinse of 0.12% chlorhexidine gluconate, such as Peridex (3M, St. Paul, Minn), is suggested before treatment. This rinse will minimize the number of microbes in the mouth and, consequently, in any splatter or aerosols generated during treatment.[21,54,73] It should be noted, however, that such mouth rinses have not proved to reduce the incidence of clinical infections.
8. After treatment, all instruments and burs must be cleaned and sterilized by sterilizers monitored with biologic indicators. Cassettes, packs, or trays should be rewrapped in original wrap, and individually packaged instruments should be placed in a covered container. Air and water syringes must be flushed, cleaned, and sterilized. Antiretraction valves (i.e., one-way flow check valves) should be installed to prevent fluid aspiration and to reduce the risk of transfer of potentially infective material. Heavy-duty rubber gloves must be worn during cleanup. The ADA and CDC recommend that all dental handpieces and "prophy" angles be heat sterilized between patients.[3,21,41,54] Before sterilization, all handpieces should be wiped with an EPA-registered disinfectant. In addition, high-speed handpieces should be run for a minimum of 30 seconds to discharge water and air, with spray directed into a high-volume evacuation system. Dental unit water lines should be periodically flushed with water or a 1:10 dilution of 5.25% sodium hypochlorite (NaOCl) to reduce biofilm formation. All regulated infectious waste must be immediately disposed of in containers that meet specific criteria. Disposal must be in accordance with applicable federal, state, and local regulations.

In 1987 the infection control decision-making process was transferred to the U.S. government through OSHA.[73] The ongoing goal of OSHA is to establish a routine and practical program of enforcing infection control standards (based on published CDC guidelines) to ensure the health and safety of all members of the dental health team. According to OSHA,

clinicians must classify personnel and tasks in the dental practice according to levels of risk of exposure and must establish "standard operating procedures" to protect the patient and staff from infection transmission.[41,54,73] OSHA requires the clinician to provide infection control training for all employees and to maintain records of such training; all hazardous substances that employees are exposed to on the job must be properly labeled; and a written hazard communications program with manufacturers' material safety data sheets (MSDSs) is needed for all hazardous substances. With the enactment of the OSHA Occupational Exposure to Bloodborne Pathogens standard, employers must make exposure determinations and develop an exposure control plan. As mentioned previously, the rule encompasses a number of critical areas (e.g., universal precautions, engineering and work practice controls, employee training, and specific recordkeeping) designed to protect employees from exposure to blood-borne pathogens, particularly HIV and hepatitis B virus. Although the OSHA standard was written principally to protect employees, it does not encompass all the infection control practices recommended by the ADA and CDC to protect clinicians and patients.

In 1994 the CDC issued its position statement on the prevention of transmission of TB in dental settings. The statement suggested that elective dental treatments for patients suspected of having TB be deferred until it has been confirmed that they are free of the disease. The CDC also stated that emergency care for a patient with TB should be provided only in facilities with appropriate respirators, negative-pressure treatment areas, and other respiratory engineering controls.[11] Compliance with OSHA regulations and with evolving infection control policies of the ADA and CDC will help provide a safer workplace for the entire dental treatment team.[21,41,54,73]

Health Insurance Portability and Accountability Act

The Health Insurance Portability and Accountability Act (HIPAA) was passed into law on August 21, 1996; the original purpose of this law was to make health care insurance "portable" so that an individual's insurance could be passed from one employer to another employer. Because of additions to help fight fraud and abuse, ensure the security of medical records, protect the privacy of a patient's confidential health information, and a worthwhile goal to replace paper transactions with electronic transactions, the HIPAA standard has become one of the most widespread and complicated regulations ever passed.[33] On April 14, 2003, HIPAA launched a whole new era of medical/dental care because it is now the responsibility of the clinician–employer to make sure employees conduct themselves in a manner that supports the provisions of the standard. Two of the rules under HIPAA that affect clinicians are the Transactions Rule and the Privacy Rule. For the purposes of this chapter, only the Privacy Rule is discussed (see Chapter 27 [online] for other information about HIPAA).

The Privacy Rule controls what is called *protected health information (PHI)*. PHI is individually identifiable health information that is held or released by a practice regardless of how it is communicated (oral, paper, or electronic). The entire Privacy Rule was created to ensure that a patient's PHI is not used or disclosed to those individuals or parties who do not need to know such information. In general, the Privacy Rule requires dental practices to take reasonable steps to limit use of disclosure of PHI to the *minimum necessary* to achieve an intended purpose. This rule does not apply to uses or disclosures made to the patient, another provider (for treatment purposes), or governmental authorities.

The clinician must employ or appoint a privacy officer to help bring the office into compliance. The privacy officer oversees all ongoing activities related to maintaining the privacy of PHI consistent with state law. It is the officer's duty to report to the clinician–employer the status of the office's compliance efforts and to develop appropriate documents such as patient request forms, acknowledgment forms, and patient authorization forms. When such documents are ready for disposal, it is the privacy officer's responsibility to see that documents containing PHI are shredded and destroyed.[33]

The Notice of Privacy Practices is a kind of "reverse" informed consent for the patient.[33] Any clinician who has a direct treatment relationship with an individual must provide that individual with a Notice of Privacy Practices. Further, the dental practice must provide a copy of the current notice to anyone who asks for it (whether a patient or not). The notice must explain how PHI may be used or disclosed by the practice, the patient's privacy rights as to PHI, and the practice's obligations as to PHI. The final Privacy Rule only requires the clinician who has a direct treatment relationship with a patient to make a "good faith" effort to obtain a patient's written "acknowledgment" that he or she has received the Notice of Privacy Practices.[33] The patient cannot be "made" to sign such a statement. In addition, the patient can file a complaint against the practice for alleged violations of privacy policies. Thus, under HIPAA, the patient has the following rights: the right to receive a copy of the practice's Notice of Privacy Practices, the right to request a restriction on uses and disclosures, the right to request receipt of confidential communications by alternative means or at alternative locations, the right to request access to inspect and copy the dental record, the right to request an amendment to the dental record, and the right to request an accounting of disclosures. With the exception of the first right, these rights are all followed by the phrase "to request." The practice does not have to grant all requests; as with any law, there are exceptions to the rules. However, if the clinician agrees to a request, any violation of the request is a violation of the privacy regulations. These issues are covered extensively in Chapter 11 and online Chapter 27.

PATIENT PREPARATION

Treatment Planning

Aside from emergencies that require immediate attention, endodontic treatment usually occurs early in the total treatment plan for the patient. Therefore any asymptomatic but irreversible pulpal and periradicular problems are managed before they become symptomatic and more difficult to handle. The most important rationale for the high priority of endodontics is to ensure that a sound, healthy foundation exists before further treatment is attempted. A stable root system within sound periradicular and periodontal tissues is paramount to the placement of any definitive restorations.

Regardless of the specifics of the case, the clinician is responsible for explaining the nature of the treatment and informing the patient of any risks, the prognosis, and other pertinent facts. Because of bad publicity and hearsay, root

canal treatment is reputed to be a horrifying experience. Consequently, some patients may be reluctant, anxious, or even fearful of undergoing root canal treatment. Thus it is imperative that the clinician educate the patient before treatment (i.e., "informing before performing")[17] to allay concerns and minimize misconceptions.

Good clinician and patient relationships are built on effective communication. Sufficient evidence suggests that clinicians who establish warm, caring relationships with their patients through effective case presentation are perceived more favorably. These clinicians also have a more positive impact on the patient's anxiety, knowledge, and compliance than those who maintain impersonal, noncommunicative relationships.[20] Most patients experience increased anxiety while in the dental chair. However, a simple but informative case presentation that answers all questions reduces patient anxiety and solidifies the patient's trust in the clinician.

Case Presentation

The ADA and the American Association of Endodontists (AAE, Chicago, IL) publish brochures (e.g., *Endodontics: Your Guide to Endodontic Treatment*[1]) to help patients understand root canal treatment. Valuable educational aids of this nature should be made available to the patient either before or immediately after case presentation. This supportive information addresses the most frequently asked questions concerning endodontic treatment. The following sections review these questions. Accompanying each question is an example of an explanation that patients should be able to understand. In addition, the clinician will find it useful to have a set of illustrations or drawings to help explain the procedure. The AAE offers specialized case presentation forms with carbonless copies for record keeping and patient use.

What Is Endodontic (Root Canal) Treatment?

Endodontics is the specialty in dentistry concerned with the prevention, diagnosis, and treatment of diseases or injuries to the dental pulp. The pulp, which some people call "the nerve," is the soft tissue inside the tooth that contains the nerves and blood vessels and is responsible for tooth development. Root canal treatment is a safe and effective means of saving teeth that otherwise would be lost.

What Causes the Pulp to Die or Become Diseased?

When a pulp is injured or diseased and unable to repair itself, it becomes inflamed and eventually dies. The most frequent causes of pulp death are extensive caries, deep restorations, trauma (e.g., severe blow to a tooth), cracks in teeth, and periodontal or gum disease. When a pulp is exposed to bacteria from caries or saliva that has leaked into the pulp system, infection can occur inside the tooth and, if left untreated, can cause infection to build up at the tip of the root, forming an abscess. Eventually the bone supporting the tooth will be destroyed, and pain and swelling will often accompany the infection. Without endodontic treatment, the tooth will eventually have to be removed.

What Are the Symptoms of a Diseased Pulp?

Symptoms may range from momentary to prolonged, mild to severe pain on exposure to hot or cold or on chewing or biting. In some cases the condition may produce no symptoms at all. The patient should be informed that the radiographic examination may not demonstrate abnormal conditions of the tooth. The clinician should also make it clear that sometimes in the absence of pain, radiographic evidence of pulpal or periradicular disease or both may be present.

What Is the Success Rate of Root Canal Therapy?

Endodontics is one of the few procedures in dentistry that has a predictable prognosis if treatment is performed properly. Studies indicate that root canal treatment is usually 90% to 95% successful. Those in the failure group may still be amenable to retreatment or surgical treatment to save the tooth, although no treatment's success can be guaranteed. In addition, patients must understand that the prognosis may vary depending on the specifics of each case and that, without good oral hygiene and a sound restoration after endodontic therapy, there may be an increased chance for failure. The need for periodic follow-up must be addressed to assess the long-term status of the tooth and periradicular tissues.

Will the Endodontically Treated Tooth Discolor After Treatment?

If the treatment is done correctly, discoloration seldom occurs. In the unlikely event that discoloration should occur, bleaching with heat or chemicals can be used to restore the natural color and shade of teeth. Some endodontically treated teeth appear discolored because they have been restored with tooth-colored restorations that have become stained or with amalgam restorations that leach silver ions. In these instances the restorations may be replaced, but often the placement of crowns or veneers is indicated.

What Are the Alternatives to Root Canal Treatment?

The only alternative is to extract the tooth, which often leads to shifting and crowding of surrounding teeth and subsequent loss of chewing efficiency. The patient should understand that often, extraction is the easy way out and, depending on the case, may prove to be more costly for the patient in the long run. The patient always reserves the right to do nothing about the problem, provided the clinician has explained the associated risks of this decision.

Will the Tooth Need a Crown or "Cap" After the Treatment?

If there is no previously existing crown, the need for a crown or "cap" depends on the amount of sound tooth structure remaining after endodontic treatment. In addition, the need for a crown or cap depends on the type of tooth and the amount of chewing force to which the tooth will be subjected. Loss of tooth structure significantly weakens the tooth and renders it more susceptible to fracture; as a result, it may be necessary to protect what is left with a restoration, such as a crown. Significant loss of tooth structure with a concomitant loss of retentive areas for coronal buildups may necessitate the placement of a metallic, resin, or ceramic post in a canal to retain the buildup material (see Fig. 5-1, *I* and *J*) (for further information about these issues, see Chapter 22).

What Does Root Canal Treatment Involve?

Treatment may require one to three appointments, depending on the diagnosis, the number of roots, and the complexity of

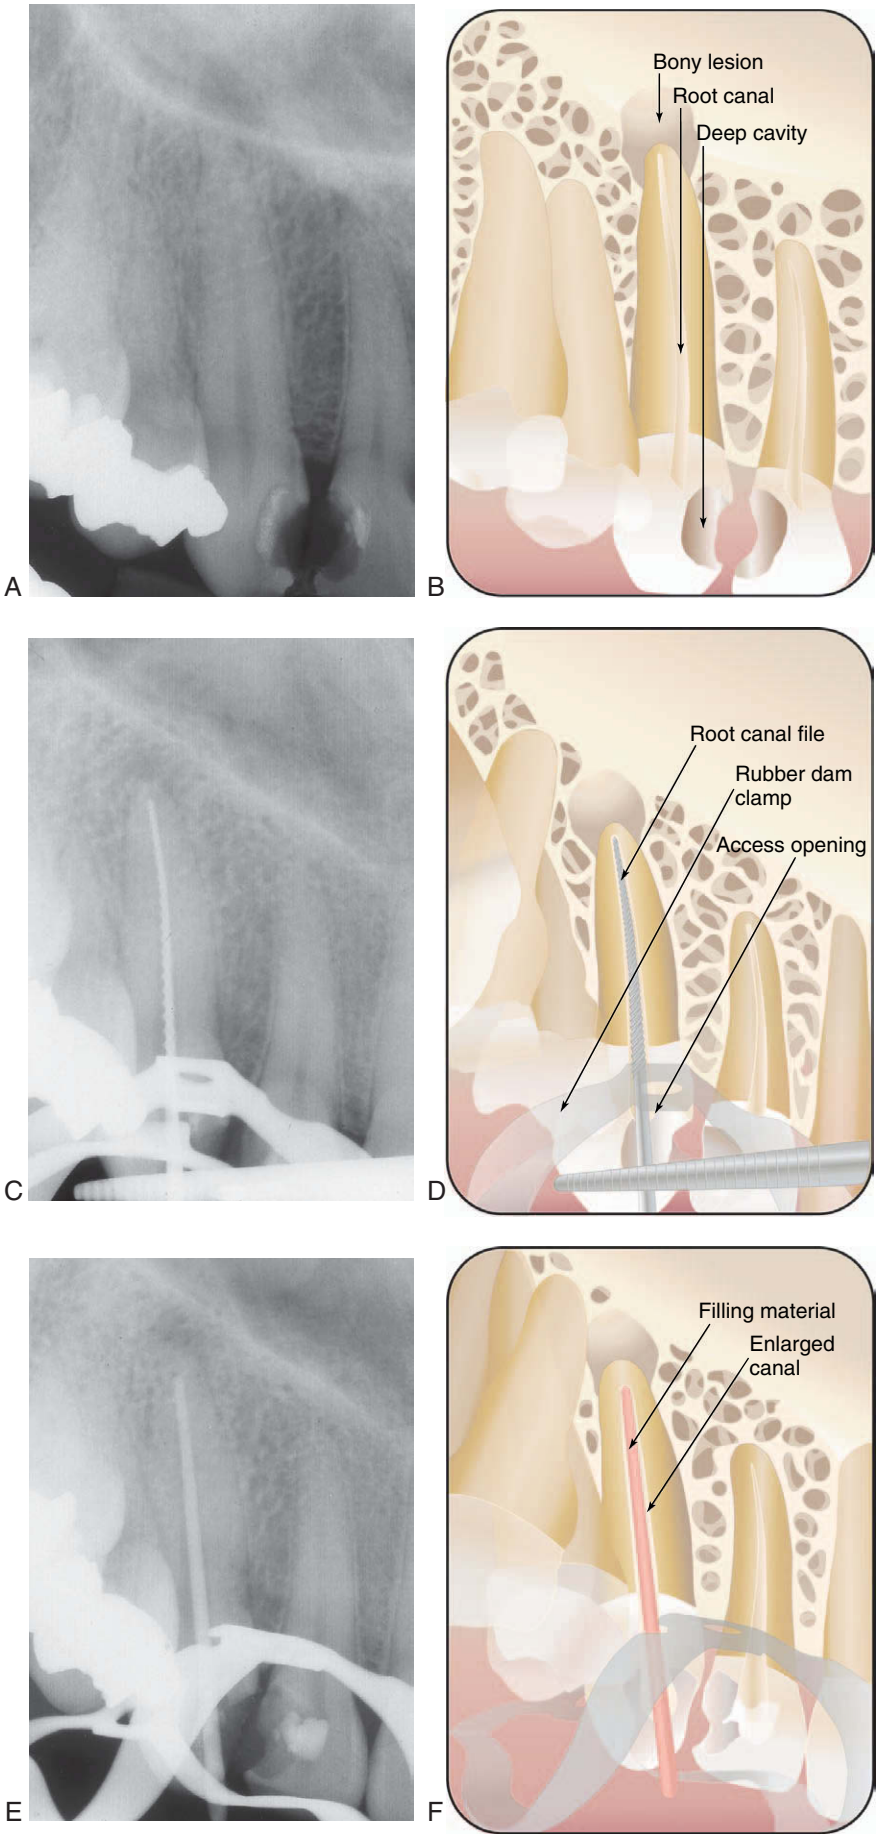

FIG. 5-1 Series of radiographs and illustrations demonstrating root canal treatment and restoration of a maxillary canine. **A-B,** Maxillary canine with periradicular lesion of endodontic origin. **C-D,** Endodontic file corresponding to length of canal; isolation with rubber dam throughout procedure. **E-F,** Endodontic filling material placed after cleaning and shaping of canal.

the case. During these appointments the clinician removes the injured or diseased pulp tissue. The root canals are cleaned, enlarged, and sealed to prevent recontamination of the root canal system. The following steps (Fig. 5-1) describe the technical aspects of the treatment (illustrations, diagrams, radiographs, and digital images should be used as aids to the presentation):

1. Local anesthesia is usually administered.
2. The tooth is isolated with a rubber dam to prevent contamination from saliva and to protect the patient. This procedure is followed at each subsequent visit.
3. An opening is made through the top of the tooth to gain entrance to the root canal system.
4. The pulp tissue is painlessly removed with special instruments called *files*.
5. Periodic radiographs ("x-rays") or digital images must be taken to ensure that these instruments correspond to the exact length of the root so that the entire tissue can be removed. Electronic apex locators can be used as adjuncts to help determine or verify lengths.
6. The root canal is cleaned, enlarged, and shaped so that it can be filled or sealed properly.
7. Sometimes medications are placed in the opening to prevent infection between appointments.
8. If treatment cannot be completed in one visit, a temporary filling is placed in the crown opening between appointments.

9. At the final appointment the canal is sealed to safeguard it from further contamination.
10. Permanent restoration of the tooth is accomplished after completion of the root canal treatment.

Some additional points should be conveyed to the patient after treatment. The patient should not be given the impression that there will be no pain after the treatment.[65] In most cases, the mild discomfort the patient may experience is transitory and can usually be treated with an over-the-counter anti-inflammatory or analgesic agent, for example, an ibuprofen-containing compound. In fact, prophylactic administration of these drugs before the patient leaves the office will help reduce posttreatment discomfort by achieving therapeutic blood levels of analgesic before the local anesthesia wears off (see Chapter 20). In certain cases, simply handing the patient a written prescription for a stronger analgesic, "just in case," conveys a feeling of empathy and caring toward the patient and strengthens the doctor–patient relationship.

If the clinician wishes to refer the patient to an endodontist for treatment, skillful words of encouragement and explanation will convey the caring and concern behind this recommendation. Many patients already feel comfortable with their clinicians and are fearful of seeing someone new. In addition, they may not understand why a general clinician chooses not to do the root canal treatment. The referring clinician can help by carefully explaining the complex nature of the case and why it would be in the patient's best interests to visit the endodontist, who is specially trained to handle complex cases.[65]

Informed Consent

Much controversy surrounds the legal aspects of informed consent. The current thinking in the courts is that for consent to be valid, it must be freely given; that all terms must be presented in language that the patient understands; and that the consent must be "informed."[17,18,57] For consent to be informed, the following conditions must be included in the presentation to the patient:

- The procedure and prognosis must be described. (This includes prognosis in the absence of treatment.)
- Alternatives to the recommended treatment must be presented, along with their respective prognoses.
- Foreseeable risks and material risks must be described.
- Patients must have the opportunity to have questions answered.[57]

It is probably in the best interests of the clinician–patient relationship to have the patient sign a valid informed consent form. With the continuous rise in dental litigation, it is important to realize that "no amount of documentation is too much and no amount of detail is too little."[57] (For further information on this subject, see Chapters 11 and 27.)

Radiation Safety

A critical portion of the endodontic case presentation and informed consent involves educating the patient about the requirement for radiographs as part of the treatment. The clinician must communicate to the patient that the benefits of radiographs far outweigh the risks of receiving small doses of ionizing radiation, as long as techniques and necessary precautions are properly executed.[2] Although levels of radiation in endodontic radiography range from only 1/100 to 1/1000 of the levels needed to sustain injury,[53,64] it is still best to keep ionizing radiation to a minimum for the protection of both the patient and the dental delivery team.

Two simple analogies can be used to help the patient understand the small risk associated with dental radiographs. A patient would have to receive 25 complete full mouth series (i.e., 450 exposures) within a very short time to significantly increase the risk of skin cancer.[53] One full mouth survey (i.e., 20 Ektaspeed [E]–speed films with rectangular collimation) has been found to deliver less than one half the amount of radiation of a single chest film and less than 1% of the amount of a barium study of the intestines.[70] Nevertheless, the principles of ALARA (as low as reasonably achievable), which are techniques used to reduce radiation exposure, should be followed as closely as possible to minimize the amount of radiation that both patient and treatment team receive. ALARA also implies the possibility that no matter how small the radiation dose, there still may be some deleterious effects.[53,70]

Principles of ALARA

In endodontic radiography, fast (i.e., sensitive) speed film should be selected.[53] Although E-speed film allows for a reduction of approximately 50% of the radiation exposure required for D speed,[26] findings in observer preference studies have been mixed as to the quality, clarity, and diagnostic capability of E film compared with D film. Processing of E-speed film is also more sensitive.[26,27,39] Specialized radiographic systems[56,70] (using direct or indirect digital intraoral radiography) involve the digitization of ionizing radiation and use considerably smaller amounts of radiation to produce an image that is available immediately after exposure (see the later section, Digital Radiographic Techniques).

Meticulous radiographic technique helps reduce the number of retakes and obviates further exposure. Film-holding devices (discussed later in the chapter) along with correct film and tube head positioning are essential to maintain film stability and produce radiographs of diagnostic quality.[53,70] A quality assurance program for film processing should also be set up to ensure that films are properly processed.[53,70]

Dental units should be operated using at least 70 kVp (peak kilovoltage). The lower the kilovoltage, the higher the patient's skin dose. Optimally, 90 kVp should be used. Units operating at 70 kVp or higher must have a filtration equivalent of 2.5 mm of aluminum to remove the extraneous low-energy x-rays before the patient absorbs them.[53,70]

Collimation also reduces exposure level. Collimation is, essentially, the restriction of the x-ray beam size by means of a lead diaphragm so that the beam does not exceed 2.75 inches (7 cm) at the patient's skin surface. Open-ended, circular, or rectangular lead-lined cylinders, known as *position-indicating devices (PIDs)*, help direct the beam to the target. However, the universal rectangular cylinder also collimates the x-ray beam by decreasing beam size even more, reducing the area of skin surface exposed to x-radiation and reducing radiation burden by approximately 50% (Fig. 5-2). These PIDs, or cones, should be at least 12 to 16 inches long, because the shorter (i.e., 8-in.) cones that provide shorter source-to-film distances permit more divergence of the beam and more exposure to the patient.[53,70] Pointed cones, illegal in some states, should not be used because of the increased amount of scatter radiation they produce.

FIG. 5-2 Universal collimator snaps on the aiming ring to extend the extra protection of a rectangular collimator to round, open-ended cones. *(Courtesy DENTSPLY Rinn, Elgin, IL.)*

On the basis of the December 2003 National Council on Radiation Protection and Measurements (NCRP) Report No. 145 on new dental x-ray guidelines (http://www.ncrponline.org/Publications/145press.html), leaded aprons are no longer required as long as other recommendations stated in the report are strictly followed; the report also states that thyroid collars are mandatory for children and should be provided for adults.[52] When exposing films, the clinician should stand behind a barrier. Plaster, cinderblock, and at least 2.5 inches of drywall provide the necessary protection from the radiation produced by dental units. If there is no barrier the clinician should stand in an area of minimal scatter radiation: at least 6 feet away from the patient and in an area that lies between 90 and 135 degrees to the beam.[53,70] All dental personnel who might be exposed to occupational x-radiation should wear film badges for recording exposure. If the concept of ALARA is strictly adhered to, no member of the dental team should receive doses close to the maximal permissible dose (MPD) (i.e., 50 millisieverts [mSv]/yr/whole body).[70]

For "declared" pregnant workers, the Nuclear Regulatory Commission limits the radiation dose to the fetus to 0.5 mSv during the gestation period. It is important to note that the MPD is specified as occupational exposure and should not be confused with exposure that patients receive as a result of radiographic procedures. Although no state-recommended maximal patient exposures exist, anyone who administers ionizing radiation is responsible for consulting the respective state's bureau of radiation control to obtain information about current laws. Nonetheless, every effort should be made to keep the radiation dose to all individuals as low as possible and to avoid any unnecessary radiation exposure.

Premedication With Antibiotics

Prophylactic coverage with antibiotics or antiinfectives is indicated only for the highest risk patients who are susceptible to infective endocarditis after bacteremia. The use of prophylactic antibiotics in these patients prevents blood-borne microorganisms from lodging on shunts and prostheses or from multiplying within a depressed system.[44,55,59,71] In 2007 there was a major revision of the 1997 guidelines.[71] The current recommendations are based on a collective body of evidence published in numerous studies over the past two decades. Studies now indicate that infective endocarditis is more likely to result from frequent random bacteremias of routine daily activities than from an isolated dental procedure. The 2007 guidelines recommend that only patients at highest risk are to receive antibiotic prophylaxis. Those cardiac conditions associated with the highest risk of an adverse outcome from endocarditis include patients with prosthetic cardiac valves, a previous history of infective endocarditis, certain congenital heart diseases, and cardiac transplantation patients who develop cardiac valvulopathies. It is also thought that antibiotic prophylaxis prevents only a small number of cases of infective endocarditis and that the risk of antibiotic-associated adverse events may actually exceed the benefit of prophylaxis.[5,66,67,71] The current recommendations of the American Heart Association (AHA, Dallas, TX) place increased emphasis on maintaining good oral hygiene in an effort to decrease the overall frequency of bacteremias that are associated with daily activities.

Conditions in the moderate-risk category include most other congenital cardiac malformations, rheumatic heart disease, hypertrophic cardiomyopathy, and mitral valve prolapse with valvular regurgitation or thickened leaflets or both. Patients with cardiac conditions in the moderate-risk category will no longer receive antibiotic prophylaxis according to the 2007 guidelines. Conditions in the negligible-risk category (i.e., no greater risk than for the general population) and for which prophylaxis is not recommended include previous coronary artery bypass graft surgery, mitral valve prolapse without valvular regurgitation, previous rheumatic fever without valvular dysfunction, and cardiac pacemakers (both intravascular and epicardial). On the basis of the recommendations in the 2007 guidelines, fewer patients will need to be covered with a prophylactic antibiotic regimen. This may raise concerns with patients who in the past have taken antibiotics for cardiac conditions and are now told that prophylaxis is no longer necessary. Therefore the clinician should be well versed in the new AHA guidelines and be prepared to discuss the revisions with inquiring patients.

The AHA has developed a standard prophylactic antibiotic regimen for patients at risk and a set of alternative regimens for those unable to take oral medications, for those who are allergic to the standard antibiotics, and for those who are not candidates for the standard regimen. The recommended standard prophylactic regimen for all dental, oral, and upper respiratory tract procedures is currently amoxicillin. This is because amoxicillin is better absorbed by the gastrointestinal tract and provides higher and more sustained serum levels than penicillin.

The major modification of the 1997 regimen was that the posttreatment dose had been eliminated; the rationale for this was that amoxicillin has a sufficiently high plasma level for an adequate time to prevent endocarditis. Erythromycin was also eliminated as a recommended drug in the penicillin-allergic patient because of the high incidence of gastrointestinal upset and the variability of the pharmokinetics of the various erythromycin preparations. The 2007 guidelines have placed less of an emphasis on invasive dental treatments as a causal factor for infective endocarditis and greater emphasis on factors associated with hygiene and oral health. The official AHA recommendations for prophylactic antibiotic regimens do not specify all clinical situations for which patients may be at risk. Thus

it is the responsibility of the clinician to exercise judgment or consult the patient's physician before giving treatment. With respect to premedication for dental patients with total joint replacements, there has been considerable controversy as to whether such patients require routine prophylaxis. In 1997 the ADA and American Academy of Orthopaedic Surgeons [AAOS, Rosemont, IL]) drafted an advisory statement[4] on antimicrobial premedication for dental patients with total joint replacements. This advisory statement was followed in 2003 by another advisory statement, which essentially is in agreement with the 1997 guidelines.[5] The joint organizations recognized that there was no agreed-on scientific evidence to support the contention that antibiotic prophylaxis is necessary to prevent metastatic infection in patients with total joint prostheses. They also agreed that the analogy between late prosthetic joint infections and infective endocarditis was invalid, because the anatomy, blood supply, types of microorganisms involved, and mechanisms of infection all differ. The ADA and AAOS concluded that antibiotic prophylaxis is not indicated for dental patients with pins, plates, and screws, nor is it routinely indicated for most dental patients with total joint replacements.

However, because limited evidence exists that some dental procedures are high-risk procedures (e.g., extractions, intraligamentary local anesthesia, endodontic surgery, and endodontic instrumentation "beyond the apex") and that some medically compromised patients with total joint replacements (e.g., those with insulin-dependent diabetes; inflammatory arthropathies, such as rheumatoid arthritis; immunosuppression; hemophilia; and previous prosthetic joint infections) may be at higher risk for hematogenous infections, an antibiotic regimen should be considered. Prophylaxis should also be recommended during the first 2 years after joint replacement. The antibiotic regimen consists of cephalexin, Cefazolin, or amoxicillin (2 g *per os,* 1 hour before procedure). For those allergic to penicillin or cephalosporin, the recommended antibiotic is clindamycin (600 mg *per os,* 1 hour before procedure). It is recommended that patients who are not allergic to penicillin but who are unable to take oral medications should receive cefazolin (1 g) or ampicillin (2 g), administered intramuscularly or intravenously, 1 hour before the dental procedure. For patients allergic to penicillin and unable to take oral medications, the recommendation is clindamycin (600 mg administered intramuscularly or intravenously, 1 hour before the dental procedure). Similar to the AHA guidelines, follow-up doses are no longer recommended. The advisory statement represents only recommended guidelines and is not intended as a standard of care, because it is impossible to make recommendations for all clinical situations in which late infection might occur in total joint prostheses. Clinicians must exercise their own clinical judgment in determining whether to premedicate a patient.

Bisphosphonate-Associated Osteonecrosis of the Jaws

Bisphosphonates are an important class of drugs that are commonly used to reduce the morbidity associated with osteoclast-mediated bone diseases. Bisphosphonates inhibit bone resorption, improving bone densities by a reduction in bone turnover. They are extremely useful in the treatment of osteoporosis, Paget's disease, hypercalcemia associated with certain malignancies such as multiple myeloma, and breast and prostate cancers. Bisphosphonates have a high affinity for bone and once incorporated into the skeleton can persist for many years; the estimated half-life for alendronate is known to be approximately 12 years.[43] Nine bisphosphonate drugs are currently approved for clinical use by the FDA. Seven of these formulations are oral bisphosphonates, with only pamidronate and zoledronate being administered intravenously. The intravenously administered forms have higher bioavailability and potencies than the oral forms.

In 2003 case reports describing necrosis of the bones of the jaw in long-term bisphosphonate patients began appearing in the literature.[10,48,50] At present, an exposed area of necrotic bone of the jaw that has been present for at least 8 weeks in a patient undergoing long-term bisphosphonate therapy, without a prior history of radiation treatment, has been defined as bisphosphonate-associated osteonecrosis of the jaw (ONJ). Most cases of ONJ have been diagnosed after a traumatic dental procedure such as a tooth extraction; however, there are also reports of spontaneous cases.[51] Most cases of ONJ have been associated with the intravenously administered bisphosphonates, but there have been reports of its occurrence with oral bisphosphonates.[61] Clinically, ONJ presents as a painful, soft tissue swelling and infection of the jaw, mobility of the teeth, and exposure of bone but at times the disease can be asymptomatic. Most intraoral sites affected are those areas of bone that are covered by thin and friable mucosa; especially vulnerable are the torus mandibularis and torus palatinus.[72] Treatment of ONJ is problematic and at present there are no evidence-based guidelines. There have been reports of limited responses to surgical debridement, segmental resections, antibiotic therapy, and hyperbaric oxygen therapy, and therefore the emphasis must be placed on prevention. Patients taking bisphosphonates must be informed of the possibility of potential oral complications and the clinician must be vigilant in assessing the known risk factors in these patients. Preventive procedures including caries control and appropriate endodontic treatment should be considered for high-risk patients to reduce the risk of developing ONJ, as its treatment is unpredictable. A multidisciplinary approach to managing patients with ONJ is advised, with the clinician working in close association with the oncologist, oral surgeon, and other specialists. Although the overall incidence appears to be low despite the vast number of patients who take these drugs, it is important to recognize that ONJ can be a life-changing, debilitating condition for those afflicted. As our present knowledge regarding bisphosphonate-associated osteonecrosis continues to evolve, the clinician is encouraged to stay informed and up to date about this relatively new pathologic entity (Table 5-1).

Antianxiety Regimens

Because patients often have been misinformed about root canal treatment, some may understandably experience increased anxiety about undergoing the procedure. Fortunately, however, the vast majority of patients are able to tolerate their anxiety, control their behavior, and allow treatment to proceed with few problems. Appropriate behavioral approaches can be used to manage most anxious dental patients. Retrospective studies[20] concerning dental anxiety have clearly demonstrated that explaining each procedure before beginning root canal treatment can effectively reduce a patient's anxiety. The clinician can also reduce patient anxiety by giving specific information

TABLE 5-1

U.S. Food and Drug Administration–Approved Bisphosphonates

Generic Name	Brand Name	Route of Administration	Manufacturer	FDA Approval Date	Common Side Effects
Alendronate sodium	Fosamax	Oral	Merck	1995	Gastrointestinal intolerance, headache, hypocalcemia, hypophosphatemia
Aldrendronate sodium plus vitamin D	Fosamax plus D	Oral	Merck	2005	Gastrointestinal intolerance, headache, bone pain, dizziness
Etidronate disodium	Didronel	Oral	Procter & Gamble	1977	Gastrointestinal intolerance, headache, bone pain, fever, increased serum creatinine
Ibandronate sodium	Boniva	Oral/intravenous	Roche and GlaxoSmithKline	2003	Gastrointestinal intolerance, headache, bone pain, hypercholesterolemia, dizziness
Pamidronate disodium	Aredia	Intravenous	Novartis	1991	Fever, fatigue, nausea, hypophosphatemia, hypokalemia, infusion site reaction
Risedronate sodium	Actonel	Oral	Procter & Gamble	1998	Gastrointestinal intolerance, headache, pain, rash, urinary tract infection, arthralgia, back pain, hypertension
Risedronate sodium plus calcium carbonate	Actonel with calcium	Oral	Sanofi-Aventis	1997	Gastrointestinal intolerance, dizziness, paresthesia, chest pain, edema, rhinitis, sinusitis
Zoledronic acid	Zometa	Intravenous	Novartis	2001	Gastrointestinal intolerance, bone pain, fever, fatigue

during treatment, by advising the patient about possible minor discomfort, and by explaining how that discomfort can be controlled. Verbal support, reassurance, and personal warmth also help to ease patient anxiety during root canal treatment. Many of these measures can be taken during the case presentation.

Although the clinician's hope and desire may not cure a patient's fear of root canal treatment, each clinician should realize that all anxious patients are not alike; therefore each patient should be managed individually. If behavioral solutions are not feasible or effective in a particular case, pharmacologic approaches to managing patient anxiety may be exercised. Selection of such pharmacotherapeutic techniques must involve a careful assessment of the relative risks and benefits of the alternative approaches. All pharmacologic treatment regimens include the need for good local anesthetic technique. For the management of mild to moderate anxiety states, these regimens range from nitrous oxide plus oxygen sedation to oral sedation to intravenous or conscious sedation (for further information on these issues, see Chapter 19 and online Chapter 26).

Pain Control by Pretreatment Administration of NSAIDs

During root canal cleaning and shaping, extrusion of small amounts of pulp tissue remnants and dentin filings is likely to occur. Often this extrusion results in additional inflammation and some posttreatment discomfort. Prophylactic administration of a nonsteroidal antiinflammatory drug (NSAID), such as 200 to 400 mg of ibuprofen 30 to 60 minutes before the procedure, has been shown to reduce or prevent posttreatment dental pain[36] (see Chapter 19 for further information).

Pain Control by Local Anesthesia

It is paramount to obtain a high level of pain control when performing root canal treatment; in no other specialty is this task as challenging or as demanding. The clinician must strive for a "painless" local anesthetic injection technique, with relatively rapid onset of analgesia (see Chapter 20).

PREPARATION OF RADIOGRAPHS

Radiographs are essential to all phases of endodontic therapy. They contribute information important for the diagnosis and the various treatment phases and help evaluate the success or failure of treatment. Because root canal treatment relies on accurate radiographs, it is necessary to master radiographic techniques to achieve films of maximal diagnostic quality. Such mastery minimizes retaking of films and avoids additional exposure of patients. Expertise in radiographic interpretation is essential for recognizing deviations from the norm and for understanding the limitations associated with endodontic radiography.

Functions, Requirements, and Limitations of the Radiograph in Endodontics

The primary radiograph used in endodontics is the periapical radiograph. In diagnosis this film is used to identify abnormal conditions in the pulp and periradicular tissues. It is also used

to determine the number of roots and canals, location of canals, and root curvatures. Because the radiograph is a two-dimensional image (a major limitation), it is often advantageous to expose additional radiographs at different horizontal or vertical angulations when treating multicanal and multirooted teeth. Exposing additional radiographs is also helpful when treating teeth with severe root curvature. These supplemental radiographs enhance visualization and evaluation of the three-dimensional structure of the tooth.

Technically, for endodontic purposes, a radiograph should depict the tooth in the center of the films. Consistent film placement in this manner will minimize interpretation errors, because the center of the films contains the least amount of distortion. In addition, at least 3 mm of bone must be visible beyond the apex of the tooth. Failure to capture this bony area may result in misdiagnosis, improper interpretation of the apical extent of a root, or incorrect determination of file lengths for canal cleaning and shaping. Finally, the image on the film must be as anatomically correct as possible. Image shape distortion caused by elongation or foreshortening may lead to interpretive errors during diagnosis and treatment.[30,70]

The bite-wing radiograph may be useful as a supplemental film. This film normally has less image distortion because of its parallel placement, and it provides critical information about the anatomic crown of the tooth. This information includes the anatomic extent of the pulp chamber, the existence of pulp stones or calcifications, recurrent caries, the depth of existing restorations, and any evidence of previous pulp therapy.[65] The bite-wing also indicates the relationship of remaining tooth structure relative to the crestal height of bone. Thus it can aid in determining the restorability of the tooth.

In addition to their diagnostic value, high-quality radiographs are mandatory during the treatment phase. Technique is even more critical, however, because working radiographs must be exposed while the rubber dam system is in place. Visibility is reduced, and the bows of the clamp often restrict precise film positioning. During treatment, periradicular radiographs are used to determine canal working lengths; the location of superimposed objects, canals, and anatomic landmarks (by altering cone angulations); biomechanical instrumentation; and master cone adaptation (see Fig. 5-1, *C* to *F*). After completion of the root canal procedure, a radiograph should be exposed to determine the quality of the root canal filling or obturation. Follow-up radiographs exposed at similar angulations enhance assessment of the success or failure of treatment (see Fig. 5-1, *I* and *J*).

The astute clinician can perceive that precise radiographic interpretation is undoubtedly one of the most valuable sources of information for endodontic diagnosis and treatment, but the radiograph is only an adjunctive tool and can be misleading. Information gleaned from proper inspection of the radiograph is not always absolute and must always be integrated with information gathered from a thorough medical and dental history, clinical examination, and various pulp-testing procedures (see Chapters 1 and 4).

Use of the radiograph depends on an understanding of its limitations *and* its advantages. The advantages are obvious: the radiograph allows a privileged look inside the jaw. The information it furnishes is essential and cannot be obtained from any other source, and its value is not diminished by a critical appraisal of its limitations.

One major limitation of radiographs is their inability to detect bone destruction or pathosis when it is limited to the cancellous bone. Studies[62] have proved that radiolucencies usually do not appear unless there is external or internal erosion of the cortical plate. This factor must be considered in evaluating teeth that become symptomatic but show no radiographic changes. In most cases, root structure anatomically approaches cortical bone and, if the plate is especially thin, radiolucent lesions may be visible before there is significant destruction of the cortical plate. Nevertheless, inflammation and resorption affecting the cortical plates must still be sufficiently extensive before a lesion can be seen on a radiograph.

Principles of Endodontic Radiography

Film Placement and Cone Angulation

For endodontic purposes, the paralleling technique produces the most accurate periradicular radiograph. Also known as the *long-cone* or *right-angle* technique, it produces improved images. The film is placed parallel to the long axis of the teeth, and the central beam is directed at right angles to the film and aligned through the root apex (Fig. 5-3, *A* and *B*). To achieve this parallel orientation it is often necessary to position the film away from the tooth, toward the middle of the oral cavity, especially when the rubber dam clamp is in position.[70] The long-cone (i.e., 16 to 20 in) aiming device is used in the paralleling technique to increase the focal spot-to-object distance. This has the effect of directing only the most central and parallel rays of the beam to the film and teeth, reducing size distortion.[49,53,70] This technique permits a more accurate reproduction of the tooth's dimensions, thus enhancing a determination of the tooth's length and relationship to surrounding anatomic structures.[30] In addition, the paralleling technique reduces the possibility of superimposing the zygomatic processes over the apices of maxillary molars, which often occurs with more angulated films, such as those produced by means of the bisecting-angle technique (Fig. 5-3, *C* and *D*). If properly used, the paralleling technique will provide the clinician with films with the least distortion, minimal superimposition, and utmost clarity.

Variations in size and shape of the oral structures (e.g., shallow palatal vault, tori, or extremely long roots) or gagging by the patient can make true parallel placement of the film impossible. To compensate for difficult placement, the film can be positioned so that it diverges as much as 20 degrees from the long axis of the tooth, with minimal longitudinal distortion. With maxillary molars, any increase in vertical angulation increases the chances of superimposing the zygomatic process over the buccal roots. A vertical angle of not more than 15 degrees should usually project the zygomatic process superiorly and away from the molar roots. To help achieve this, a modified paralleling technique[19] that increases vertical angulation by 10 to 20 degrees can be used. Although this orientation introduces a small degree of foreshortening, it increases periradicular definition in this troublesome maxillary posterior region. The Snapex system (DENTSPLY Rinn, Elgin, IL), a film holder and aiming device originally designed for the bisecting-angle technique, has been altered for the modified paralleling technique.[19] In conjunction with this technique, a distal angulated radiograph (i.e., a 10- to 20-degree horizontal shift of the cone from the distal, with the beam directed toward the mesial)

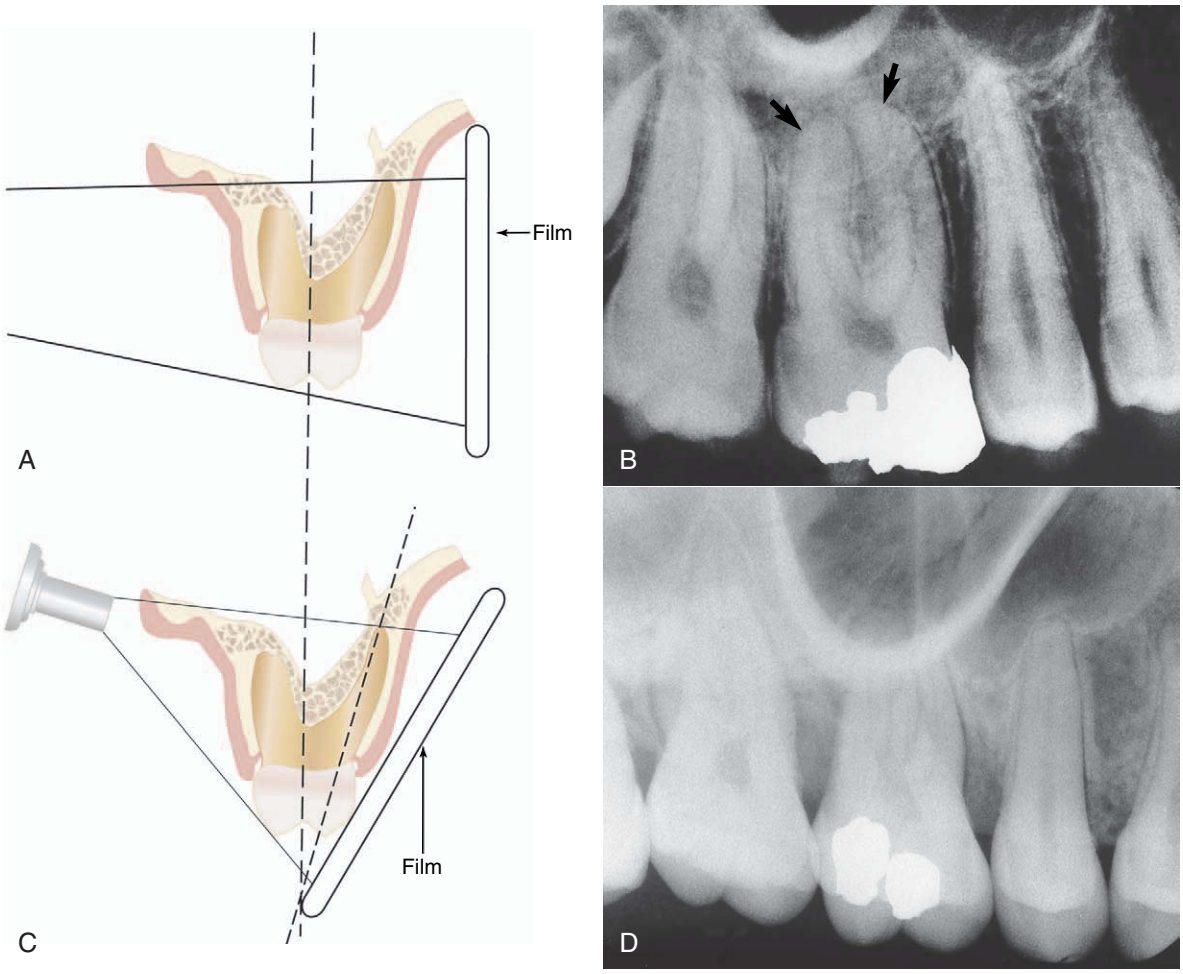

FIG. 5-3 A, Paralleling, or right-angle, technique. **B,** Projection of the zygomatic process above the buccal root apices by the right-angle technique, allowing visualization of the apices *(arrows)*. **C,** Bisecting-angle technique. **D,** Superimposition of the zygomatic process over the buccal root apices of the maxillary first molar by the bisecting-angle technique.

tends to project buccal roots and the zygomatic process to the mesial, thus enhancing anatomic clarity.[19]

The bisecting-angle technique is not preferred for endodontic radiography. However, when a modified paralleling technique cannot be used, there may be no choice because of difficult anatomic configurations or patient management problems.[19,49,53,70] The basis of this technique is to place the film directly against the teeth without deforming the film (see Fig. 5-3, *C* and *D*). The structure of the teeth, however, is such that with the film in this position, an obvious angle exists between the plane of the film and the long axis of the teeth. This causes distortion, because the tooth is not parallel to the film. If the x-ray beam is directed at a right angle to the film, the image on the film will be shorter than the actual tooth (i.e., foreshortened). If the beam is directed perpendicularly to the long axis of the teeth, the image will be much longer than the tooth (i.e., elongated). Thus, by directing the central beam perpendicular to an imaginary line that bisects the angle between tooth and film, the length of the tooth's image on the film should be the same as the actual length of the tooth.

Although the projected length of the tooth is correct, the image will show distortion because the film and object are not parallel and the x-ray beam is not directed at right angles to both. This distortion increases along the image toward its apical extent. The technique produces additional error potential, because the clinician must imagine the line bisecting the angle (an angle that, in itself, is difficult to assess). In addition to producing more frequent superimposition of the zygomatic arch over apices of maxillary molars, the bisecting-angle technique causes greater image distortion than the paralleling technique and makes it difficult for the clinician to reproduce radiographs at similar angulations to assess healing after root canal treatment[28] (see Fig. 5-3, *C* and *D*).

Film Holders and Aiming Devices

Film holders and aiming devices are required for the paralleling technique because they reduce geometric distortion caused by misorientation of the film, central beam, and tooth.[19,49,53,65,70] They also minimize cone cutting, improve diagnostic quality, and allow similarly angulated radiographs to be exposed during treatment and at recall. By eliminating the patient's finger from the x-ray field and thus the potential for displacing the film, these devices help to minimize retakes and make it easier for the patient and clinician to properly position the film.

A number of commercial devices are available that position the film parallel and at various distances from the teeth, but

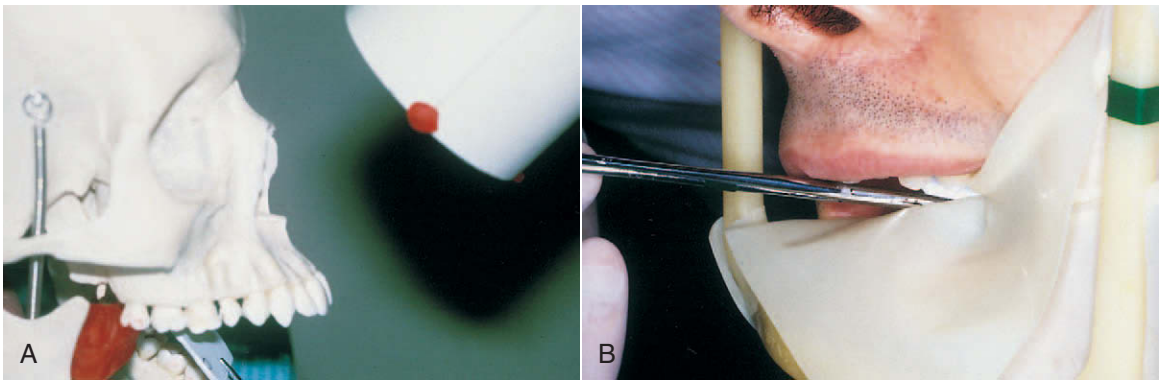

FIG. 5-4 A, With the paralleling technique, the tube head is positioned at a 90-degree angle to the film. The hemostat aids in film placement and in cone alignment. Note that the hemostat is resting on the mandibular anterior teeth so that the film is parallel with the long axis of the maxillary central incisors. **B,** Releasing a corner of the rubber dam aids in hemostat placement so that the film can be properly aligned. (***A,*** *Courtesy Dr. Eddy Tidwell;* ***B,*** *courtesy Dr. Michelle Speier.)*

FIG. 5-6 XCP instruments hold the radiograph film packets and aid in cone alignment. Cone cutting is prevented, and consistent angulation can be achieved. *(Courtesy DENTSPLY Rinn, Elgin, IL.)*

one of the most versatile film-holding devices is the hemostat. The clinician positions a hemostat-held film, and the handle is used to align the cone vertically and horizontally. The patient then holds the hemostat in the same position, and the cone is positioned at a 90-degree angle to the film (Fig. 5-4, *A*). When taking working radiographs, a radiolucent, plastic, rubber dam frame, such as an Ostby or Young frame, should be used and not removed. To position the hemostat or other film-holding device, a corner of the rubber dam is released for visibility and to allow the subsequent placement of the device-held film (Fig. 5-4, *B*). The Stabe disposable film holder (DENTSPLY Rinn, Elgin, IL) (Fig. 5-5) is another film-holding device that is ideal for taking pretreatment and posttreatment films.

Besides the Dunvale Snapex system mentioned earlier, the major commercial film-holding and aiming devices include the XCP (extension cone paralleling) instruments, the EndoRay II endodontic film holder, the Uni-Bite film holder, the Snap-A-Ray film holder, the Snapex system film holder with aiming device, and the Crawford film holder system (Figs. 5-6 to 5-10).

Variations in the use of the XCP system, for example, can prevent displacement of the rubber dam clamp and increase periradicular coverage during endodontic procedures. The film is placed off center in the bite block, and the cone is placed off center with respect to the aiming ring. This allows for placement of the bite block adjacent to the rubber dam clamp without altering the parallel relation of the cone to the film. A customized hemostat (with rubber bite block attached) can

also be made to assist film placement during the taking of working radiographs. Other specialized film holders, such as the EndoRay and the Crawford film holder system, have been designed to help the clinician secure parallel working films with the rubber dam clamp in place. In general, these holders all have an x-ray beam–guiding device for a proper beam–film relationship and a modified bite block and film holder for proper positioning over or around the rubber dam clamp (see Fig. 5-10).

Exposure and Film Qualities

The intricacies of proper kilovoltage, milliamperage, and time selection serve as examples of how the diagnostic quality of a film may be altered by changes in the film's density and contrast.[53,70] Density is the degree of darkening of the film, whereas contrast is the difference between densities. The amount of darkening depends on the quantity and quality of radiation delivered to the film, the subject thickness, and the developing or processing conditions. Milliamperage controls the electron flow from cathode to anode; the greater the electron flow per unit of time, the greater will be the quantity of radiation produced. Proper density is primarily a function of milliamperage and time. Kilovoltage also affects film density by controlling the quality and penetrability of the rays. Higher kilovoltage settings produce shorter wavelengths that are more penetrating than the longer wavelengths produced at lower settings.[53,70] The ability to control the penetrability of the rays by alterations in kilovoltage affects the amount of radiation reaching the film and the degree of darkening or density. Altering exposure time or milliamperage or both for each respective unit can control variations in density.[53,70]

Contrast is defined as the difference between shades of gray or as the difference between densities. Most variation observed in endodontic radiography occurs because of subject contrast, which depends on the thickness and density of the subject and the kilovoltage used. Thus kilovoltage is really the only exposure parameter under the clinician's control that directly affects subject contrast.[30,53,70] Exposure time and milliamperage control only the number of x-rays; therefore they influence mainly the density of the film image. A radiographic film may exhibit a long-scale, or low, contrast (i.e., more shades of gray or more useful densities); high-kilovoltage techniques (e.g., 90 kVp) produce this long scale of contrast as a result of the increased penetrating power of the rays. This results in images with many more shades of gray and less distinct differences. Films exposed at low kilovoltage settings (e.g., 60 kVp) exhibit short-scale, or high, contrast, with sharp differences between a few shades of gray, black, and white.[53,70] Although they are perhaps more difficult to read, films exposed at higher kilovoltage settings (e.g., 90 kVp) make it possible to discriminate between images, often enhancing diagnostic quality; films exposed at a lower kilovoltage (e.g., 70 kVp) have better clarity and contrast between radiopaque and radiolucent structures, such as endodontic instruments near the root apex. Nevertheless, the optimal kilovoltage and exposure time should be individualized for each radiograph unit and exposure requirement.

Processing

Proper darkroom organization, film handling, and adherence to the time and temperature method of film processing play important roles in producing films of high quality.[53] For the sake of expediency in the production of working films in endodontics, rapid processing methods are used to produce relatively good films in less than 1 to 2 minutes (Fig. 5-11).[53,70] Although the contrast when using rapid-processing chemicals is lower than that achieved by conventional techniques, the radiographs have sufficient diagnostic quality to be used for treatment films and are obtained in less time and with less patient discomfort. Rapid-processing solutions are available

FIG. 5-11 Chairside darkroom allows rapid processing of endodontic working films. *(Courtesy DENTSPLY Rinn, Elgin, IL.)*

commercially, but they tend to vary in shelflife, in tank life, and in the production of films of permanent quality.

To maintain the radiographic image for documentation, it is recommended that after an image has been evaluated it be returned to the fixer for 10 minutes more and then washed for 20 minutes and dried. An alternative is to reprocess the film by means of the conventional technique. Double film packets can also be used for working films: one can be processed rapidly and the other conventionally. Regardless of what method is used for working films, a controlled time and temperature method should be used for the diagnostic qualities desired in pretreatment, posttreatment, and recall radiographs. All radiographs taken during the course of endodontic treatment should be preserved as a part of the patient's permanent record.

Examination and Differential Interpretation

Radiographic interpretation is not strictly the identification of a problem and the establishment of a diagnosis. The clinician must read the film carefully, with an eye toward diagnosis and treatment. Frequently overlooked are the small areas of resorption, invaginated enamel, separated files, minute fracture lines, extra canals or roots, curved and calcified canals, and, in turn, the potential problems they may create during treatment (Fig. 5-12). If a thorough radiographic examination is conducted, problems during treatment, additional time, and extra expense can be avoided or at least anticipated. As mentioned earlier, additional exposures at various angulations may be necessary to gain better insight into the three-dimensional structure of a tooth.

Many anatomic structures and osteolytic lesions can be mistaken for periradicular pathoses. Among the more commonly misinterpreted anatomic structures are the mental foramen and the incisive foramen. These radiolucencies can be differentiated from pathologic conditions by exposures at different angulations and by pulp-testing procedures. Radiolucencies not associated with the root apex will move or be projected away from the apex by varying the angulation. Radiolucent areas resulting from sparse trabeculation can also simulate radiolucent lesions. In such cases these areas must be differentiated from the lamina dura and periodontal ligament space.

A commonly misinterpreted osteolytic lesion is periapical cemental dysplasia ("cementoma") (Fig. 5-13). The use of pulp-testing procedures and follow-up radiographic examinations will prevent the mistake of diagnosing this as a periradicular pathosis. The development of this lesion can be monitored radiographically from its early, more radiolucent stage through its mature or more radiopaque stage.

Other anatomic radiolucencies that must be differentiated from periradicular pathoses are the maxillary sinus, nutrient canals, nasal fossa, and lateral or submandibular fossa. Many systemic conditions can mimic or affect the radiographic appearance of the alveolar process. A discussion of these conditions is beyond the scope of this chapter, but the reader is encouraged to read further in any oral pathology textbook.

Lamina Dura: A Question of Integrity

One key challenge in endodontic radiographic interpretation is to understand the integrity, or lack of integrity, of the lamina dura, especially in its relationship to the health of the pulp. Anatomically, the lamina dura[70] is a layer of compact bone (i.e., cribriform plate or alveolar bone proper) that lines the tooth socket. Noxious products emanating from the root canal system can effect a change in this structure that is visible radiographically. X-ray beams passing tangentially through the socket must pass through many times the width of the adjacent alveolus, and they are attenuated by this greater thickness of bone, producing the characteristic "white line." If, for example, the beam is directed more obliquely so that it is not as attenuated, the lamina dura appears more diffuse, or it may not be discernible at all. Therefore the presence or absence and integrity of the lamina dura are determined largely by the shape and position of the root and, in turn, by its bony crypt, in relation to the x-ray beam. This explanation is consistent with the radiographic and clinical findings of teeth with normal pulps and no distinct lamina dura.[62]

Changes in the integrity of the periodontal ligament space, the lamina dura, and the surrounding periradicular bone certainly have diagnostic value, especially when recent radiographs are compared with previous ones. However, the significance of such changes must be tempered by a thorough understanding of the features that give rise to these images.

Buccal Object Rule (Cone Shift)

In endodontic therapy it is imperative that the clinician know the spatial or buccolingual relation of an object within the tooth or alveolus. The technique used to identify the spatial relation of an object is called the *cone-* or *tube-shift technique*. Other names for this procedure are the *buccal object rule, Clark's rule,* and the *SLOB* (same lingual, opposite buccal) rule.[31,53,60,70] Proper application of the technique allows the clinician to locate additional canals or roots, to distinguish between objects that have been superimposed, and to distinguish between various types of resorption. It also helps the clinician to determine the buccolingual position of fractures and perforative defects, to locate foreign bodies, and to locate anatomic landmarks in relation to the root apex, such as the mandibular canal.[65]

The buccal object rule relates to the manner in which the relative position of radiographic images of two separate objects changes when the projection angle at which the images were made is changed. The principle states that the object closest to

Banchs.)*

the buccal surface appears to move in the direction opposite the movement of the cone or tube head, when compared with a second film. Objects closest to the lingual surface appear to move (on a film) in the same direction that the cone moved; thus the "same lingual, opposite buccal" rule. Figure 5-14 shows three simulated radiographs of a buccal object (yellow circle) and a lingual object (red triangle) exposed at different horizontal angles. The positions of the objects on each radiograph are compared with the reference structure (i.e., the mesial root apex of the mandibular first molar). The first radiograph (see Fig. 5-14, *A* and *B*) shows superimposition of the two objects; in this case the tube head was positioned for a straight-on view. In the second radiograph (see Fig. 5-14, *C* and *D*), the tube head was shifted mesially, and the beam was directed at the reference object from a more mesial angulation. In this case the lingual object (red triangle) moved mesially with respect to the reference object, and the buccal object (yellow circle) moved distally with respect to the reference object. In the third radiograph (see Fig. 5-14, *E* and *F*), the tube head was shifted distally and the beam was directed at the reference object from a more distal angulation; here the triangle moved distally with respect to the mesial root of the mandibular first molar, and the circle moved mesially. These radiographic relations confirm that the lingual object (red triangle) moves in the same direction with respect to reference structures as the radiograph tube and that the buccal object (yellow circle) moves in the opposite direction of the radiograph tube. Thus, according to the rule, the object farthest

FIG. 5-13 Variations in stages of periapical cemental dysplasia (i.e., cementoma) on the four mandibular incisors. All teeth are vital. *(Courtesy Dr. Francisco A. Banchs.)*

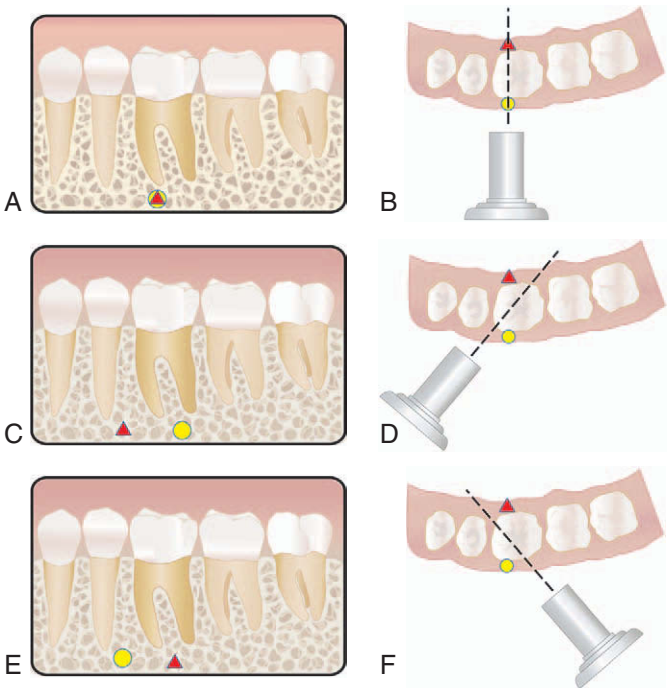

FIG. 5-14 Objects may be localized with respect to reference structures by using the buccal object rule (i.e., tube-shift technique). **A-B,** A straight-on view will cause superimposition of the buccal object *(yellow circle)* with the lingual object *(red triangle)*. **C-D,** Using the tube-shift technique, the lingual object *(red triangle)* will appear more mesial with respect to the mesial root of the mandibular first molar, and the buccal object *(yellow circle)* will appear more distal on a second view projected from the mesial. **E-F,** The object *(red triangle)* on the lingual surface will appear more distal with respect to the mesial root of the mandibular first molar, and the object *(yellow circle)* on the buccal surface will appear more mesial on a view projected from the distal aspect.

(i.e., most buccal) from the film moves farthest on the film with respect to a change in horizontal angulation of the radiograph cone. In an endodontically treated mandibular molar with four canals (Fig. 5-15), a straight-on view results in superimposition of the root-filled canals on the radiograph. If the cone is angled from mesial to distal, the mesiolingual and distolingual canals will move mesially and the mesiobuccal and distobuccal canals will move distally on the radiograph, when compared with the straight-on view.

The examples cited previously involve application of the buccal object rule, using changes in horizontal angulation. The clinician should be aware that this rule also applies to changes in vertical angulation (Fig. 5-16). To locate the position of the mandibular canal relative to mandibular molar root apices, radiographs must be taken at different vertical angulations. If the canal moves with or in the same direction as the cone head, the canal is lingual to the root apices; if the mandibular canal moves opposite the direction of the cone head, the canal is buccal to the root apices. The clinician should recognize the wide range of applicability of the buccal object rule in determining the buccolingual relationship of structures not visible in a two-dimensional image.

Digital Radiographic Techniques

The replacement of traditional radiographic film with digital sensors offers many advantages to radiography. The evolution of computer technology for radiography has allowed for nearly instantaneous image acquisition, image enhancement, storage, retrieval, and even transmission of images to remote sites in a digital format. The major advantages of using digital radiography in endodontics are that radiographic images are obtained immediately and radiation exposure is reduced from 50% to 90% compared with conventional film-based radiography.[56,70] The primary disadvantages of digital imaging systems are their high initial cost and potential for reduction in image quality when compared with conventional radiography.

Digital imaging systems require an electronic sensor or detector, an analog-to-digital converter, a computer, and a monitor or printer for image display.[70] (See Chapters 28 and

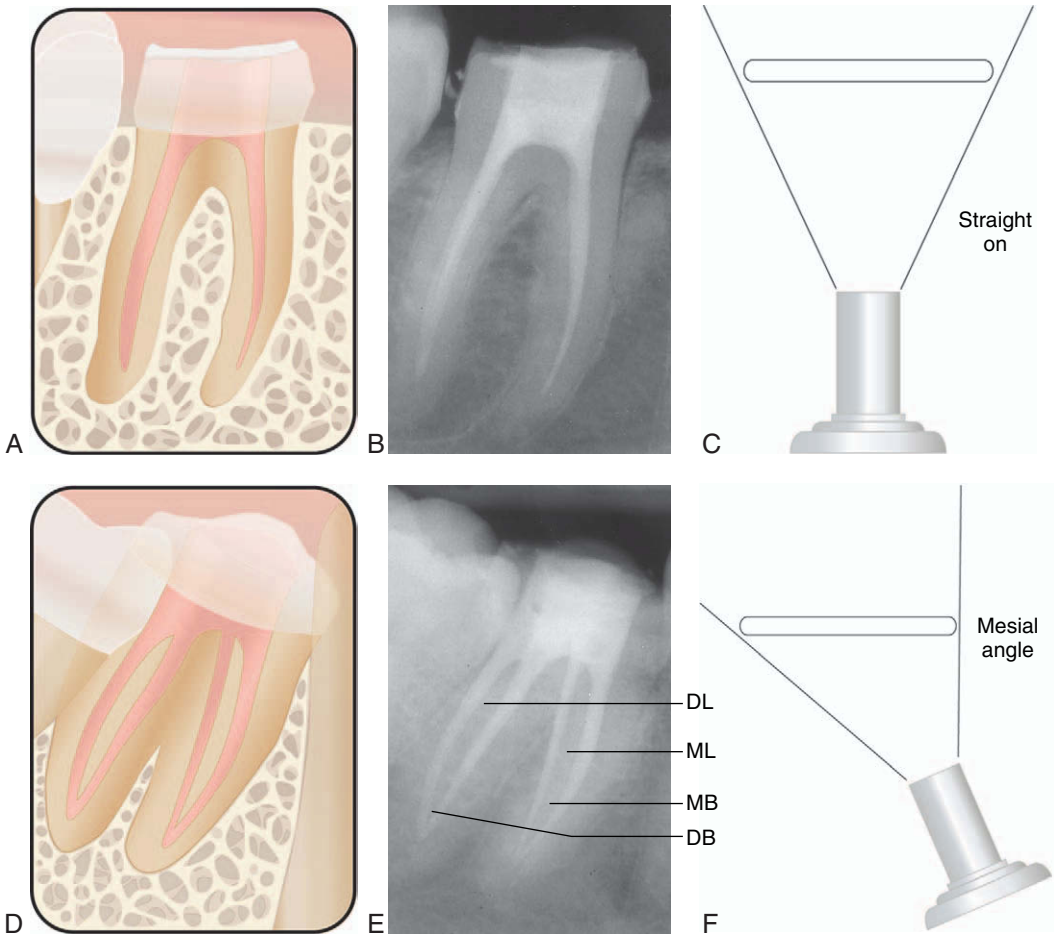

FIG. 5-15 Comparison of straight-on and mesial-angled views of an endodontically treated mandibular molar with four canals. **A-C,** Straight-on view of the mandibular molar shows superimposition of the root canal fillings. **D-F,** Mesiodistal angulation produces separation of the canals. The mesiolingual *(ML)* and distolingual *(DL)* root-filled canals move mesially (i.e., toward the cone), and the mesiobuccal *(MB)* and distobuccal *(DB)* root-filled canals move distally (i.e., away from the cone) on the radiograph.

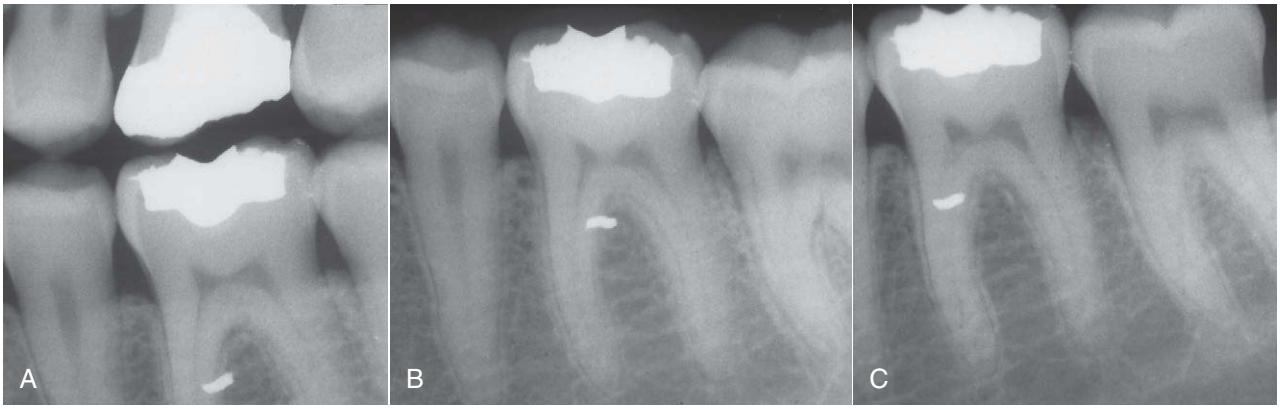

FIG. 5-16 Examples of the buccal object rule, using shifts in vertical and horizontal angulations. **A,** Bite-wing radiograph (straight-on view with minimal horizontal and vertical angulation) depicts amalgam particle superimposed over the mesial root of the mandibular first molar. To determine the buccolingual location of the object, the tube-shift technique (buccal object rule) must be applied. **B,** The periapical radiograph was exposed by shifting the vertical angulation of the cone (i.e., the radiograph beam was projected more steeply upward). Because the amalgam particle moved in the opposite direction to that of the cone (compared with the bite-wing radiograph), the amalgam particle lies on the buccal aspect of the tooth. **C,** The periapical radiograph was exposed by shifting the horizontal angulation of the cone. (The radiograph was exposed from a distal angle.) Compared with both **A** and **B,** each taken straight-on with minimal horizontal angulation, the amalgam particle moved opposite the direction of movement of the cone or tube head, confirming that the amalgam particle lies on the buccal aspect of the tooth.

29 online for a further discussion of digital imaging systems and how they function.)

Digitization of ionizing radiation first became a reality in the late 1980s with the development of the original RadioVisioGraphy (RVG) system by Dr. Francis Mouyen.[56] This system later was marketed as the RVGui (Kodak Dental Systems/Carestream Health website, http://www.kodakdental.com/en/digital-imaging/intraoral-radiography/kodak-rvg-6100.aspx). Other available systems include Dexis digital x-ray (Dexis, Des Plaines, IL) and computed dental radiography (CDR) (Schick Technologies, Long Island City, NY) (Fig. 5-17, *A* and *C*). The FDA has approved all these systems.

Direct digital systems have three components: (1) the "radio" component, (2) the "visio" component, and (3) the "graphy" component. The "radio" component consists of a high-resolution sensor with an active area that is similar in size to conventional film. However, length, width, and thickness vary slightly depending on the respective system (Fig. 5-17, *B* and *E*). The sensor is protected from x-ray degradation by a fiberoptic shield, and it can be disinfected. Specially designed multiple types of sensor holders are available; for infection control, disposable plastic sheaths are used to cover the sensor when it is in use (see Fig. 5-17, *E*). Wireless CDR sensors have become available through Schick Technologies. This technology provides cable-free sensors to allow enhanced mobility at chairside (see Fig. 5-17, *C* and *D*). CDR Wireless is the first wireless direct digital radiography system. Wireless sensors provide greater mobility at chairside while reportedly providing the same level of image quality acquired with conventional CDR systems. Sensors instantly transmit images directly from the mouth. The image is automatically transmitted to the computer via radio waves. Images do not need to be processed as with traditional film and storage phosphor plates. Chemical processing as with traditional film is not needed. Also, sensors do not need to be downloaded, erased, or reset between shots.

The second component of a direct digital system, the "visio" portion, consists of a video monitor and display-processing unit (see Fig. 5-17, *A* and *C*). As the image is

transmitted to the processing unit, it is digitized and stored by the computer. The unit magnifies the image for immediate display on the video monitor; it also can produce colored images and display multiple images simultaneously, including a full mouth series on one screen. Because the image is digitized, further manipulation of the image is possible; this includes enhancement, contrast stretching, and reversing. A zoom feature is also available to enlarge a portion of the image up to full-screen size.

The third component of a direct digital system is the "graphy," a high-resolution video printer that provides a hard copy of the screen image, using the same video signal. In addition, a digital intraoral camera can be integrated with most systems. Indirect digital imaging or cordless systems, such as Digora (Soredex-Finndent, Conroe, Texas) and the DenOptix digital imaging system (Gendex, Des Plaines, IL), involve the use of a reusable filmlike plate without wires. The image to be scanned by a laser (to digitize it before viewing on the computer) is recorded on this plate. Although indirect digital imaging still incorporates reduced radiation exposure and image manipulation, it usually takes slightly longer before the image can be viewed.

The advantages of both direct and indirect digital radiography seem numerous, but the primary ones include the elimination of standard radiograph film and processing chemicals, a significant reduction in exposure time (i.e., 80% to 90% reduction, when compared with D-speed film), and rapid image display. Virtually all systems can be linked with electronic record systems so that patient data can be stored, accessed, and transmitted easily. An exposure time in the range of hundredths of a second is all that is needed to generate an image.[70] One study showed that digital radiographic resolution was slightly lower than that produced with silver halide film emulsions, but the radiographic information may be increased with the electronic image treatment capabilities of the system.[56] These systems appear to be promising for endodontics and for the clinician.

Digital subtraction radiography[58] is a sensitive method for detecting changes in radiographic density over time. In endodontics, digital subtraction radiography may be especially useful for evaluating osseous healing after treatment and as an aid in diagnosis. By definition, subtraction radiography requires that two images have nearly identical image geometry; specialized positioning devices and bite registrations aid in matching the images. The subtracted image is a composite of the images, representing their variations in density. By subtracting all anatomic structures that have not changed between radiographic examinations, changes in diagnostic information become easier to interpret. Any change is displayed on the resultant image against a neutral, gray background. Advances[58] in computer technology have incorporated built-in algorithms to correct for variations in exposure and projection geometry. These advances have also enabled colorization of density changes so that hard tissue gain is represented by one color and hard tissue loss is represented by another color.

Orascopy and Endoscopy

Orascopy[7] (Fig. 5-18, *A*), and related endoscopic instruments, have been adapted for enhanced visualization in endodontics and consist of either flexible or rigid fiberoptic endoscopes. These fiberoptic probes are available in various diameters; the probes provide a large depth of field, and refocusing is not needed after the initial focus. Once the probe is applied, the clinician views the conventional or surgical site from the magnified image displayed on the monitor. Endoscopic endodontics allows the clinician to have a nonfixed field of vision, and probes can be manipulated at various angles and distances from an object without loss of focus or image clarity. With orascopy, finite fracture lines, accessory canals, missed canals and isthmuses, and apical tissues can be viewed (Fig. 5-18, *B-E*). Evolving technology will likely enhance the precision and accuracy of the fiberoptic probes.

PREPARATION FOR ACCESS: TOOTH ISOLATION

The use of the rubber dam is mandatory in root canal treatment.[16,18] Developed in the nineteenth century by S.C. Barnum, the rubber dam has evolved from a system that was designed to isolate teeth for placement of gold foil to one of sophistication for the ultimate protection of both patient and clinician.[65] The advantages[8,12,16,29,32] and absolute necessity of the rubber dam must always take precedence over convenience and expediency (a rationale often cited by clinicians who condemn its use). When properly placed, the rubber dam facilitates treatment by isolating the tooth from obstacles (e.g., saliva and tongue) that can disrupt any procedure. Proper rubber dam placement can be done quickly and will enhance the entire procedure.

The rubber dam is used in endodontics because it ensures the following[6,16,29,37,65]:

1. The patient is protected from aspiration or swallowing of instruments, tooth debris, medicaments, and irrigating solutions.
2. The clinician is protected from litigation because of patient aspiration or swallowing of an endodontic file. *Routine placement of the rubber dam is considered the standard of care.*[17,18]
3. A surgically clean operating field is isolated from saliva, blood, and other tissue fluids. The dam reduces the risk of cross-contamination of the root canal system, and it provides an excellent barrier to the potential spread of infectious agents.[16,29] *It is a required component of any infection control program.**
4. Soft tissues are retracted and protected.
5. Visibility is improved. The rubber dam provides a dry field and reduces mirror fogging.
6. Efficiency is increased. The rubber dam minimizes patient conversation during treatment and the need for frequent rinsing.

The clinician should be aware that in some situations, especially in teeth with crowns, access into the pulp system may be difficult without first orienting root structure to the adjacent teeth and periodontal tissues. Radiographically, the coronal pulp system is often obscured by the restoration, and, as a result, the clinician may misdirect the bur during access. In these cases it may be necessary to locate the canal system before placing the dam. In doing so the clinician can visualize root topography, making it easier to orient the bur toward the

Shulman.)*

long axis of the roots and prevent perforation. Once the root canal system is located, however, the rubber dam should be immediately placed.

Armamentarium

The mainstay of the rubber dam system is the dam itself. These autoclavable sheets of thin, flat latex come in various thicknesses (e.g., thin, medium, heavy, extraheavy, and special heavy) and in two different sizes (5 × 5 and 6 × 6 in). For endodontic purposes, the medium thickness is probably best because it tends to tear less easily, retracts soft tissues better than the thin type, and is easier to place than the heavier types. However, a thinner gauge may be desirable to decrease tension if retainer placement is questionable or if the retainer is resting on a band. The dam is also manufactured in various colors, ranging from light yellow to blue to green to gray. The darker colored dams may afford better visual contrast, thus reducing eye strain. However, the lighter colored dams, because of their translucency, have the advantage of naturally illuminating the operating field and allowing easier film placement underneath the dam. Depending on individual preference and specific conditions associated with a tooth, the clinician may find it necessary to vary the color and thickness of the rubber dam used. Glare and eyestrain can be reduced and contrast enhanced by routinely placing the dull side of the dam toward the clinician.

For patients with latex allergies, a nonlatex rubber dam is available from Coltène/Whaledent (Cuyahoga Falls, OH) (Fig. 5-19). This powder-free, synthetic dam comes in one size (6 × 6 in.) and in one thickness (medium gauge). It has a shelflife of 3 years but only one third the tensile strength of a latex dam. Other companies provide nitrile rubber dams.

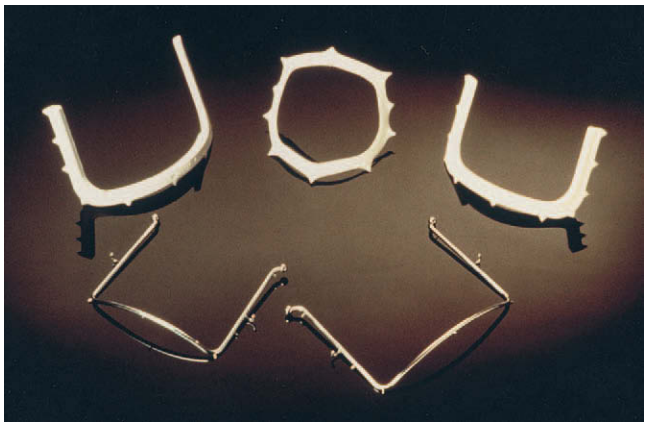

FIG. 5-20 Plastic radiolucent and metal rubber dam frames. *Top left,* plastic frame from Young Dental; *top center,* plastic Ostby frame from Coltène/Whaledent.

Another component of the rubber dam system is the rubber dam frame, which is designed to retract and stabilize the dam. Both metal and plastic frames are available, but plastic frames are recommended for endodontic procedures. They appear radiolucent, do not mask key areas on working films, and do not have to be removed before film placement. The Young Dental (Earth City, MO) rubber dam frame (plastic type), and the Nygaard-Ostby (N-O) frame (Hygenic brand; Coltène/Whaledent) are examples of radiolucent frames used in endodontics (Fig. 5-20). New to endodontics is a specially designed foldable plastic frame (Fig. 5-21), with a hinge to facilitate film or sensor placement without disengaging the entire frame. The disposable Insti-Dam (Zirc, Buffalo, MN) (Fig. 5-22) and HandiDam (Aseptico, Woodinville, WA) rubber dam systems also provide a radiolucent plastic frame. The OptraDam

FIG. 5-21 Foldable plastic rubber dam frame (Plast-Frame) with hinge to allow for easy film/sensor placement. *(Courtesy Hager Worldwide, Odessa, FL.)*

(Ivoclar Vivadent, Amherst, NY) is another disposable single-isolation device with a flexible outer ring, eliminating the need for an additional frame. Although metal frames (see Fig. 5-20) can be used, their radiopacity tends to block out the radiograph. If removed, this may result in destabilization of the dam and salivary contamination of the canal system, negating the disinfected environment that was previously attained.

Rubber dam clamps or retainers anchor the dam to the tooth requiring treatment or, in cases of multiple tooth isolation, to the most posterior tooth. They also aid in soft tissue retraction. These clamps are made of stainless steel, and each consists of a bow and two jaws. Regardless of the type of jaw configuration, the prongs of the jaws should engage at least four points on the tooth. This four-point clamp-to-tooth relationship stabilizes the retainer and prevents any rocking, which in itself can be injurious to both hard and soft tissues.[38,47]

Clamps are available from a variety of manufacturers and are specifically designed for all classes of teeth with a variety of anatomic configurations (Fig. 5-23). For most uncomplicated endodontic isolations, the clinician's basic armamentarium should consist of winged clamps, a butterfly-type clamp for anterior teeth, a universal premolar clamp, a mandibular molar clamp, and a maxillary molar clamp. The wings, which are extensions of the jaws, not only provide for additional soft tissue retraction but also facilitate placement of the rubber dam, frame, and retainer as a single unit (see the next section, Methods of Rubber Dam Placement).

Other retainers are designed for specific clinical situations in which clamp placement may be difficult. For example, when minimal coronal tooth structure remains, a clamp with apically inclined jaws may be used to engage tooth structure at or below the level of the free gingival margin. Retainers with serrated jaws, known as tiger clamps, also may increase stabilization of broken-down teeth. Another type of retainer, the S-G (Silker-Glickman) clamp, should also be included in the clinician's armamentarium (Fig. 5-24). Its anterior extension allows for retraction of a dam around a severely broken-down tooth, and the clamp itself is placed on a tooth proximal to the one being treated.

The remaining components of the rubber dam system include the rubber dam punch and the rubber dam forceps.

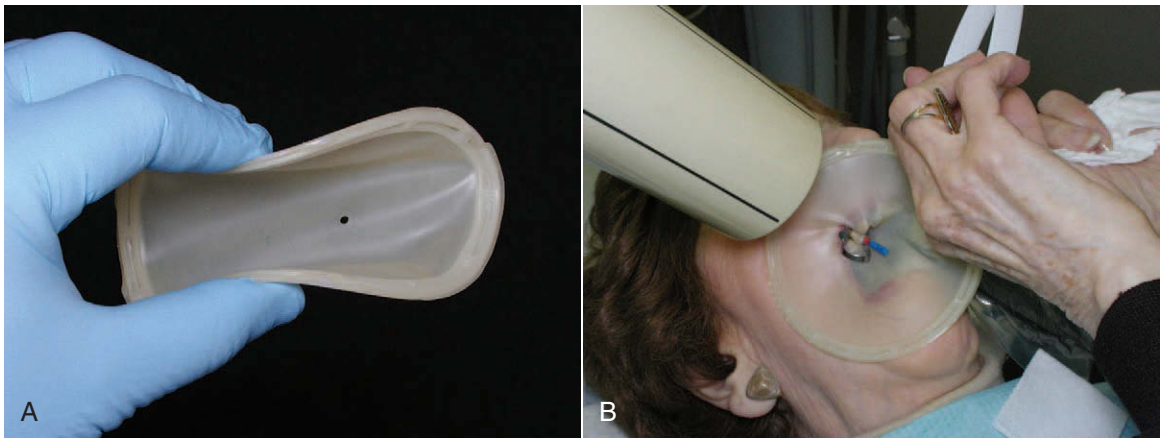

FIG. 5-22 Insti-Dam is a disposable dam system available in both latex and nonlatex. **A,** Bendable flexible frame allows for easy placement. **B,** Use of Insti-Dam during endodontic treatment. *(Courtesy Zirc, Buffalo, MN.)*

FIG. 5-24 The Silker-Glickman (S-G) clamp for isolation of severely broken-down teeth. *(Courtesy The Smile Center, Deerwood, MN.)*

The punch has a series of holes on a rotating disk from which the clinician can select according to the size of the tooth or teeth to be isolated. The forceps holds and carries the retainer during placement and removal.

Methods of Rubber Dam Placement

As mentioned earlier, an expedient method of dam placement is to position the bow of the clamp through the hole in the dam and place the rubber over the wings of the clamp (a winged clamp is required). The forceps stretch the clamp to maintain the position of the clamp in the dam, and the dam is attached to the plastic frame, allowing for the placement of the dam, clamp, and frame in one motion (Fig. 5-25). Once the clamp is secured on the tooth, the dam is teased under the wings of the clamp with a plastic instrument.

Another method is to place the clamp, usually wingless, on the tooth and then stretch the dam over the clamped tooth (Fig. 5-26).[29,56] This method offers the advantage of enabling the clinician to see exactly where the jaws of the clamp engage the tooth, thus avoiding possible impingement on the gingival tissues. Gentle finger pressure on the buccal and lingual apron of the clamp before the dam is placed can be used to test how securely the clamp fits. Variations of this method include placing the clamp and dam first, followed by the frame, or placing the rubber dam first, followed by the clamp and then the frame.[65]

A third method, the split-dam technique, may be used to isolate anterior teeth without using a rubber dam clamp. Not only is this technique useful when there is insufficient crown structure, as in the case of horizontal fractures, but also it prevents the possibility of the jaws of the clamp chipping the margins of teeth restored with porcelain crowns or laminates. Studies[38,47] on the effects of retainers on porcelain-fused-to-metal restorations and tooth structure itself have demonstrated that there can be significant damage to cervical porcelain, as well as to dentin and cementum, even when the clamp is properly stabilized. Thus for teeth with porcelain restorations, ligation with dental floss is recommended as an alternative method to retract the dam and tissues, or the adjacent tooth can be clamped.

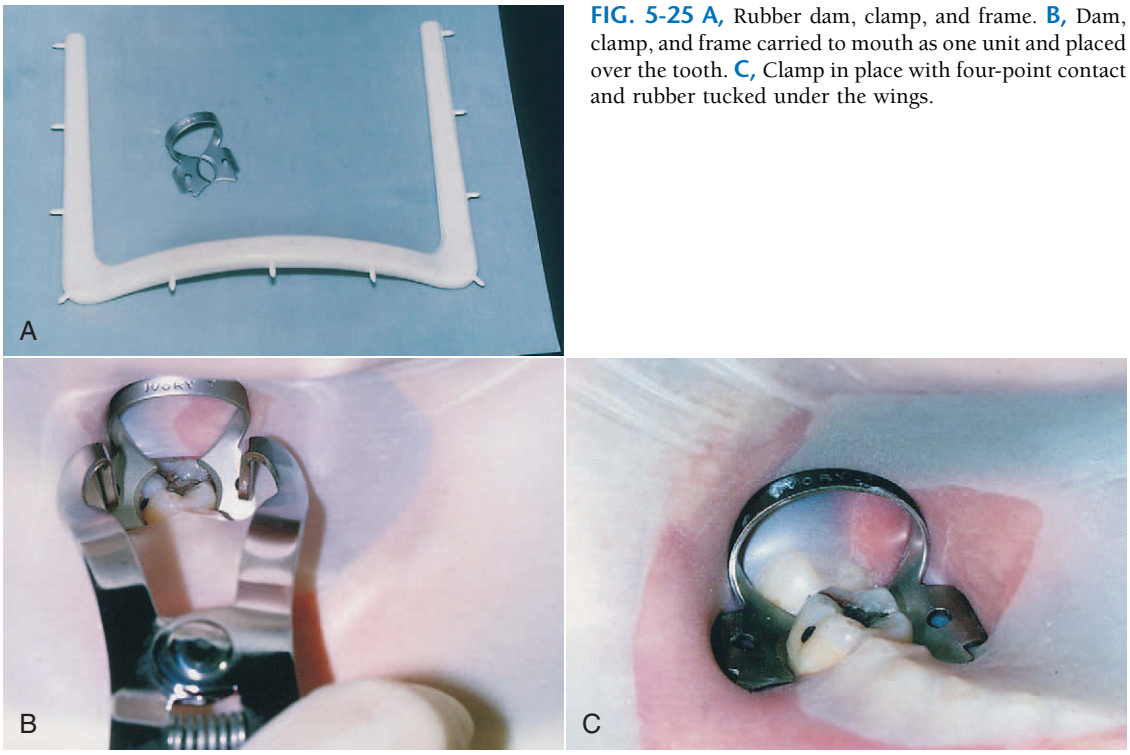

FIG. 5-25 A, Rubber dam, clamp, and frame. **B,** Dam, clamp, and frame carried to mouth as one unit and placed over the tooth. **C,** Clamp in place with four-point contact and rubber tucked under the wings.

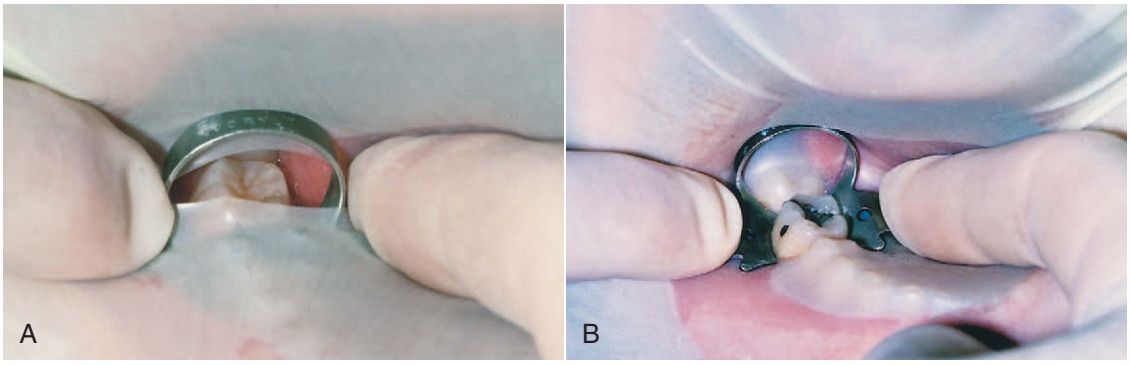

FIG. 5-26 A, After the clamp is placed, the dam is attached to the frame and gently stretched over the clamped tooth with the index finger of each hand. **B,** The clamp is tested for a secure fit with gentle finger pressure (alternately) on the buccal and lingual aspects of the clamp apron.

In the split-dam method (Fig. 5-27), two overlapping holes are punched in the dam. A cotton roll is placed under the lip in the mucobuccal fold over the tooth to be treated. The rubber dam is stretched over the tooth to be treated and over one adjacent tooth on each side. The edge of the dam is carefully teased through the contacts on the distal sides of the two adjacent teeth. Dental floss helps carry the dam down around the gingiva. The tension produced by the stretched dam, aided by the rubber dam frame, secures the dam in place. The tight fit and the cotton roll help produce a relatively dry field. If the dam has a tendency to slip, a premolar clamp may be used on a tooth distal to the three isolated teeth or even on an adjacent tooth (see Fig. 5-27, *A*). The clamp is placed over the rubber dam, which then acts as a cushion against the jaws of the clamp.

Aids in Rubber Dam Placement

Punching and Positioning of Holes

The rubber dam may be divided into four equal quadrants, and the proper place for the hole is estimated according to which tooth is undergoing treatment. The more distal the tooth, the closer to the center of the dam the hole is placed. This method becomes easier as the clinician gains experience. The hole must be punched cleanly, without tags or tears. If the dam is torn,

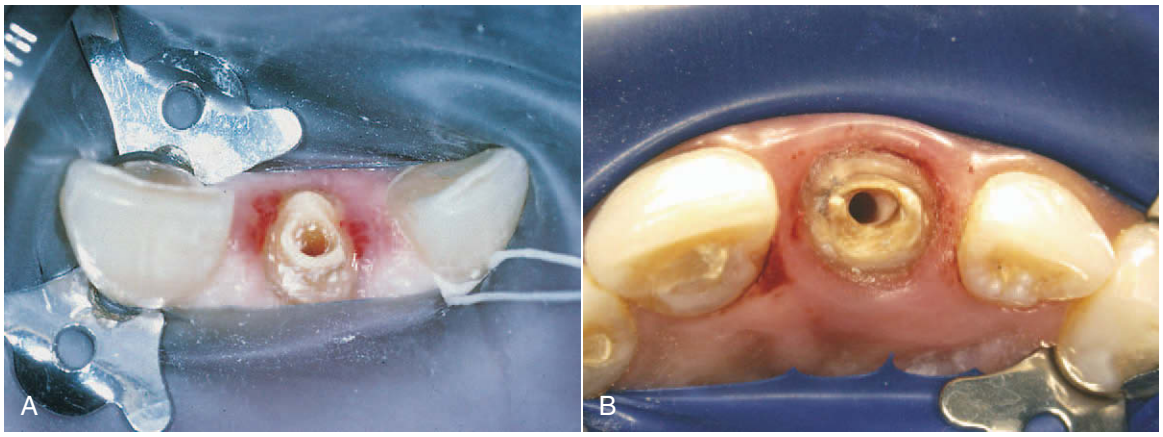

FIG. 5-27 Split-dam technique. **A,** Premolar clamp on maxillary central incisor along with ligation on the maxillary canine prevents dam slippage and aids in dam retraction during endodontic treatment on broken-down maxillary lateral incisor. **B,** Split dam used during post removal and retreatment of a maxillary central incisor. (***A,*** *Courtesy Dr. James L. Gutmann;* ***B,*** *courtesy Dr. Francisco A. Banchs.)*

it may leak or permit continued tearing when stretched over the clamp and tooth.

Orientation of the Dam and Bunching

The rubber dam must be attached to the frame with enough tension to retract soft tissues and prevent bunching, without tearing the dam or displacing the clamp. The rubber dam should completely cover the patient's mouth without infringing on the patient's nose or eyes. To prevent bunching of the dam in the occlusal embrasure, only the edge of the interseptal portion of the dam is teased between the teeth. Dental floss is then used to carry the dam through the contacts. These contacts should always be tested with dental floss before the dam is placed. A plastic instrument is used to invert the edge of the dam around the tooth to provide a seal.

Problem Solving in Tooth Isolation

Leakage

The best way to prevent seepage through the rubber dam is meticulous placement of the entire system. Proper selection and placement of the clamp; sharply punched, correctly positioned holes; use of a dam of adequate thickness; and inversion of the dam around the tooth all help reduce leakage through the dam and into the root canal system.[6,37,46,65] Nevertheless, there may be clinical situations in which small tears, holes, or continuous minor leaks may occur. These often can be patched or blocked with Cavit (3M), OraSeal caulking (UltraDent Products, South Jordan, UT), rubber base adhesive,[9] "liquid" rubber dam, or periodontal packing. If leakage continues, the dam should be replaced with a new one.

Because salivary secretions can seep through even a well-placed rubber dam, persons who salivate excessively may require premedication to reduce saliva flow to a manageable level. Failure to control salivation may result in salivary contamination of the canal system and pooling of saliva beneath the dam, as well as drooling and possible choking. Such occurrences can disrupt treatment and should be prevented. Excessive saliva flow can be reduced with an anticholinergic drug, such as atropine sulfate, propantheline bromide (Pro-Banthine), methantheline (Banthine), or glycopyrrolate (Robinul).[34] Therapeutic doses of atropine sulfate for adults range from 0.3 to 1 mg *per os,* 1 to 2 hours before the procedure. The synthetic anticholinergic drug propantheline bromide reportedly has fewer side effects than methantheline.[34] The usual adult dose of propantheline bromide for an adult is 7.5 to 15 mg, taken orally 30 to 45 minutes before the appointment. Because anticholinergics can cause undesirable autonomic effects, especially through various drug interactions, they should be used only in specific cases and only as a last resort.

Unusual Tooth Shapes or Positions That Cause Inadequate Clamp Placement

Some teeth do not conform to the variety of clamps available. These include partially erupted teeth, teeth prepared for crowns, and teeth fractured or broken down to the extent that their margins are subgingival. To handle these cases, rubber dam retainers may be customized by modifying the jaws to adapt to a particular tooth (Fig. 5-28).[69] In partially erupted teeth or cone-shaped teeth, such as those prepared for full coverage, one technique[68] is to place spots of self-curing resin on the cervical surface of the tooth. These resin beads act as a scaffold for the retainer during treatment. Another method[32] is to place small acid-etched composite lips on the teeth; these resin lips serve as artificial undercuts and remain on the teeth between appointments. When the root canal treatment is complete, the resin beads are easily removed. In multiple-treatment cases involving misshapen teeth, a customized acrylic retainer[63] can be used in conjunction with a dam to isolate the operating field.

Loss of Tooth Structure

If insufficient tooth structure prevents the placement of a clamp, the clinician must first determine whether the tooth is periodontally sound and restorable. Meticulous and thorough treatment planning often can prevent embarrassing situations for both the doctor and patient. One example is the case in which the endodontic treatment is completed before restorability is determined; it is then discovered that the tooth cannot be restored.

Once a tooth is deemed restorable but the margin of sound tooth structure is subgingival, a number of methods should be

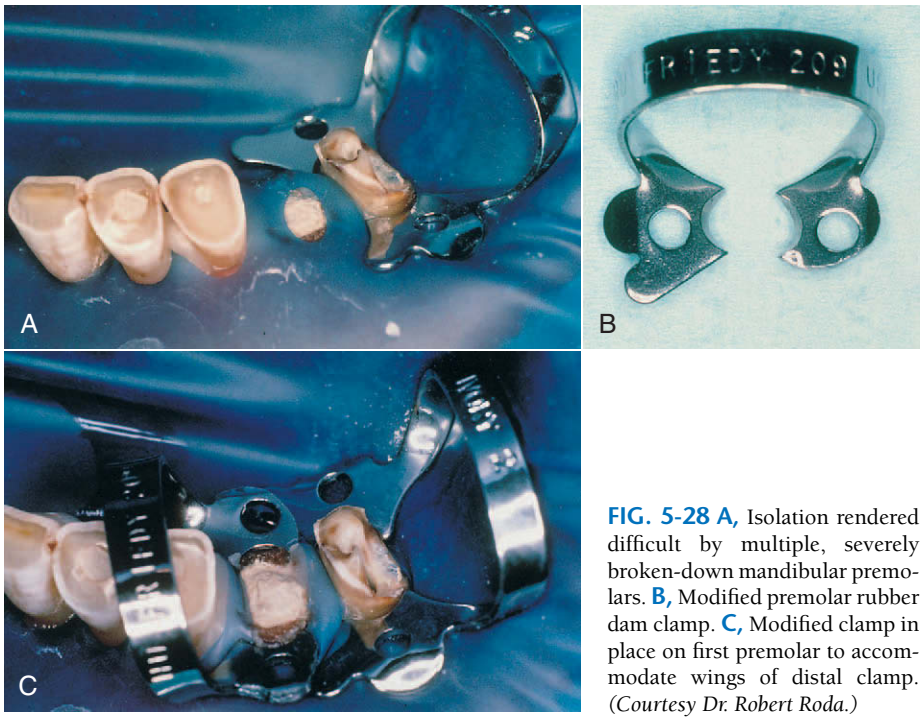

FIG. 5-28 A, Isolation rendered difficult by multiple, severely broken-down mandibular premolars. **B,** Modified premolar rubber dam clamp. **C,** Modified clamp in place on first premolar to accommodate wings of distal clamp. *(Courtesy Dr. Robert Roda.)*

considered. As mentioned earlier, less invasive methods, such as using a clamp with prongs inclined apically or using an S-G clamp, should be attempted first (see Fig. 5-24). If neither of these techniques effectively isolates the tooth, the clinician may consider clamping of the attached gingiva and alveolar process. In this situation it is imperative that profound soft tissue anesthesia exists before clamp placement. Although the procedure may cause some minor posttreatment discomfort, the periodontal tissues recover quickly with minimal posttreatment care.

Restorative Procedures

If none of the techniques mentioned previously is desirable, a variety of restorative methods may be considered to build up the tooth so that a retainer can be placed properly.[45,46,65] A preformed copper band, a temporary crown, or an orthodontic band (Figs. 5-29 and 5-30) may be cemented over the remaining natural crown. This band or crown not only enables the clamp to be retained successfully but also serves as a seal for the retention of intracanal medicaments and the temporary filling between appointments, if more than one appointment is necessary. These temporary bands or crowns have several disadvantages. One of their main problems is their inability to provide a superior seal. Another concern is that particles of these soft metals or cement can block canal systems during access opening and instrumentation. Third, these temporary crowns and bands, if they become displaced or are not properly contoured, can cause periodontal inflammation.

On occasion, so little tooth structure remains that even band or crown placement is not possible. In these cases it becomes necessary to replace the missing tooth structure to facilitate placement of the rubber dam clamp and prevent leakage into the pulp cavity during the course of treatment.[45,46,65] Replacement of missing tooth structure can be accomplished with composite resins; glass ionomer cements, such as Ketac-Silver (3M, St. Paul, MN), Fuji II (GC America, Alsip, IL) (Fig. 5-31), or Photac-Fil (3M); or dentin-bonding systems, such as Adper Scotchbond (3M), the Tenure bonding system (Den-Mat, Santa Maria, CA), Gluma (Heraeus Kulzer, South Bend, IN), OptiBond (Kerr, Orange, CA), PermaQuik (UltraDent Products, South Jordan, UT), or C&B-Metabond (Parkell, Edgewood, NY).[65] Although these newer dentin-bonding systems form a strong, immediate bond and are generally simple to use, any restorative method for building up a broken-down tooth is time-consuming, can impede endodontic procedures, and may duplicate restorative treatment. Many restorations that have been hollowed out by access cavities are weakened and require redoing.

Canal Projection

Canal projection is a technique that facilitates preendodontic buildup of broken-down coronal and radicular structure while preserving individualized access to the canal.[42] Although any of a number of syringeable materials (glass ionomer cements, temporary cements, permanent cements, etc.) and even "packable" composites may be used to project the canals, bonded injectable autopolymerizing composites have proven to be the most versatile and reliable buildup material for this technique (Fig. 5-32). The advantages of the technique are numerous:

Isolation: When deep coronal–radicular defects prevent clamp retention, a tooth is often considered to be endodontically untreatable. Canal projection essentially replaces missing structures to facilitate clamp retention, rendering many structurally debilitated teeth endodontically treatable.

Seal of chamber floor: The accessory canals that exit the chamber floor into the furcation are well documented and can conduct inflammatory agents from the deteriorating pulpal system into the furcation. In addition, when caries or

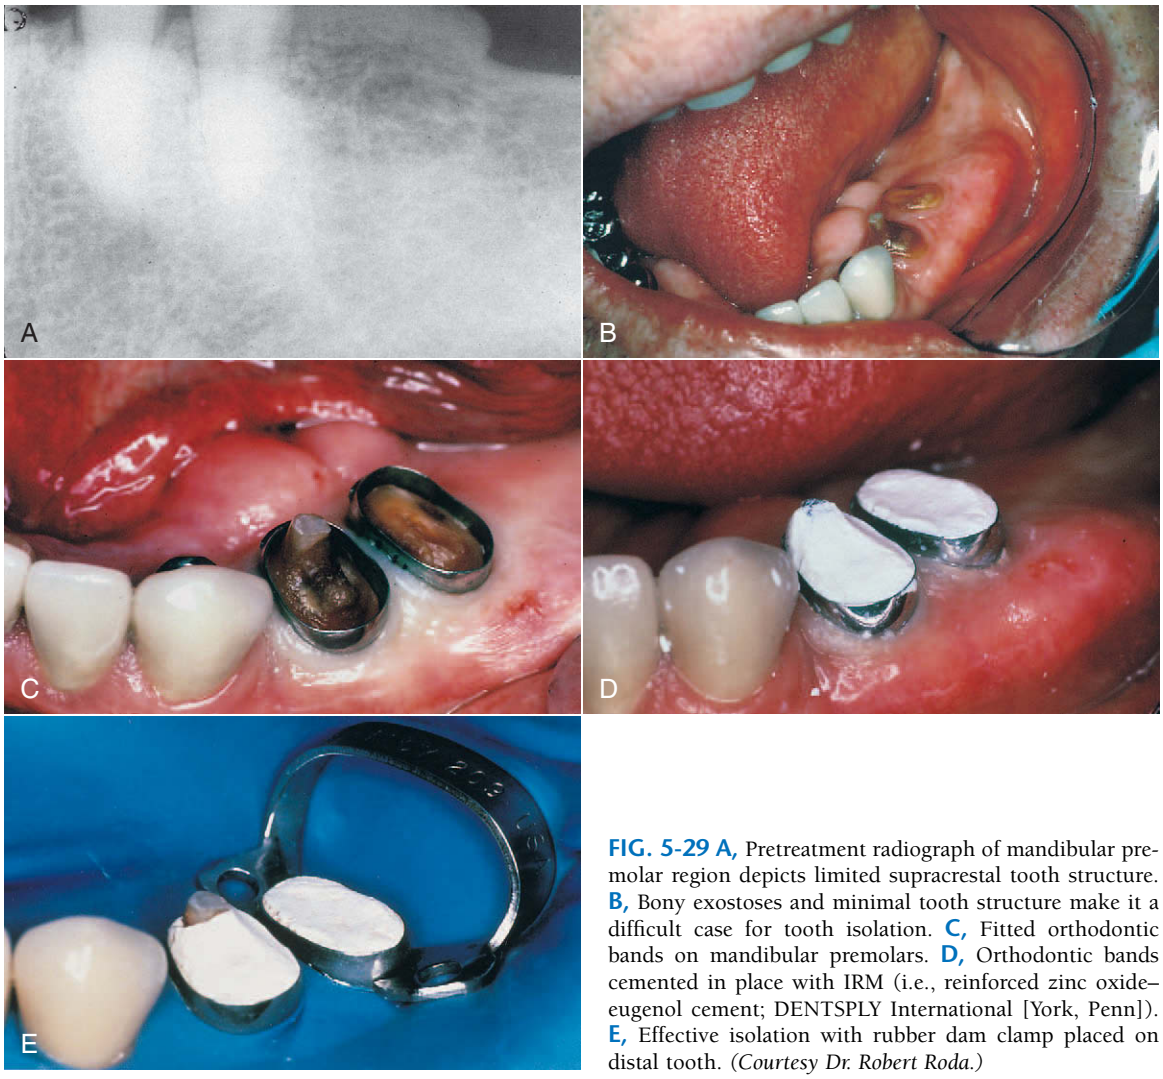

FIG. 5-29 A, Pretreatment radiograph of mandibular premolar region depicts limited supracrestal tooth structure. **B,** Bony exostoses and minimal tooth structure make it a difficult case for tooth isolation. **C,** Fitted orthodontic bands on mandibular premolars. **D,** Orthodontic bands cemented in place with IRM (i.e., reinforced zinc oxide–eugenol cement; DENTSPLY International [York, Penn]). **E,** Effective isolation with rubber dam clamp placed on distal tooth. *(Courtesy Dr. Robert Roda.)*

exploratory procedures lead to a paper-thin chamber floor, the risk of contaminants extending into the furcal apparatus increases significantly. Often such complicated cases require multiple visits, and the interappointment interval with customary temporary coronal seal provides opportunities for serious furcation degradation, particularly if a patient does not return in a timely fashion for completion of treatment. Sealing the chamber floor early in treatment greatly reduces this risk. As an initial step in the endodontic process, canal projection using bonded composite achieves this early objective.

Elongation of canals: The canal projection process elongates the "hydraulic chamber" of each canal from the access cavity floor to the occlusal surface, offering advantages during the hydraulic condensation of obturation materials. Essentially all currently accepted warm vertical compaction techniques (conventional warm vertical compaction, warm sectional compaction, and continuous wave compaction) rely on the rheology that takes place between the chamber floor and the primary exit of the canal. These methods focus their hydraulic effects on the apical region while only incidentally addressing those accessory and lateral canals that exit from the more coronal aspects of the system. In contrast, when the canal is projected, the hydraulic chamber is elongated as much as 5 to 10 mm such that the rheology occurs not just between the chamber floor and the primary canal exit but also between the occlusal surface and the primary exit. This allows for additional warm vertical compaction "strokes," additional warm "sections" of gutta-percha, or additional milliseconds spent in the continuous wave of compaction. Regardless of which hydraulic condensation method is used, canal projection provides greater opportunity to address coronally positioned exits.

Overlay of perforation repair: Early repair of perforation defects can have a significant effect on success of perforation treatment. As such, performing perforation repair before completion of endodontic therapy is often preferable. The delicate nature of these types of repairs, however, leaves them vulnerable to reaggravation during subsequent cleaning, shaping, and obturation procedures. It can be most disheartening to perform a complicated perforation repair procedure only to see it herniate into adjacent periodontal ligament and bone under obturation hydraulics. Delaying the repair until endodontic therapy is completed may put

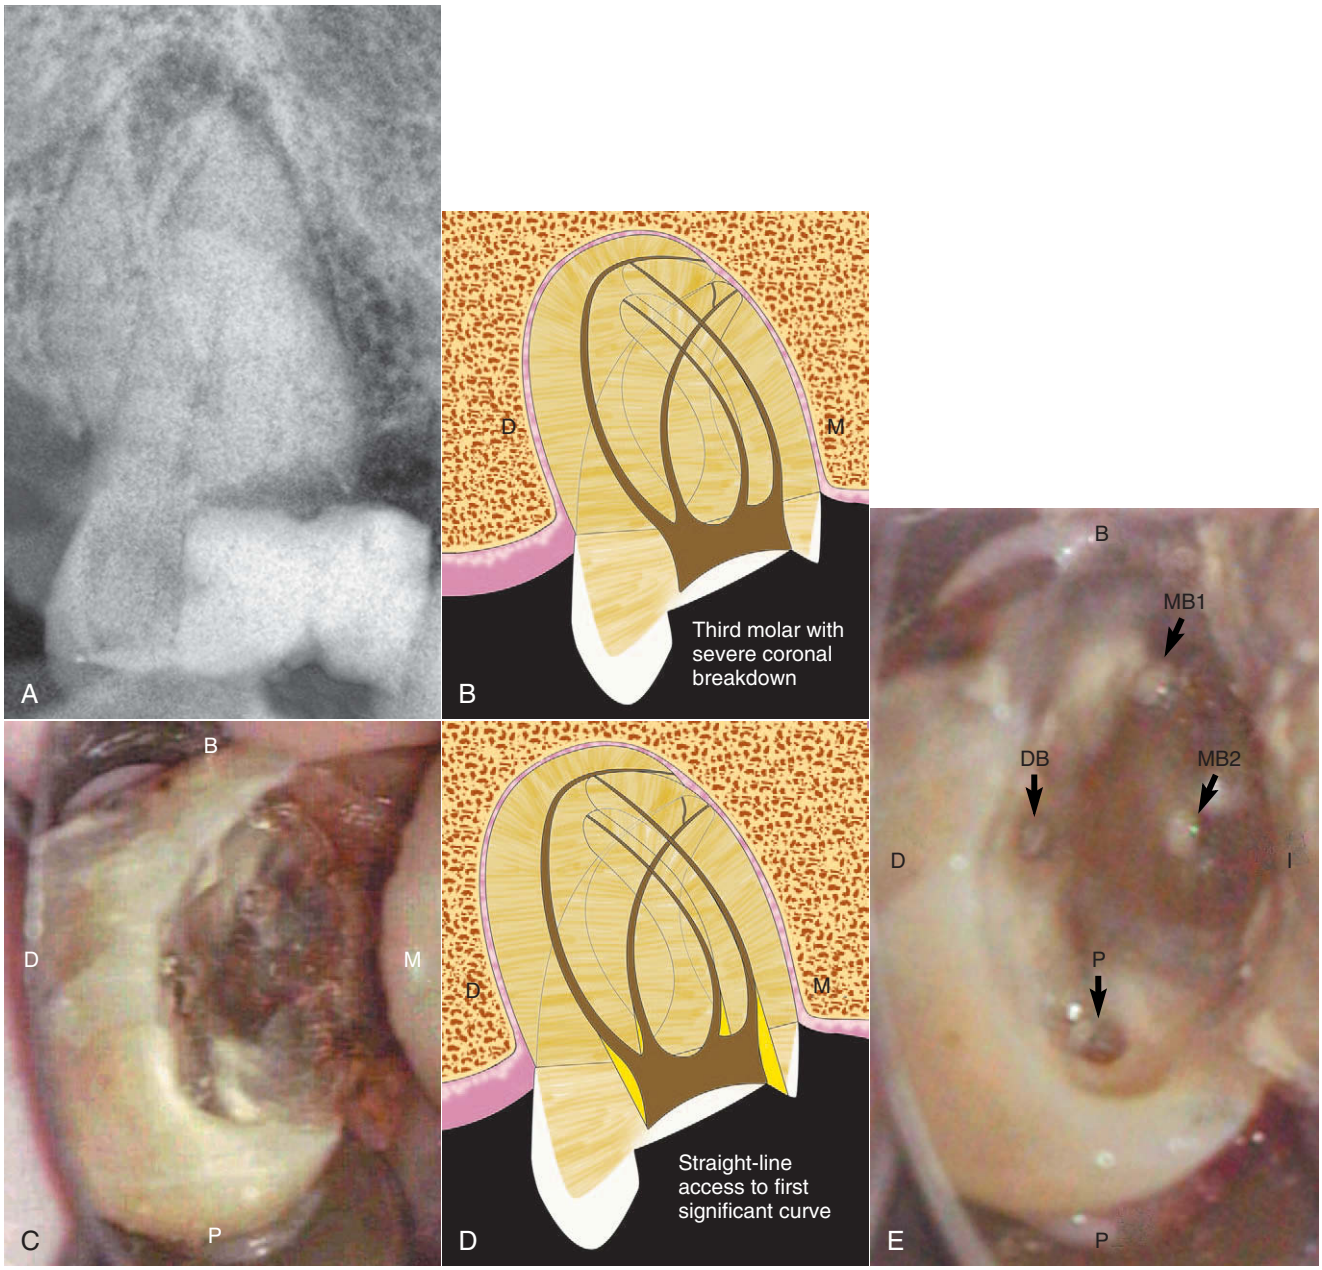

FIG. 5-32 Canal projection technique. **A-C,** In a tooth with severe coronal breakdown, after gaining access and locating all canals, it is essential to perform a thorough high-magnification examination of the floor and walls and to examine, as deeply as possible, all canals to ensure that all branchings and other possible irregularities have been identified before proceeding. **D,** In curved canals, straight-line access is created to the first significant curvature by removing dentin "triangles" with small, slow-speed round burs, working into the bulk of each root (i.e., working away from the furcal aspect of the root). **E,** If there is no significant curvature in a particular canal, then the orifice should be dimpled to the depth of a #2 slow-speed round bur. An appropriate matrix barrier is applied, and all bondable surfaces are etched and primed. Files are selected that will fit well into the body of each canal, and projectors (CJM Engineering, Santa Barbara, CA), tapered plastic sleeves available in various dimensions, are placed onto the files. The files are then inserted into the canals, and the projectors are slid apically until they are drawn into the seat of the previously prepared straight-line access or dimples.

the tooth at risk if the treatment cannot be completed in a single visit. In addition, performing endodontic therapy in the presence of an unrepaired perforation may needlessly expose the perforation site to irritating solvents and irrigants and to accidental penetration by instruments. In many cases, perforation repair with mineral trioxide aggregate (MTA) can be performed before completion of endodontic therapy.[28] After confirmation that the MTA has set, canal projection offers a means of fortifying the repair by overlaying it with a bonded resin or glass ionomer before proceeding with endodontic therapy.

Prevention of perforation: In those circumstances that lead to a paper-thin chamber floor, the risk of inadvertent perforation with a file, explorer, or bur can be reduced or

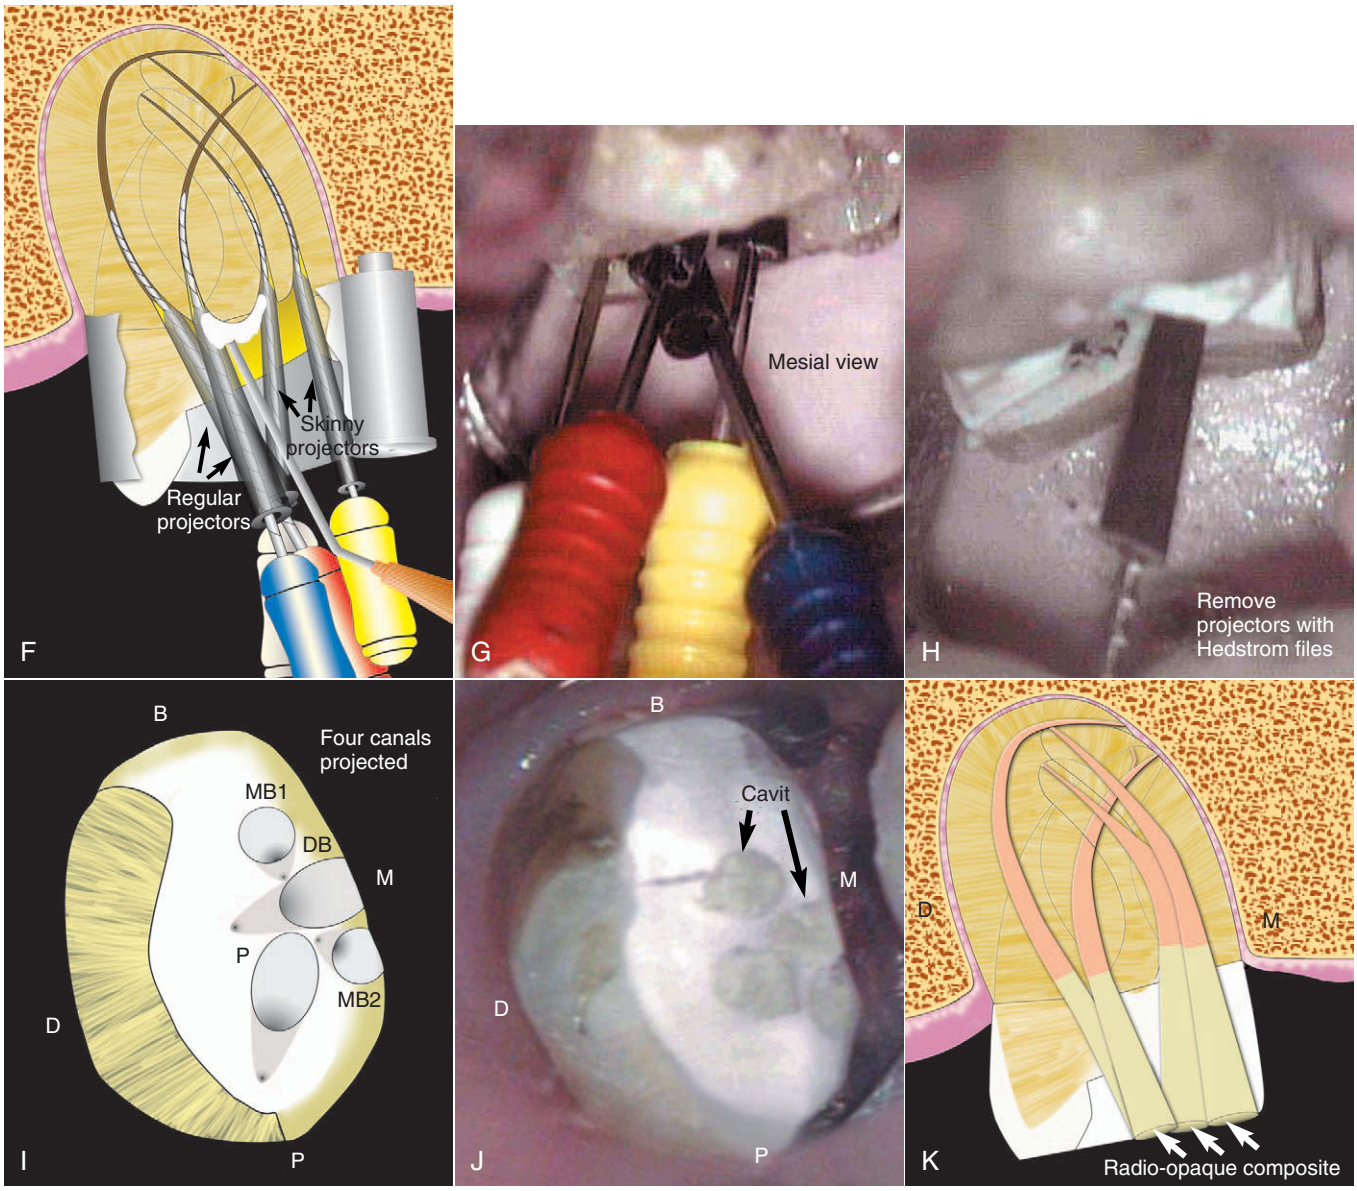

FIG. 5-32, cont'd F-G, In this particular example, regular projectors were used in the D and P canals and skinny projectors were used in the MB1 and MB2 canals to accommodate their proximity to each other. With the canals occupied by the files and projectors, autopolymerizing bonding agent is applied and distributed over all primed surfaces with a blast of air. Autopolymerizing composite buildup material is then injected from the chamber floor to the cavosurface of the access cavity. On early signs of polymerization, the files are removed, leaving the projectors embedded in the buildup material. A bull-nosed diamond is used to contour the composite and to flatten the occlusal surface along with the embedded projectors. Leaving the projectors embedded at this stage prevents composite debris from collecting in the projected canals. **H,** The projectors are removed by engaging a #60 Hedström file in the lumen of each projector and withdrawing. The external surfaces of projectors are treated with a releasing agent that provides for reliable removal from all types of buildup material. **I,** Depending on how the projectors are arranged relative to each other as they traverse from the chamber floor through the access cavity to the occlusal surface, the projected orifices will lie in various configurations on the occlusal surface. This procedure creates durable endodontic reference points. **J,** If a second treatment visit is required, the projected canals may be conveniently sealed by snipping 2 mm from the large-diameter end of the projectors, reinserting them into their respective canals, and sealing with Cavit. On the patient's return, the Cavit seals are removed with a #6 slow-speed round bur, a #60 Hedström file is again engaged in the lumen of each projector, and the projectors are withdrawn, leaving the canals free of temporary filling debris. **K,** After cleaning, shaping, and obturation, the projected portions of the canals are "dressed" with a high-speed football diamond to remove residual sealer and to freshen the composite, making it receptive to the final composite that is injected directly over gutta-percha from the subchamber level to the cavosurface of each projected canal.

Continued

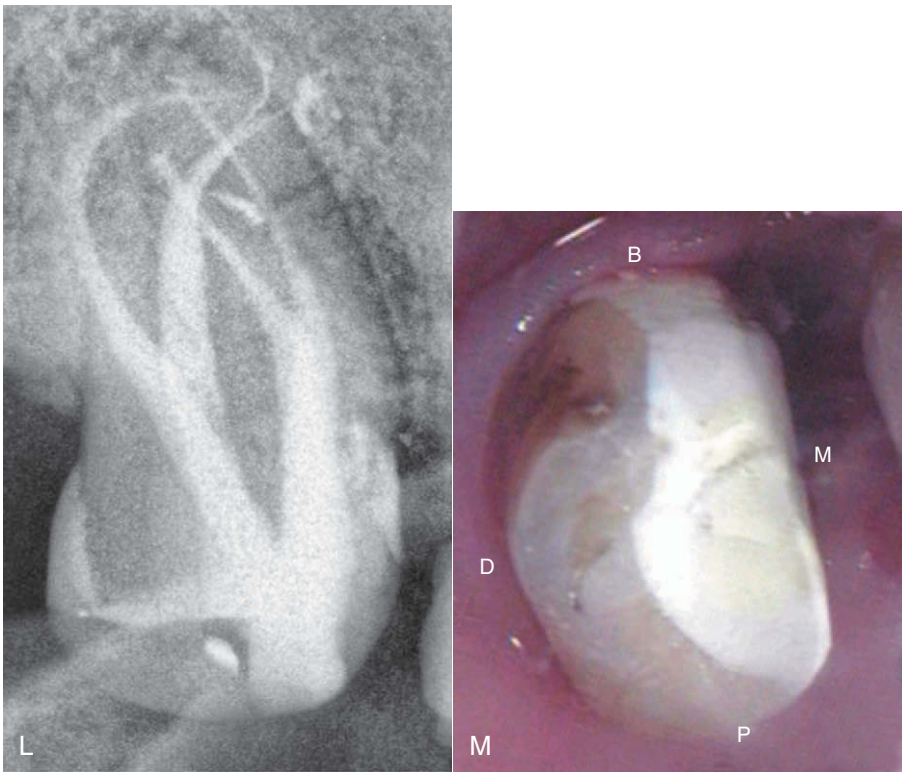

FIG. 5-32, cont'd L, Selecting a composite for this final step that is more radiopaque than the buildup composite creates a unique radiographic appearance showing the canal continuously flowing from the root end to the occlusal surface. **M,** Crown preparation can proceed immediately. A post can be easily placed through the projection buildup at the completion of endodontic therapy. Using either a high-speed football diamond or a slow-speed #8 round bur, the projected portion of the canal to receive the post is enlarged to the level of the chamber floor. According to the particular type of post to be placed, the radicular aspect of the canal is prepared in the typical fashion, and the post is cemented or bonded into the canal. The coronal portion of the post should be surrounded by syringeable composite, effectively anchoring the buildup to the natural tooth structure. *D,* Distal; *M,* mesial; *B,* buccal; *P,* palatal; *DB,* distobuccal; *MB1,* main mesiobuccal canal; *MB2,* second mesiobuccal canal. *(Courtesy Dr. C. John Munce.)*

eliminated by placing a preendodontic buildup via canal projection.

Recontour of irregularities on chamber floor and walls: Irregularities on the access cavity floor and walls can lead to complications during treatment. Misdirected access cavities, divots in walls, misdirected post preparations and ledges, and so on can be "corrected" by essentially reconstructing the walls and floor around "internal matrix barriers" via canal projection.

Reduced potential for crack initiation or propagation: On posterior teeth in particular, the period between initiation of endodontic therapy and placement of a restoration that provides cuspal protection can introduce the risk of coronal–radicular fracture—the longer the time period, the greater the risk. Bonded coronal buildup has been shown to reduce this risk.[24,35] Bonded canal projection performed at the first endodontic treatment visit imparts a measure of protection against the development of a fracture from the time treatment is initiated until the tooth is permanently restored. In teeth that present with incipient fractures, early placement of a bonded buildup can reduce the likelihood of propagation of these fractures as well.

Prevention of ingrowth of tissues: When coronal or radicular defects extend to axial walls at or beyond the gingival level, tissue ingrowth leads to contamination during endodontic therapy and subsequent restorative procedures. Preendodontic buildup, as with canal projection, eliminates this complexity.

Individualization of canals: In multicanal teeth, as the projectors pass through the buildup material to the occlusal surface, they can be oriented such that they are slightly separated from each other before the buildup material polymerizes. This can simplify management of canals that lie in close proximity to each other on the chamber floor. It also provides for individualization of the canals so that specific solvents, irrigants, medicaments, lubricants, and other agents can be placed into specific canals.

Elimination of "blind exploration" on the chamber floor and improvement of mechanics related to handpiece-driven files: Once all canals have been located, straight-line access created, and the canals projected to the occlusal surface of the buildup, the resultant projected orifices will lie clearly visible on the surface of the projection buildup, no longer obscured by prominent marginal ridges and other visual obstructions. This also creates a significant advantage for entry of handpiece-driven files—particularly nickel–titanium files—into mesial canals of molars. By virtue of their increased long-axis dimension, the tips of handpiece-driven files can be difficult to introduce into mesial canals, and nickel–titanium files are even more difficult because they will not retain a bend. When the canals are projected onto the occlusal surface of the preendodontic buildup, however, it becomes a simple matter to place the file tip within the rim of the projected canal on the occlusal surface, and then by merely advancing the file, it is driven smoothly into the canal.

Periodontal Procedures

As a result of excessive crown destruction or incomplete eruption, the presence of gingival tissue may preclude the use of a clamp without severe gingival impingement. Various techniques of gingivectomy (Fig. 5-33) or electrosurgery have been suggested for cases in which the remaining tooth structure still

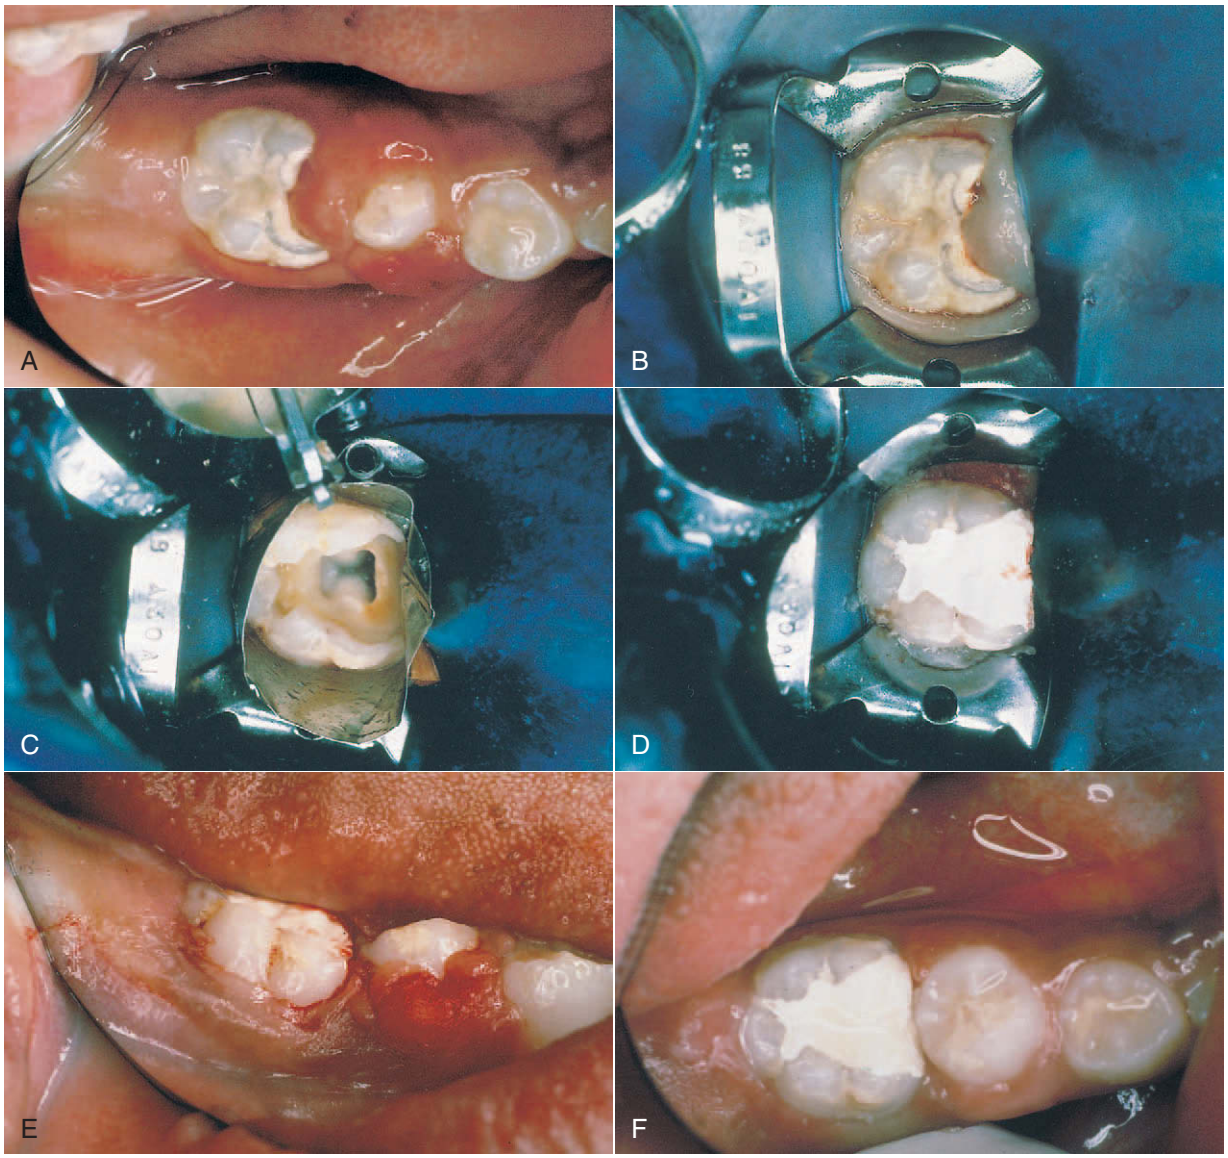

FIG. 5-33 A, Gingival hypertrophy on mandibular molar and erupting premolar of a young patient; mandibular molar requires root canal treatment. **B,** Rubber dam clamp impinging on gingival tissues; tissue removed with scalpel. **C,** Automatrix placed immediately after tissue removal; bleeding was minimal. **D,** Placement of IRM temporary restoration after pulpectomy. **E,** Posttreatment facial view immediately after gingivectomy; note hemostasis. **F,** Six-week posttreatment occlusal view exhibits fully exposed mandibular molar and recently erupted premolar. (*Courtesy Dr. Robert Roda.*)

lies above the crestal bone. With an inadequate zone of attached gingiva, osseous defects, or a poor anatomic form, an apically positioned flap with a reverse bevel incision is the technique of choice to "lengthen" the crown.[45,46]

Electrosurgery and the conventional gingivectomy are crown-lengthening procedures for teeth that have sufficient attached gingiva and no infrabony involvement.[45,46] The electrosurgery method offers the advantage of leaving a virtually bloodless site for immediate rubber dam placement. Electrosurgery units have become highly sophisticated and are capable of providing both cutting and coagulating currents that, when used properly, will not cause cellular coagulation. The wide variety of sizes and shapes of surgical electrodes enables the clinician to reach areas inaccessible to the scalpel. Further, electrosurgery facilitates the removal of unwanted tissue in such a manner as to recreate normal gingival architecture. This feature, combined with controlled hemostasis, makes the instrument extremely useful in the preparation of some teeth for placement of the rubber dam clamp.

The main drawback of electrosurgery is the potential for damage to the adjacent tissues; if the electrode contacts bone, significant destruction of bone can occur. As a result this technique is not recommended when the distance between the crestal level of bone and the remaining tooth structure is minimal. Compared with electrosurgery, conventional gingivectomy presents the major problem of hemorrhage after the procedure; this forces delay of endodontic treatment until tissues have healed.

The apically positioned flap[45,46] is a crown-lengthening technique for teeth with inadequate attached gingiva, infrabony pockets, or remaining tooth structure below the level of crestal bone. With this technique as well, endodontic treatment should be delayed until sufficient healing has occurred.

Orthodontic Procedures

The most common indication for orthodontic extrusion is a fracture of the anterior tooth margin below the crestal bone.[45,46] The clinician should be aware that, because bone and soft tissue attachments follow the tooth during extrusion, crown-lengthening procedures after extrusion are often necessary to achieve the desired clinical crown length and restore the biologic and aesthetic tissue relationships. Ultimately, the purpose of orthodontic extrusion is to erupt the tooth to provide 2 to 3 mm of root length above crestal bone level.

SUMMARY

Success in endodontic therapy is predicated on a host of factors, many of which are controllable before the clinician ever initiates treatment. Proper and thorough preparation of both patient and tooth for endodontic treatment should lay the groundwork for a relatively trouble-free experience that will increase the chances for the ultimate success of the entire treatment.

CHAPTER

6

Armamentarium and Sterilization

PAUL D. ELEAZER

CHAPTER OUTLINE

SELECTION OF THE ARMAMENTARIUM
PRETREATMENT STERILIZATION AND DISINFECTION
TREATMENT
GENERAL CONSIDERATIONS FOR THE OFFICE
FUTURE CONSIDERATIONS

Preparation for endodontic treatment requires a somewhat different approach compared with many other types of dental therapy. Endodontic treatment breaks through the body's primary protective barrier, the integumentary system. Teeth are a specialized part of this system that also includes skin and mucous membranes; collectively, the integumentary system serves to protect humans from invasion by microbes, among other functions. This barrier is breached when caries, trauma, or other insults provide entry into the pulpal space of a tooth. Sterile instruments and proper technique are needed to avoid contamination by microorganisms or noxious chemicals during endodontic therapy.

The well-prepared clinician realizes that a posttreatment infection could be caused by a break in sterile technique. The astute clinician realizes that time spent before treatment in the organization and sterilization of instruments and supplies will lead to fewer posttreatment patient problems and result in a more efficient practice.

In addition to the need for impeccable sterility, endodontics differs from many other aspects of dentistry. Access and visibility are severely limited by the nature of the irregular and branching canal spaces within the roots. Individual variation means that clinicians cannot know exactly what condition is present throughout the entire root canal system (see Chapter 7 for more details). Enhanced lighting and magnification have resolved visual access problems to some extent (Figs. 6-1 to 6-4). Nevertheless, limitations remain and there continues to be a need for special instruments and techniques.

SELECTION OF THE ARMAMENTARIUM

Preparation for treatment begins with selection of the armamentarium for routine endodontic patient care. Instruments used for every patient should be assembled and sterilized before use. Box 6-1 lists a typical armamentarium that can be customized for the individual clinician (Figs. 6-5 to 6-7).

Root canal instruments of appropriate length and type, including files, reamers, broaches, and specialized burs, may be sterilized separately because variables (e.g., tooth length, canal size, and clinical diagnosis) may affect this part of the armamentarium. Additional items that are needed occasionally (e.g., chlorhexidine and an intraosseous injection kit) should be in sterile containers and readily available to the dental assistant (Figs. 6-8 and 6-9). This approach provides a basic endodontic setup tray with optional items sterilized and ready for use in individual cases. The overarching philosophical approach is to develop a standard setup for all patients and to have readily available specialized kits for specific procedures or clinical situations.

PRETREATMENT STERILIZATION AND DISINFECTION

The next phase after selection of the armamentarium is to develop a pretreatment sterilization plan. *Sterile* is defined as the absence of life forms. *Disinfection* means killing most life forms, especially pathogens. As commonly used, the term *disinfection* does not include killing spores. Manufacturers' claims for disinfectants are based on performance against *Mycobacterium*, which is the genus that includes the species that causes tuberculosis (TB). For assessing virucidal efficacy, the astute clinician should be aware that agents that kill the hardy hepatitis B virus will likely be effective at destroying all viruses.

The Centers for Disease Control and Prevention (CDC, Atlanta, GA) released new guidelines for sterilization in 2003, and these are available on the Internet (http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5217a1.htm).[12] Box 6-2 lists the elements of a typical sterilization plan. These guidelines clarify the need for staff training programs to ensure that sterilization procedures are effective. Specific items include weekly monitoring of the effectiveness of the process with biologic monitors, for example, packets of spores are placed in the sterilizer

BOX 6-1

Armamentarium for Routine Endodontic Patient Care

- Mirror
- Periodontal probe and standard dental explorer
- Anesthetic syringe
- Rubber dam instruments
  - Rubber dam punch
  - Rubber dam clamp holder
  - Rubber dam frame
- High-speed handpiece and burs
- Low-speed handpiece and burs
- Long shank excavator (31L)
- Canal-irrigating syringe(s), with container(s) for solution(s)
- Mixing spatula and mixing surface
- Obturation instruments
- Plastic instrument for temporary filling

for one cycle. The spores are then placed in growth medium to ensure that all have been killed. Overpacking the sterilizer is a common reason for inadequate sterilization because steam cannot penetrate as well. Thus assessment of the effectiveness of the sterilization plan is an essential feature of pretreatment planning (Fig. 6-10). The results of weekly monitoring should be kept in a log.

Monitoring the sterilizer by watching the gauges or relying on printouts of temperature, pressure, and time helps to ensure patient safety, but weekly biologic monitoring guards against sensor failure. Heat-sensitive indicators, such as special tapes that change color when exposed to sterilizer temperatures, are

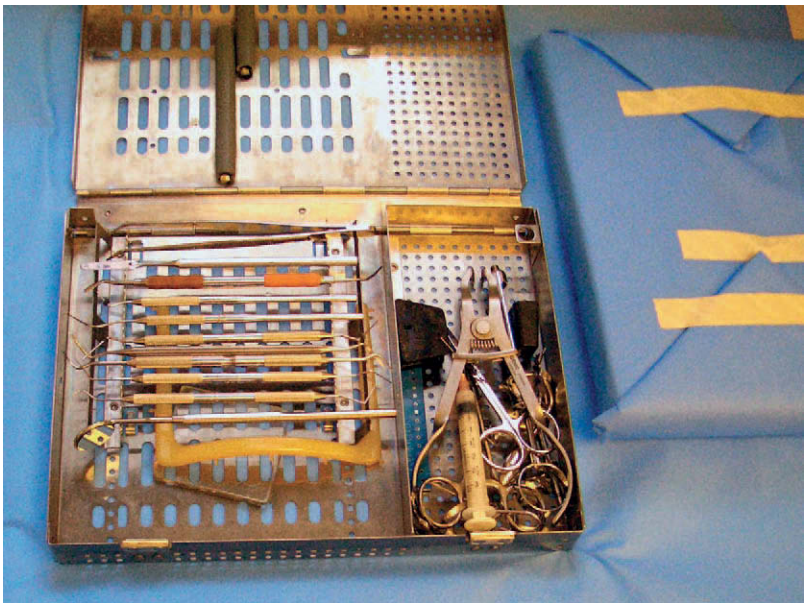

FIG. 6-5 IMS (instrument management system) cassette. *(Courtesy Hu-Friedy, Chicago, IL.)*

FIG. 6-6 Cassette wrapped in porous autoclave paper in preparation for sterilization. *(Courtesy Hu-Friedy, Chicago, IL.)*

also ineffective to ensure proper sterilization because these heat-sensing indicators merely show that the desired temperature has been reached, not that sufficient time has passed for proper killing. Accordingly, they are best used to simply record that the package was autoclaved; they should not be interpreted to indicate sterility.

Further guidelines about sterilizers include drying of instruments before removing them from the sterilizer. Wet wraps may tear easily or allow microbes to reach the sterile contents by wicking through the wrap. In addition, cooling avoids thermal injury to personnel. Some of the new sterilizers work faster because they vacuum air from the chamber before sterilization; these models also cool faster because of a second vacuum cycle after sterilization.

Another guideline reinforces the previous policy that the pathway from the sterilizer to the point of use should not cross the path of contaminated instruments as they are brought from the treatment area, cleaned, and packaged for resterilization. Thus separate areas are required for cleaning/sorting/packaging and for sterilization and cool down.

BOX 6-2

Elements of a Sterilization Plan

1. Transporting contaminated items from the operatory
   a. Items must be stored in a container to prevent perforation
2. Instrument-processing area
   a. Instruments must be sorted, cleaned (e.g., removal of all visible debris by scrubbing, ultrasonic cleaner), and rinsed with water in an area separate from sterilization
   b. Instruments should be inspected, assembled into trays, and wrapped for sterilization in packages containing sterilization indicator
   c. Instrument packages should be sterilized according to approved methods
   d. Instruments should be stored for event-related use
3. Environmental infection control
   a. Clinical contact surfaces (barrier protection, spray disinfectants)
   b. Dental unit water lines
   c. Housekeeping surfaces
4. Nonregulated and regulated medical waste
5. Monitoring plan
6. Training plan

Modified from Kohn WG, Collins AS, Cleveland JL, et al: Centers for Disease Control and Prevention (CDC): Guidelines for infection control in dental health-care settings—2003. MMWR Recomm Rep 52(RR-17):1, 2003. Available at http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5217a1.htm.

Approved methods of sterilization include pressurized steam (autoclaving), pressurized heated chemicals, dry heat, and cold chemicals (Figs. 6-11 to 6-13). Cold chemicals are not favored because the time cycle is difficult to monitor; they are recommended only for those items that cannot be heat sterilized. Room temperature chemical sterilants are not time efficient enough to be popular in dentistry. Cold sterilants

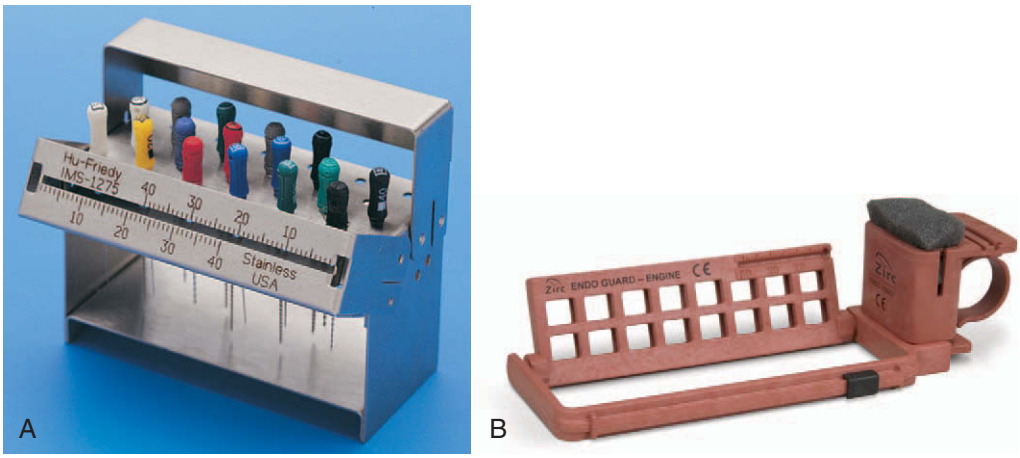

FIG. 6-7 A, File stand. **B,** File stand for rotary instruments. (***A,*** *Courtesy Hu-Friedy, Chicago, IL.* ***B,*** *Courtesy Zirc, Buffalo, MN.)*

FIG. 6-8 Ruddle post removal system. *(Courtesy SybronEndo, Orange, CA.)*

FIG. 6-9 Micro-apical placement device for insertion of MTA filling. *(Courtesy Roydent Dental Products, Johnson City, TN.)*

generally require extended soak times. Their proper use necessitates rinsing in sterile water to remove traces of disinfectant and handling with sterile tongs or sterile gloves to place them in a sterile storage container after treatment. Cold sterilants are poisonous and can be harmful to patients, even in small amounts.

Do not pack instrument sets tightly. Boxes with plenty of holes to admit steam through the overwrap are ideal. Closed boxes should be autoclaved with the lids ajar. Autoclaving is the typical method of sterilization for most health care facilities. The usual cycle is 30 minutes at 250° F (121° C) at 15 psi. Many offices use two autoclaves. This allows for rapid sterilization of handpieces or other expensive equipment to reduce inventory requirement, as well as serving as a backup when one machine is broken. Flash sterilization at higher temperatures of 273° F (134° C) for 10 minutes and 30 psi is also approved. The Statim brand autoclave (SciCan, Toronto, ON, Canada) uses the higher temperatures to reduce cycle time.

A Chemiclave chemical vapor sterilizer uses a solution of 72% ethanol and 0.23% formaldehyde in place of water in its "autoclave." This avoids the instrument corrosion typical of steam autoclaves. It uses 270° F (132° C) at 20 psi for 20 minutes, including drying time. It could be argued that a longer cycle time may be needed to meet guidelines for safety margins.[18] Ventilation or filtration is required to handle

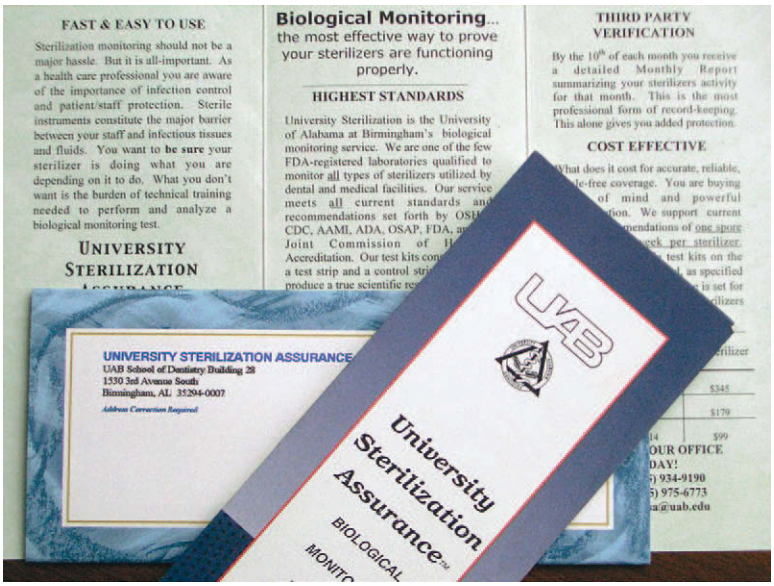

FIG. 6-10 Sterilizer monitoring service. Each week an envelope containing test spores is included in a sterilizer cycle and then mailed to the test center. Sterilizer performance is confirmed when no spores grow in culture. This lab is U.S. Food and Drug Administration (FDA) approved to monitor all types of sterilizers. *(Courtesy Dr. John Ruby, University of Alabama at Birmingham.)*

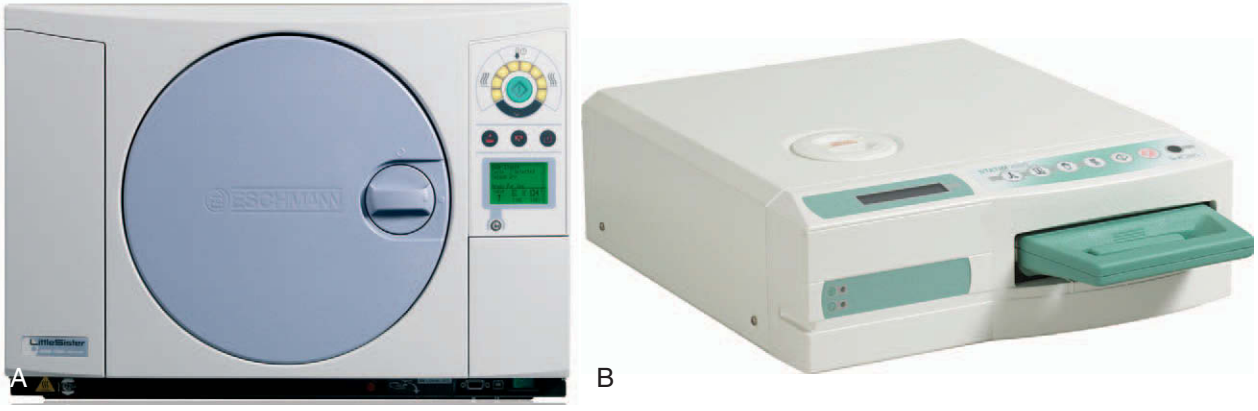

FIG. 6-11 Rapid-cycle autoclaves. **A,** Automatic, programmable autoclave. **B,** Statim cassette autoclave. *(**A,** Courtesy Eschmann Equipment, Lancing, West Sussex, England. **B,** Courtesy SciCan, Toronto, ON, Canada.)*

FIG. 6-12 Chemiclave chemical vapor sterilizer. *(From Bird DL, Robinson DS: Torres & Ehrlich Modern Dental Assisting, St. Louis, 2009, Saunders/Elsevier.)*

formaldehyde fumes. Chemiclave chemicals can dissolve into liquids, so liquids should be steam autoclaved.

Dry heat sterilizers, either still air in an oven or forced air, also avoid corrosion of instruments. After preheating the instruments to sterilizing temperature, still air models provide sterility in 1 hour at 375° F (191° C). The Cox sterilizer (Alfa Medical, Hempstead, NY) uses forced hot air of the same temperature and sterilizes in 6 minutes. Wrapped packs increase the time needed for processing. Hot air sterilizers may require special wraps.

In-operatory sterilizers were once popular among clinicians for decontaminating instruments during treatment. Such sterilizers achieved 450° F (218° C), and typical cycles consisted of a few seconds for metal instruments.[31] Glass beads or salt were used to transfer dry heat to endodontic canal instruments. These sterilizers are no longer approved for use because of the possibility that clinicians relied on them for sterilization between patients. One study found that they were ineffective at killing spores on cotton and paper products.[31] Endodontic instruments used for recapitulation in a canal as it is progressively decontaminated may be disinfected chemically.[16]

After patient treatment, barriers should be removed and surfaces disinfected (Fig. 6-14). Aerosols generated by dental care can land anywhere, and therefore all surfaces that may be touched during treatment of the next patient should be disinfected. Special attention should be given to instrument holders and hoses. Door and drawer pulls should be included in the disinfection routine or covered with barriers. Pens, pencils, and even patient charts should be considered contaminated.

Disinfection of the treatment room includes wiping all surfaces to be used with an appropriate disinfectant. Governmental agencies catalog such disinfectants as low-level and intermediate-level disinfectants, and Table 6-1 provides

TABLE 6-1

Chemicals for Disinfection

Level	Spectrum	Use	Examples
Low level	All bacteria except mycobacteria and spores Some fungi and some viruses	Surfaces without blood	Quaternary ammoniums, some phenolics, some iodoforms
Intermediate level	Mycobacteria, not spores Most fungi and most viruses	Surfaces with blood	Quaternary ammoniums with alcohol, chlorines, phenolics, iodoforms
High level	All microbes except spores	Immersion	Glutaraldehyde, strong peroxides, *o*-phthalaldehyde

Note that high-level disinfectants are used as room-temperature sterilizing solutions with extended contact times.

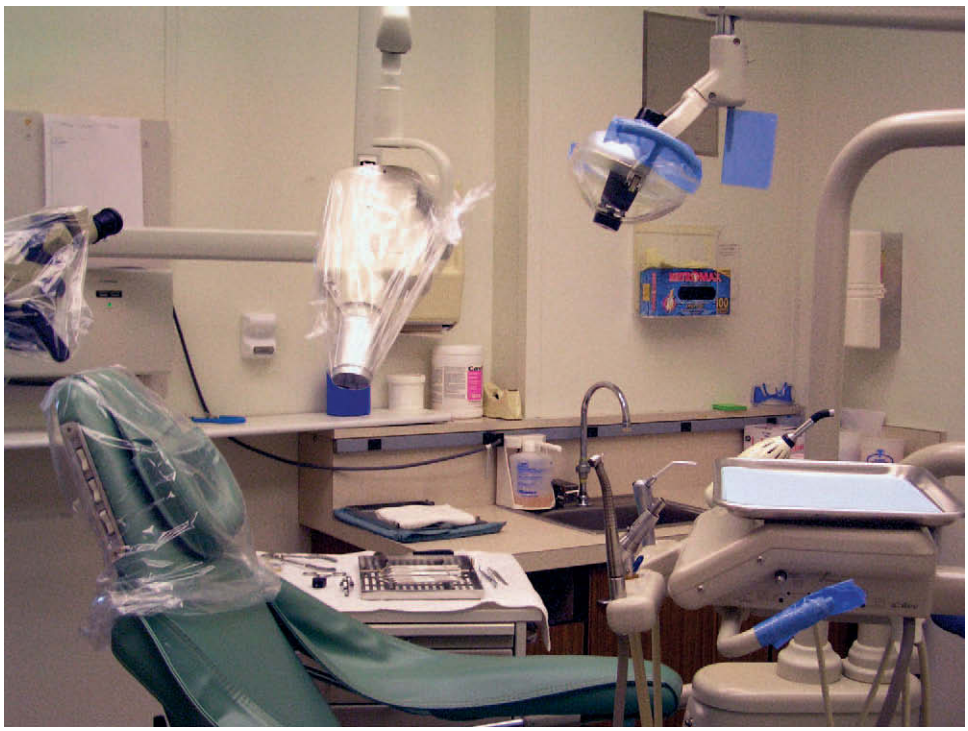

FIG. 6-14 Operatory plastic film barriers in place.

examples. High-level disinfectants are cold sterilizers. Low-level disinfectants are for surfaces that are not contaminated by blood. In dentistry, blood contamination is likely, and therefore intermediate-level disinfectants seem appropriate. Many low-level disinfectants are the same chemicals found in higher-level disinfectants. Greater concentrations often allow a given chemical to be classed higher.

After disinfection of the treatment surfaces, dental assistants should wash their hands and reglove before proceeding with barrier placement and opening of sterile packs. Fresh barriers should be placed on light handles, dental unit switches, chair controls, and so on. X-ray generators and microscopes can be effectively isolated by using large plastic bags, such as dental chair covers or laundry bags. Other items for barrier consideration include electric pulp testers and other thermal pulp testers. Recycled anesthetic cartridges used for ice testing should be autoclaved before adding water and freezing.

Some people express concern that resistance to disinfectants may occur, as has happened with antibiotics. This is not likely because disinfectants (in appropriate concentration) kill rapidly, and thus bacteria are not able to adapt to them.

The current report of the CDC indicates that sterile packs will remain sterile if they remain dry in closed cabinets and if the sterile wrapping remains intact.[12,21] This philosophy means that routine resterilization is not needed. Resterilization is indicated if the wrap has been exposed to fluids that may wick into the sterile side of the package or if an instrument has broken through the wrap. Packages should be dated for identification in case the biologic monitor shows incomplete spore kill.

An additional concern involves microbes in dental water lines. Chlorination or other municipal disinfection has brought a substantial improvement in public health in the last century. However, these steps do not ensure sterile water. Just as dental plaque bacteria colonize on teeth and cause problems, plastic water lines within the dental unit are a haven for bacteria to colonize. The sticky, dental plaque–like water-line biofilm grows unhindered by the slow water movement in dental water lines. Bacteria from patients can travel upstream into dental water lines. The relatively small numbers of bacteria allowable in municipal water supplies flourish within the dental unit, even in independent water bottles (Fig. 6-15). It is now known that biofilms establish themselves in these systems quickly. One approach to cleaning independent dental water lines is weekly use of strong chemicals, although staff compliance is a potential problem.[27] Another approach is continuous use of low-concentration chemicals.[10] Flushing water lines will not eliminate the biofilm, yet a 20- to 30-second flush between patients remains recommended to avoid microbes from one patient being transmitted to the next.[12] Regular culturing of dental unit water lines remains the only method to ensure that a system meets the CDC and U.S. Environmental Protection Agency (EPA) no-more-than-minimum standard of 500 colony-forming units (CFU)/ml of water (Fig. 6-16).

The American Dental Association goal is less than 200 CFU/ml, and the European Union strives for less than 100 CFU/ml.

One can readily see that organization and quality control monitoring are essential to avoid contamination of the endodontic treatment field. Organization should be a key item in assembling the armamentarium, sterilization of instruments before treatment, and preparation of the treatment area with disinfectants and barriers. Attention to every detail is needed to avoid microbial contamination.

FIG. 6-15 Independent water source. Water is pressurized by compressed air. *(Courtesy DentalEZ, Bay Minette, AL.)*

TREATMENT

Collection of a proper medical history is mandatory for proper treatment planning. Many examples illustrate the need for thorough consideration of medical aspects unique to each patient. For example, mutations of the tubercle bacillus, *Mycobacterium tuberculosis,* now endow it with resistance to multiple antibiotics. Infectious microscopic droplets hang in the air for hours after dental treatment, and this is a particular concern when treating patients with TB. These droplets pose a serious risk for staff and other patients. For public health reasons, patients with active TB must be treated in a special negative–air pressure room. Treatment room air must be vented outside through high-efficiency filters that are then properly treated. The use of pretreatment oral irrigants containing chlorhexidine gluconate has been recommended for reduction of microflora in aerosols.[12]

Patients with heart defects may also need special treatment.[9] Oral bacteria that escape from the oral cavity or from an endodontic infection can cause serious complications or even initiate disease in healthy hearts.

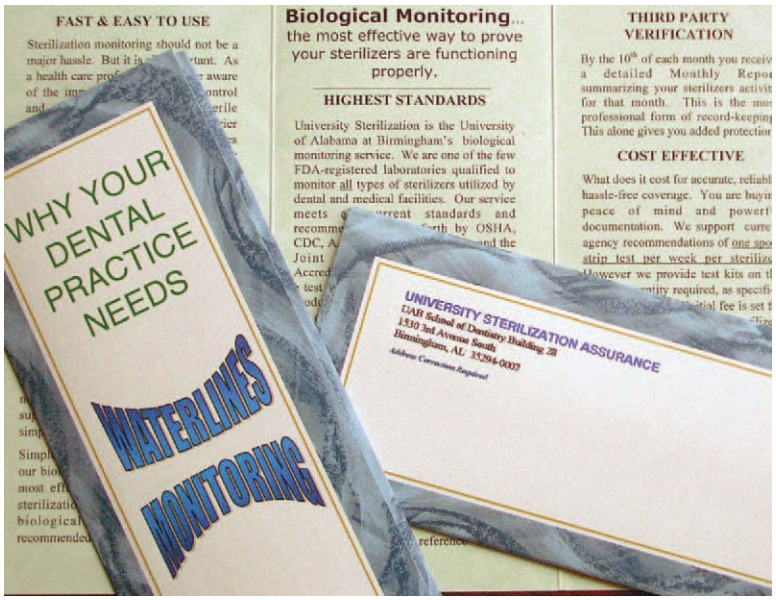

FIG. 6-16 Waterline monitoring service. This laboratory uses U.S. Environmental Protection Agency (EPA) methods to determine heterotrophic bacterial counts for drinking water. *(Courtesy Dr. John Ruby, University of Alabama at Birmingham.)*

Clothing worn by office personnel is a concern for staff safety. The purpose of protective fabric is to avoid contamination of skin and street clothes. Regulations mandate coverage of forearms. The garb should be changed if visibly soiled or wet by potentially infectious matter. *The protective clothing should not be worn outside the office.* Laundering at home is a potential source of contamination of family members and is not allowed.

Eye protection and masks should be donned before washing and gloving. Glasses and masks protect thin mucous membranes from possible contamination. Documentation of virus transmission via the conjunctiva of the eye has resulted in the recommendation for protection of these membranes.[26] Risk of human immunodeficiency virus (HIV) transfer to a health care worker exposed by mucous membrane is estimated to be about 0.1%.[15] Eyeglasses should have side shields.

Microscope controls should be covered with a barrier, such as a large plastic bag used for laundry or a dental chair cover. The plastic can be torn and stretched over the objective lens. The eyepieces should be adjusted for use with glasses (Fig. 6-17). Those who wear magnifying loupes should not adjust them during treatment unless followed by regloving. An assistant not involved with treatment may do so, or a barrier that can be immediately discarded may be used to adjust glasses or replace wet masks.

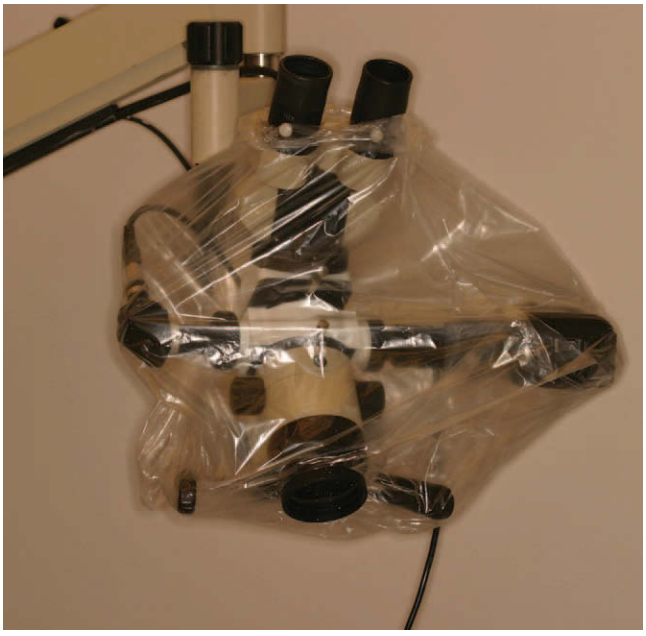

FIG. 6-17 Microscope controls covered with a barrier. *(Courtesy Dr. S. Craig Rhodes.)*

Masks commonly available for use in dentistry protect the wearer only partially. Small droplets containing bacteria can pass through most clinical masks. Wet masks are even less efficient and should be changed immediately. Masks that do not seal around the face fail to give maximal protection. The ideal mask has not yet been developed.

Dental treatment produces large amounts of potentially contaminated droplets during treatment. Rubber dam use reduces the aerosol, but infected pulp tissue can serve as a source for aerosol-borne biocontaminants. Most droplets from dental treatment quickly fall out of the air because of their relatively large size, but small particles can remain suspended in the air for long periods. Microbes are carried via these small droplets deep into lungs, where they cause infection. Airborne transmission definitely accounts for the spread of Legionnaires' disease, TB, severe acute respiratory syndrome (SARS), and influenza. Other diseases may spread by droplets. Use of a preprocedural mouth rinse reduces the aerosol along with proper high-velocity evacuation common in large-bore dental evacuators.[14,19]

Hand washing should precede gloving. Long fingernails and jewelry that could puncture glove material or shelter bacteria from the washing process should be avoided. Recently, a new latex glove material has been tested. Apparently, guayule (pronounced *why-YOU-lee;* Yulex, Maricopa, AZ) rubber

proteins have low allergenic potential. It is derived from a plant in the desert of southwestern United States.[1]

Sterile gloves should be worn for surgical procedures. Examination-type gloves may harbor microbes from the point of manufacture or from contamination at the point of use. Hand lotions may degrade the rubber of gloves and should not be used until treatment has concluded for the day. Sharp jewelry and artificial nails can penetrate the gloves, even if such penetrations are too small to be seen; thus they should not be worn with gloves. The glove material weakens during use, especially when using hand files. Gloves should be changed between patients and more often if harshly used. Interruption of treatment to answer the telephone or to develop a radiograph presents an opportune time for fresh gloves.

Evaluation of sterile technique often discloses contamination early in the treatment process. Procedures such as diagnosis or application of the rubber dam contaminate gloves. Gloves should be considered only a barrier for staff protection. Patient protection comes from careful attention to sterile technique, including not allowing nonsterile gloves to touch anything that will go into the root canal.

Because of the lack of total protection with gloves, it is recommended that a disinfectant hand wash be used. Chlorhexidine has a property called *substantivity,* meaning that it bonds to skin and maintains antibacterial action longer than other surgical scrubs. Alcohol-based hand rubs have recently become popular for hospital workers. Presently available waterless techniques appear less effective than a surgical soap-and-water method.[7]

Reducing bacteria within the oral cavity before treatment should be of concern to every clinician for every procedure. Degerming the oral cavity with an appropriate mouthwash before treatment has been recommended by Bender and Montgomery[2] as a means of reducing bacteremia.[11] Sterile technique should be used. Application of the rubber dam will typically contaminate gloves, and one approach is to change gloves after dam application. Another possibility is to have the assistant place the rubber dam and then reglove.[20]

Sharps should be handled with caution. Needles should be recapped with one hand to avoid possible injury to the hand holding the needle cover. Needles are available that recap automatically. Scalpel blades should be placed and removed from the handle by means of a hemostat or needle holder, with consideration to where hands are positioned, to avoid an injury in case something slips.

Disinfection of the canal continues to be a heavily researched topic. At present the only agent that dissolves pulp tissue is sodium hypochlorite. This explains its continued popularity among clinicians. Studies have demonstrated that 7 minutes of tissue contact time with sodium hypochlorite dissolves 75% of a tissue plug in vitro.[6,13,17] Dilute concentrations of sodium hypochlorite are less effective for dissolving remaining tissue, and therefore the full-strength concentration is popular. However, it should be remembered that even dilute solutions can cause untoward reactions if injected periapically or exposed to oral tissues. Another clinical use for sodium hypochlorite is for disinfection of gutta-percha cones. A 1-minute exposure to 1% or a 5-minute exposure to 0.5% has been shown to be an effective gutta-percha disinfectant.[3]

Small instruments such as canal files may be dropped into a chairside container of disinfectant when no longer needed. This approach will provide some protection to staff members if they are accidentally stuck by an instrument in the cleaning and repackaging process. Such an approach will not positively ensure protection from infectious agents but will certainly reduce risk. Some clinicians have adopted the approach of using files as disposable instruments. Files require sterilization before treatment, except those few sterilized by the manufacturer.[25] After single use, files can be discarded in the chairside sharps container. This philosophy of single use has the added advantage of reducing the possibility of fracture of instruments caused by repeated use (see also Chapters 8 and 9).

An often overlooked clinical problem concerns decontamination of radiographs. The use of digital radiography has improved patient protection with single-use sleeves covering the digital sensor. Proper technique dictates placing the barrier over the digital sensor when other barriers are placed before treatment commences. The barrier should completely cover the holder, or a sterilized holder or disposable holder should be used for each patient.

Conventional radiographic films or gloves worn from the treatment area into the developing area can contaminate this area. Staff should be required to disinfect conventional films and deglove before leaving the treatment room. Hand washing and regloving should occur before treatment continues.

Reusable instruments should be taken to a dedicated area for removal of gross debris by scrubbing or preferably by ultrasonic bath. Heavy gloves along with eye protection and a mask should be worn during instrument processing for sterilization. The ultrasonic bath should be a germicide to minimize infection spread to office workers. The ultrasonic bath cover should be used to reduce aerosols. Automatic instrument washers are also available for added cleaning efficiency and worker protection. Dedicated washers use copious amounts of high-temperature water to rapidly prepare instrument packs for autoclaving. The difficulty of thoroughly cleaning endodontic instruments was reported by researchers, who found that 76% of endodontic files from dental offices were contaminated with proteinaceous material.[28]

If time is not available to clean instruments immediately, they should be placed in a disinfectant bath to prevent drying of foreign material on the instruments because dried material is more difficult to remove.

If scrubbing is the only feasible means of cleaning, heavy puncture-resistant gloves should be worn and brushes should be long handled to minimize the risk of percutaneous injury. After the ultrasonic bath the instruments should be rinsed in tap water and wrapped for sterilization. Many offices favor cassette systems to lessen the risk of a stick injury. Staff should be cautioned about the risk of a sharp instrument protruding through an opening in a cassette, even one that is wrapped.

As instruments move along a path from dirty to clean and then sterile, the path should not cross itself in order to avoid cross-contamination.

GENERAL CONSIDERATIONS FOR THE OFFICE

Government guidelines spell out requirements for staff education.[12] Staff meetings are strongly recommended because of the many advantages of well-educated personnel in the dental office. Proof of staff meetings should be kept in a log. Box 6-3 includes items for consideration.

BOX 6-3

Written Records for Consideration by Clinicians

1. Manufacturer safety data sheets (MSDSs)
2. Posting of Department of Labor policies, for example, workers' compensation; may vary by state
3. Written infection control plan, including the following:
   a. Infection control coordinator (perhaps the clinician)
   b. Written plan to minimize exposure to infection by staff
   c. Annual record of employee training, with record of immediate training for new hires and those changing to jobs with patient contact
   d. Written plan for postexposure actions following potential infection transmission. Records of worker injury will necessitate a record that will remain in employee's confidential record. The written plan should prearrange for the following:
      (1) Reporting criteria and procedures, to include date, time, and details of injury, and infectious status of patient (perhaps on a previously prepared reporting form)
      (2) Evaluation by a physician (establish a relationship with a physician before injury occurs)
      (3) Counseling (establish a relationship with a counselor before injury occurs)
      (4) Treatment (probably with the physician listed in [2])
      (5) Medical follow-up (probably with the physician listed in [2])
4. Vaccinations, with log of appropriate updates (boosters)
5. Log of skin test for tuberculosis, especially for baseline for new hires
6. Log of sterilizer monitoring
   a. Log of pressure, temperature, and time of each load
   b. Weekly log of results of biologic monitor for each sterilizer
7. Log of hand-washing education and critique of employees' performance on a regular basis
8. Log of education about barrier placement need and technique and critique of employees' performance on a regular basis
9. Log of sharps hygiene education and critique of employees' performance on a regular basis
10. Log of annual review of exposure plan
11. Log of results of dental water monitoring
12. Log of medical and other waste education and critique of employees' performance on a regular basis
13. Log of patients who make unscheduled return visits for possible infection control breach
14. Plan for health care workers infected with various agents, including possible restriction of patient contact and conditions for return to full duty (e.g., workers with hepatitis A are restricted from patient contact until after the seventh day of onset of jaundice) (see Table 1 of reference 11, p. 8).

Modified from Table 5 of Kohn WG, Collins AS, Cleveland JL, et al: Centers for Disease Control and Prevention (CDC): Guidelines for infection control in dental health-care settings—2003. MMWR Recomm Rep 52(RR-17):1, 2003.

Vaccinations for all employees working in the treatment room must include the hepatitis B series of three injections. Other vaccinations are recommended as a means of preventing disease. Such expense is minimal considering lost time and possible sequelae to valuable workers. Box 6-4 includes the 2005 vaccination recommendations of the CDC.[12]

BOX 6-4

Vaccinations for Diseases Potentially Spread to Dental Office Workers

- Hepatitis B
- Influenza, needed yearly
- Measles
- Mumps
- Rubella (German measles)
- Varicella (chickenpox)

It is now evident that antibody levels to hepatitis B wane over time. CDC findings suggest that 60% of those vaccinated will have no detectable antibodies after 12 years.[4] Hepatitis B is a serious threat to unprotected individuals. The risk of clinical hepatitis B to an unvaccinated health care worker stuck with a needle from a patient positive for both hepatitis B surface antigen and hepatitis B e antigen is 22% to 31%.[5]

Janitors and those who dispose of dental office wastes must be protected from harm. They should be protected from sharps such as canal instruments that are misplaced in an area they will clean. Janitors need education in use of personal protective equipment, such as heavy gloves and appropriate disinfectants.

Dental offices do not generate large volumes of medical wastes.[23] Dental offices are estimated to generate only 1% to 2% of their waste as medical waste. The majority of waste is not subject to regulation. Used gloves, masks, and protective garb and barriers are not regulated waste.

Sharps are part of regulated medical waste. Sharps include needles, scalpel blades, endodontic instruments, and other items capable of breaking the skin. Used anesthetic cartridges are classified as sharps because they could break and cause an injury if placed in regular waste. Sharps should be discarded at the point of use in a rigid container with a biohazard label. After sealing this puncture-resistant container with a tamperproof seal, the container can be discarded in normal fashion.

Regulated medical waste includes items soaked in blood or saliva, such as 2 × 2 inch gauze or cotton rolls. This type of medical waste must be sealed in a leak-resistant biohazard bag that does not contain sharps. This type of waste could be placed in a sharps container. State regulations should be consulted before discarding biohazard bags in regular waste.

Liquid medical wastes, such as contents of a vacuum system separator, can be disposed of in a sanitary sewer, although care should be taken to avoid splatter when pouring into a toilet or sink. Normal protective gear including office garb, eyeglasses, and mask is needed for pouring liquid medical waste into a drain.

Some municipalities mandate mercury separators (endodontic offices may be exempt). These separators remove the heavy metal before it enters the city waste system and help the local government comply with regulations regarding mercury in solid waste and effluent from sewage treatment.

Nitrous oxide scavengers remove some of the gas exhaled by patients. These devices reduce but do not eliminate the gas from the office. Scavengers are connected to the central dental vacuum system and require a high flow rate. The vacuum system exhaust should be piped outside rather than into the mechanical room, where it may reenter the office air, because

nitrous oxide interferes with deoxyribonucleic acid (DNA) synthesis. Further, nitrous oxide increases the rate of congenital abnormalities in children of both males and females exposed to the gas in the dental office environment.[8]

FUTURE CONSIDERATIONS

Patient concerns will likely surface as more knowledge about existing pathogens becomes apparent and new pathogens arise. Clinicians should be ready to modify their practices and procedures to allay fears. Increased use of disposable products is likely. Many clinicians are already using new canal files for each patient.

A potential threat on the horizon are prions *(PREE-onz)*. Prions are glycoproteins found on cell surfaces. Modified versions of normal prions cause various slow-moving, often fatal diseases of the nervous system. Prions are almost impossible to sterilize in a dental office and they have an affinity for stainless steel. They can be killed by certain caustic chemical treatments, such as sodium hydroxide. Current World Health Organization (WHO, Geneva, Switzerland) recommendations for reprocessing heat-resistant instruments call for keeping instruments moist until decontamination begins, because drying strongly stabilizes the bond of prions to the instruments. Prions are also resistant to formalin or glutaraldehyde fixatives, with their bond strengthened as well. The WHO describes several methods to rid dirty instruments of prions before repackaging and routine sterilization.[33] The following methods, performed prior to routine sterilization, yield the best protection for office worker as well as patients.

Method 1: Immerse contaminated instruments in a pan of 1 N sodium hydroxide and heat in a gravity displacement autoclave for the normal cycle of 121° C for 30 min.

Method 2: Immerse in either 1 N sodium hydroxide or full-strength bleach (20,000 ppm available chlorine) for 1 hour; rinse; transfer to a dry, open pan; and heat in a gravity displacement autoclave at 121° C for 1 hour.

Method 3: Immerse in either 1 N sodium hydroxide or full-strength bleach (20,000 ppm available chlorine) for 1 hour; rinse; transfer to a dry, open pan; and autoclave in either a gravity displacement autoclave at 121° C or a conventional autoclave at 134° C for 1 hour.

Method 4: Immerse and boil in 1 N sodium hydroxide for 10 minutes.

Method 5: Immerse in 1 N sodium hydroxide or full-strength bleach for 1 hour, rinse and subject to routine sterilization.

Method 6: Autoclave at 134° C for 18 minutes.

Note that 1 N sodium hydroxide is made by adding 40 g of the crystal to 1 liter of distilled water.

Note that freshly opened 5.25% bleach (sodium hypochlorite) contains 25,000 ppm available chlorine. The WHO recommendations call for 20,000 ppm available chlorine. Today many commercial concentrations are 6%.

Research based on new technology will surely define more expeditious means of destroying prions. Investigations have explored the use of an industrial fabrication method, that is, low-pressure oxygen–argon plasma made by radiofrequency energy, to decontaminate and sterilize in one quick process. One study[32] found organic matter, about 1 µm thick, on endodontic files that had been decontaminated and sterilized by a local dental practice. One third of the files had contaminant thicknesses exceeding 50 µm. After plasma exposure for unspecified times, no nitrogen was present, suggesting the destruction of proteinaceous matter. Calcium remaining was interpreted as lingering dentin.[32] Although prions have high resistance to proteases, endopeptidases, such as keratinase, have been suggested as potential aids.[22] Disposal of contaminated files is best accomplished by incineration.[33]

Because of fears of the public about disease transmission in the dental office, many endodontists consider all canal instruments as single-use items. This overcomes the difficulty of staff injury during cleaning and repackaging. Apparently, complete cleaning of endodontic files is quite difficult with current procedures. Another study reports that ultrasonic baths are better than hand brushing, and that disinfectant washers are also a step in the right direction, albeit not completely effective.[30] Investigators found that even after cleaning by hand and ultrasonication, plus aggressive 24-hour immersion in disinfectants concentrated enough to corrode nickel–titanium files, residual debris remained.[29]

At present no vaccination exists against hepatitis C. Fortunately, the rate of disease transmission to health care workers is low. The estimates of disease transmission from a needle stick range up to 7%.[24]

Other hazards may also arise. Clinicians must keep abreast of research findings and changes in guidelines from regulatory agencies. New inventions and techniques will help clinicians deal with the current threats, as immunizations and innovations become available to make the workplace safer for staff and patients.

Air in the treatment room may contain spores. Although this has not been found to be problematic at present, it presents a possible concern for the future.

CHAPTER 7

Tooth Morphology and Access Cavity Preparation

FRANK J. VERTUCCI and JAMES E. HADDIX

CHAPTER OUTLINE

COMPONENTS OF THE ROOT CANAL SYSTEM
ROOT CANAL ANATOMY
ANATOMY OF THE APICAL ROOT
OBJECTIVES AND GUIDELINES FOR ACCESS CAVITY PREPARATION
- Objectives
- Guidelines

MECHANICAL PHASES OF ACCESS CAVITY PREPARATION
- Armamentaria
- Access Cavity Preparations

CHALLENGING ACCESS PREPARATIONS
- Teeth With Minimal or No Clinical Crown
- Heavily Restored Teeth (Including Those With Full Veneer Crowns)
- Teeth With Calcified Canals
- Crowded Teeth
- Rotated Teeth

ERRORS IN ACCESS CAVITY PREPARATION
MORPHOLOGY AND ACCESS CAVITY PREPARATIONS FOR INDIVIDUAL TEETH

The hard tissue surrounding the dental pulp can take a variety of configurations and shapes. A thorough knowledge of tooth morphology, careful interpretation of angled radiographs, and adequate access to and exploration of the tooth's interior are prerequisites for treatment. Magnification and illumination are indispensable aids. This chapter describes and illustrates tooth morphology and explains the techniques crucial to achieving unobstructed direct access to the root canal and apical foramina. This chapter is divided into eight major sections: (1) components of the root canal system, (2) root canal anatomy, (3) anatomy of the apical root, (4) objectives and guidelines for access cavity preparation, (5) mechanical phases of access cavity preparation, (6) challenging access preparations, (7) errors in access cavity preparation, and (8) morphology and access cavity preparations for individual teeth.

Only after correct completion of this phase of therapy can the clinician perform thorough shaping and cleaning and three-dimensional (3-D) obturation. The optimal endodontic result is difficult to achieve if the access is not properly prepared. The clinician must have an understanding of the complexity of the root canal system to understand the principles and problems of shaping and cleaning, to determine the apical limits and dimensions of preparations, to perform microsurgical procedures successfully and to correct procedural errors.

Practitioners must have a thorough understanding of the internal anatomic relationships of teeth and must be able to visualize these relationships before undertaking endodontic therapy. Careful evaluation of two or more periapical radiographs, exposed at different horizontal angulations of the x-ray cone, is mandatory. These radiographs provide important information about root canal morphology. The clinician must keep in mind that the inclination of the x-ray tube significantly influences the ability to detect root canal systems present in premolar teeth. For example, if the horizontal angle is varied by either 20 or 40 degrees, the number of root canals seen in the maxillary first and second premolars and the mandibular first premolars coincides with the number of canals actually present.[131] However, in the mandibular second premolar, only the 40-degree horizontal angle correctly identifies the root canal morphology. The critical importance of a careful reading of each radiograph before and during root canal therapy is well recognized. As shown in a case report of five canals in a mandibular first molar, the radiographic appearance significantly aided recognition of the complex canal morphology.[69] This study concluded that "any attempt to develop techniques that require fewer radiographs runs the risk of missing information which may be significant for the success of therapy."

However, conventional radiographs may not always determine the correct morphology, particularly when only a buccolingual view is taken. In one study, 790 extracted mandibular incisors and premolars were radiographed to assess the incidence of canal bifurcation in a root.[144] When the *fast break* guideline was used (i.e., interpreting a sudden disappearance or narrowing of a canal as a sign of canal division [e.g., bifurcation]; Fig. 7-1), the result was failure to diagnose one third of

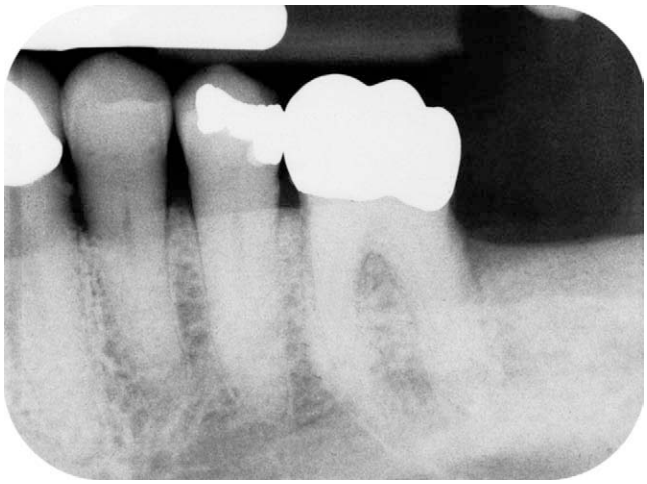

FIG. 7-1 Periapical radiographs can reveal clues to root canal morphology. Abrupt disappearance of the large canal in the mandibular premolars usually signifies a canal bifurcation.

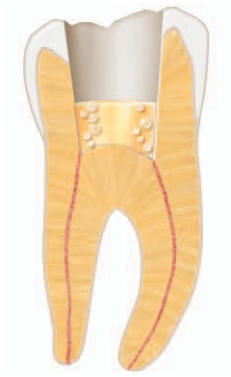

FIG. 7-2 Allowing sodium hypochlorite (NaOCl) to remain in the pulp chamber may help locate a calcified root canal orifice. Tiny bubbles may appear in the solution, indicating the position of the orifice.

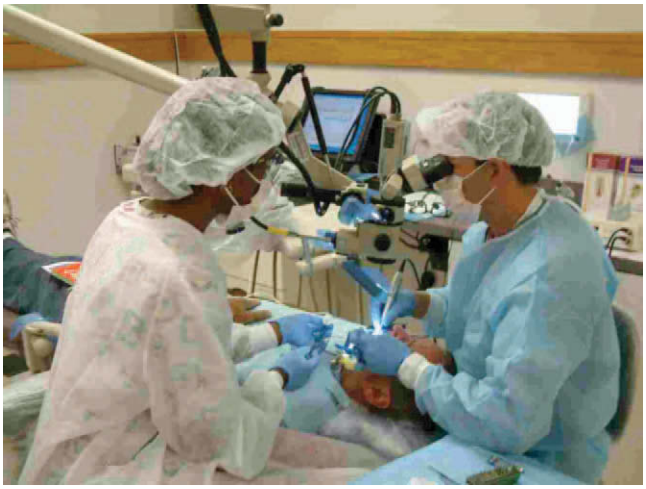

FIG. 7-3 The dental operating microscope (DOM) has vastly improved locating and negotiating of canal anatomy.

these divisions from a single radiographic view. Thus, evaluation of the root canal system is most accurate when the clinician uses information from several radiographic views together with a thorough clinical exploration of the interior and exterior of the tooth. Alternatively, the recent development of micro-CT has greatly increased our understanding of the complexities and three-dimensional relationships of the root canal systems (see also Chapter 9 and online Chapter 29).

The main objectives of root canal therapy are thorough shaping and cleaning of all pulp spaces and complete obturation of these spaces with an inert filling material. The presence of an untreated canal may be a reason for failure. A canal may go untreated because the clinician fails to detect it. It is extremely important that clinicians use all the armamentaria at their disposal to locate and treat the entire root canal system. The complexity of the spaces that must be accessed, shaped, cleaned, and filled is remarkable. However, even under the most difficult circumstances, current endodontic techniques have an exceptionally high rate of success.

Diagnostic measures are important aids in the location of root canal orifices. These measures include obtaining multiple pretreatment radiographs or cone beam CT (CBCT, see online Chapter 26), examining the pulp chamber floor with a sharp explorer, troughing grooves with ultrasonic tips, staining the chamber floor with 1% methylene blue dye, performing the sodium hypochlorite "champagne bubble" test (Fig. 7-2), and visualizing pulp chamber anatomy[108] and root canal bleeding points. Sequential application of 17% aqueous ethylenediaminetetraacetic acid (EDTA) and 95% ethanol (using the Stropko irrigator fitted with a 27-gauge notched irrigating needle) has been recommended for effective cleaning and drying of the pulp chamber floor before visual inspection of the canal system.[199]

An important aid for locating root canals is the dental operating microscope (DOM), which was introduced into endodontics to provide enhanced lighting and visibility (Fig. 7-3). The DOM enhances the clinician's ability to remove dentin with great precision, thereby minimizing procedural errors. Numerous studies have shown that it also significantly improves the clinician's ability to locate and negotiate canals. For example, the number of second mesiobuccal (MB-2) canals identified in maxillary molars increased from 51% with the naked eye to 82% with the microscope.[13] In another study, 41% of MB-2 canals were identified when magnifying loupes were used, and 94% were identified when the DOM was used.[181] Other clinicians have noted that use of the DOM improves the detection of MB-2 canals to more than 90% in maxillary first molars and 60% in maxillary second molars.[109,199] All these studies demonstrate that magnification and illumination greatly enhance root canal therapy. In contrast, one group of investigators determined that dental loupes and the DOM were equally effective for locating MB-2 canals in maxillary molars.[29] Other investigators determined that the DOM did not significantly enhance the ability to locate canals but did improve the ability to negotiate them.[79] Nevertheless, most clinicians would agree that the DOM makes canals easier to locate by magnifying and illuminating the grooves in the pulpal floor and by distinguishing the color differences of the dentin of the floor and walls.[43,108]

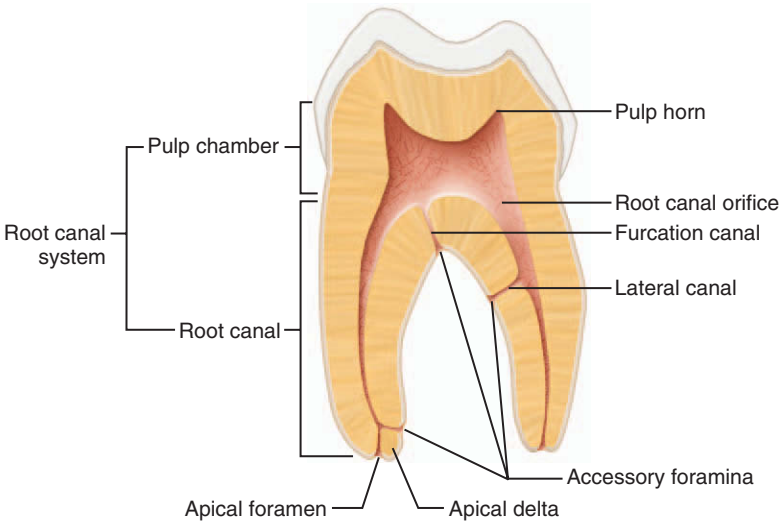

FIG. 7-4 Major anatomic components of the root canal system.

COMPONENTS OF THE ROOT CANAL SYSTEM

The entire space in the dentin where the pulp is housed is called the *root canal system* (Fig. 7-4). The outline of this system corresponds to the external contour of the tooth. However, factors such as physiologic aging, pathosis, and occlusion all potentially modify its dimensions through the production of secondary and tertiary dentin and cementum. The root canal system is divided into two portions: the pulp chamber, located in the anatomic crown of the tooth, and the pulp or root canal(s), found in the anatomic root. Other features are the pulp horns; accessory, lateral, and furcation canals; canal orifices; apical deltas; and apical foramina. A root canal begins as a funnel-shaped canal orifice, generally at or just apical to the cervical line, and ends at the apical foramen, which opens onto the root surface at or within 3 mm from the center of the root apex.[30,80,81,163,215,220] Nearly all root canals are curved, particularly in a faciolingual direction. These curvatures may pose problems during shaping and cleaning procedures because they are not evident on a standard facial radiograph. Angled views are necessary to determine their presence, direction, and severity. A curvature may be a gradual curve of the entire canal or a sharp curvature near the apex. Double S-shaped canal curvatures also can occur. In most cases the number of root canals corresponds to the number of roots; however, an oval root may have more than one canal.

Accessory canals are minute canals that extend in a horizontal, vertical, or lateral direction from the pulp to the periodontium. In 74% of cases they are found in the apical third of the root, in 11% in the middle third, and in 15% in the cervical third.[215] Accessory canals contain connective tissue and vessels but do not supply the pulp with sufficient circulation to form a collateral source of blood flow. They are formed by the entrapment of periodontal vessels in Hertwig's epithelial root sheath during calcification.[49] Pathologically, they are significant because they serve as avenues for the passage of irritants, primarily from the pulp to the periodontium (see also Chapter 18).

Accessory canals may also occur in the bifurcation or trifurcation of multirooted teeth.[215] One study[219] called these *furcation canals* (Fig. 7-5). Furcation canals form as a result of the entrapment of periodontal vessels during the fusion of the diaphragm, which becomes the pulp chamber floor.[49] In mandibular molars these canals occur in three distinct patterns (Fig. 7-6). Tables 7-1 and 7-2 present the incidence of furcation canals for each tooth.

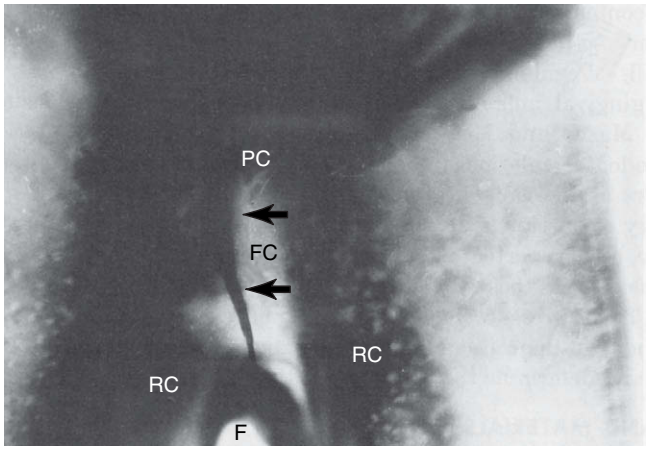

FIG. 7-5 Mandibular first molar showing a furcation canal (*FC, arrows*). *F,* Furcation; *PC,* pulp chamber floor; *RC,* root canal.

According to the findings of scanning electron microscopy (SEM), the diameter of furcation openings in mandibular molars varies from 4 to 720 µm.[216] The number of furcation canals ranges from none to more than 20 per specimen. Foramina on both the pulp chamber floor and the furcation surface were found in 36% of maxillary first molars, 12% of maxillary second molars, 32% of mandibular first molars, and 24% of mandibular second molars (Fig. 7-7). Mandibular teeth have a higher incidence of foramina involving both the pulp chamber floor and the furcation surface (56%) than do maxillary teeth (48%). No relationship was found between the incidence of accessory foramina and the occurrence of pulp chamber calcification or the distance from the chamber floor to the furcation. Radiographs failed to demonstrate the presence of furcation and lateral canals in the coronal portion of these roots. In one study, the pulp chamber floor of 200 permanent molars was

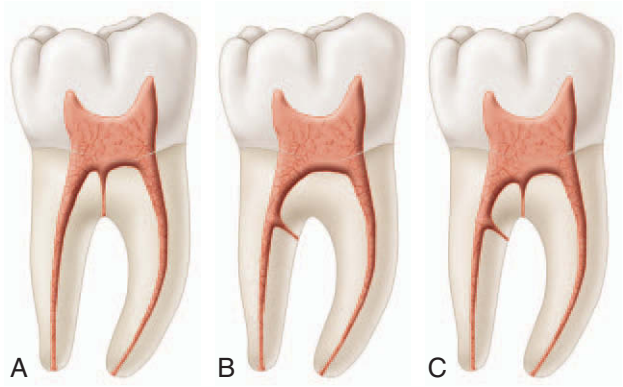

FIG. 7-6 Accessory canals occur in three distinct patterns in the mandibular first molars. **A,** In 13% a single furcation canal extends from the pulp chamber to the intraradicular region. **B,** In 23% a lateral canal extends from the coronal third of a major root canal to the furcation region (80% extend from the distal root canal). **C,** About 10% have both lateral and furcation canals.

stained with 0.5% basic fuscin dye.[85] Patent furcation canals were detected in 24% of maxillary and mandibular first molars, 20% of mandibular second molars, and 16% of maxillary second molars. These canals may be the cause of primary endodontic lesions in the furcations of multirooted teeth (Fig. 7-8) and provide a rationale for placing adhesive restorations on the floor of the pulp chamber to prevent furcal breakdown.

ROOT CANAL ANATOMY

Together with diagnosis and treatment planning, the knowledge of common root canal morphology and its frequent variations is a basic requirement for endodontic success. The significance of canal anatomy has been underscored by studies demonstrating that variations in canal geometry before shaping and cleaning had a greater effect on the changes that occurred during preparation than did the instrumentation techniques.[160-162]

From the early work of Hess and Zurcher[88] to more recent studies[33,82,101,184] demonstrating the anatomic complexities of the root canal system, it has long been established that a root with a tapering canal and a single foramen is the exception rather than the rule. Investigators have shown multiple foramina, additional canals, fins, deltas, intercanal connections, loops, C-shaped canals, and furcation and lateral canals in most teeth.[50,54,150,163,190,215] Consequently, in treating each tooth the clinician must assume that complex anatomy occurs often enough to be considered normal. The first premolar in Fig. 7-9, *A* is a good example of complex anatomy. The extra root is not obvious in a pretreatment radiograph (see Fig. 7-9, *B*). Figure 7-10 shows a cross-section of a similar tooth. This tooth has a fine, ribbon-shaped canal system instead of two distinct canals. Both these teeth present challenges for shaping, cleaning, and obturation.

The clinician must be familiar with the various pathways root canals take to the apex. The pulp canal system is complex, and canals may branch, divide, and rejoin. Weine[232] categorized

the root canal systems in any root into four basic types. Others,[218] using cleared teeth in which the root canal systems had been stained with hematoxylin dye, found a much more complex canal system; they identified eight pulp space configurations, which can be briefly described as follows (Fig. 7-11):

Type I: A single canal extends from the pulp chamber to the apex (1).

Type II: Two separate canals leave the pulp chamber and join short of the apex to form one canal (2-1).

Type III: One canal leaves the pulp chamber and divides into two in the root; the two then merge to exit as one canal (1-2-1).

Type IV: Two separate, distinct canals extend from the pulp chamber to the apex (2).

Type V: One canal leaves the pulp chamber and divides short of the apex into two separate, distinct canals with separate apical foramina (1-2).

Type VI: Two separate canals leave the pulp chamber, merge in the body of the root, and redivide short of the apex to exit as two distinct canals (2-1-2).

Type VII: One canal leaves the pulp chamber, divides and then rejoins in the body of the root, and finally redivides into two distinct canals short of the apex (1-2-1-2).

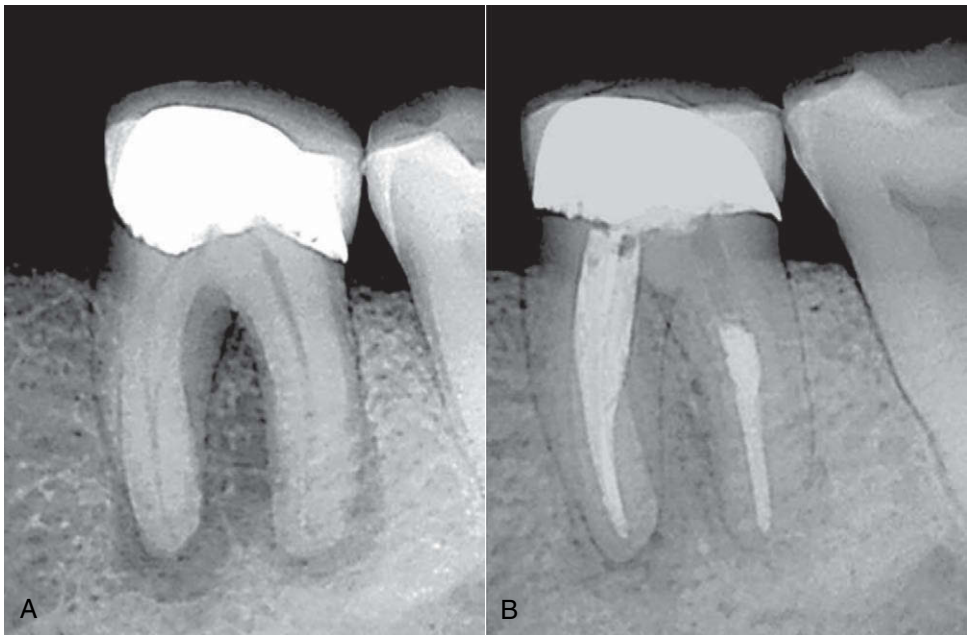

FIG. 7-8 A, Pretreatment radiograph of a mandibular first molar showing furcation and periradicular radiolucencies. **B,** One-year follow-up radiograph showing significant healing. *(Courtesy Dr. Raed S. Kasem, Clearwater, FL.)*

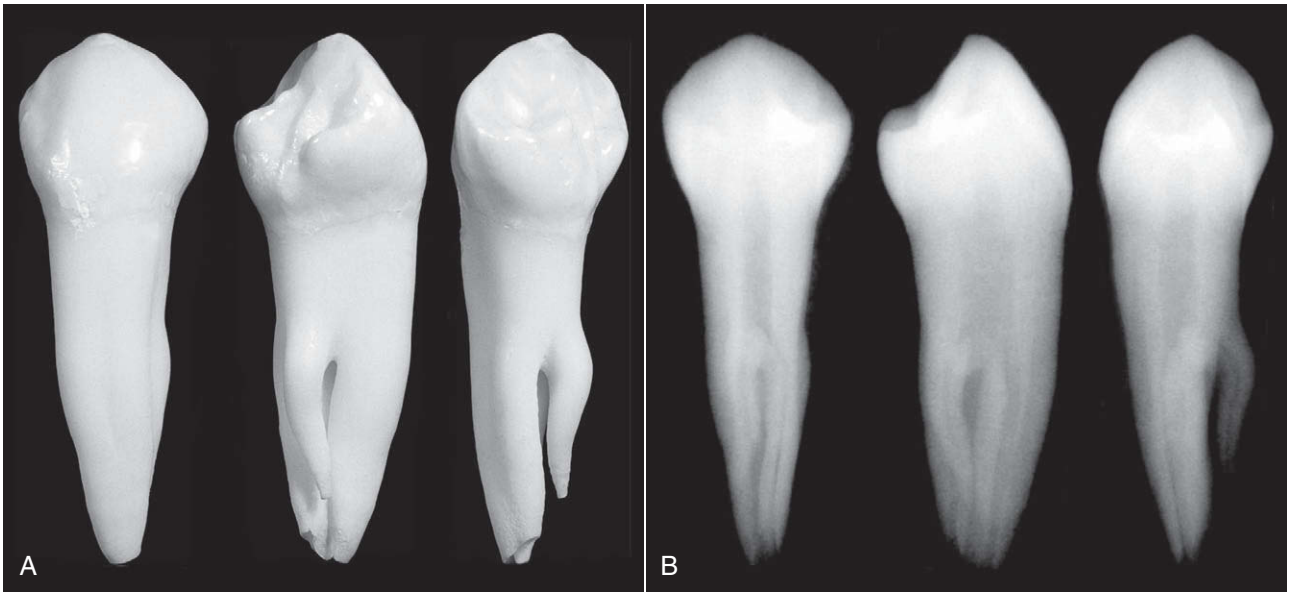

FIG. 7-9 A, Mandibular first premolar with three separate roots trifurcating at midroot. **B,** Radiograph of the three views. Small canals diverging from the main canal create a configuration that is difficult to prepare and obturate biomechanically.

Type VIII: Three separate, distinct canals extend from the pulp chamber to the apex (3).

The percentages of human permanent teeth with these canal configurations are presented in Tables 7-3 and 7-4. The anatomic variations present in these teeth are listed in Tables 7-1 and 7-2. The only tooth that showed all eight possible configurations was the maxillary second premolar.

Other studies using more than 1000 teeth have described similar morphologic results.[33] Another study used more than 1000 teeth and described similar morphologic results with the exceptions that one canal was found in 23% of maxillary laterals, 55% of mesiobuccal roots of maxillary second molars, and 30% of distal roots of mandibular second molars.[33] The differences are most likely the result of variations of populations in the two studies.[10] Another group studied 100 mandibular anterior teeth and found two new root canal types.[101] In one configuration, two separate canals extended from the pulp chamber to midroot, where the lingual canal divided into two; all three canals joined in the apical third of the root and exited as one canal (Fig. 7-12, *A*). In the other configuration, one canal left the pulp chamber, divided into two in the middle third of the root, then rejoined to form one canal, which again split and exited as three separate canals with separate foramina (Fig. 7-12, *B*). Another set of variants was first observed in the

mandibular molars of Burmese; this study revealed seven additional canal configurations (Fig. 7-13).[82] These include three canals joining into one or two canals; two canals separating into three canals; two canals joining, redividing into two, and terminating as one canal; four canals joining into two; four canals extending from orifice to apex; and five canals joining into four at the apex. Another study evaluated gender-specific root canal configurations in 2800 teeth.[184] Of these specimens 99% were identical to those in the Vertucci classification. The remaining 1% (36 teeth) represented 14 additional canal morphologies, which occurred twice as often in mandibular teeth. These authors concluded that gender plays a role in determining canal morphology and that both gender and ethnic origin should be considered in the pretreatment evaluation for root canal therapy.

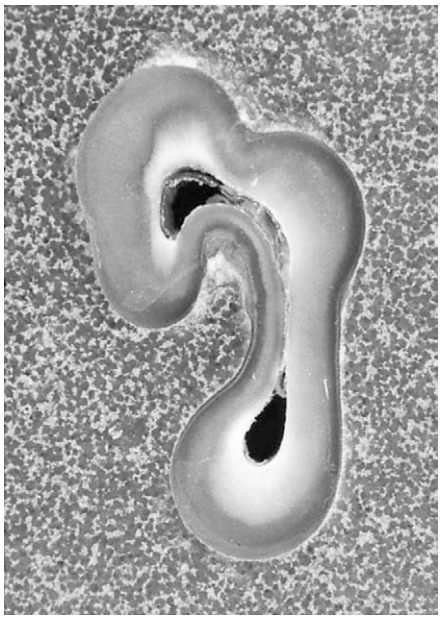

FIG. 7-10 Root section of a premolar showing a ribbon-shaped canal system.

In addition to in vitro studies, a large number of case reports have described a variety of complex canal configurations (see tables 7-8 to 7-27). Some authors have been critical of case studies reporting "freak" cases thought to be rare.[231] However, reports of complex anatomy from both in vitro and in vivo investigations seem to be increasing. This emphasizes the adage that it is easier to recognize an anatomic feature if one is already prepared to see it.

Specific types of canal morphology appear to occur in different racial groups. For example, compared with Caucasian patients, those of African descent have a higher number of extra canals in both the mandibular first premolar (33% versus 14%) and the mandibular second premolar (8% versus 3%).[211] In addition, patients of Asian descent have different percentages of canal configurations than those reported in studies dominated by white and black populations.[223-225,229] One well-recognized ethnic variant is the higher incidence of single-rooted and C-shaped mandibular second molars in Asians compared with other populations.[127] However, this is not always the case; the occurrence of two canals in the

mesiobuccal root of maxillary first molars in Japanese patients is similar to that described for other ethnic groups.[233] All this information makes it clear that the clinician is confronted daily with highly complex and variable root canal systems. All available armamentaria must be used to achieve a successful outcome.

Examination of the pulp chamber floor can reveal clues to the location of orifices and to the type of canal system present. Importantly, if only one canal is present, it usually is located in the center of the access preparation. All such orifices, particularly if oval shaped, must be explored thoroughly with apically precurved small K-files (Fig. 7-14). If only one orifice is found and it is not in the center of the root, another orifice probably exists, and the clinician should search for it on the opposite side (Fig. 7-15). The relationship of the two orifices to each other is also significant. The closer they are, the greater the chance the two canals join at some point in the body of

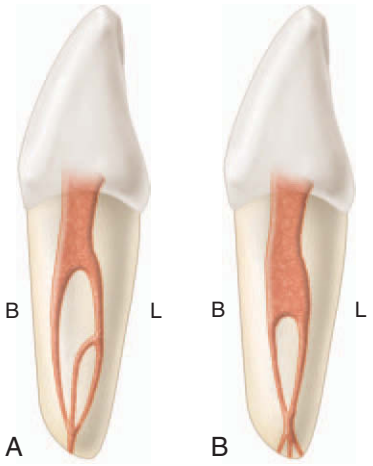

FIG. 7-12 Diagrammatic representation of Kartal and Yanikoglu's canal configurations. *B,* Buccal; *L,* labial.

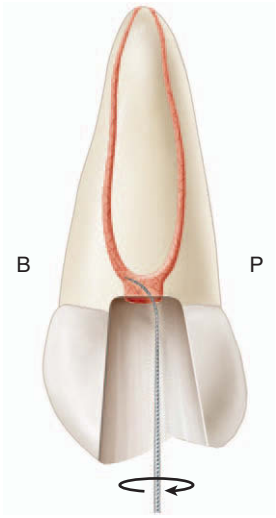

FIG. 7-14 An oval orifice must be explored with apically curved small instruments. The clinician should place the file tip in the orifice with the tip curved to the buccal side when trying to locate the buccal canal. A curved file tip is placed toward the palate to explore for the palatal canal. *B,* Buccal; *P,* palatal.

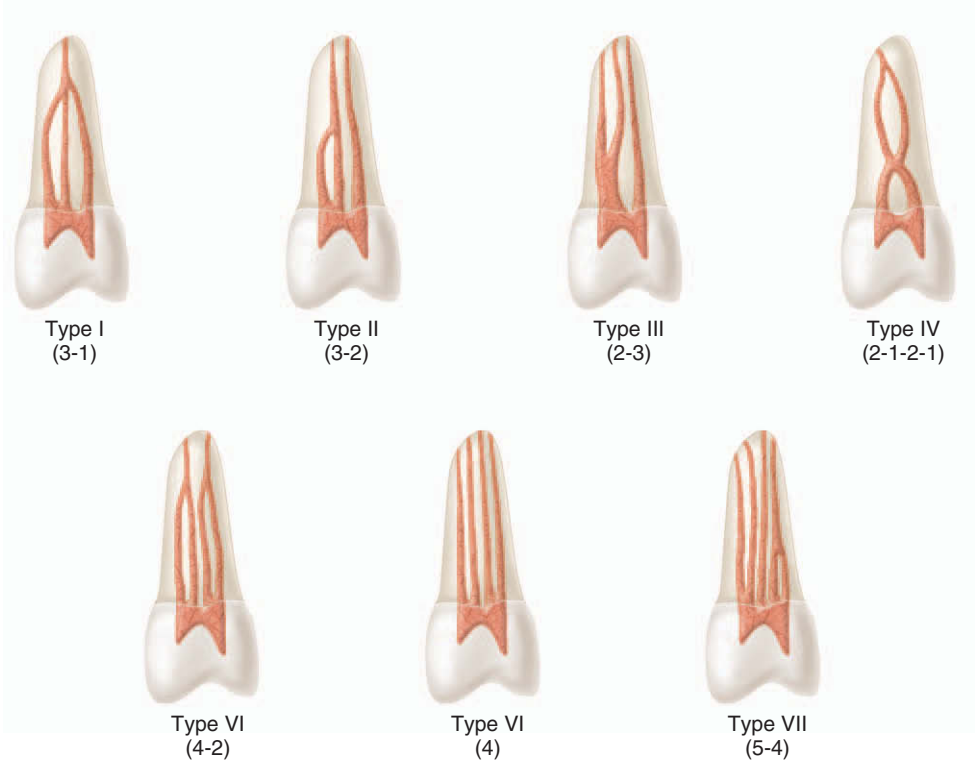

FIG. 7-13 Diagrammatic representation of Gulabivala and co-workers' supplemental canal configurations.

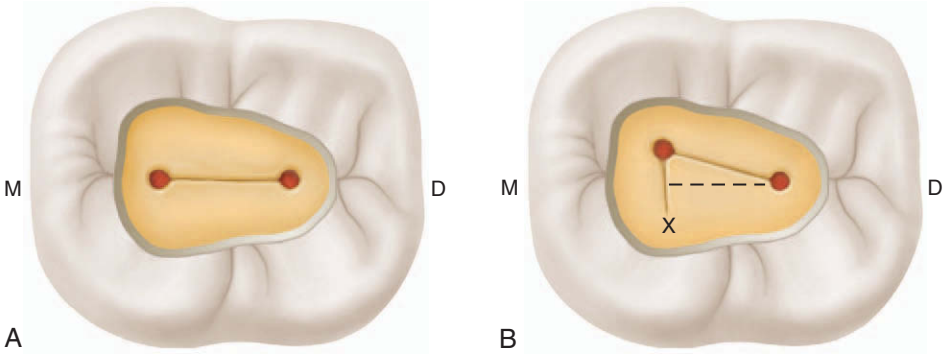

FIG. 7-15 A, In a mandibular second molar with two canals, both orifices are in the mesiodistal midline. **B,** If two orifices are not directly in the mesiodistal midline, a search should be made for another canal on the opposite side, using Krasner and Rankow's laws of anatomy in the area of "X." *D,* Distal; *M,* mesial.

the root. As the distance between orifices in a root increases, the greater the chance is that the canals will remain separate. The more separation between orifices the less the degree of canal curvature.[42] The direction a file takes when introduced into an orifice is also important. If the first file inserted into the distal canal of a mandibular molar points either to the buccal or to the lingual aspect, the clinician should suspect a second canal. If two canals are present, they will be smaller than a single canal.

Whenever a root contains two canals that join to form one, the lingual/palatal canal generally is the one with direct access to the apex. This anatomy is best treated by preparing and obturating this canal to the apex and the buccal canal to the point of juncture. If both canals are enlarged to the apex, an hourglass preparation results; the point where the two canals join is more constricted than the preparation at the apex. Filling such a configuration leaves voids in the apical third and invites treatment failure, particularly if microorganisms or their by-products remain in the canal. Rotary nickel–titanium files must be used cautiously with this type of anatomy because instrument separation can occur as the file traverses the sharp curvature into the common part of the canal. When one canal separates into two, the division is buccal and palatal/lingual, and the lingual canal generally splits from the main canal at a sharp angle, sometimes nearly a right angle (Fig. 7-16). One investigator[191] recommends visualizing this configuration as a lower case letter h. The buccal canal is the straight-line portion of the h; the lingual canal exists about midroot at a sharp angle from the buccal canal. This requires modification of the access to achieve unobstructed passage of instruments into the lingual canal.

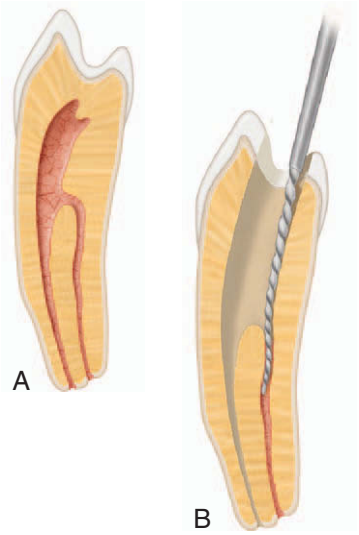

FIG. 7-16 A, Mesial view of a mandibular premolar with a Vertucci type V canal configuration. The lingual canal separates from the main canal at nearly a right angle. **B,** This anatomy requires widening of access in a lingual direction to achieve straight-line access to the lingual canal. This should be done with the dental operating microscope.

ANATOMY OF THE APICAL ROOT

The classic concept of apical root anatomy is based on three anatomic and histologic landmarks in the apical region of a root: the apical constriction (AC), the cementodentinal junction (CDJ), and the apical foramen (AF). Kuttler's description of the anatomy of the root apex has the root canal tapering from the canal orifice to the AC, which generally is 0.5 to 1.5 mm coronal to the AF (Fig. 7-17).[110] The AC generally is considered the part of the root canal with the smallest diameter; it also is the reference point clinicians use most often as the apical termination for shaping, cleaning, and obturation. Pulp blood vessels are narrow at the AC, which makes successful treatment of inflammation in the canal difficult. Posttreatment discomfort generally is greater when this area is violated by instruments or filling materials, and the healing process may be compromised.

The CDJ is the point in the canal where cementum meets dentin; it is the point where pulp tissue ends and periodontal tissues begin. The location of the CDJ in the root canal varies considerably. It generally is not in the same area as the AC, and estimates place it approximately 1 mm from the AF.[178,193]

From the AC, or minor apical diameter, the canal widens as it approaches the AF, or major apical diameter. The space between the major and minor diameters has been described as funnel shaped or hyperbolic, or as having the shape of a morning glory. The mean distance between the major and minor apical diameters is 0.5 mm in a young person and 0.67 mm in an older individual.[110] The distance is greater in older individuals because of the buildup of cementum.

The AF is the "circumference or rounded edge, like a funnel or crater, that differentiates the termination of the cemental canal from the exterior surface of the root."[110] The

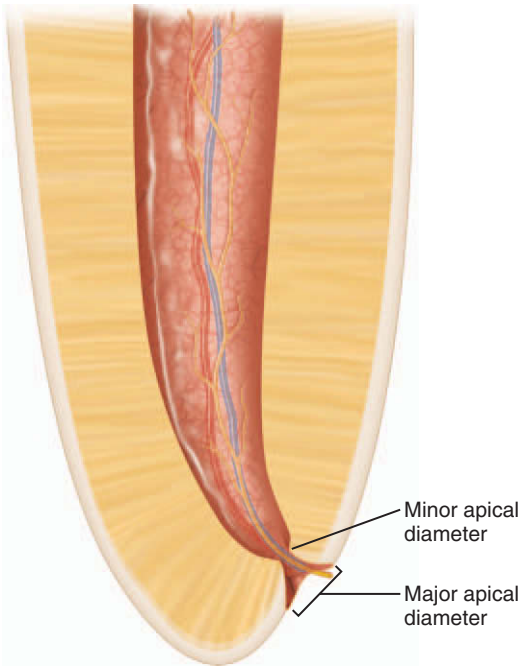

FIG. 7-17 Morphology of the root apex. From its orifice the canal tapers to the apical constriction, or minor apical diameter, which generally is considered the narrowest part of the canal. From this point the canal widens as it exits the root at the apical foramen, or major apical diameter. The space between the minor and major apical diameters is funnel shaped.

diameter of the foramen is 502 µm in individuals 18 to 25 years of age and 681 µm in those over age 55, which demonstrates the growth of the AF with age.[110] By comparison, these sizes are larger than the cross-sectional diameter of #50 and #60 endodontic files, respectively. The AF does not normally exit at the anatomic apex but rather is offset 0.5 to 3 mm. This variation is more marked in older teeth through cementum apposition. Studies have shown that the AF coincides with the apical root vertex in 17% to 46% of cases.*

The location and diameter of the CDJ differ from those of the AF in maxillary anterior teeth.[167] The extension of cementum from the AF into the root canal differs considerably, even when opposite canal walls are compared. Cementum reaches the same level on all canal walls in only 5% of cases. The greatest extension generally occurs on the concave side of the canal curvature. This variability confirms that the CDJ and the AC generally are not in the same area and that the CDJ should be considered just a variable junction at which two histologic tissues meet in the root canal. The diameter of the canal at the CDJ varies considerably; it was determined to be 353 µm for the central incisors, 292 µm for the lateral incisors, and 298 µm for the canines.[167] These measures approximate the size of #30 to #35 endodontic files.

In maxillary anterior teeth, the root apex and main AF coincided in 17% of examined central incisors and canines and in 7% of lateral incisors.[136] Both the root apex and the AF of the central incisors and canines were displaced distolabially, whereas those of the lateral incisors were displaced distolingually. The perpendicular distance from the root apex to the AC and both mesiodistal and labiolingual root canal diameters at the AC are shown in Table 7-5. The labiolingual diameter in all maxillary anterior teeth is approximately 50 µm more than the mesiodistal diameter. This has definite implications for shaping and cleaning procedures because only the mesiodistal diameter is evident on radiographs.

Scanning electron microscopy has been used to determine the number and size of main apical foramina, their distance from the anatomic apex, and the size of accessory foramina. In one study, more than one main foramen was found in all teeth except the palatal root of maxillary molars and the distal root of mandibular molars.[142] No main foramen was seen in 24% of maxillary premolars and 26% of maxillary incisors. The mesial roots of mandibular molars (50%) and maxillary premolars (48%), and the mesial roots of maxillary molars (42%), had the highest percentage of multiple main foramina. This finding is consistent with observations that blunted roots usually have more than one root canal. The mean values for the size of the main foramen are listed in Table 7-6. Sizes ranged from 210 µm

for the maxillary premolars to 392 µm for the distal roots of the mandibular molars.

All groups of teeth had at least one accessory foramen. The maxillary premolars had the most and the largest accessory foramina (mean value, 53 µm) and the most complicated apical morphologic makeup. The mandibular premolars had strikingly similar characteristics, a possible reason why root canal therapy may fail in premolar teeth.

The morphology of the apical root varies tremendously; it includes numerous accessory canals; areas of resorption and repaired resorption; attached, embedded, and free pulp stones; and varying amounts of irregular secondary dentin.[137,138] Primary dentinal tubules are found less often than in the coronal dentin and are more or less irregular in direction and density. Some areas are completely devoid of tubules. Fine tubular branches (300 to 700 µm in diameter) that run at a 45-degree angle to the main tubules and microbranches (25 to 200 µm in diameter) that run at a 90-degree angle to the main tubules are often present (Fig. 7-18). This variable structure in the apical region presents challenges for root canal therapy. Obturation techniques that rely on the penetration of adhesives into dentinal tubules may not provide successful sealing in the apical region. Therefore the formation of a hybrid layer may become an important part of adhesive systems used in the apical root canal. Conversely, the reduction in dentinal tubules in this apical region leads to reduced chances of bacterial invasion into the dentinal walls of the root.

Considerable controversy exists over the exact termination point for root canal therapy.[187] Clinical determination of apical canal morphology is difficult at best. The existence of an AC may be more conceptual than real. Several studies have reported that a traditional single AC was present less than half the time, particularly when apical root resorption and periradicular pathosis were factors.[47,57,186,232] The apical root canal often is tapered, or walls are parallel to each other, or the canal has multiple constrictions. Some authors therefore have recommended the following termination points: 1 mm from the apex when no bone or root resorption has occurred; 1.5 mm from the apex when only bone resorption has occurred; and 2 mm from the apex when both bone and root resorption have occurred.[232]

Because locating the AC and AF is difficult clinically, some researchers contend that the radiographic apex is a more reliable reference point.[246] These authors recommend that root canal procedures terminate at or within 3 mm from the radiographic apex, depending on the pulpal diagnosis. For vital cases, clinical and biologic evidence indicates that a favorable point at which to terminate therapy is 2 to 3 mm short of the radiographic apex.[104,189] This leaves an apical pulp stump, which prevents extrusion of irritating filling materials into the periradicular tissues. With pulp necrosis, bacteria and their by-products may be present in the apical root canal, which could jeopardize healing. Studies have shown that, in these cases, a better success rate is achieved when therapy ends at or within 2 mm of the radiographic apex.[103,104,189] When therapy ended short of the 2-mm point or extended past the radiographic apex, the success rate declined by 20%. For retreatment cases, therapy should extend to or preferably 1 to 2 mm short of the radiographic apex to prevent overextension of instruments and filling materials into the periradicular tissues.

Other investigators who evaluated apical and periradicular tissues after root canal therapy concluded that the most favorable prognosis was obtained when procedures were terminated at the AC, and the worst prognosis was produced by treatment that extended beyond the AC.[112-115,172] Procedures terminated more than 2 mm from the AC had the second worst prognosis. These findings occurred with vital and necrotic tissue and when bacteria were present beyond the AF. Sealer or guttapercha (or both) in the periradicular tissues, lateral canals, and apical ramifications may cause a severe inflammatory reaction. However, the authors of the studies acknowledge the difficulty of locating the AC clinically. Some researchers recommend that clinicians terminate all therapy at or beyond the radiographic apex and fill all apical ramifications and lateral canals.[180]

The apical limit of instrumentation and obturation continues to be the subject of major controversy in root canal therapy. However, modern electronic apex locators are reliable instruments that can help the clinician determine the working length of the root canal.

Two hallmarks of the apical region are its variability and unpredictability. The tremendous variation in canal shapes and diameters complicates cleaning and shaping procedures in all dimensions. Successful treatment depends on the anatomy of the root canal system, the dimensions of the canal walls, and the final size of enlarging instruments.

Sometimes the initial file chosen for exploring the canal anatomy and for binding in the canal is used as a measure of the diameter of the apical root canal. However, this technique does not accurately gauge the size of oval-shaped apical root canals. In one study, file binding occurred in 75% of such cases when the file contacted only one side of the apical canal wall, and it occurred without any apical wall contact in the remaining 25%. In 90% of the canals, the diameter of the initial instrument was smaller than the short diameter of the canal.[243] Consequently, using the first file to bind for gauging the diameter of the apical canal and as guidance for apical enlargement is not reliable. More recent studies have suggested that this problem could be remedied by removing the interferences in the coronal and middle thirds of the canal.[45,116] For example, radicular flaring before canal exploration removes interferences and increases the initial file size that is snug at the apex (almost two file sizes greater).[45] Early flaring gives the clinician a better sense of the size of the apical canal, allowing better decisions about the final diameter needed for apical shaping

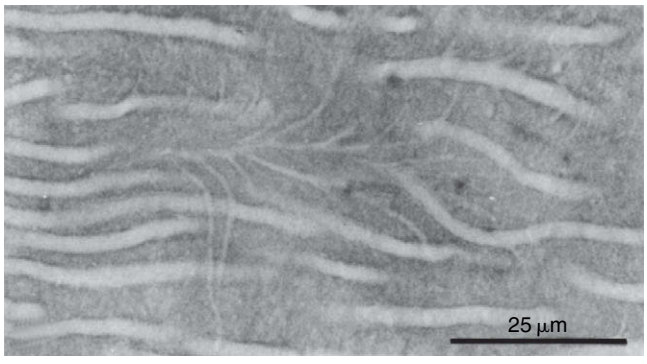

FIG. 7-18 Fine tubules and microbranches can be seen in the apical part of the root. *(From Mjör IA, Nordahl I:* Arch Oral Biol *41:401, 1996.)*

and cleaning. This is another advantage of the crown-down instrumentation technique.

The correlations between maximal canal diameters and instrument diameters varied considerably in a study that compared the shape of the apical root canal of maxillary first molars with the D_0 diameter of endodontic instruments.[71] Evaluation of the root canal diameter showed that a circular shape (the two diameters were equal) predominated in the palatal and MB-2 canals; a flat shape (the larger diameter exceeded the smaller by more than the radius) occurred most often in the main mesiobuccal (MB-1) canal; and both circular and flat shapes were found in the distobuccal canal. Flat and ribbon-shaped canals persisted near the apex even in elderly patients and mainly in the MB-1 canal. This finding was believed to arise from concentric narrowing of ribbon-shaped canals, primarily along the smaller diameter. Oval canals narrowed mainly along the larger diameter and tended to become more circular. The authors of this study concluded that the maxillary first molar has a very complicated canal shape at the apical limit and that this anatomy makes shaping, cleaning, and obturation difficult, particularly in the MB-1 and distobuccal canals. Because of this variability, guidelines for instrument calibers that would guarantee adequate canal preparation are virtually impossible to establish.

One comprehensive study reviewed the apical root canal diameters and tapers of each tooth group and demonstrated that root canals often are long and oval or ribbon shaped in the apical 5 mm (Table 7-7).[244] A long oval canal was defined as having a ratio of the diameters of the long-to-short canal axes greater than 2. This type of canal morphology was found to occur in 25% of the cross-sections studied. In these roots the buccal/lingual diameter is greater than the mesial/distal diameter. This finding held true for all canals except the palatal canal of maxillary molars. These canal measurements suggest

that apical preparations should be taken to larger sizes than previously recommended.

The authors of another study concluded that "because of long oval canals, larger canal tapers in the buccal–lingual direction, wider ranges in the apical diameters of canals, and the lack of technology to measure these diameters, it is very difficult if not impossible to adequately debride all canals by instrumentation alone."[210] This fact was further emphasized by research that showed that neither the balanced force instrumentation method nor rotary nickel–titanium files allowed controlled preparation of the buccal and lingual extensions of oval canals.[174,245] The instruments created a round bulge in the canal, leaving the extensions unprepared and filled with smear layer and debris. Another series of studies evaluated the effectiveness of five nickel–titanium rotary instrumentation systems on canal debridement and found that all techniques left 35% or more of the canal surface area unchanged.[160,162]

The results of all these studies are fairly predictable, considering the highly variable and irregular morphology of root canal systems and the endodontic intracanal instruments currently in use, which cannot contact all the recesses present along canal walls. These instruments do a good job of shaping the canal but a poor job of accomplishing total canal debridement.

In an attempt to find better ways to clean and disinfect root canals, one group of investigators determined that enlarging canals to greater than the traditionally recommended apical sizes was the only way to remove culturable bacteria from the canal effectively.[35] The larger apical sizes optimized irrigation and disinfection and facilitated mechanical elimination of microbes. A similar study concluded that an increase in the size of canal instrumentation at working length produced an increase in canal cleanliness.[214] Irrigant volume, the number of instrument changes, and the depth of penetration of irrigant needles were less important factors contributing to canal debridement. A potential adverse effect of enlarging the apical canal diameter may be an increased risk of procedural errors or root fractures or both. Further research in this area is required.[1]

As a supplement to these procedures, acoustic streaming by sonic and ultrasonic irrigation appears to enhance the cleanliness of oval canals (Fig. 7-19).[98,121] However, further research must be done to determine the best combination of treatment techniques to effectively debride these highly variable root canal systems.

One study used high-resolution computerized tomography to create a detailed, 3-D model of the root canal system.[161] This method permits precise measurement of canal volume, area, and dimensions. The mean canal diameters in the apical 0.5 mm of maxillary molars were measured for the MB-1 canal (188 ± 5 μm), the distobuccal canal (174 ± 12 μm), and the palatal canal (318 ± 23 μm). Such information goes a long way toward the establishment of final instrumentation sizes for cleaning and shaping.

The apical anatomy studies also indicate that the root apex should be resected 2 to 3 mm during surgical procedures; this removes most of the unprepared and unfilled accessory canals, eliminating a potential reservoir of pathogens.[90,142] In one study, researchers used a bevel perpendicular to the long axis of the root, and apical ramifications and accessory canals increasingly were eliminated by 1 mm of root resection (52% and 40%, respectively), 2 mm of root resection (78% and 40%), and 3 mm of root resection (98% and 93%).[106] This showed that root-end resections of 3 mm are most effective for eliminating most of these structures.

In root-end resections a bevel perpendicular to the long axis of a root exposes a small number of microtubules.[137,138] However, a root resection with a 45-degree bevel exposes a significantly greater number of tubules, increasing the chance of leakage into and out of the root canal.[208,217] To prevent this, root-end cavity preparations should extend coronally to the height of the bevel (Fig. 7-20).

The root apex contains a variety of anatomic structures and tissue remnants. Intercanal connections can become exposed, and a single foramen may become multiple foramina. Treatment results are poor if this altered anatomy is not recognized, prepared, and obturated. One study evaluated the root apex of teeth with refractory apical periodontitis that did not respond to root canal therapy and found that 70% had significant apical ramifications.[222] This incidence strongly suggests a close relationship between the anatomic complexity of the root canal system and the persistence of periradicular pathosis.

An *isthmus* is a narrow, ribbon-shaped communication between two root canals that contains pulp or pulpally derived

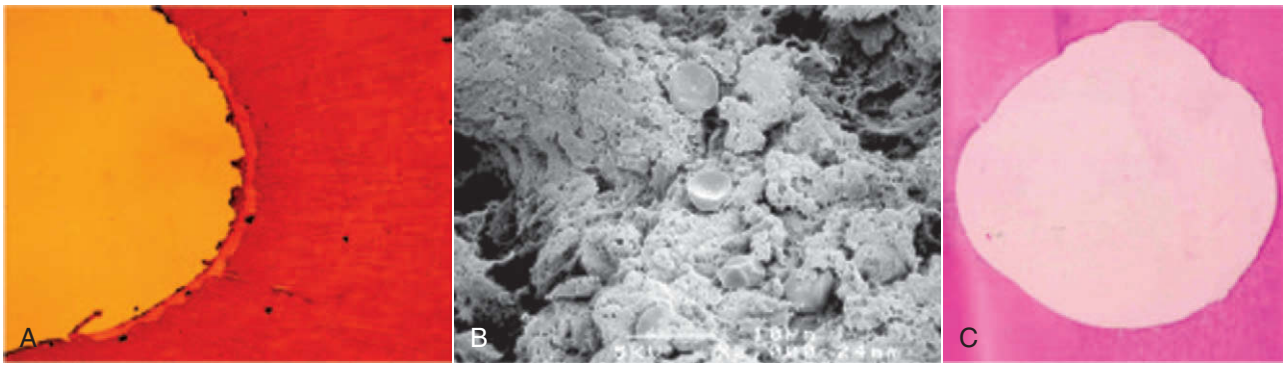

FIG. 7-19 A, Cross-section of a mandibular anterior tooth showing pulp remnants in the recesses of root canal walls in the apical 1 mm after preparation with a rotary nickel–titanium bur (size 40, #.08 taper) and manual irrigation (6% NaOCl and RC-Prep). **B,** Electron photomicrograph of the canal wall in **A,** showing canal wall debris (×3000). **C,** Cross-section of the mandibular anterior tooth showing clean canal walls in the apical 1 mm after preparation with a rotary nickel–titanium bur (size 40, #.08 taper) and sonic acoustic irrigation with 6% NaOCl.

tissue. All isthmi must be found, prepared, and filled during surgery, because they can function as bacterial reservoirs. Any root with two or more canals may have an isthmus. Therefore the presence of an isthmus should be suspected whenever multiple canals are seen on a resected root surface. In one study, the authors recommended that methylene blue dye be used to aid visualization of the outline of the resected root surface and thus detection of an isthmus.[34]

In one study, isthmi in the mesiobuccal root of maxillary first molars were found most often 3 to 5 mm from the root apex.[239] A complete or partial isthmus was found at the 4-mm level 100% of the time. In another study, partial isthmi were found more often than complete isthmi.[204]

Identification and treatment of isthmi are vital to the success of surgical procedures.[34] Investigators [106] identified five types of isthmi that can be found on a beveled root surface (Fig. 7-21).

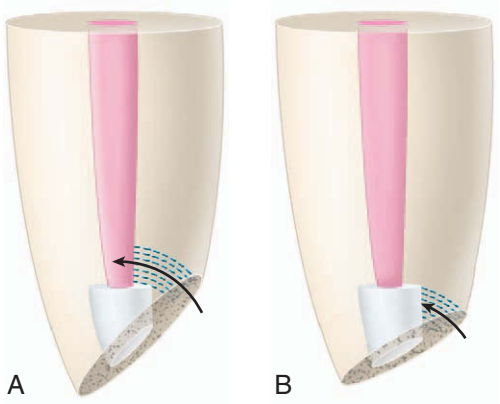

FIG. 7-20 Leakage through dentinal tubules originating at the beveled root surface. **A,** Reverse filling does not extend coronally to the height of the bevel. *Arrows* indicate a possible pathway for fluid penetration. **B,** Reverse filling extends coronally to the height of the bevel, blocking fluid penetration *(arrows)* into the root canal space. *(Redrawn from Vertucci FJ, Beatty RG:* J Endod *12:335, 1986.)*

Isthmi are found in 15% of anterior teeth; in maxillary premolar teeth, they are found in 16% at the 1-mm resection level and in 52% at the 6-mm resection level. The prevalence of isthmi increases in the mesiobuccal root of the maxillary first molar, from 30% to 50% as the root is resected from the 2- to 4-mm level. Eighty percent of the mesial roots of mandibular first molars have isthmi at the 3- to 4-mm resection level, whereas 15% of distal roots have isthmi at the 3-mm level. Microsurgical endodontic techniques have enabled clinicians to visualize the resected root surface and identify the isthmus, prepare it with ultrasonic tips, and fill the root-end preparation with acceptable materials. The recognition and microendodontic treatment of canal isthmi have significantly reduced the failure rate of endodontic surgery.[174,175]

OBJECTIVES AND GUIDELINES FOR ACCESS CAVITY PREPARATION

Objectives

Access is the first and arguably most important phase of nonsurgical root canal treatment. A well-designed access preparation is essential for a good endodontic result.[203] Without adequate access, instruments and materials become difficult to handle properly in the highly complex and variable root canal system. The objectives of access cavity preparation are (1) to remove all caries, (2) to conserve sound tooth structure, (3) to completely unroof the pulp chamber, (4) to remove all coronal pulp tissue (vital or necrotic), (5) to locate all root canal orifices, (6) to achieve straight- or direct-line access to the apical foramen or to the initial curvature of the canal, and (7) to establish restorative margins to minimize marginal leakage of the restored tooth.

A properly prepared access cavity creates a smooth, straight-line path to the canal system and ultimately to the apex, or position of the first curvature (Fig. 7-22). Straight line access provides the best chance of debridement of the entire canal space and reduces the risk of file breakage.[140] When prepared correctly the access cavity allows complete irrigation, shaping and cleaning, and quality obturation. Ideal access results in straight entry into the canal orifice, with the line angles forming

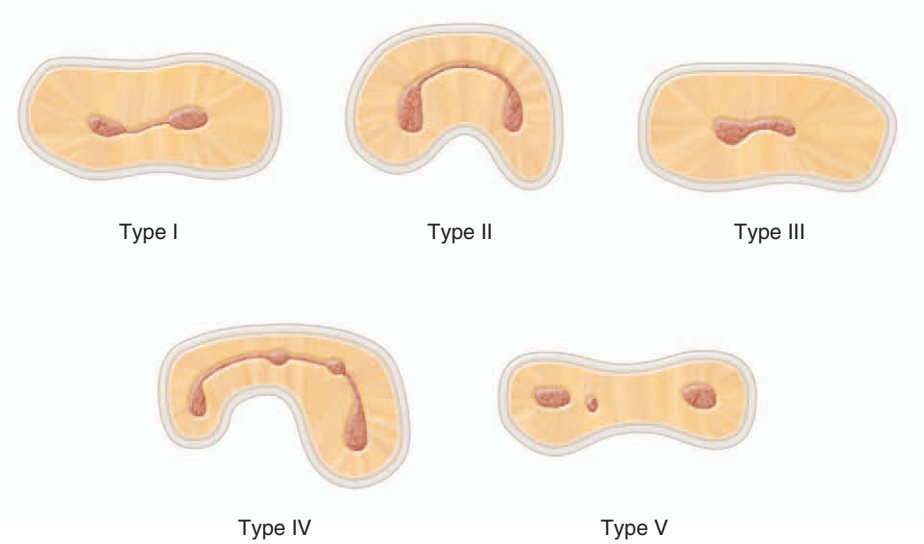

FIG. 7-21 Schematic representation of isthmus classifications described by Kim and colleagues.[106] Type I is an incomplete isthmus; it is a faint communication between two canals. Type II is characterized by two canals with a definite connection between them (complete isthmus). Type III is a very short, complete isthmus between two canals. Type IV is a complete or incomplete isthmus between three or more canals. Type V is marked by two or three canal openings without visible connections.

FIG. 7-22 Straight-line access to a canal. The instrument should not be deflected until it reaches the initial canal curvature. In some cases coronal tooth structure must be sacrificed to obtain direct access to the pulp chamber.

a funnel that drops smoothly into the canal(s). Projection of the canal center line to the occlusal surface of the tooth indicates the location of the line angles. Connection of the line angles creates the outline form. Modifications of the outline form may be needed to facilitate location of canals and to create a convenience form. The clinician must find a balance between creating adequate access and removing too much dentin, which could compromise the final restoration or promote crown fracture.

Guidelines

The guidelines described in the following sections are essential for the completion of an ideal access preparation.

Visualization of the Likely Internal Anatomy

Because internal anatomy dictates access shape, the first step in preparing an access cavity is visualization of the position of the pulp space in the tooth. This visualization requires evaluation of angled periapical radiographs and examination of tooth anatomy at the coronal, cervical, and root levels. Diagnostic radiographs help the clinician estimate the position of the pulp chamber, the degree of chamber calcification, the number of roots and canals, and the approximate canal length. Palpation along the attached gingiva aids the determination of root location and direction. The clinician uses the information from these assessments to choose the direction of initial bur penetration.

Evaluation of the Cementoenamel Junction and Occlusal Anatomies

Traditionally, access cavities have been prepared in relation to the occlusal anatomy. However, complete reliance on the occlusal anatomy is dangerous because this morphology can change as the crown is destroyed by caries and reconstructed with various restorative materials. Complete dependence on the occlusal anatomy may explain the occurrence of some procedural errors. In one a study involving 500 pulp chambers, Krasner and Rankow[108] found that the cementoenamel junction (CEJ) was the most important anatomic landmark for determining the location of pulp chambers and root canal orifices. The study demonstrated the existence of a specific and consistent anatomy of the pulp chamber floor. These authors proposed nine guidelines, or laws, of pulp chamber anatomy to help clinicians determine the number and location of orifices on the chamber floor (Fig. 7-23).

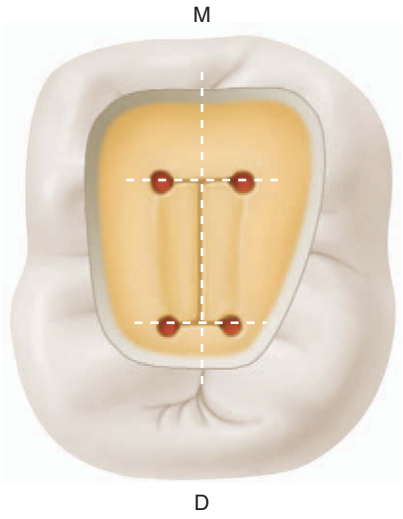

FIG. 7-23 Diagrammatic representation of Krasner and Rankow's first and second laws of symmetry and first through third laws of orifice location. *D,* Distal; *M,* mesial.

Law of centrality: The floor of the pulp chamber is always located in the center of the tooth at the level of the CEJ.

Law of concentricity: The walls of the pulp chamber are always concentric to the external surface of the tooth at the level of the CEJ, that is, the external root surface anatomy reflects the internal pulp chamber anatomy.

Law of the CEJ: The distance from the external surface of the clinical crown to the wall of the pulp chamber is the same throughout the circumference of the tooth at the level of the CEJ, making the CEJ is the most consistent repeatable landmark for locating the position of the pulp chamber.

First law of symmetry: Except for the maxillary molars, canal orifices are equidistant from a line drawn in a mesiodistal direction through the center of the pulp chamber floor.

Second law of symmetry: Except for the maxillary molars, canal orifices lie on a line perpendicular to a line drawn in a mesiodistal direction across the center of the pulp chamber floor.

Law of color change: The pulp chamber floor is always darker in color than the walls.

First law of orifice location: The orifices of the root canals are always located at the junction of the walls and the floor.

Second law of orifice location: The orifices of the root canals are always located at the angles in the floor–wall junction.

Third law of orifice location: The orifices of the root canals are always located at the terminus of the roots' developmental fusion lines.

More than 95% of the teeth these investigators examined conformed to these laws.[108] Slightly fewer than 5% of mandibular second and third molars did not conform because of the occurrence of C-shaped anatomy.

Preparation of the Access Cavity Through the Lingual and Occlusal Surfaces

Access cavities on anterior teeth usually are prepared through the lingual tooth surface, and those on posterior teeth are prepared through the occlusal surface. These approaches are the best means of achieving straight-line access and diminishing esthetic and restorative concerns. Some authors have recommended that the traditional anterior access for mandibular incisors be moved from the lingual surface to the incisal surface in selected cases.[132] This allows better access to the lingual canal and improves canal debridement (Fig. 7-24).

Removal of All Defective Restorations and Caries Before Entry Into the Pulp Chamber

The clinician must remove all defective restorations before entering the root canal system. With an open preparation, canals are much easier to locate, and shaping, cleaning, and obturation are much easier to perform. In one study,[1] it was determined that clinicians were about 40% more likely to miss fractures, caries, and marginal breakdown if restorations were not completely removed. Working through restorations also allows restorative debris to become more easily lodged in the canal system (see Fig. 7-74, D).

All carious dentin must be removed during access preparation. This removal prevents irrigating solutions from leaking past the rubber dam into the mouth and prevents carious dentin and its bacteria from entering the root canal system. If a chamber wall is perforated during removal of carious dentin, allowing leakage of saliva into the pulp spaces, the wall must be repaired immediately with a temporary filling material, preferably from inside the cavity preparation. Sometimes removal of extensive defective restorations and carious dentin may not leave enough tooth structure for placement of a rubber dam clamp to seal against salivary contamination. A crown-lengthening procedure should be performed to correct this situation before the root canal procedure is begun.

FIG. 7-24 An incisal access cavity on mandibular anterior teeth may allow for improved straight-line access and canal debridement.

Removal of Unsupported Tooth Structure

Preparation of an access cavity results in the removal of part of the central portion of the tooth thereby reducing the tooth's resistance to occlusal stresses. After completing the preparation, the clinician should remove all unsupported tooth structure to assess restorability and to prevent tooth fracture. Unnecessary removal of sound tooth structure should be avoided.

Creation of Access Cavity Walls That Do Not Restrict Straight- or Direct-line Passage of Instruments to the Apical Foramen or Initial Canal Curvature

Complete clinician control over all enlarging and filling instruments is vital. Sufficient tooth structure must be removed to allow instruments to be placed easily into each canal orifice without interference from canal walls, particularly when a canal curves severely or leaves the chamber floor at an obtuse angle. Hence, access design is dependent not only on the orifice location, but also on the position and curvature of the entire canal. The walls of the root canal, rather than the walls of the access preparation, must guide the passage of instruments down the canal. Failure to follow this guideline results in treatment errors, including root perforation, misdirection of an instrument from the main canal (ledge formation), instrument separation, or creation of an incorrect canal shape (apical transportation). Following this guideline minimizes the occurrence of procedural errors and maximizes the effectiveness of shaping, cleaning, and obturation instruments.

Delay of Dental Dam Placement Until Difficult Canals Have Been Located and Confirmed

Difficulty can arise in gaining access into teeth that are crowded and rotated, fractured to the free gingival margin, heavily restored and calcified, or part of a fixed prosthesis. In these situations the clinician's best course of action may be to prepare the initial part of the access cavity before placing the dental dam so that the inclination of root eminences can be visualized; this information can be used as an indicator of the direction of the long axis of the treated tooth. Micro-Openers (DENTSPLY Maillefer, Tulsa, OK) (Fig. 7-25) are excellent instruments for locating canal orifices when a dental dam has not been placed. These flexible, stainless steel hand instruments have #.04 and #.06 tapered tips. They also have offset handles that provide enhanced visualization of the pulp chamber.

The dental dam must be placed once the roof of the pulp chamber has been penetrated and the canals identified.

Location, Flaring, and Exploration of All Root Canal Orifices

A sharp endodontic explorer is used to locate canal orifices and to determine their angle of departure from the pulp

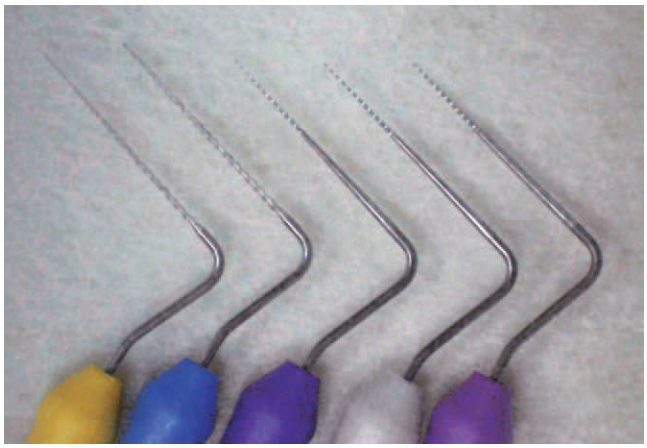

FIG. 7-25 Set of Micro-Openers (DENTSPLY Maillefer, Tulsa, OK) for canal identification and enlargement.

chamber. Next, all canal orifices and the coronal portion of the canals are flared to make instrument placement easier. The canals are then explored with small, precurved K-files (#6, #8, or #10). The clinician must take care to keep these instruments within the confines of the canal system until the working length has been accurately determined. A lubricating agent (e.g., RC-Prep [Premier Dental Products, Plymouth Meeting, PA], a water-based preparation that will not congeal vital pulp tissue), may be used on instruments and introduced into the canal. Congealed pulp tissue may form a collagen plug that blocks the apex, preventing complete shaping and cleaning.

Inspection of the Pulp Chamber, Using Magnification and Adequate Illumination

Magnification and illumination are particularly important in root canal therapy, especially for determining the location of canals; negotiating constricted, curved, and calcified canals; and débriding and removing tissue and calcifications from the pulp chamber. Enhanced vision allows the clinician to see internal dentin color changes and subtle landmarks that may not be visible to the unaided eye. Surgical loupes, endodontic endoscopes,[12] and the DOM are some of the commercially available instruments that can help the clinician accomplish these goals. A clinician trained in microscopic techniques has a better chance of locating and negotiating intricate root canal systems.

Tapering of Cavity Walls and Evaluation of Space Adequacy for a Coronal Seal

A proper access cavity generally has tapering walls with its widest dimension at the occlusal surface. In such a preparation, occlusal forces do not push the temporary restoration into the cavity and disrupt the seal. At least 3.5 mm of temporary filling material (e.g., Cavit [3M, St. Paul, MN]) is needed to provide an adequate coronal seal for a short time.[230] Recently, canal orifice plugs of composite, glass ionomer, and mineral trioxide aggregate (ProRoot MTA; DENTSPLY Tulsa Dental Specialties, Tulsa, OK) have shown promise in reducing the risk of bacterial contamination of the canal system when microleakage occurs at the coronal–restorative margins.[96]

MECHANICAL PHASES OF ACCESS CAVITY PREPARATION

Armamentaria

The preparation of an access cavity requires the following equipment:

- Magnification and illumination
- Handpieces
- Burs
- Endodontic explorer (DG-16, DE-17)
- Endodontic spoon
- #17 operative explorer
- Ultrasonic unit and tips

Magnification and Illumination

The access cavity cannot be prepared adequately without the use of magnification and an appropriate light source. At the least, the clinician needs surgical loupes with an auxiliary light source (see Chapter 6). The DOM is the preferred means of magnification and illumination.

Handpieces

An experienced clinician with good tactile awareness is likely to perform most phases of access preparation with a high-speed handpiece. After penetration of the dentin, a less experienced clinician may benefit from the increased tactile awareness offered by a slow-speed handpiece. For challenging access cavity preparations, especially those involving calcified and receded pulp chambers, even experienced clinicians may sacrifice cutting speed and efficiency in favor of the increased cutting control of the slow-speed handpiece or an ultrasonic tip used with the DOM.

Burs

Numerous burs have been developed to assist the clinician with access cavity preparation. Providing a detailed, unabridged list of these burs would be difficult, and most clinicians have their own set of preferred access burs. In reality, creating an access cavity that meets the previously stated guidelines is more important than worrying about which burs are used in the process. This discussion therefore covers some of the more common access burs.

Round carbide burs (sizes #2, #4, and #6) (Fig. 7-26) are used extensively in the preparation of access cavities. They are used to remove caries and to create the initial external outline shape. They also are useful for penetrating through the roof of the pulp chamber and for removing the roof. Some clinicians prefer to use a fissure carbide bur (Fig. 7-27) or a diamond bur with a rounded cutting end (Fig. 7-28) to perform these procedures. The advantage of the fissure carbide and diamond round-end burs is that they also can be used for some of the axial wall extensions of the access cavity preparation. However, when these burs are used for this purpose by inexperienced clinicians, their cutting ends can gouge the pulp floor and axial walls (see Fig. 7-75, *A*).

Fissure carbide and diamond burs with safety tips (i.e., noncutting ends) (Fig. 7-29) are safer choices for axial wall extensions. They can be used to extend and favorably orient the axial walls of the pulp chamber. Because they have no cutting end, the burs can be allowed to extend to the pulp floor, and the entire axial wall can be moved and oriented all

FIG. 7-26 Access burs: #2, #4, and #6 round carbide burs.

FIG. 7-27 Access bur: #57 fissure carbide bur.

in one plane from the enamel surface to the pulp floor. Such a technique produces axial walls free of gouges as the final access extensions are created. Fissure carbide and diamond burs also can be used to level off cusp tips and incisal edges, which are used as reference points for the working length determination.

Round diamond burs (sizes #2 and #4) (Fig. 7-30) are needed when endodontic access must be made through porcelain or ceramometal restorations. Diamond burs are less traumatic to porcelain than carbide burs and are more likely to

FIG. 7-28 Access bur: round-end cutting tapered diamond bur.

FIG. 7-29 Access burs: Safety-tip tapered diamond bur *(left)*; safety-tip tapered carbide bur *(right)*.

penetrate the porcelain without cracking or fracturing it. They should always be used with water spray to control heat buildup in porcelain restorations. After penetrating the porcelain the clinician should switch to a carbide bur for metal or dentin penetration because of this bur's greater cutting efficiency.

FIG. 7-30 Access burs: #2 and #4 round diamond burs.

FIG. 7-31 Access bur: Transmetal bur.

A trend in restorative dentistry is the increased use of zirconia-based crowns and onlays. Zirconia has different mechanical and thermal characteristics than metal. Carbide burs do not cut zirconia efficiently or safely. Zirconia is a brittle material and, when cut, can develop cracks that propagate through the framework and lead to eventual failure of the crown or onlay. Diamond bur–manufacturing companies are aware of these issues and they are currently introducing medium- and fine-grit diamond burs that efficiently cut zirconia. These diamond burs should be used with copious water spray to minimize heat buildup in the zirconia crowns during access preparations. Also, some diamond burs degrade rapidly when cutting through zirconia and should be thrown away after one use.

Many teeth requiring access cavity preparations have metal restorations that must be penetrated. These restorations may be amalgams, all-metal cast restorations, or metal copings of porcelain fused to metal crowns. A transmetal bur (Fig. 7-31) is excellent for this purpose because of its exceptional cutting efficiency. To penetrate a metal restoration, the clinician should always use a new transmetal bur with water spray for maximal cutting effect.

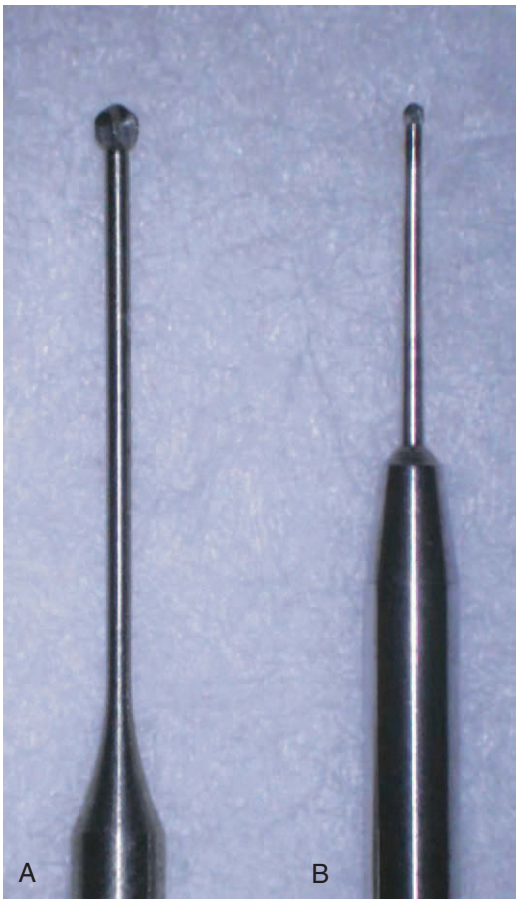

FIG. 7-32 Access burs. **A,** Mueller bur. **B,** LN bur.

If a tooth has a receded pulp chamber and calcified orifices, the clinician often must cut into the root to locate and identify the canal orifices. Extended-shank round burs, such as the Mueller bur (Brasseler USA, Savannah, GA) (Fig. 7-32, *A*) and the LN bur (DENTSPLY Maillefer, Tulsa, OK) (Fig. 7-32, *B*), are useful for this purpose. The Munce Discovery bur (CJM Engineering, Santa Barbara, CA) is similar to the Mueller but has a stiffer shaft and is available in smaller head sizes. The extra-long shank of these burs moves the head of the handpiece away from the tooth, improving the clinician's visibility during this delicate procedure. As an alternative, ultrasonic units offer good visibility with precision cutting.

Once the orifices have been located, they should be flared or enlarged and blended into the axial walls of the access cavity. This process permits the intracanal instruments used during shaping and cleaning to enter the canal(s) easily and effortlessly. Gates-Glidden burs can be used for this purpose, starting with smaller sizes and progressing to the larger sizes (Fig. 7-33). More recently, #.12 tapered rotary endodontic files (Fig. 7-34) have been used for the flaring and blending procedure. When using either of these two techniques for canal flaring, the clinician must guard against removing excessive dentin on the furcation side of a root canal, which could create a "strip" perforation.

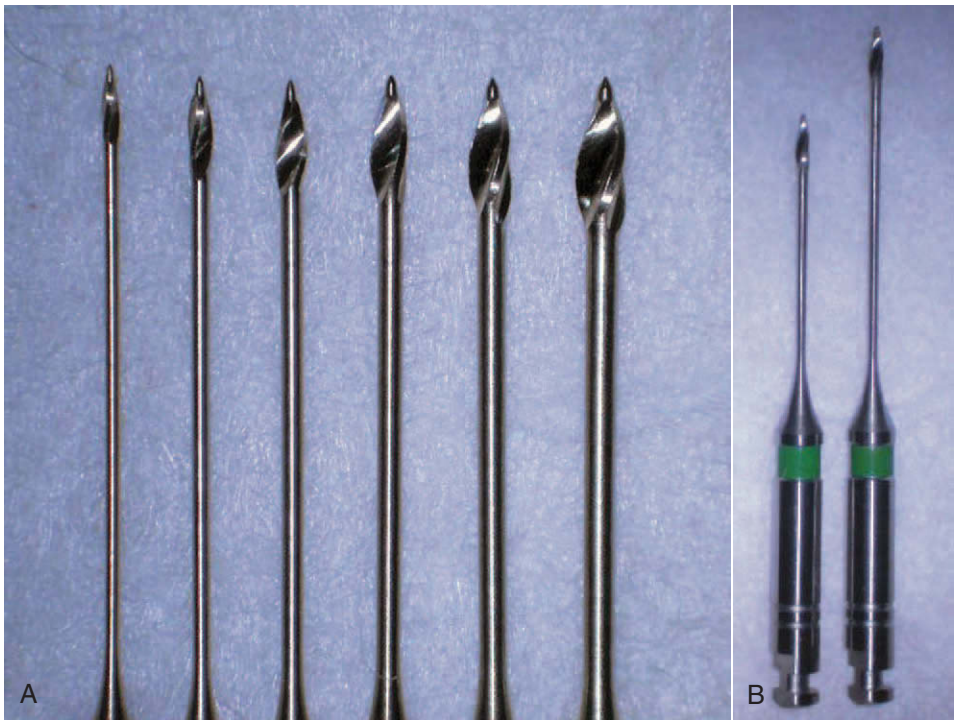

FIG. 7-33 Access burs. **A,** Gates-Glidden burs, 1 through 6. **B,** Gates-Glidden burs, short shank *(left)* and regular shank *(right)*.

FIG. 7-34 Access bur: #.12 taper nickel–titanium orifice opener.

Endodontic Explorer, Endodontic Spoon, #17 Operative Explorer

Various hand instruments are useful for preparing access cavities. The DG-16 endodontic explorer (Fig. 7-35) is used to identify canal orifices and to determine canal angulation. The JW-17 endodontic explorer (Fig. 7-35) (CK Dental Industries, Orange, CA) serves the same purpose, but its thinner, stiffer tip can be useful for identifying calcified canals. The endodontic spoon (Fig. 7-36) can be used to remove coronal pulp and carious dentin. A #17 operative explorer is useful for detecting any remaining pulp chamber roof, particularly in the area of a pulp horn (Fig. 7-37).

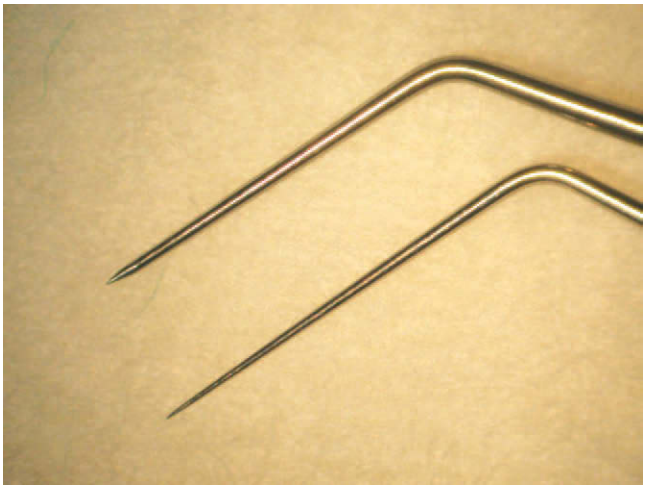

FIG. 7-35 Access instruments: DG-16 endodontic explorer *(top)*; JW-17 endodontic explorer *(bottom)*.

Ultrasonic Unit and Tips

An ultrasonic unit (Fig. 7-38) and tips specifically designed for endodontic procedures can be valuable aids in the preparation of access cavities. Ultrasonic tips (Fig. 7-39) can be used to trough and deepen developmental grooves to remove tissue

FIG. 7-36 Access instrument: Endodontic spoon.

FIG. 7-37 Removal of the pulp horn is evaluated with a #17 operative explorer.

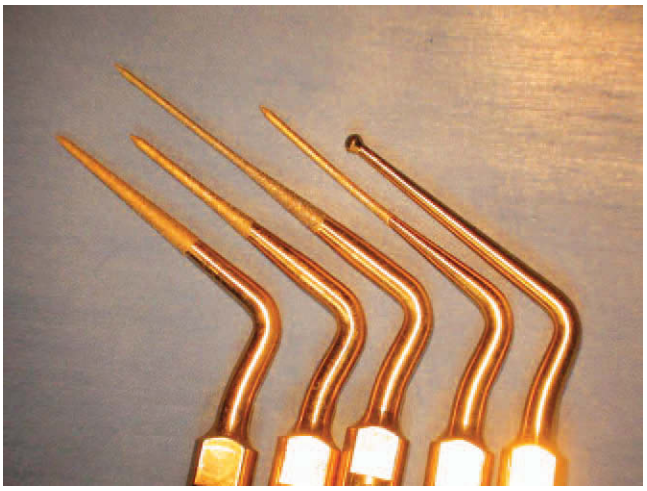

FIG. 7-39 Endodontic ultrasonic tips.

and explore for canals. Ultrasonic systems provide outstanding visibility compared with conventional handpiece heads, which typically obstruct vision. Fine ultrasonic tips are smaller than conventional round burs, and their abrasive coatings allow clinicians to sand away dentin and calcifications conservatively when exploring for canal orifices.

Access Cavity Preparations

Anterior Access Cavity Preparations

Many of the same steps are used in similar tooth types to prepare an access cavity. The following discussion outlines the steps for maxillary and mandibular anterior teeth. Tooth-specific access concerns are illustrated and discussed in the section Morphology and Access Cavity Preparations for Individual Teeth, later in the chapter.

REMOVAL OF CARIES AND PERMANENT RESTORATIONS

Caries typically is removed early, before the pulp chamber is entered. This minimizes the risk of contamination of the pulp chamber or root canal(s) with bacteria. Defective permanent restorations, whether amalgams, composite resins, or crowns, must be removed entirely to prevent coronal leakage from contaminating the pulp chamber, the root canal(s), or both after the endodontic appointment. Removal of defective permanent restorations also permits straight-line access and prevents restorative fragments from becoming lodged in the root canal system (see Fig. 7-74, *D*). If recurrent decay is detected or suspected, the permanent restoration must be removed entirely to prevent coronal contamination of the pulp chamber.

The management of intact permanent restorations when recurrent caries is not present requires some judgment. Amalgam and composite restorations typically are removed entirely to improve visibility during the search for root canal orifices. As stated in an earlier study,[1] clinicians were about 40% more likely to miss fractures, caries, and marginal breakdown if restorations were not completely removed. However, the clinician may want to retain the proximal portion of a class II restoration that extends subgingivally to aid in rubber dam isolation. When parts of existing permanent restorations are

not removed, the clinician usually can widen the access opening larger than is ideal at the expense of removing restorative material, not sound tooth structure. The remaining permanent restoration material is removed at the end of the appointment before the temporary restoration is placed.

Often clinicians decide to perform endodontic therapy through intact crowns rather than removing or replacing them. These access cavities are repaired after completion of the root canal procedure. The patient and the clinician must realize that visibility can be compromised in these circumstances, particularly if a DOM is not used. The clinician can enhance visibility by beveling the crown's cavosurface margins and by making sure all axial walls are glassy smooth.

INITIAL EXTERNAL OUTLINE FORM

Once caries and restorations have been addressed, the clinician creates an initial external outline opening on the lingual surface of the anterior tooth. This step often is performed during the removal of caries and restorations. For an intact tooth, the clinician should begin in the center of the lingual surface of the anatomic crown (Fig. 7-40, *A*). A #2 or #4 round bur or a tapered fissure bur is used to penetrate through the enamel and slightly into the dentin (approximately 1 mm). An outline form is created, similar in geometry to an ideal access shape for the particular anterior tooth (see Fig. 7-40, *B*); it is one half to three quarters the projected final size of the access cavity. Because most of this step involves removal of enamel, the high-speed handpiece is used for cutting efficiency. The bur is directed perpendicular to the lingual surface as the external outline opening is created (see Fig. 7-40, *C*).

PENETRATION OF THE PULP CHAMBER ROOF

Experienced clinicians can comfortably penetrate the pulp chamber roof with a high-speed handpiece, but less experienced clinicians may find the increased tactile sensation of a slow-speed handpiece a safer option. Continuing with the

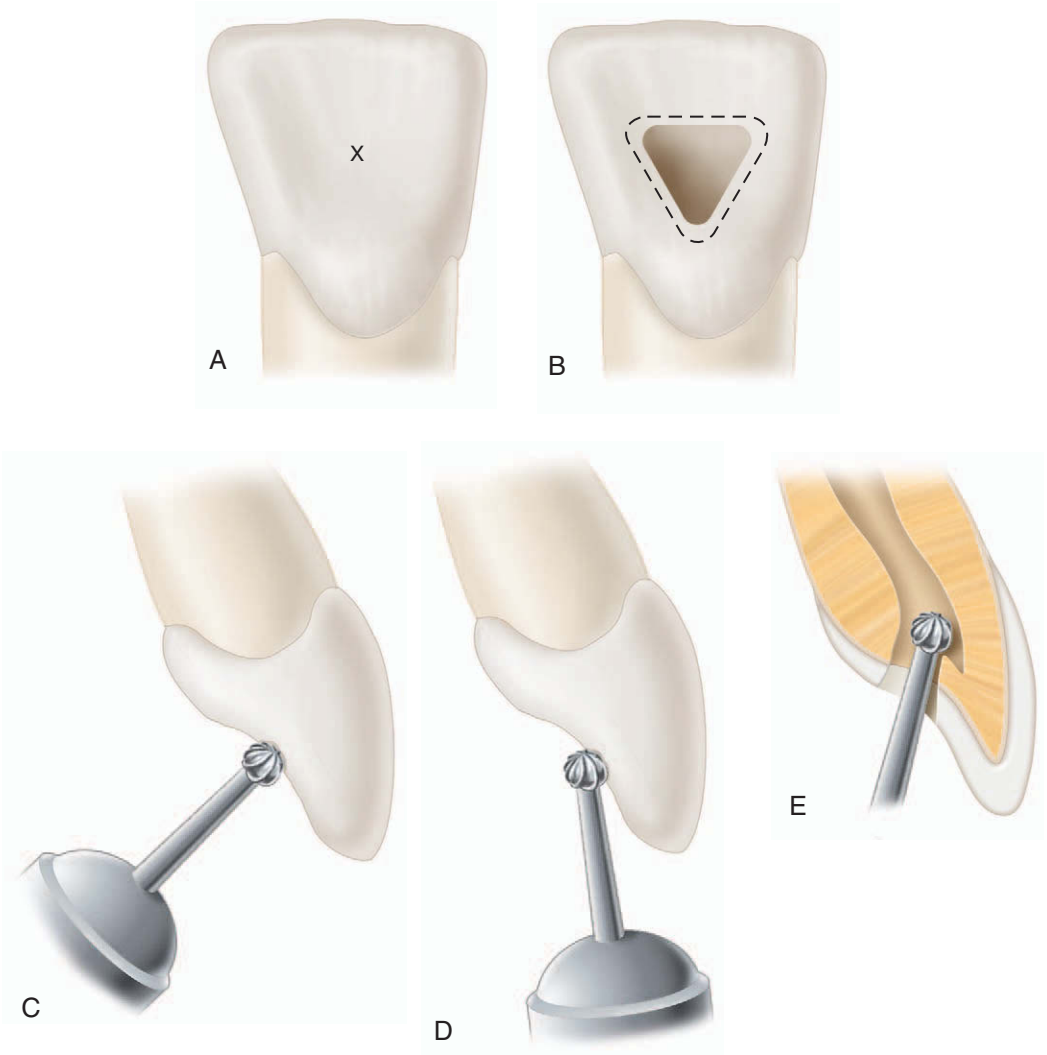

FIG. 7-40 A, In anterior teeth the starting location for the access cavity is the center of the anatomic crown on the lingual surface (*X*). **B,** Preliminary outline form for anterior teeth. The shape should mimic the expected final outline form, and the size should be one half to three fourths the size of the final outline form. **C,** The angle of penetration for the preliminary outline form is perpendicular to the lingual surface. **D,** The angle of penetration for initial entry into the pulp chamber is nearly parallel to the long axis of the root. **E,** Completion of removal of the pulp chamber roof; a round carbide bur is used to engage the pulp horn, cutting on a lingual withdrawal stroke.

same round or tapered fissure bur, the clinician changes the angle of the bur from perpendicular to the lingual surface to parallel to the long axis of the root (see Fig. 7-40, *D*). Penetration into the tooth is accomplished along this root's long axis until the roof of the pulp chamber is penetrated; frequently a drop-in effect is felt when this occurs. The clinician should measure the distance from the incisal edge to the roof of the pulp chamber on a dimensionally accurate pretreatment radiograph and limit penetration to this distance. If the drop-in effect is not felt at this depth, the clinician should evaluate the situation carefully to prevent a gouge or perforation. The depth and angle of penetration should be assessed for any deviation away from the long axis of the root in both the mesiodistal and buccolingual dimensions, and the penetration angle should be realigned if necessary. If all looks good, the clinician should probe the access opening with an endodontic explorer, using magnification and illumination. Often the sharp explorer tip penetrates through the pulp chamber roof with firm pressure. Angled radiographs should be taken to assess progress if any confusion or doubt exists. A little caution and concern at this stage can prevent an iatrogenic mishap (see Fig. 7-75, *C*).

COMPLETE ROOF REMOVAL

Once the pulp chamber has been penetrated, the remaining roof is removed by catching the end of a round bur under the lip of the dentin roof and cutting on the bur's withdrawal stroke (see Fig. 7-40, *E*). Because each tooth has a unique pulp chamber anatomy, working in this manner allows the internal pulp anatomy to dictate the external outline form of the access opening. In vital cases, pulp tissue hemorrhage can impair the clinician's ability to see the internal anatomy. In such cases, as soon as enough roof has been removed to allow instrument access, the coronal pulp should be amputated at the orifice level with an endodontic spoon or round bur and the chamber irrigated copiously with sodium hypochlorite. If the hemorrhage continues, a tentative canal length can be established by measuring the pretreatment radiograph. A small broach coated with a chelating agent then can be introduced into the canal and rotated, thereby amputating the radicular pulp at a more apical level. This procedure is followed by irrigation with sodium hypochlorite. After hemorrhage has been controlled, allowing visibility, all of the pulp chamber roof, including the pulp horns, must be removed and all internal walls must be flared to the lingual surface of the tooth. Complete roof removal is confirmed with a #17 operative explorer if no "catches" are discovered as the explorer tip is withdrawn from the pulp chamber along the mesial, distal, and facial walls.

IDENTIFICATION OF ALL CANAL ORIFICES

After the pulp chamber has been unroofed, the canal orifices are located with an endodontic explorer (Fig. 7-41). This instrument is to the endodontist what a periodontal probe is to the periodontist. Used for reaching, feeling, and often digging at the hard tissue, it is the tactile extension of the clinician's fingers. Natural anatomy indicates the usual places for orifices, but restorations, dentinal protrusions, and dystrophic calcifications can dictate the actual configuration the clinician encounters. While probing the chamber floor, the explorer often penetrates or dislodges calcific deposits blocking an orifice. It also can be used to evaluate straight-line access. Positioning the explorer in an orifice allows the clinician to check the shaft for clearance from the axial walls and to determine the angle at which a canal departs the main chamber (Fig. 7-42).

FIG. 7-41 An endodontic explorer is used to search for canal orifices.

The endodontic explorer is preferred over the rotating bur as the instrument for locating canal orifices. Not only is the explorer a safer option, its double-ended design also offers two angles of approach. The clinician should keep in mind the probability of finding additional canals in the tooth and the most likely anatomic location of these canals.

In a study[94] involving maxillary molars, the authors looked at several pretreatment variables and their influence on the clinician's likelihood of detecting root canals. The results of this study indicated that the number of root canals detected varied according to age and caries. Age was a significant factor in detecting fewer canals, most likely due to the calcification and morphologic changes that occurs in root canals as a patient ages. The presence of caries at the time of treatment resulted in the detection of greater number of root canals. However, because caries was associated with younger individuals in this study, age seems to play the dominant role in the clinician's likelihood of detecting root canals.

REMOVAL OF THE LINGUAL SHOULDER AND ORIFICE AND CORONAL FLARING

Once the orifice(s) has been identified and confirmed, the lingual shoulder is removed. This structure is the lingual shelf of dentin that extends from the cingulum to a point approximately 2 mm apical to the orifice (Fig. 7-43). Its removal aids straight-line access and allows for more intimate contact of files with the canal's walls for effective shaping and cleaning.

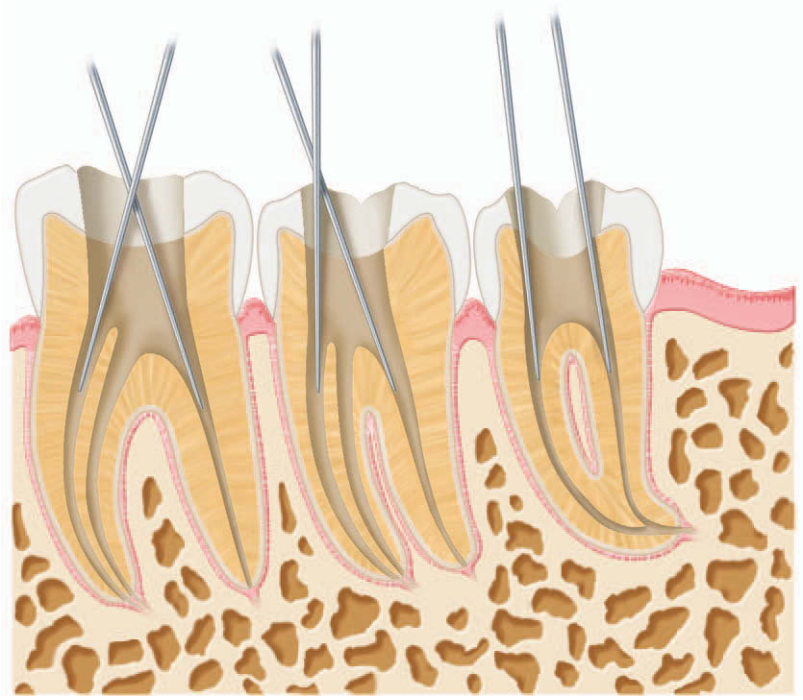

FIG. 7-42 Root canal orifices are explored to assess straight-line access and to determine the path of insertion for endodontic instruments.

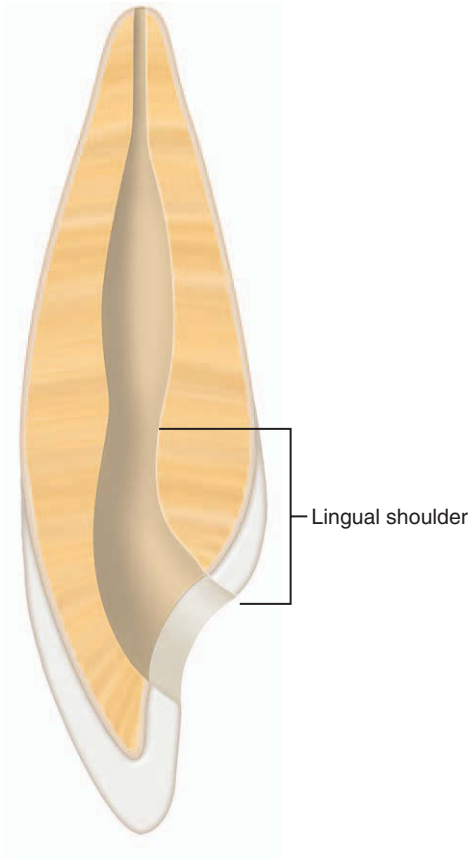

FIG. 7-43 Lingual shoulder of the anterior tooth, extending from the cingulum to 2 mm apical to the orifice.

The lingual shoulder can be removed with a tapered safety-tip diamond or carbide bur or with Gates-Glidden burs. The tip of a fine safety-tip diamond bur is placed approximately 2 mm apical to the canal orifice and inclined to the lingual during rotation to slope the lingual shoulder. The clinician must be careful when using this bur to avoid placing a bevel on the incisal edge of the access preparation (Fig. 7-44). When Gates-Glidden burs are used, the largest that can passively be placed 2 mm apical to the orifice is used first. During rotation, the bur is leaned against the lingual shoulder and withdrawn. The clinician can increase the size of these burs sequentially, depending on the size of the canal, and repeat the shaping of the lingual wall until the lingual shoulder of dentin has been eliminated.

During this process the orifice should also be flared so that it is contiguous with all walls of the access preparation. This can be done with small to large Gates-Glidden burs. These burs are used in a circumferential filling motion, flaring each wall of the canal in sequence. To prevent iatrogenic mishaps on thin walls facing a root concavity, these burs should be placed passively into the canal and rotated as they are gently leaned against a canal wall and withdrawn.

Another approach to flaring the orifice involves the use of rotary nickel–titanium orifice openers; they should be used at slow speeds and low torque.

STRAIGHT-LINE ACCESS DETERMINATION

After the lingual shoulder has been removed and the orifice(s) flared, the clinician must determine whether straight-line access has been achieved. Ideally, an endodontic file can approach the apical foramen or the first point of canal curvature undeflected. Unnecessary deflection of the file can result in numerous consequences related to loss of instrument control. Deflected instruments function under more stress than

FIG. 7-44 Placing an incisal bevel on the lingual surface of a maxillary anterior tooth can lead to fracture of the permanent restoration during occlusal function.

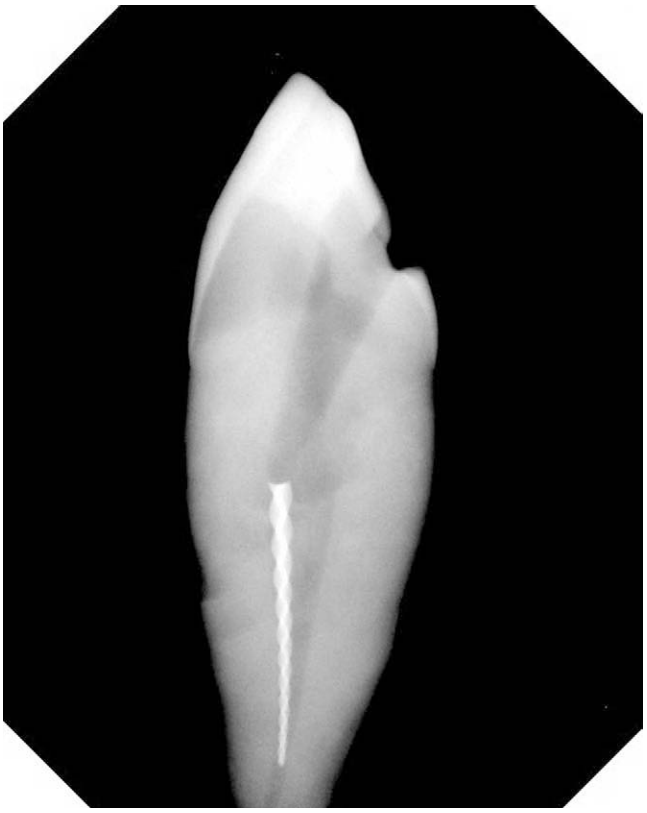

FIG. 7-45 Separation of a rotary endodontic instrument as a result of underextended access preparation rather than canal binding.

undeflected instruments and are more susceptible to separation during the shaping and cleaning process (Fig. 7-45). Deflected instruments also lack access to critical areas of the canal and therefore do not shape and clean effectively. Attempts to shape and clean without straight-line access often lead to procedural errors such as ledging, transportation, and zipping (Fig. 7-46). A ledge is an iatrogenically created root canal wall irregularity that may impede placement of an intracanal instrument to the apex. Transportation occurs in the portion of the canal apical to a curvature when canal wall structure opposite the curve is removed, tending to straighten the canal curvature. Zipping, or elliptication of the apical foramen, occurs when an overextended file transports the outer wall of the apical foramen. Conversely, undeflected instruments provide better tactile sensation, which is necessary for "feeling" the canal anatomy and "feeling" how the file is performing in the root canal system.

Straight-line access is evaluated by inserting into the canal the largest file that fits passively to the apical foramen or the point of the first canal curvature. This internal length can be determined by measuring a diagnostic pretreatment periapical radiograph. The file is inserted gently and withdrawn as the clinician "feels" for canal binding or deflection. If deflection is detected, the clinician must reevaluate the adequacy of lingual shoulder removal before changing the incisal edge position of the access preparation. Inadequate removal of the lingual shoulder causes the file to deflect in a facial direction, and an

FIG. 7-46 Inadequate access preparation. The lingual shoulder was not removed, and incisal extension is incomplete. The file has begun to deviate from the canal in the apical region, creating a ledge.

FIG. 7-47 A, The lingual ledge of dentin remains, deflecting the file toward the labial wall. As a result, portions of the lingual canal wall will not be shaped and cleaned. **B,** Removal of the lingual ledge results in straight-line access.

inexperienced clinician may overextend the incisal edge of the access preparation in an attempt to achieve straight-line access (Fig. 7-47). If the lingual shoulder has been adequately removed and the file still binds on the incisal edge, the access cavity should be extended farther incisally until the file is not deflected. The final position of the incisal wall of the access cavity is determined by two factors: (1) complete removal of the pulp horns and (2) straight-line access.

VISUAL INSPECTION OF THE ACCESS CAVITY

The clinician should inspect and evaluate the access cavity, using appropriate magnification and illumination. Although this can be done during any stage of the preparation, it should always be done at this point. The axial walls at their junction with the orifice must be inspected for grooves that might indicate an additional canal. The orifice and coronal canal must be evaluated for a bifurcation (see Fig. 7-14).

REFINEMENT AND SMOOTHING OF RESTORATIVE MARGINS

The final step in the preparation of an access cavity is to refine and smooth the cavosurface margins. Rough or irregular margins can contribute to coronal leakage through a permanent or temporary restoration. Proper restorative margins are important because anterior teeth may not require a crown as the final restoration. Definite, smooth cavosurface margins allow the clinician to place and finish a composite resin final restoration with the precision necessary to minimize coronal leakage. Such leakage could jeopardize the success of the root canal procedure.

Another factor the clinician must consider when finalizing the access margins of a maxillary anterior tooth is that the final composite resin restoration will be placed on a functional tooth surface. The incisal edges of the mandibular anterior teeth slide over these maxillary lingual surfaces during excursive jaw movement. Therefore the restorative margins of maxillary anterior teeth should be created to allow a bulk of restorative material at the margin. Butt joint margins are indicated rather than beveled margins, which produce thin composite edges that can fracture under excursive functional loads and ultimately result in coronal leakage. Obviously, if the anterior tooth requires a crown as the final restoration, the access cavosurface margin becomes a less critical factor.

INDIVIDUAL ANTERIOR TEETH

Please see the figures in the section Morphology and Access Cavity Preparations for Individual Teeth, later in the chapter.

Posterior Access Cavity Preparations

The process of preparing access cavities on posterior teeth is similar to that for anterior teeth, but enough differences exist to warrant a separate discussion.

REMOVAL OF CARIES AND PERMANENT RESTORATIONS

The discussion of caries and permanent restoration removal presented in the previous section, Anterior Access Cavity Preparations, applies equally to posterior teeth. Posterior teeth requiring root canal therapy typically have been heavily restored or the carious process is extensive. Such conditions, along with the complex pulp anatomy of posterior teeth, can make the access process challenging.

INITIAL EXTERNAL OUTLINE FORM

The removal of caries and existing restorations often accomplishes the creation of an initial external outline form. As with anterior teeth, the pulp chamber of posterior teeth is positioned in the center of the tooth at the level of the CEJ. An access starting location must be determined for an intact tooth. In maxillary premolars this point is on the central groove between the cusp tips (Fig. 7-48). Crowns of mandibular premolars are tilted lingually relative to their roots (Fig. 7-49), and the starting location must be adjusted to compensate for this tilt (Fig. 7-50). In mandibular first premolars the starting location is halfway up the lingual incline of the buccal cusp on a line connecting the cusp tips. Mandibular second premolars require less of an adjustment because they have less lingual inclination. The starting location for this tooth is one third the way up the lingual incline of the buccal cusp on a line connecting the buccal cusp tip and the lingual groove between the lingual cusps.

To determine the starting location for molar access cavity preparations, the clinician must establish the mesial and distal boundary limitations (Fig. 7-51). Evaluation of bite-wing radiographs is an accurate method of assessing the mesiodistal extensions of the pulp chamber. The mesial boundary for both the maxillary and mandibular molars is a line connecting the mesial cusp tips. Rarely are pulp chambers found mesial to this imaginary line. A good initial distal boundary for maxillary molars is the oblique ridge. For mandibular molars the initial distal boundary is a line connecting the buccal and lingual grooves. For molars the correct starting location is

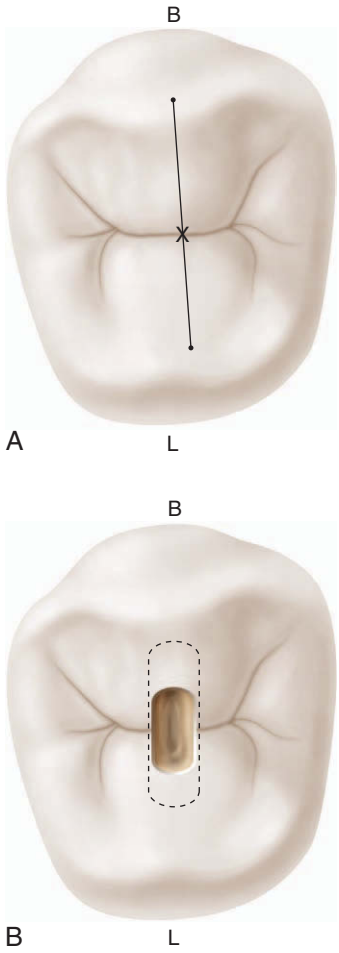

FIG. 7-48 A, Starting location for access to the maxillary premolar (*X*). **B,** Initial outline form (*dark area*) and projected final outline form (*dashed line*). *B,* Buccal; *L,* lingual.

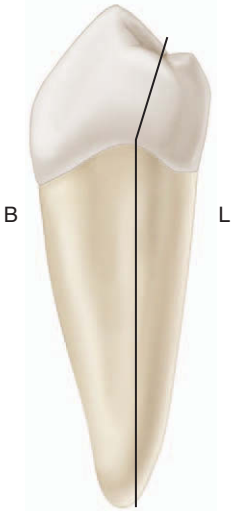

FIG. 7-49 The crown of a mandibular premolar is tilted lingually relative to the root. *B,* Buccal; *L,* lingual.

on the central groove halfway between the mesial and distal boundaries.

Penetration through the enamel into the dentin (approximately 1 mm) is performed with a #2 round bur for premolars and a #4 round bur for molars. A tapered fissure bur may be used instead of round burs. The bur is directed perpendicular to the occlusal table, and an initial outline shape is created at about one half to three fourths its projected final size. The premolar shape is oval and widest in the buccolingual dimension. The molar shape is also oval initially; it is widest in a buccolingual dimension for maxillary molars and in a mesiodistal direction for mandibular molars. The final outline shape for molars is triangular (for three canals) or rhomboid (for four canals); however, the canal orifices dictate the position of the corners of these geometric shapes. Therefore, until the orifices have been located, the initial outline form should be left as an oval.

PENETRATION OF THE PULP CHAMBER ROOF

Continuing with the same round or tapered fissure bur, the clinician changes the angle of penetration from perpendicular to the occlusal table to an angle appropriate for penetration through the roof of the pulp chamber. In premolars the angle is parallel to the long axis of the root(s) both in the mesiodistal and buccolingual directions. Failure to analyze this penetration angle carefully can result in gouging or perforation because premolar roots often are tilted relative to the occlusal plane. In molars the penetration angle should be toward the largest canal, because the pulp chamber space usually is largest just occlusal to the orifice of this canal. Therefore, in maxillary molars the penetration angle is toward the palatal orifice, and in mandibular molars it is toward the distal orifice (Fig. 7-52).

As with anterior teeth, penetration is limited to the distance measured on a pretreatment radiograph to just penetrate the roof of the pulp chamber. If the drop-in effect is not felt at this depth, the clinician should carefully evaluate the angle of penetration before drilling deeper. In multirooted posterior teeth, the clinician must guard against lateral and furcation perforations. Aggressive probing with an endodontic explorer often can help locate the pulp chamber.

COMPLETE ROOF REMOVAL

A round bur, a tapered fissure bur, or a safety-tip diamond or carbide bur is used to remove the roof of the pulp chamber completely, including all pulp horns (Fig. 7-53, *A* and *B*). Visibility problems caused by vital pulp hemorrhage should be handled as described in the previous section for anterior teeth (see Anterior Access Cavity Preparations). The goal is to funnel the corners of the access cavity directly into the orifices, and a safety-tip diamond or carbide bur performs this task nicely; it can be set on the pulp floor and the entire axial wall shaped at one time with little chance of gouging (Fig. 7-54). The safety-tip diamond or carbide bur is passed between the orifices along the axial walls to remove the roof, taper the internal walls, and create the desired external outline shape simultaneously.

IDENTIFICATION OF ALL CANAL ORIFICES

In posterior teeth with multiple canals, the canal orifices play an important role in determining the final extensions of the external outline form of the access cavity. Ideally, the orifices

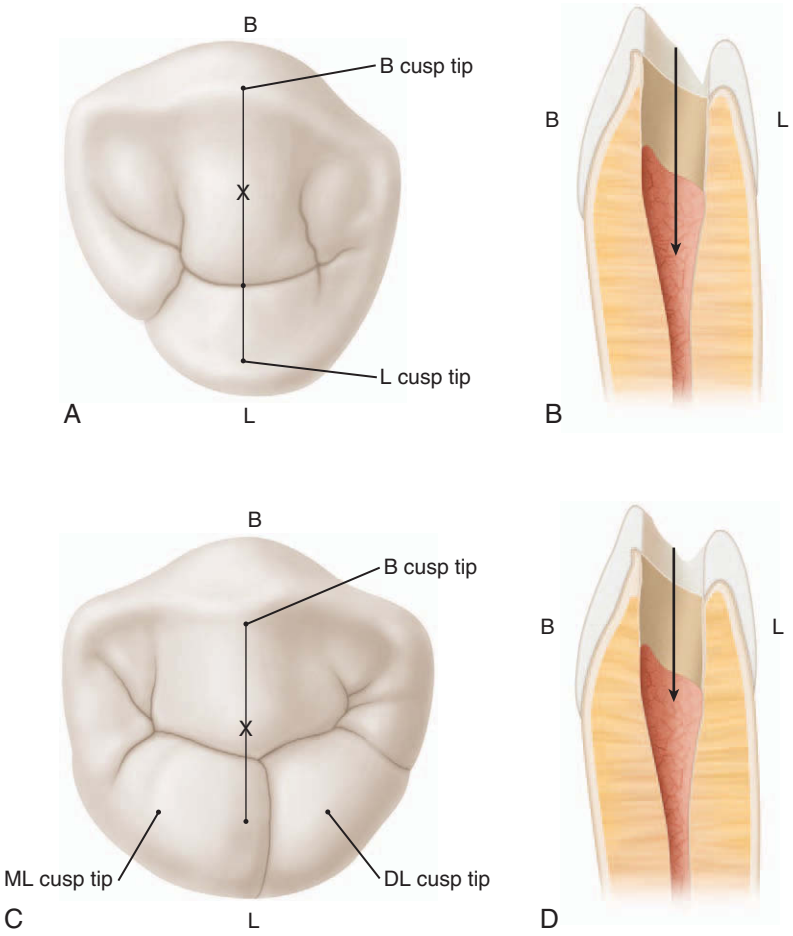

FIG. 7-50 A, Mandibular first premolar and access starting location (*X*) (occlusal view). **B,** Mandibular first premolar and starting location (proximal view). **C,** Mandibular second premolar and access starting location (*X*) (occlusal view). **D,** Mandibular second premolar and starting location (proximal view). *B*, Buccal; *DL*, distolingual; *L*, lingual; *ML*, mesiolingual.

are located at the corners of the final preparation to facilitate the shaping and cleaning process. Internally, the access cavity should have all orifices positioned entirely on the pulp floor and should not extend into an axial wall. Extension of an orifice into the axial wall creates a mouse hole effect (Fig. 7-55), which indicates internal underextension and impedes straight-line access. In such cases the orifice must be repositioned onto the pulp floor without interference from axial walls.

REMOVAL OF THE CERVICAL DENTIN BULGES AND ORIFICE AND CORONAL FLARING

In anterior teeth the lingual shoulder is the internal anatomic structure that must be removed as an impediment to straight-line access. In posterior teeth the internal impediments are the cervical dentin bulges and the natural coronal canal constriction. The cervical bulges are shelves of dentin that frequently overhang orifices in posterior teeth, restricting access into root canals and accentuating existing canal curvatures. These bulges can be removed with safety-tip diamond or carbide burs or Gates-Glidden burs. The instruments should be placed at the orifice level and leaned toward the dentin bulge to remove the overhanging shelf (see Fig. 7-53, *C* and *D*).

After the shelf has been removed, the orifice and constricted coronal portion of the canal can be flared with Gates-Glidden burs, which are used in a sweeping upward motion with lateral pressure away from the furcation. An alternative method is to use a #.10 or #.12 tapered engine-driven nickel–titanium file to establish the upper canal shape. As the orifice is enlarged, it should be tapered and blended into the axial wall so that the clinician can slide from the corner of the external outline form down the axial wall into the orifice without encountering any obstructions (Fig. 7-56).

STRAIGHT-LINE ACCESS DETERMINATION

As with anterior teeth, straight-line access is paramount to successful shaping. Files must have unimpeded access to the apical foramen or the first point of canal curvature to perform properly during shaping and cleaning. The clinician must assess each canal for straight-line access and make all adjustments necessary to achieve this goal (see Fig. 7-56, *O*).

VISUAL INSPECTION OF THE PULP CHAMBER FLOOR

Please refer to the earlier section under Anterior Access Cavity Preparations; and Fig. 7-57.

REFINEMENT AND SMOOTHING OF THE RESTORATIVE MARGINS

In both temporary and interim permanent restorations, the restorative margins should be refined and smoothed to minimize the potential for coronal leakage. The final permanent restoration of choice for posterior teeth that have undergone root canal therapy is a crown or onlay.

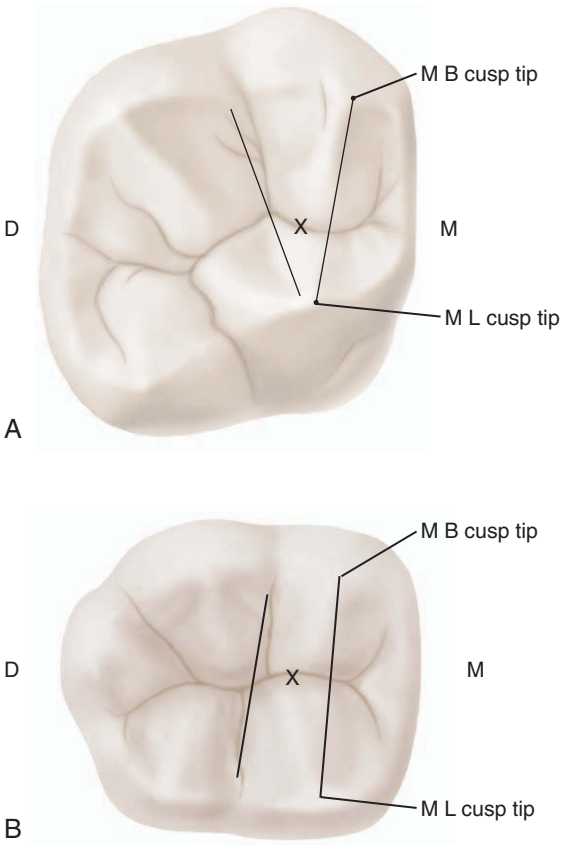

FIG. 7-51 A, Mesial and distal boundary of a maxillary molar showing the access starting location (*X*). **B,** Mesial and distal boundary of a mandibular molar showing the access starting location (*X*). *D*, Distal; *M*, mesial; *MB*, mesiobuccal; *ML*, mesiolingual.

INDIVIDUAL POSTERIOR TEETH

CHALLENGING ACCESS PREPARATIONS

Teeth With Minimal or No Clinical Crown

Several factors can cause the loss of a significant portion of a tooth's clinical crown. Caries left untreated can cause loss of coronal tooth structure. Badly decayed teeth typically can fracture under occlusal function because of the undermined and unsupported remaining tooth structure. Similarly, teeth that

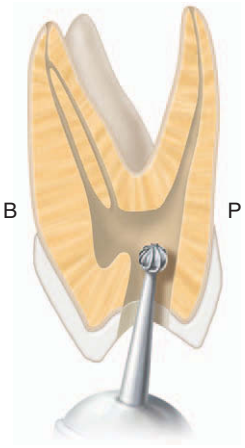

FIG. 7-52 Angle of penetration toward the largest canal (palatal) in a maxillary molar. *B*, Buccal; *P*, palatal.

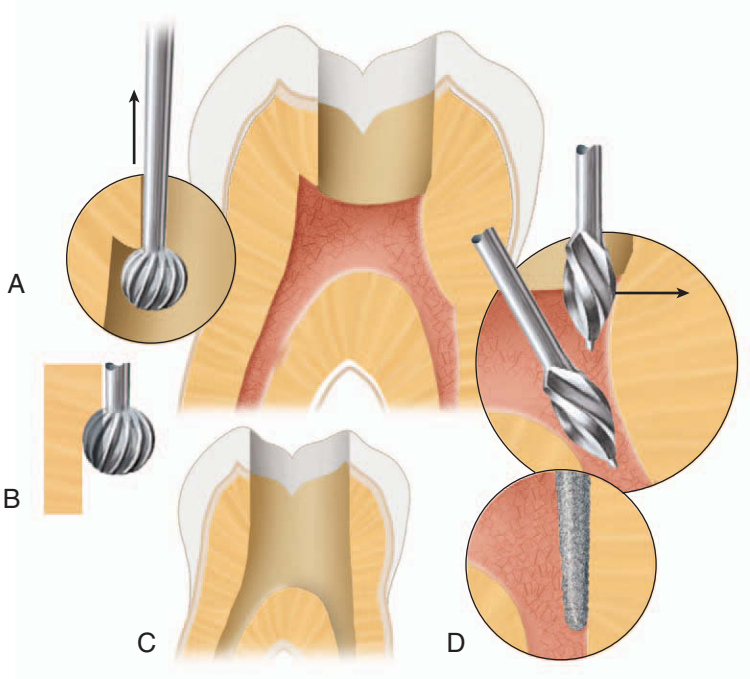

FIG. 7-53 A, Pulp roof/pulp horn removal. The round bur hooks under the lip of the pulp horn. **B,** The bur is rotated and withdrawn in an occlusal direction to remove the lip. **C,** Removal of a cervical dentin bulge. have been heavily restored with amalgam, composite resin, or glass ionomer restorative materials can have minimal coronal tooth structure. These restorative materials provide no extracoronal support for the tooth, and the fillings can fall out during occlusal function, leaving little or no clinical crown remaining. External trauma can cause the clinical crown to fracture, sometimes shearing off to the free gingival margin.

Creating an access cavity on a tooth with little or no clinical crown might seem to be a simple procedure. In young teeth, traumatic fractures often expose the pulp chamber, making preparation easy. However, in older teeth that have had caries or large restorations, the pulp chambers typically have receded or calcified. Loss of significant coronal anatomy to guide penetration angles can make access quite difficult.

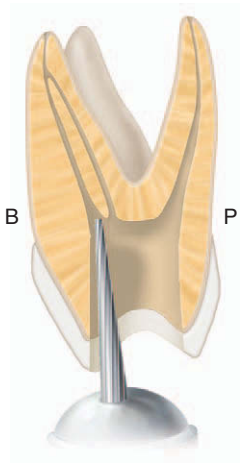

FIG. 7-54 Safety-tip carbide bur is used to shape the axial wall in one plane from the orifice to the cavosurface margin. *B,* Buccal; *P,* palatal.

Before beginning an access cavity on these teeth, the clinician should study their root angulation on pretreatment radiographs and examine the cervical crown anatomy with an explorer (Fig. 7-58). Pulp chambers are located at the center of the crown at the level of the CEJ. Access often is started without a dental dam in place so that root eminences can be visualized and palpated as access is attempted (Fig. 7-59). Because the external root anatomy is formed by odontoblasts in the pulp, by visualizing the root anatomy both radiographically and clinically, the clinician should have a good idea of access penetration angles. Every effort is made to stay centered within the root for the best chance of locating the pulp canal.[25] The depth of penetration needed to reach the pulp canal is measured on a pretreatment radiograph. If the clinician reaches this depth without locating the canal, two radiographs should be taken before the process proceeds. A straight-on radiograph shows whether the preparation is deviating in a mesial or distal direction. Applying the buccal-object rule, an angled radiograph shows a buccal or lingual deviation in penetration. After checking these radiographs, the clinician can redirect the penetration angle if necessary and move the preparation apically. As soon as the pulp canal is identified, the dental dam must be placed and the access preparation finalized, using the guidelines discussed earlier in this chapter.

Heavily Restored Teeth (Including Those With Full Veneer Crowns)

Restorative materials often alter the external anatomic landmarks on the crown of a tooth, making access preparation difficult. Restorative materials and full crowns rarely reproduce the original tooth anatomy in the exact same position.

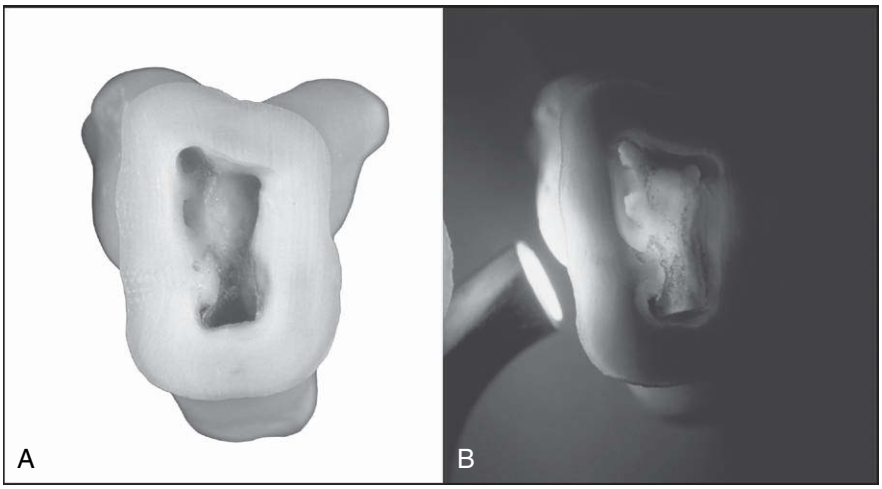

FIG. 7-57 A fiberoptic light can be applied to the cervical aspect of the crown to help obtain maximal visibility with magnification. Transillumination often reveals landmarks otherwise invisible to the unaided eye.

FIG. 7-58 The cervical area of the tooth is explored before access is started.

The crown-to-root angulation often is altered when large restorations or crowns correct occlusal discrepancies (Fig. 7-60). Most restorative materials block the passage of light into the internal aspects of the tooth, resulting in poor visibility during preparation of the access cavity. All these factors, singly or together, complicate the preparation of access cavities on heavily restored teeth.[1] The DOM and transillumination of the cervical area of a heavily restored tooth can greatly improve visibility and reveal landmarks that otherwise would be missed (see Fig. 7-57).

In most cases, complete removal of large restorations is the wisest course (Fig. 7-61). These restorations often have leaky, defective margins or recurrent caries or both. Removing the restoration allows the clinician better visibility of the internal anatomic structures through direct visualization and increased light penetration. With increased visibility the clinician can check for recurrent caries and fracture lines on the pulp chamber walls or floor. As stated earlier in a study,[1] clinicians are 40% more likely not to detect these anomalies when restorations are not removed completely. Better visibility also makes locating receded or calcified canals easier.

Coronal leakage often occurs when parts of large restorations are left in the tooth because the restorations are loosened by the vibration of the access drilling. Another reason to remove these restoration remnants completely is to prevent pieces of the restorative material from falling into the root canal. Instruments can rub against restoration fragments during shaping and cleaning, creating filings that can be carried into the canal system (see Fig. 7-74, D). Complete removal prevents these problems.

Complete removal of an extensive restoration from the cervical region of the tooth permits more direct access to the root canal(s). For example, class V restorations often cause calcification of the coronal canal, making location of the canal through the occlusal approach quite difficult. Removal of the class V restoration allows more direct access to the calcified canal, which makes location and treatment much easier. Any remaining canals can be treated through the conventional occlusal access cavity (Fig. 7-62).

When an extensive restoration is a full or partial veneer crown, the restoration must be evaluated thoroughly. If any concerns arise about recurrent decay or leaky margins, the crown should be removed before the access cavity is prepared. Removal of the crown allows elimination of all recurrent caries and improves the visibility of the pulp spaces.

Creation of an access through an intact full or partial veneer crown should be done with caution. When such restorations are placed, they often change the crown-to-root angulation to correct preexisting occlusal discrepancies. Full veneer crowns also can alter tooth rotation. Both these situations make the preparation of access cavities challenging. Pretreatment radiographs can be helpful, but the metal in the full veneer crown often masks the underlying pulp chamber. In these situations the clinician's best approach is to stay as centered in the tooth as possible, using all available clinical and radiographic information. The DOM and transillumination of the CEJ are valuable aides in this process.

Metal veneer crowns are best penetrated with new, sharp carbide burs. Round burs work well, but tungsten carbide transmetal burs are more efficient. These crosscut fissure burs are specifically designed to cut through metal restorative materials. Porcelain or ceramometal restorations must be handled delicately to minimize the potential for fracture. The clinician should use a round diamond bur and copious water spray to penetrate the porcelain. After porcelain penetration, a

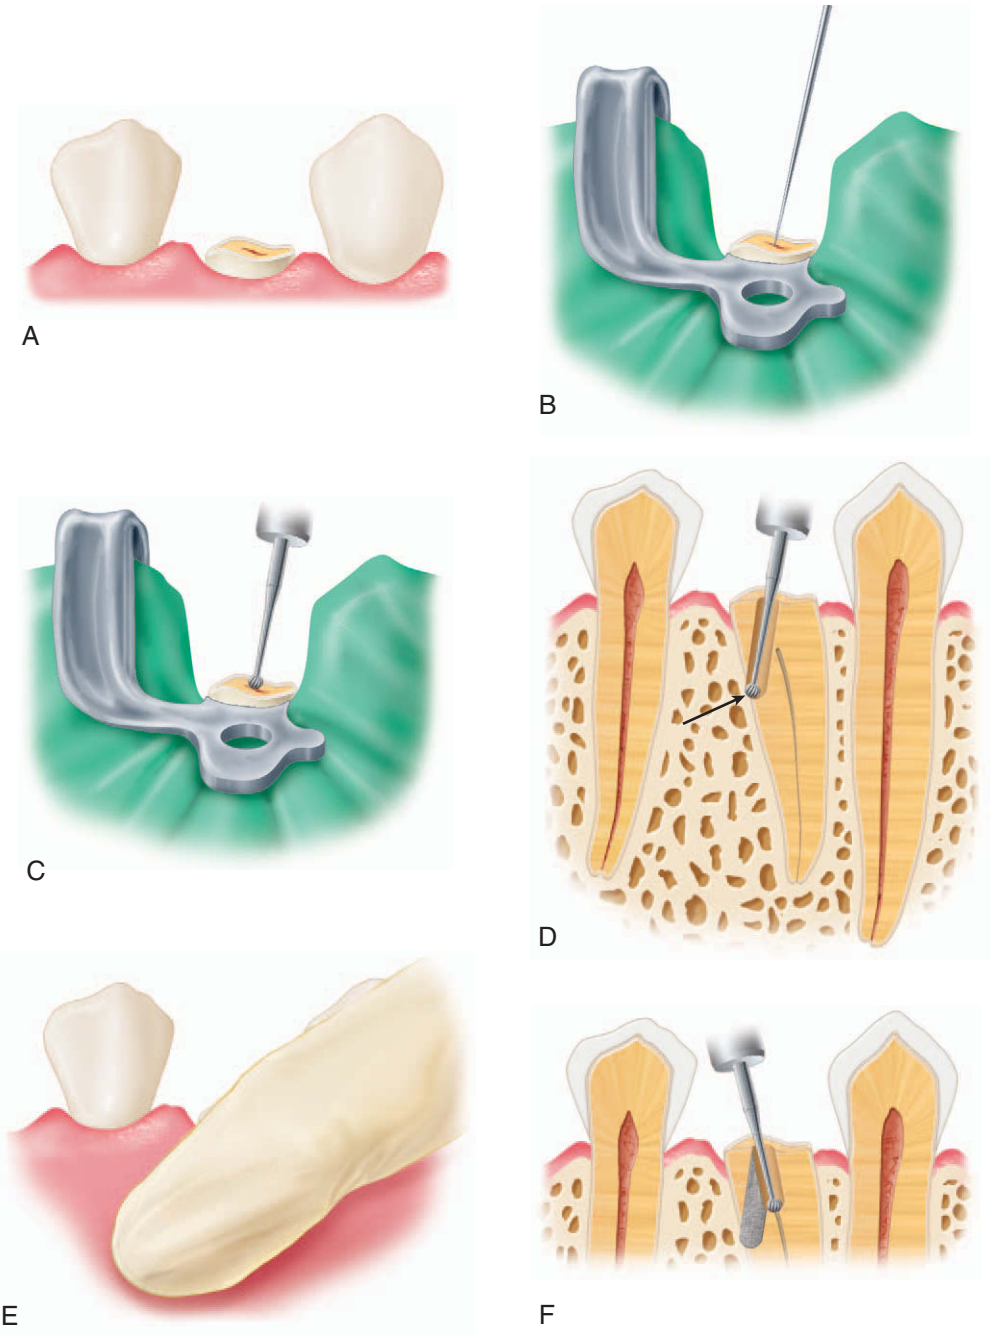

FIG. 7-59 Access cavity preparation when the anatomic crown is missing. **A,** A mandibular first premolar with the crown missing. **B,** An endodontic explorer fails to penetrate the calcified pulp chamber. **C,** A long-shank round bur is directed in the assumed long axis of the root. **D,** Perforation of the root wall (*arrow*), resulting from the clinician's failure to consider root angulation. **E,** Palpation of the buccal root anatomy without a dental dam in place to determine root angulation. **F,** Correct bur angulation after repair of the perforation with mineral trioxide aggregate (MTA; DENTSPLY Tulsa Dental Specialties, Tulsa, OK). The dental dam is placed as soon as the canal is identified.

transmetal bur and copious water spray should be used to penetrate the metal coping; the water spray minimizes heat buildup, which could fracture the porcelain (Fig. 7-63).

Many clinicians tend to be too conservative when preparing an access cavity through a veneer crown. An attempt to save the crown often leads to an underextended preparation. All the guidelines for access cavity preparations discussed earlier must be followed. When the preparation is complete, the clinician should search the margins and internal spaces for caries, leakage, and fractures. If no problems are discovered, the clinician may proceed with shaping and cleaning, leaving the full veneer crown in place.

Teeth With Calcified Canals

A pretreatment radiograph (Figs. 7-64 and 7-65) often appears to reveal total or nearly total calcification of the pulp chamber

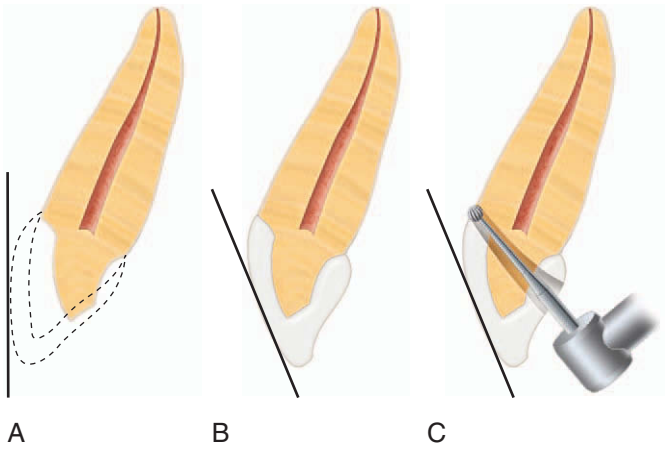

FIG. 7-60 Access cavity error resulting from alteration of the original tooth contours by a full veneer crown. **A,** Original crown contour of the tooth. **B,** A full veneer crown is used to change the original crown contour for esthetic purposes. **C,** Access perforation resulting from reliance on the full veneer crown contour rather than the long axis of the root.

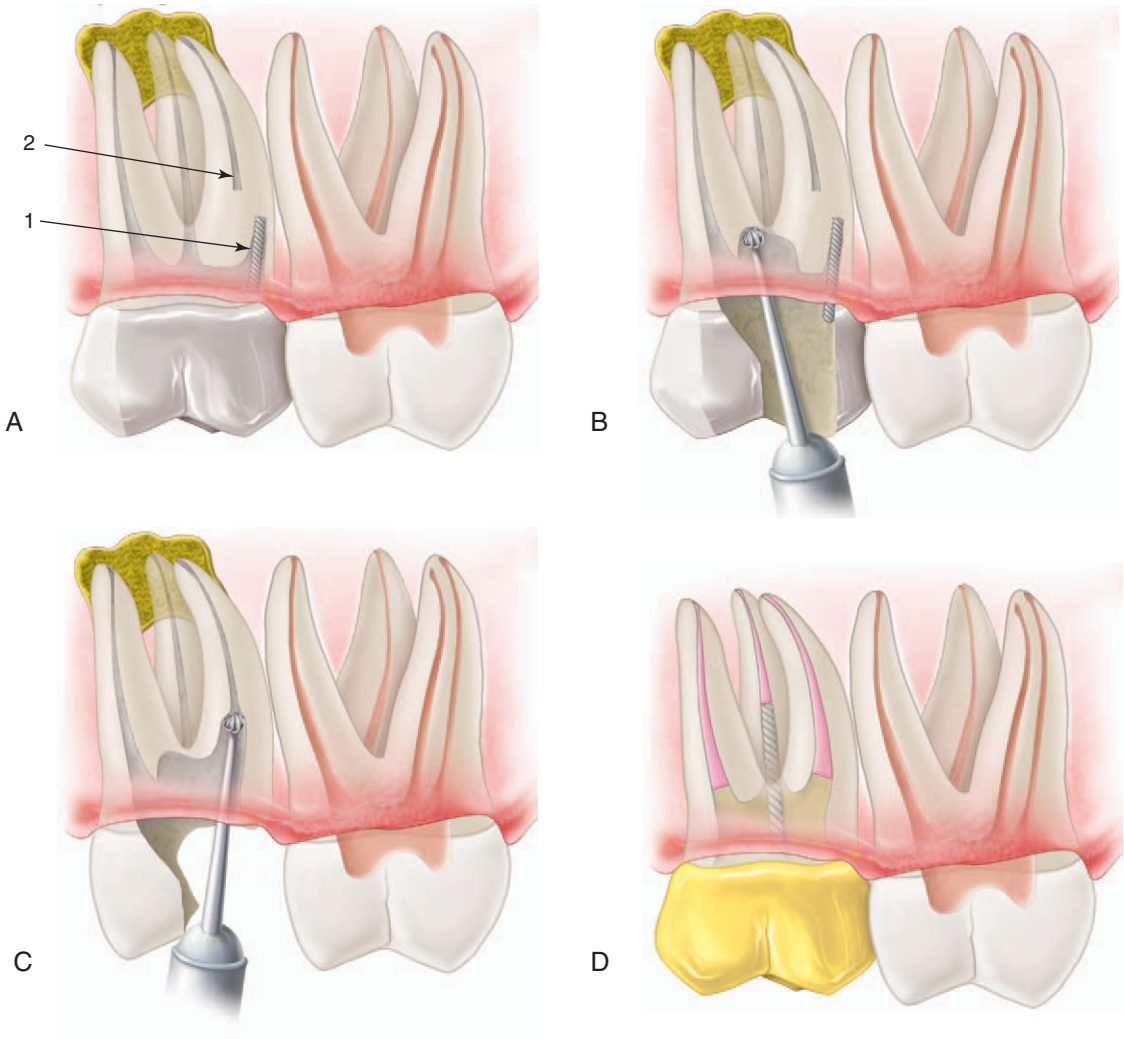

FIG. 7-61 A, In a heavily restored maxillary second molar that requires root canal therapy, the clinician may attempt access to the canals. Pretreatment radiographs demonstrate three important factors: (1) a reinforcing pin is in place *(arrow)*; (2) at least two thirds of the coronal portion is restorative material; and (3) the mesiobuccal canal appears calcified *(arrow)*. These factors suggest complete excavation. **B,** A patient may ask the clinician to attempt an unexcavated search for the canals; this may result in a furcal perforation, compromising the prognosis. In such cases the patient should be engaged in the decision to continue treatment, which unquestionably involves removal of the existing restoration. **C,** A safer, more conservative approach is to remove the amalgam, the pin, and any old cements. Careful excavation, using enhanced vision, results in access to the pulp chamber. **D,** The clinician now can perform sound root canal therapy, followed by internal reinforcement and full coverage.

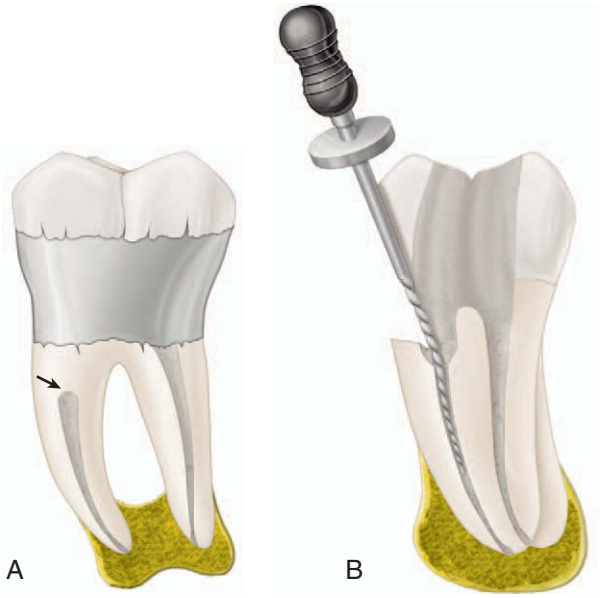

FIG. 7-62 A, Extensive class V restoration necessitated by root caries and periodontal disease that led to canal calcification *(arrow)*. **B,** Access to the canal is occluded by calcification. Removal of the facial restoration may be required to obtain access from the buccal surface.

and radicular canal spaces. Unfortunately, these spaces have adequate room to allow passage of millions of microorganisms. Chronic inflammatory processes (e.g., caries, medications, occlusal trauma, and aging) often cause narrowing of the root canal system. Canals become less calcified as they approach the root apex. Despite severe coronal calcifications, the clinician must assume that all canals exist and must be shaped, cleaned, and obturated to the canal terminus.

Teeth with severe pulp calcification may present problems with locating and negotiating root canals. The use of magnification and transillumination, as well as careful examination of color changes and pulp chamber shapes, can help the clinician safely locate canals. The clinician should search for root canal orifices only after completely preparing the pulp chamber and cleaning and drying its floor (95% denatured ethanol is useful for drying the floor and enhancing visibility). A fiberoptic light directed through the CEJ can reveal subtle landmarks and color changes that may not otherwise be visible. The chamber floor is darker in color than its walls, and developmental grooves connecting orifices are lighter in color than the chamber floor. The clinician must be aware of these color differences when searching for calcified orifices and must keep in mind that root canal orifices are located at the angles formed by the floor and walls and at the end points of developmental grooves. Additional aids for locating calcified root canals

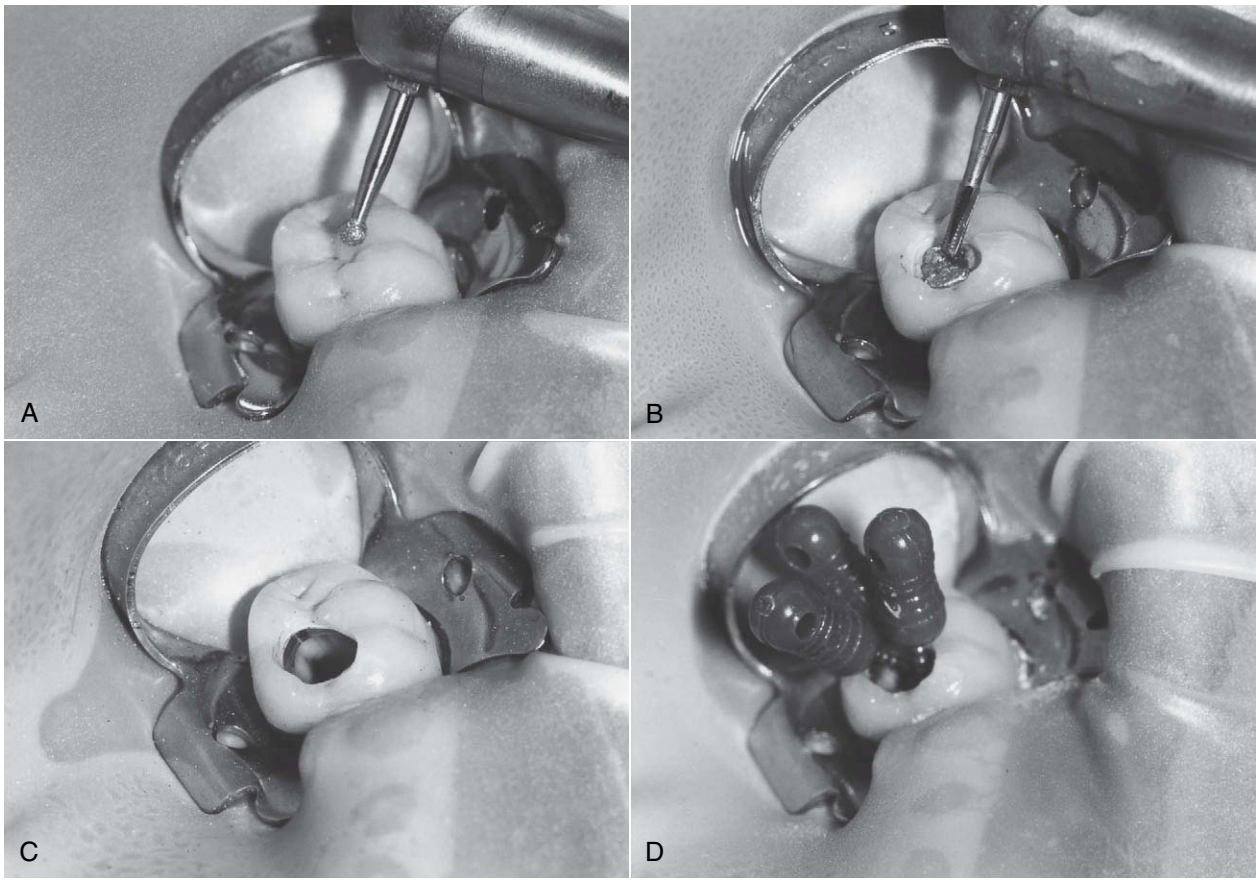

FIG. 7-63 Access cavity preparation through a ceramometal crown. **A,** A round diamond bur is used to penetrate the porcelain. **B,** After the access outline has been made with the round diamond bur, a transmetal bur is used to cut through the metal. **C,** Prepared access cavity, which allows a direct approach to the canals. **D,** Test files can be placed on the access cavity walls without impingement.

FIG. 7-64 Radiograph taken when a patient's symptoms (i.e., nonlingering cold sensitivity and sensitivity to sweets) first appeared. The mandibular first molar was not treated endodontically because tests showed it to be vital. Caries was removed from under the mesial amalgam, and calcium hydroxide was placed over the cavity proximal to the pulp space.

FIG. 7-65 Radiograph of the mandibular first molar in Fig. 7-64 taken 13 years later shows severe calcification of the pulp chamber and periradicular radiolucencies.

include staining the pulp chamber floor with 1% methylene blue dye, performing the sodium hypochlorite "champagne bubble" test (see Fig. 7-2) and searching for canal bleeding points.

In severely calcified teeth, calcified dentin must be removed slowly down the root. The clinician can use long, thin ultrasonic tips under the high magnification of a DOM to avoid removing too much tooth structure. As the search moves apically, two radiographs must be taken, one from the straight-on direction and the other from an angled direction. A very small piece of lead foil placed at the apical extent of the penetration can provide a radiographic reference.

Uncovering calcified canals is a challenge. When the canal is located, a small K-file (#6, #8, or #10) coated with a chelating agent should be introduced into the canal to determine patency. This file should not be removed until some canal enlargement has occurred. It should be used in short up-and-down movements and in a selective circumferential filing motion with most of the lateral pressure directed away from

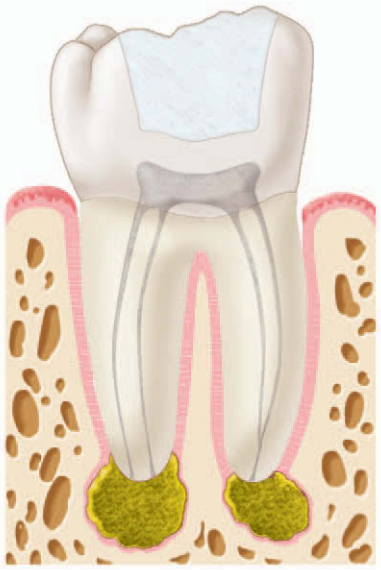

FIG. 7-66 Mandibular first molar with a class I restoration, calcified canals, and periradicular radiolucencies. Presumably pulp exposure has occurred, resulting in calcification and ultimately necrosis of the pulp tissue.

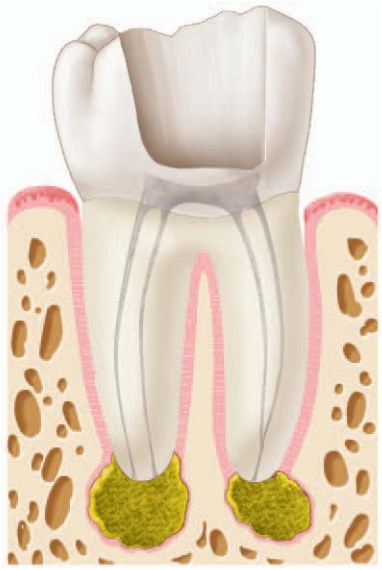

FIG. 7-67 Excavation of a restoration and base material. The clinician should extend the cavity preparation toward the assumed location of the pulp chamber, keeping in mind that pulp chambers are located in the center of the tooth at the level of the cementoenamel junction (*CEJ*).

the furcation. This safely enlarges the coronal canal and moves it laterally to avoid the furcation. It also creates a path of insertion for larger files and for preflaring burs. Figures 7-64 through 7-71 illustrate several methods that can be used to locate calcified spaces. For the most successful results, the sequence should be followed as shown.

The wise clinician stops excavating dentin if a canal orifice cannot be found to avoid weakening the tooth structure.

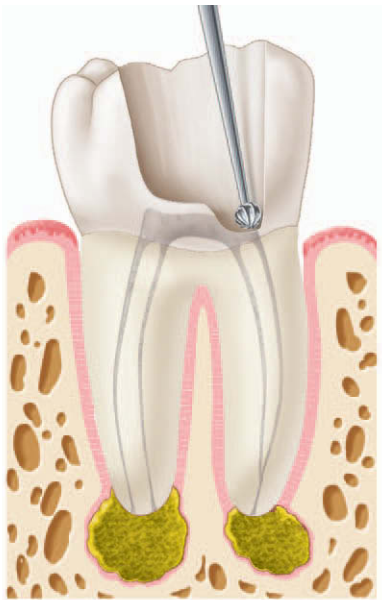

FIG. 7-68 The clinician uses a long-shank #2 or #4 round bur to remove dentin, attempting to locate calcified canals by following Krasner and Rankow's anatomic laws.

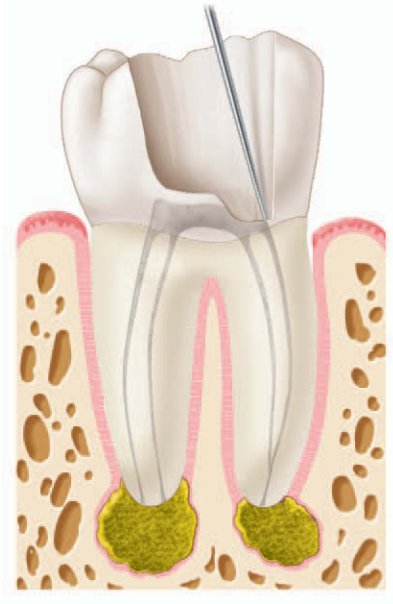

FIG. 7-69 An endodontic explorer is used to probe the pulp floor. A straight ultrasonic tip may be used to remove dentin. Angled radiographs must be taken to monitor progress.

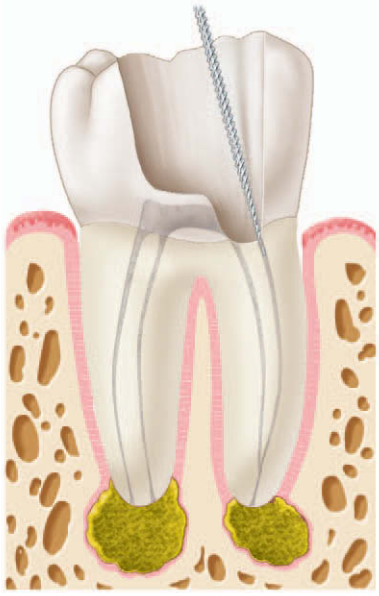

FIG. 7-70 At the first indication of a canal space, the smallest instrument (i.e., a #.06 or #.08 file) should be introduced into the canal. Gentle passive movement, both apical and rotational, often produces some penetration. A slight pull, signaling resistance, usually is an indication that the canal has been located. This should be confirmed by radiographs.

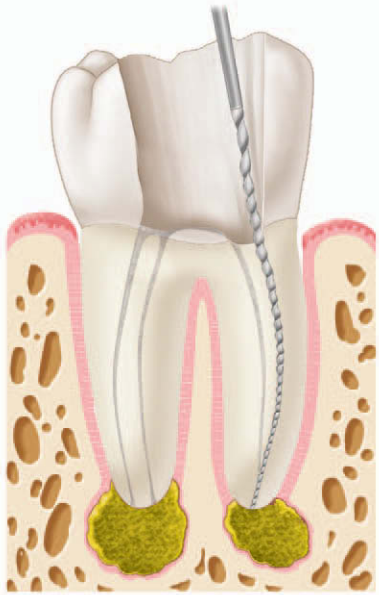

FIG. 7-71 A small hand K-file negotiates the canal to its terminus. An apex locator or radiograph is used to confirm the file's position.

Serious errors can arise from overzealous or inappropriate attempts to locate canals. Root wall or furcation perforations can occur even with the most careful search. In such cases the communication with the periodontal tissues must be repaired immediately (Fig. 7-72). Retrograde surgical procedures may be a more conservative approach to treating the tooth when compared with perforations or root fractures. No rapid technique exists for dealing with calcified root canals. Painstaking removal of small amounts of dentin with the aid of the DOM and radiographic confirmation has proved to be the safest approach.

Crowded Teeth

Conventional access preparations may not be possible in patients with crowded teeth. The decision regarding an alternative approach must be based on straight-line access

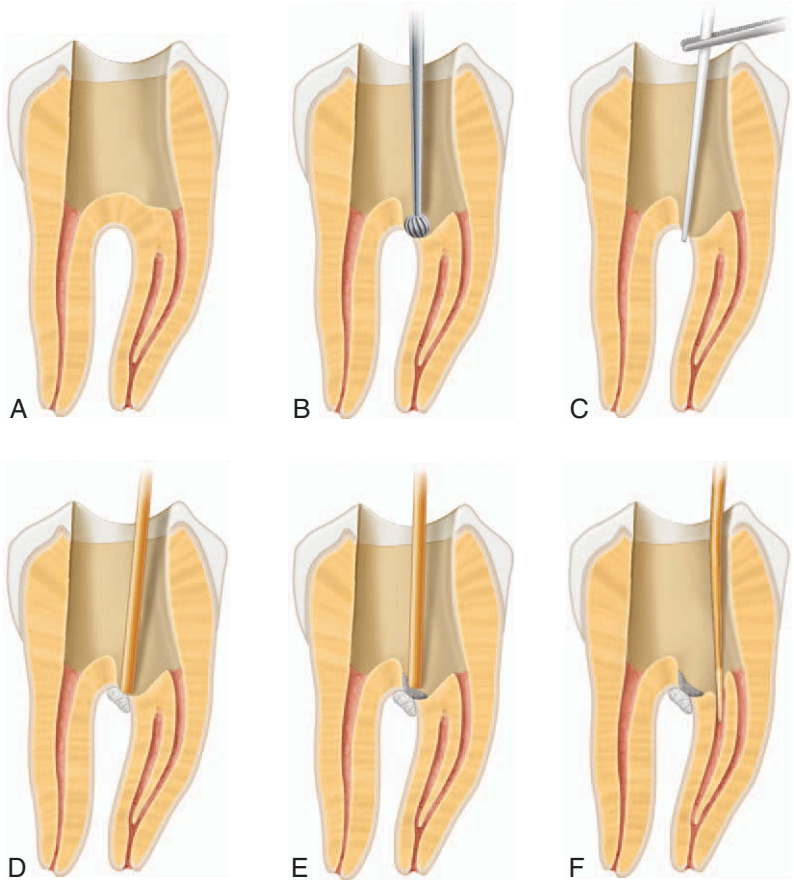

FIG. 7-72 Perforation repair. **A,** Access is gained into two canals, but the calcified canal orifice has not been located. **B,** Minute furcal perforation noted during the search for the canal. **C,** Absorbent points are used to control hemorrhage. **D,** CollaCote (Zimmer Dental, Carlsbad, CA) is introduced to provide a base for repair material. **E,** MTA (DENTSPLY Tulsa Dental, Tulsa, OK) is introduced. **F,** Location of the calcified canal; enhanced vision, including the dental operating microscope, is recommended.

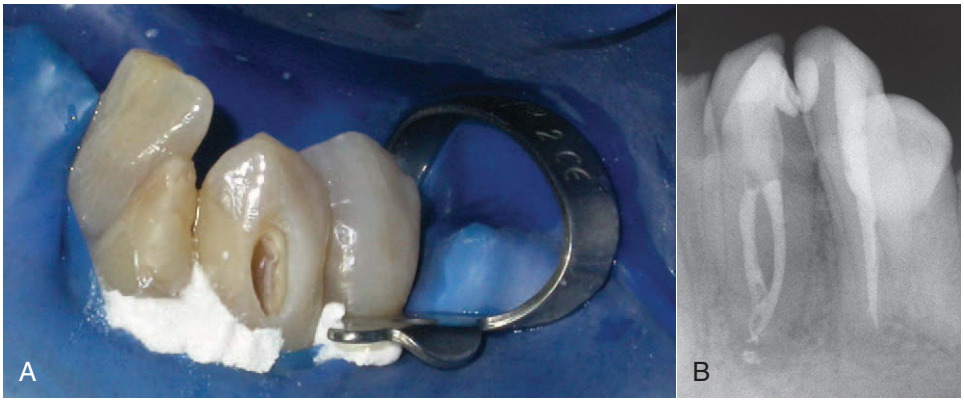

FIG. 7-73 A, Access cavity on crowded mandibular teeth. The access preparation is performed through the buccal surface on tooth #22. Tooth #23 also has been accessed through the buccal surface; root canal therapy was performed, and the access cavity was permanently restored with composite. **B,** Obturation.

principles and conservation of tooth structure. In certain circumstances a buccal access preparation may be the treatment of choice (Fig. 7-73). Modern restorative materials have made repair of this access esthetically acceptable.

Rotated Teeth

Rotated teeth can present problems for the clinician during access cavity preparation because of the altered crown-to-root relationships. According to one investigator,[141] diagnostic periapical radiographs, although only two dimensional, are indispensable for "determining the anatomic relationship of the crown to the root and the angle of the root in the arch." When these factors are identified, the clinician should visualize likely access variations before entering the tooth. Perforations in rotated teeth during access preparation usually occur because of faulty angulation of the bur with respect to the long axis of the root.

Other problems also can occur when tooth angulations are not considered during preparation of an access cavity. Such problems include the following:

- Mistaken identification of an already located canal, resulting in a search in the wrong direction for additional canals. Whenever a difficult canal is located, a file should be placed in the canal and an angled radiograph taken. This determines which canal has been located. A search for another canal orifice can then begin in the correct direction
- Failure to locate a canal or extra canals
- Excessive gouging of coronal or radicular tooth structure
- Instrument separation during attempts to locate an orifice
- Failure to debride all pulp tissue from the chamber

The best way to handle these problems is to prevent them from occurring. A thorough radiographic examination is crucial. The initial outline form occasionally can be created without the dental dam; this facilitates positioning of the bur with the long axis of the tooth. Bur penetration for both depth and angulation should be confirmed frequently with radiographs.

ERRORS IN ACCESS CAVITY PREPARATION

Unfortunately, errors can occur in the preparation of an access cavity. Most are the result of failure to follow the access guidelines; others reflect a lack of understanding of the internal and external tooth morphology. Common errors are discussed and illustrated in Figs. 7-74 through 7-76.

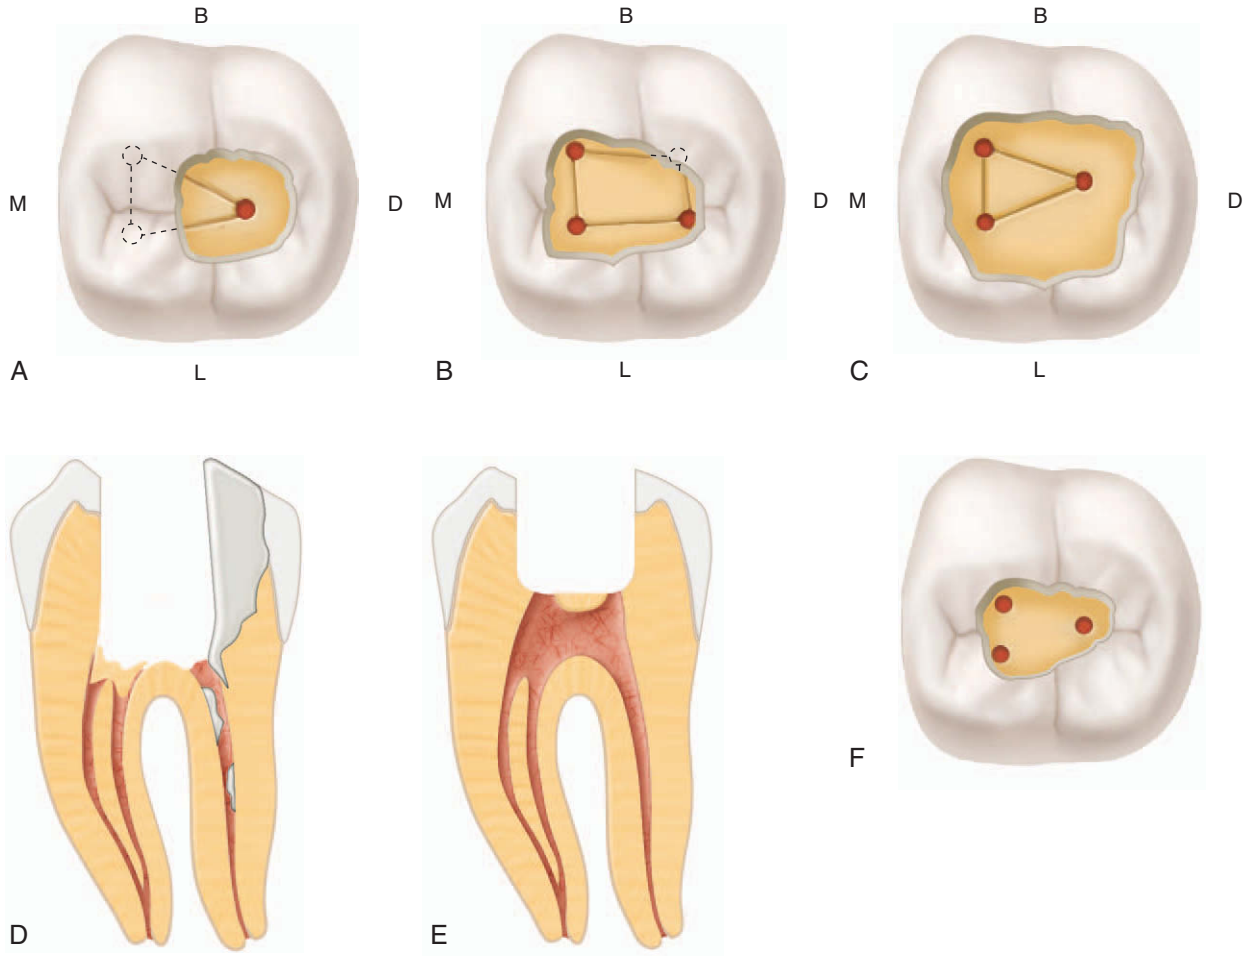

FIG. 7-74 A, Poor access placement and inadequate mesial extension leave both mesial orifices uncovered. Information about the position and location of pulp chambers can be obtained through evaluation of pretreatment radiographs, especially bite-wing radiographs, and assessment of the tooth anatomy at the cementoenamel junction (CEJ). **B,** Inadequate extension of the distal access cavity leaves the distobuccal canal orifice unexposed. All developmental grooves must be traced to their termination and must not be allowed to disappear into an axial wall. **C,** Gross overextension of the access cavity weakens the coronal tooth structure and compromises the final restoration. This mistake results from failure to determine correctly the position of the pulp chamber and the angulation of the bur. **D,** Allowing debris to fall into canal orifices results in an iatrogenic mishap. Amalgam fillings and dentin debris block canal orifices, preventing proper shaping and cleaning. Complete removal of the restoration and copious irrigation help prevent this problem. **E,** Failure to remove the roof of the pulp chamber is a serious underextension error; the pulp horns have been exposed. Bite-wing radiographs are excellent aids in determining vertical depth. **F,** Access preparation in which the roof of the pulp chamber remains and the pulp horns have been mistaken for canal orifices. The whitish color of the roof, the depth of the access cavity, and the lack of developmental grooves are clues to this underextension. Root canal orifices generally are positioned at or slightly apical to the CEJ. *B,* Buccal; *D,* distal; *L,* lingual; *M,* mesial.

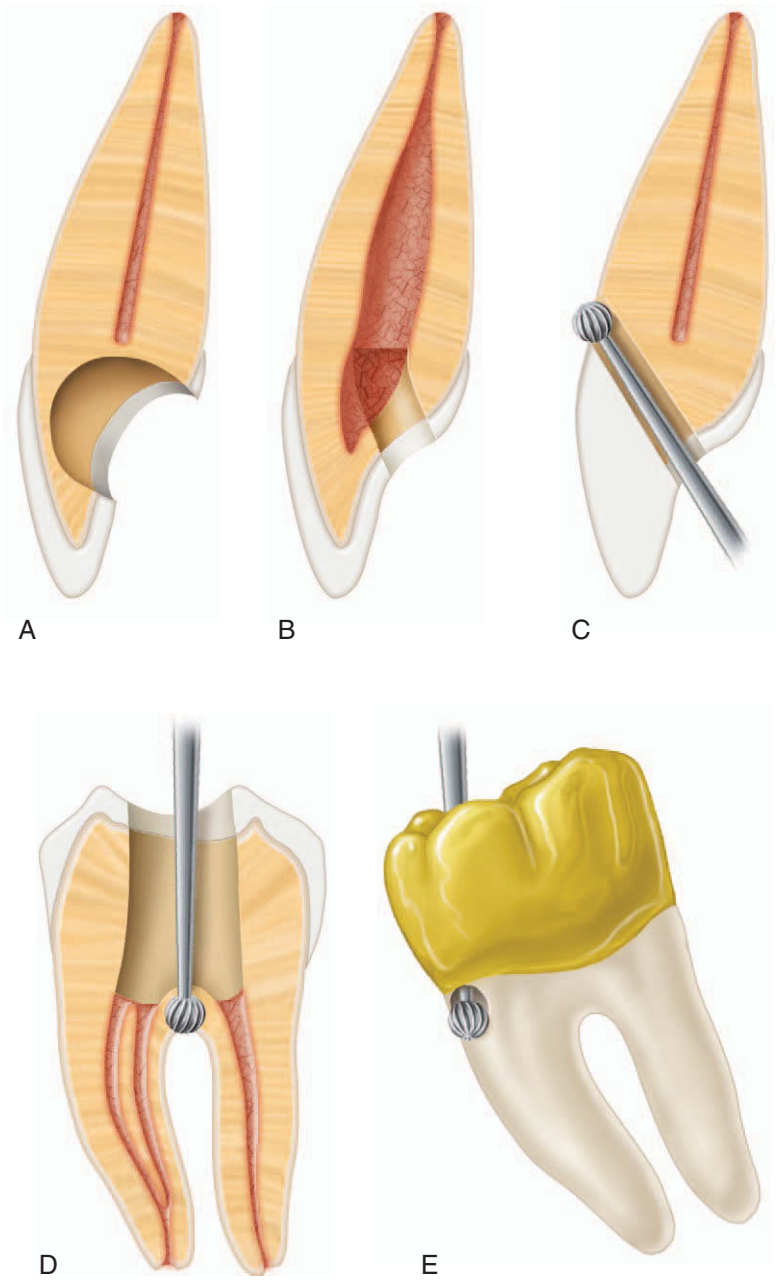

FIG. 7-75 A, Overzealous tooth removal caused by improper bur angulation and failure to recognize the lingual inclination of the tooth. This results in weakening and mutilation of the coronal tooth structure, which often leads to coronal fractures. **B,** Inadequate opening; the access cavity is positioned too far to the gingival with no incisal extension. This can lead to bur and file breakage, coronal discoloration because the pulp horns remain, inadequate instrumentation and obturation, root perforation, canal ledging, and apical transportation. **C,** Labial perforation caused by failure to extend the preparation to the incisal before the bur shaft entered the access cavity. **D,** Furcation perforation caused by failure to measure the distance between the occlusal surface and the furcation. The bur bypasses the pulp chamber and creates an opening into the periodontal tissues. Perforations weaken the tooth and cause periodontal destruction. They must be repaired (see Fig. 7-72) as soon as they are made for a satisfactory result. **E,** Perforation of the mesial tooth surface caused by failure to recognize that the tooth is tipped and failure to align the bur with the long axis of the tooth. This is a common error in teeth with full crowns. Even when these perforations are repaired correctly, they usually cause a permanent periodontal problem because they occur in a difficult maintenance area.

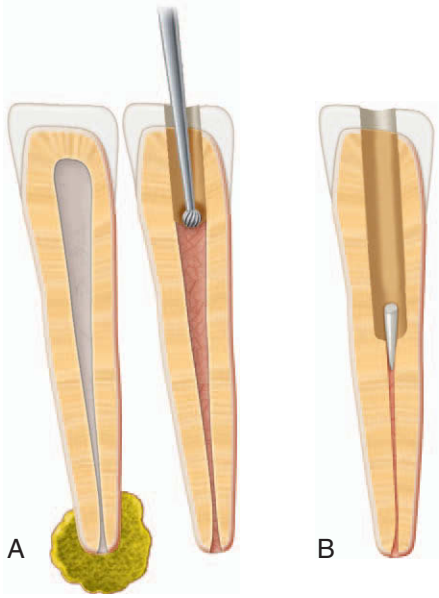

FIG. 7-76 A, The most embarrassing error, with the greatest potential for medical and legal damage, is entering the wrong tooth because of incorrect dental dam placement. When the crowns of teeth appear identical, the clinician should mark the tooth with a felt-tip marker before the dental dam is placed. **B,** Burs and files can be broken if used with an improper motion, excessive pressure, or before the access cavity has been properly prepared. A broken instrument may lock into the canal walls, requiring excessive removal of tooth structure to retrieve it. On occasion, fragments may not be retrievable.

MORPHOLOGY AND ACCESS CAVITY PREPARATIONS FOR INDIVIDUAL TEETH

The anatomy shown in the following figures was obtained from human teeth through the use of recently developed 3-D imaging techniques. The teeth were scanned in a high-resolution, microcomputer-assisted tomographic scanner. The data were then manipulated with proprietary computer programs to produce the 3-D reconstructions and visualization. The following individuals made this project possible:

Maxillary Central Incisor

The root canal system outline of the maxillary central incisor reflects the external surface outline. A newly erupted central incisor has three pulp horns, and the pulp chamber is wider mesiodistally than buccolingually. A lingual shoulder usually is present, and it must be removed to gain access to the lingual wall of the root canal. The lingual shoulder prevents direct access to the root canal and deflects files labially, often resulting in a ledge or perforation. In cross-section, the root canal at the CEJ is triangular in young teeth and oval in older teeth. It gradually becomes round as it approaches the apical foramen. Multiple canals are rare (Table 7-8), but lateral canals are common.

The external access outline form for the maxillary central incisor is a rounded triangle with its base toward the incisal aspect (Figs. 7-77 through 7-81). The width of the triangular base is determined by the distance between the mesial and distal pulp horns. The mesial and distal external walls should converge toward the cingulum. All internal walls should funnel to the root canal orifice. If the lingual shoulder has been removed properly, the entire orifice should be seen through the access opening. The incisal internal wall should approach the lingual surface of the tooth in a near butt joint to allow for a bulk of restorative material on this functional surface.

Variation

The outline form of the access cavity changes to a more oval shape as the tooth matures and the pulp horns recede because the mesial and distal pulp horns are less prominent.

Maxillary Lateral Incisor

The pulp chamber outline of the maxillary lateral incisor is similar to that of the maxillary central incisor; however, it is smaller, and two or no pulp horns may be present. This tooth is wider mesiodistally than buccolingually. A cross-section at the CEJ shows a pulp chamber centered in the root, and its shape may be triangular, oval, or round. The clinician must know the anatomy of the pulp chamber before starting the access cavity. From the CEJ the pulp canal becomes round in cross-section in the midroot and apical areas. The lingual shoulder of dentin must be removed before instruments can be used to explore the canal. Normally only one root canal is present, but two and three canals have been reported (Table 7-9).

The external access outline form for the maxillary lateral incisor may be a rounded triangle or an oval, depending on the prominence of the mesial and distal pulp horns (Figs. 7-82 through 7-85). When the horns are prominent, the rounded triangular shape is compressed mesiodistally relative to a central incisor, producing a more slender triangle. The outline form usually is oval if the mesial and distal pulp horns are not prominent. All other aspects of the access preparation are the same as those for the central incisor.

The maxillary lateral incisor often has anomalies. One such variation in form is the presence of a lingual radicular or developmental groove.[119,149-151,154-157] Although this groove may be present on the roots of all anterior teeth, it is more common in the maxillary lateral. The groove can lose its periodontal attachment as a result of both periodontal and endodontic etiologies. There is generally direct communication between the groove and the pulp cavity and this occurs primarily through dentinal tubules.

Dens invaginatus is another anomaly and this has been classified into three types based on severity,[188] from simple to more complex. Type 1 is an invagination that is confined to the crown. Type 2 is an invagination that extends past the cementoenamel junction but does not involve the periradicular tissues. Type 3 is an invagination that extends beyond the cementoenamel junction and can have a second apical foramen. Often surgical and orthograde root canal therapy is necessary to treat this condition.*

Maxillary Canine

The root canal system of the maxillary canine is similar in many ways to that of the maxillary incisors. A major difference is that it is wider labiolingually than mesiodistally. Another difference is that it has no pulp horns. Its smallest pointed incisal edge corresponds to the single cusp. The pulp chamber outline at the CEJ is oval. A lingual shoulder is present, which may prevent shaping and cleaning of the root canal in its lingual dimension. From this point, the root canal remains oval until it approaches the apical third of the root, where it becomes constricted. Because of this oval shape, the clinician must take care to circumferentially file labially and palatally to shape and clean the canal properly. Usually one root canal is present, although two canals have been reported (Table 7-10). The thin buccal bone over the canine eminence often disintegrates, and fenestration is an occasional finding. Accurate determination of the length is critical. Another effect of this fenestration is a slight, permanent apical pressure sensitivity that occasionally occurs after root canal therapy. This sensitivity can best be corrected by apical root surgery.

The external access outline form is oval or slot shaped because no mesial or distal pulp horns are present (Figs. 7-86 through 7-89). The mesiodistal width of the slot is determined by the mesiodistal width of the pulp chamber. The incisogingival dimension is determined by straight-line access factors and removal of the lingual shoulder. The incisal extension often approaches to within 2 to 3 mm of the incisal edge to allow for straight-line access. The incisal wall meets the lingual surface of the canine in a butt joint to provide adequate thickness for restorative material, because this tooth is heavily involved in excursive occlusal guidance and function. All internal walls funnel to the orifice.

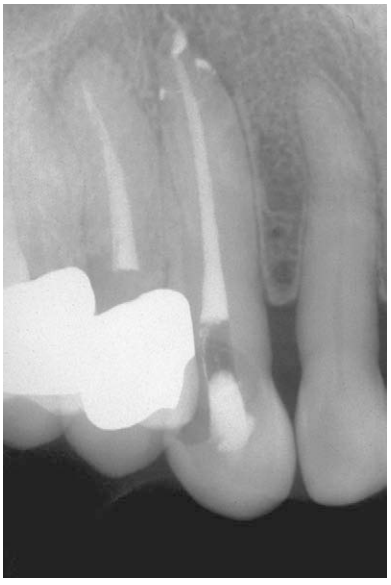

FIG. 7-88 Canine with multiple accessory foramina.

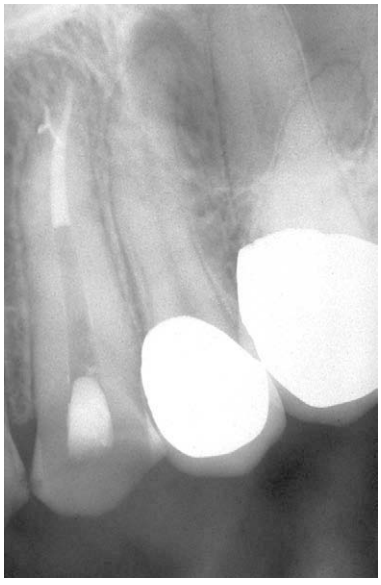

FIG. 7-89 Canine with lateral canal dividing into two canals.

Maxillary First Premolar

The majority of maxillary first premolars have two root canals regardless of the number of roots. Ethnicity plays a factor in that Asian people have a higher incidence of one canal than do other ethnic groups.[118]

A furcation groove or developmental depression on the palatal aspect of the buccal root is another anatomic feature. Its prevalence has been reported as between 62% and 100%.[97,202] This groove may pose a risk to endodontic and prosthodontic treatment of this tooth. At the deepest part of the invagination, the average dentin thickness was found to be 0.81 mm.

The pulp chamber of the maxillary first premolar is considerably wider buccolingually than mesiodistally. In the buccolingual dimension the chamber outline shows a buccal and a palatal pulp horn. The buccal pulp horn usually is larger. From the occlusal level the chamber maintains a similar width to the floor, which is located just apical to the cervical line. The palatal orifice is slightly larger than the buccal orifice. In cross-section at the CEJ, the palatal orifice is wider buccolingually and kidney shaped because of its mesial concavity. From the floor, two root canals take on a round shape at midroot and rapidly taper to their apices, usually ending in extremely narrow, curved root canals. The palatal canal usually is slightly larger than the buccal canal. The maxillary first premolar may have one, two, or three roots and canals; it most often has two (Table 7-11). If two canals are present, they are labeled buccal and palatal; three root canals are designated mesiobuccal, distobuccal, and palatal. Directional positioning of endodontic pathfinder files can help identify the anatomy. The roots are considerably shorter and thinner than in the canines. In double-rooted teeth the roots most often are the same length. The buccal root can fenestrate through the bone, leading to the same problems that arise with canines (i.e., inaccurate apex location, chronic posttreatment sensitivity to palpation over the apex, and an increased risk of an irrigation accident).

The maxillary first premolar is prone to mesiodistal root fractures and fractures at the base of the cusps, particularly the buccal cusp. If a fracture is suspected, all restorations should be removed and the coronal anatomy inspected with fiberoptic light and magnification. Full occlusal coverage is required after root canal therapy to prevent cuspal and/or crown/root fracture.

The access preparation for the maxillary first premolar is oval or slot shaped (Figs. 7-90 through 7-94). It also is wide buccolingually, narrow mesiodistally, and centered mesiodistally between the cusp tips. In fact, the mesiodistal width should correspond to the mesiodistal width of the pulp chamber. The buccal extension typically is two thirds to three fourths up the buccal cusp incline. The palatal extension is approximately halfway up the palatal cusp incline. The buccal and palatal walls funnel directly into the orifices. Because of the mesial concavity of the root, the clinician must take care not to overextend the preparation in that direction, as this could result in perforation.

Variation

When three canals are present, the external outline form becomes triangular with the base on the buccal aspect. The mesiobuccal and distobuccal corners of the triangle should be positioned directly over the corresponding canal orifices (see Fig. 7-91, *D*).

FIG. 7-92 Lateral bony lesion associated with a filled lateral canal.

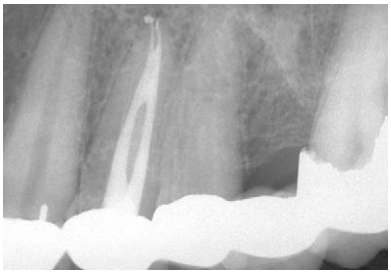

FIG. 7-93 Two canals that have fused and then redivided.

FIG. 7-94 Three canals.

Maxillary Second Premolar

The root canal system of the maxillary second premolar is wider buccolingually than mesiodistally. This tooth may have one, two, or three roots and canals (Table 7-12). Two or three canals can occur in a single root. Directional positioning of the endodontic pathfinder or a small file can help identify the anatomy. The mesiodistal and buccolingual aspects of the pulp chamber are similar to those of the first premolar. A buccal and a palatal pulp horn are present; the buccal pulp horn is larger. A single root is oval and wider buccolingually than mesiodistally. The canal(s) remain oval from the pulp chamber floor and taper rapidly to the apex.

The roots of the maxillary second premolar are approximately as long as those of the first premolar, and apical curvature is common, particularly with large maxillary sinus cavities. The proximity of this tooth to the sinus can lead to drainage of a periradicular abscess into the sinus and exposure of the sinus during apical root surgery.

Like the maxillary first premolar, the second premolar is prone to mesiodistal root fractures and fractures at the base of the cusps, usually the buccal cusp. If a fracture is suspected, all restorations in the tooth should be removed and the coronal anatomy inspected with a fiberoptic light and magnification. Full occlusal coverage is required after root canal therapy to prevent cusp and/or crown/root fracture.

When two canals are present, the maxillary second premolar access preparation is nearly identical to that of the first premolar. Because this tooth usually has one root, if two canals are present, they are nearly parallel to each other and the external outline form must have a greater buccolingual extension to permit straight-line access to these canals than with the first premolar with two roots and diverging canals. If only one canal is present, the buccolingual extension is less and corresponds to the width between the buccal and palatal pulp horns (Figs. 7-95 through 7-99). If three canals are present, the external access outline form is the same triangular shape illustrated for the maxillary first premolar (see Fig. 7-91, D).

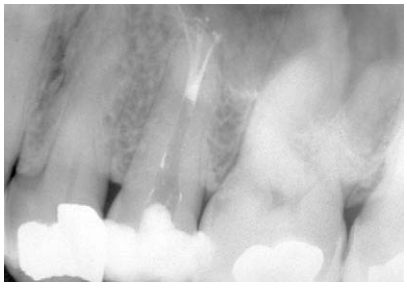

FIG. 7-99 Single canal that has split into three canals.

Maxillary First Molar

The maxillary first molar is the largest tooth in volume and one of the most complex in root and canal anatomy. The pulp chamber is widest in the buccolingual dimension, and four pulp horns are present (mesiobuccal, mesiopalatal, distobuccal, and distopalatal). The pulp chamber's cervical outline form has a rhomboid shape, sometimes with rounded corners. The mesiobuccal angle is an acute angle; the distobuccal angle is an obtuse angle; and the palatal angles are basically right angles. The palatal canal orifice is centered palatally; the distobuccal orifice is near the obtuse angle of the pulp chamber floor; and the main mesiobuccal canal orifice (MB-1) is buccal and mesial to the distobuccal orifice and is positioned within the acute angle of the pulp chamber. The second mesiobuccal canal orifice (MB-2) is located palatal and mesial to the MB-1. A line drawn to connect the three main canal orifices—the mesiobuccal (MB) orifice, distobuccal (DB) orifice, and palatal (P) orifice—forms a triangle, known as the molar triangle.

The three individual roots of the maxillary first molar (i.e., mesiobuccal root, distobuccal root, and palatal root) form a tripod. The palatal root is the longest, has the largest diameter, and generally offers the easiest access. It can contain one, two, or three root canals (Table 7-13). The palatal root often curves buccally at the apical one third, which may not

Maxillary First Molar—cont'd

be obvious on a standard periapical radiograph. From its orifice the palatal canal is flat, ribbonlike, and wider in a mesiodistal direction. The distobuccal root is conical and may have one or two canals (Table 7-14). From its orifice, the canal(s) first is oval and then becomes round as it approaches the apical third of the root. The mesiobuccal root has generated more research and clinical investigation than any other root in the mouth. It may have one, two, or three root canals (Table 7-15). A single mesiobuccal canal is oval and wider buccolingually; two or three canals are more circular. In general, a concavity exists on the distal aspect of the mesiobuccal root, which makes this wall thin. The clinician must take care not to instrument the wall excessively because a strip perforation may result.

The DOM has been used to study the location and pathway of the MB-2 canal in maxillary first and second molars.[79] The clinician must always keep in mind that the location of the MB-2 canal varies greatly; this canal generally is located mesial to or directly on a line between the MB-1 and palatal orifices, within 3.5 mm palatally and 2 mm mesially of the MB-1 orifice (Figs. 7-100 and 7-101). These authors[79] found that not all MB-2 orifices lead to a true canal. A true MB-2 orifice was present in only 84% of molars in which a second orifice was identified (Fig. 7-102).[197]

Negotiation of the MB-2 canal often is difficult; a ledge of dentin covers its orifice, the orifice has a mesiobuccal inclination on the pulp floor, and the canal's pathway often takes one or two abrupt curves in the coronal part of the root. Most of these obstructions can be eliminated by troughing or countersinking with ultrasonic tips mesially and apically along the mesiobuccal pulpal groove (Figs. 7-103 through 7-107). This procedure causes the canal, when present, to shift mesially, meaning that the access wall must be moved farther mesially. Troughing may need to be 0.5 to 3 mm deep. Care must be taken to avoid furcal wall perforation of this root. Apical to the troughing level the canal may

Maxillary First Molar—cont'd

be straight or may curve sharply to the distobuccal, buccal, or palatal.

Because the maxillary first molar almost always has four canals, the access cavity has a rhomboid shape, with the corners corresponding to the four orifices (MB-1, MB-2, DB, and P) (see Fig. 7-103). One study demonstrated that the access cavity should not extend into the mesial marginal ridge.[241] Distally, the preparation can invade the mesial portion of the oblique ridge, but it should not penetrate through the ridge. The buccal wall should be parallel to a line connecting the MB-1 and DB orifices and not to the buccal surface of the tooth.

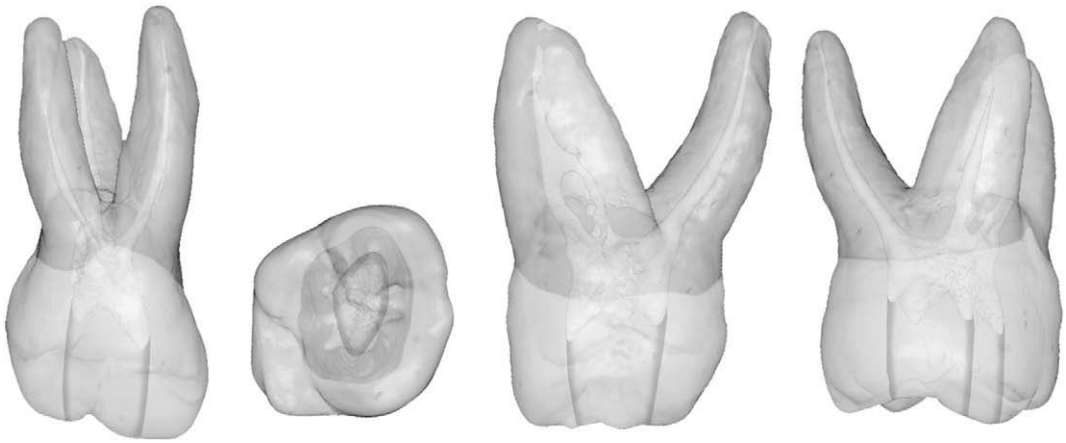

FIG. 7-100 Maxillary first molar. Average time of eruption, 6 to 7 years; average age of calcification, 9 to 10 years; average length, 20.8 mm. Root curvature (most common to least common): mesiobuccal root—distal, straight; distobuccal root—straight, mesial, distal; palatal root—buccal, straight.

Maxillary Second Molar

Coronally, the maxillary second molar closely resembles the maxillary first molar. The root and canal anatomy are similar to those of the first molar, although differences occur. The distinguishing morphologic feature of the maxillary second molar is that its three roots are grouped closer together and are sometimes fused. Also, they generally are shorter than the roots of the first molar and not as curved. The second molar usually has one canal in each root; however, it may have two or three mesiobuccal canals, one or two distobuccal canals, or two palatal canals (Tables 7-16 to 7-18). Four canals are less likely to be present in the second molar than in the first molar. The three main orifices (MB, DB, and P) usually form a flat triangle and sometimes almost a straight line (Figs. 7-108 through 7-113). The mesiobuccal canal orifice is located more to the buccal and mesial than in the first molar; the distobuccal orifice approaches the midpoint between the mesiobuccal and palatal orifices; and the palatal orifice usually is located at the most palatal aspect of the root. In general, the canal orifices in the maxillary second molar are closer mesially to each other than they are in the maxillary first molar.

The floor of the pulp chamber is markedly convex, which gives the canal orifices a slight funnel shape. On occasion the canals curve into the chamber at a more horizontal angle, requiring removal of a lip of dentin so that a canal can be entered more in a direct line with the axis. Teeth with fused roots occasionally have only two canals; in rare cases, they have only one. Teeth with two canals usually have a buccal and a palatal canal of equal length and diameter (see Fig. 7-109, B). These parallel root canals are frequently superimposed radiographically, but they can be imaged by exposing the radiograph from a distal angle. To enhance radiographic

*Number represents the percentage of cases in which one canal separates into two.

visibility, especially when interference arises from the malar process, a more perpendicular and distoangular radiograph may be exposed. When two roots are present, each root may have one canal or the buccal root may have two canals that join before reaching a single foramen. One study found that two palatal roots and two palatal canals occur in 1.47% of these teeth.[159]

When four canals are present, the access cavity preparation of the maxillary second molar has a rhomboid shape and is a smaller version of the access cavity for the maxillary first molar (see Fig. 7-110). If only three canals are present, the access cavity is a rounded triangle with the base to the buccal. As with the maxillary first molar, the mesial marginal ridge need not be invaded. Because the tendency in maxillary second molars is for the distobuccal orifice to move closer to a line connecting the MB and P orifices, the triangle becomes more obtuse and the oblique ridge usually is not invaded.

If only two canals are present, the access outline form is oval and widest in the buccolingual dimension. Its width corresponds to the mesiodistal width of the pulp chamber, and the oval usually is centered between the mesial pit and the mesial edge of the oblique ridge.

Maxillary Second Molar—cont'd

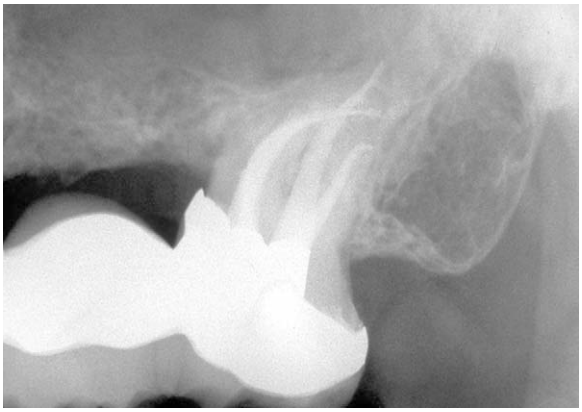

FIG. 7-111 Severely curved mesiobuccal root with a right-angle curve in the distobuccal (DB) root.

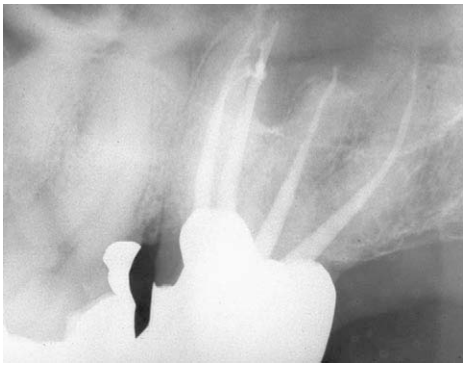

FIG. 7-112 Four canals (MB-1, MB-2, DB, and P) can be seen.

FIG. 7-113 Four canals with two distinct palatal roots and canals.

Maxillary Third Molar

Loss of the maxillary first and second molars often is the reason the third molar must be considered as a strategic abutment. Another indication for root canal therapy and full coverage is a fully functioning mandibular third molar in an arch that has sufficient room for full eruption and oral hygiene.

Careful examination of the root morphology is important before treatment is determined. The radicular anatomy of the third molar is completely unpredictable, and it may be advisable to explore the root canal morphology to evaluate the likelihood and degree of success. Even so, many third molars have adequate root formation; given reasonable accessibility, they can serve well as functioning dentition after root canal therapy.

The root anatomy of the maxillary third molar varies greatly. This tooth can have one to four roots and one to six canals, and C-shaped canals also can occur. The third molar usually has three roots and three root canals (Table 7-19; Figs. 7-114 through 7-116). The tooth may be tipped significantly to the distal, the buccal, or both, which creates an even greater access problem than with the second molar.

The access cavity form for the third molar can vary greatly. Because the tooth typically has one to three canals, the access preparation can be anything from an oval that is widest in the buccolingual dimension to a rounded triangle similar to that used for the maxillary second molar. The MB, DB, and P orifices often lie nearly in a straight line as the DB orifice moves even closer to the line connecting the MB and P orifices. The resultant access cavity is an oval or highly obtuse triangle.

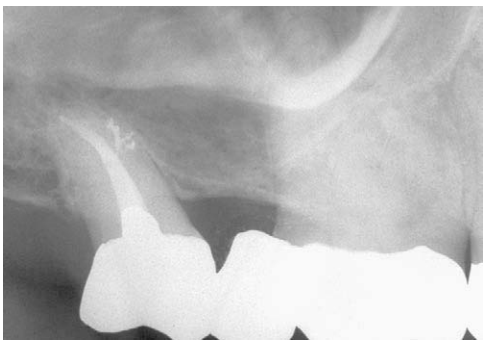

FIG. 7-116 Distal bridge abutment with major accessory canal.

Mandibular Central and Lateral Incisors

The root canal systems and access cavities for the two mandibular incisors are so similar they are discussed together. As with the maxillary incisors, a lingual shoulder must be eliminated to allow direct-line access. The shoulder conceals the orifice to a second canal that, if present, is found immediately beneath it. Unlike the maxillary incisors, the pulp outline of the mandibular incisors is wider labiolingually. At the CEJ the pulp outline is oval, wider labiolingually than mesiodistally. At midroot the canal outline is still oval, but the canal is more constricted and narrower labiolingually. Most mandibular incisors have a single root with what radiographically appears to be a long, narrow canal. However, it is a broad canal labiolingually. Often a dentinal bridge is present in the pulp chamber that divides the root into two canals. The two canals usually join and exit through a single apical foramen, but they may persist as two separate canals. On occasion one canal branches into two canals, which subsequently rejoin into a single canal before reaching the apex (Table 7-20). One study determined that a relationship existed between crown size (expressed as the M-D/F-L index) and the incidence of bifid root canals in these teeth.[228] Double root canals occur more often in teeth with a smaller index.

The mandibular incisors, because of their small size and internal anatomy, may be the most difficult access cavities to prepare. The external outline form may be triangular or oval, depending on the prominence of the mesial and distal pulp horns (Figs. 7-117 through 7-120). When the form is triangular, the incisal base is short and the mesial and distal legs are long incisogingivally, creating a long, compressed triangle. Without prominent mesial and distal pulp horns, the oval external outline form also is narrow mesiodistally and long incisogingivally. One study[148] determined that by age 40 years the mandibular incisor pulp chamber has decreased in size sufficiently to routinely justify an oval access cavity. Complete removal of the lingual shoulder is critical, because this tooth often has two canals that are buccolingually oriented, and the lingual canal most often is missed. To avoid missing this canal, the clinician should extend the access preparation well into the cingulum gingivally. Because the lingual surface of this tooth is not involved with occlusal function, butt joint junctions between the internal walls and the lingual surface are not required.

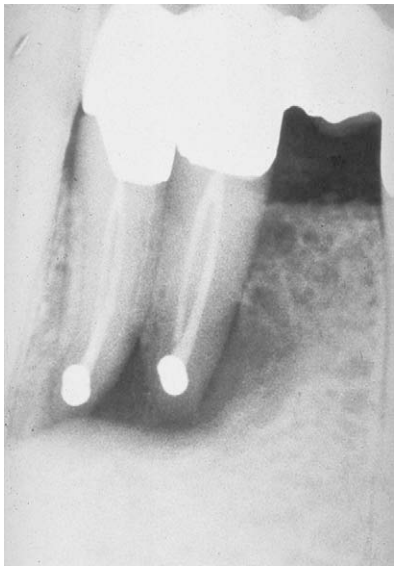

FIG. 7-120 Two canals in the mandibular lateral and central incisors.

Mandibular Canine

The root canal system of the mandibular canine is very similar to that of the maxillary canine, except that the dimensions are smaller, the root and root canal outlines are narrower in the mesiodistal dimension, and the mandibular canine occasionally has two roots and two root canals located labially and lingually (Table 7-21). The root canal of the mandibular cuspid is narrow mesiodistally but usually very broad buccolingually. A lingual shoulder must be removed to gain access to the lingual wall of the root canal or to the entrance of a second canal. The lingual wall is almost slitlike compared with the larger buccal wall, which makes the canal a challenge to shape and clean.

The access cavity for the mandibular canine is oval or slot shaped (Figs. 7-121 through 7-126). The mesiodistal width corresponds to the mesiodistal width of the pulp chamber. The incisal extension can approach the incisal edge of the tooth for straight-line access, and the gingival extension must penetrate the cingulum to allow a search for a possible lingual canal. As with the mandibular incisors, butt joint relationships between internal walls and the lingual surface are not necessary.

Mandibular First Premolar

As a group, the mandibular premolars are difficult to treat. They have a high flare-up and failure rate. A possible explanation may be the extreme variations in root canal morphology in these teeth. The root canal system of the mandibular first premolar is wider buccolingually than mesiodistally. Two pulp horns are present: a large, pointed buccal horn and a small, rounded lingual horn. At the cervical line the root and canal are oval; this shape tends to become round as the canal approaches the middle of the root. If two canals are present, they tend to be round from the pulp chamber to their foramen. In another anatomic variation, a single, broad root canal may bifurcate into two separate root canals. Direct access to the buccal canal usually is possible, whereas the lingual canal may be quite difficult to find. The lingual canal tends to diverge from the main canal at a sharp angle. In addition, the lingual inclination of the crown tends to direct files buccally, making location of a lingual canal orifice more difficult. To counter this situation, the clinician may need to extend the lingual wall of the access cavity farther lingually; this makes the lingual canal easier to locate. The mandibular first premolar sometimes may have three roots and three canals (Table 7-22). One study reported a C-shaped canal anatomy in this tooth.[14]

The oval external outline form of the mandibular first premolar typically is wider mesiodistally than its maxillary counterpart, making it more oval and less slot shaped (Figs. 7-127 through 7-131). Because of the lingual inclination of the crown, buccal extension can nearly approach the tip of the buccal cusp to achieve straight-line access. Lingual extension barely invades the poorly developed lingual cusp incline. Mesiodistally the access preparation is centered between the cusp tips. Often the preparation must be modified to allow access to the complex root canal anatomy frequently seen in the apical half of the tooth root.

FIG. 7-129 Two canals. *(Courtesy Dr. Raed Kasem, Clearwater, FL.)*

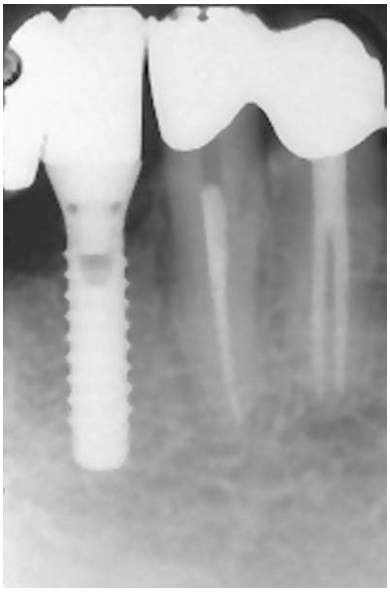

FIG. 7-130 Single canal that has divided into two.

FIG. 7-131 Three canals.

Mandibular Second Premolar

The mandibular second premolar is similar to the first premolar, with the following differences: the lingual pulp horn usually is larger; the root and root canal are more often oval than round; the pulp chamber is wider buccolingually; and the separation of the pulp chamber and root canal normally is distinguishable compared with the more regular taper in the first premolar. The canal morphology of the mandibular second premolar is similar to that of the first premolar with its many variations: two, three, and four canals and a lingually tipped crown. Fortunately, these variations are found less often in the second premolar (Table 7-23).

The access cavity form for the mandibular second premolar varies in at least two ways in its external anatomy. First, because the crown typically has a smaller lingual inclination, less extension up the buccal cusp incline is required to achieve straight-line access. Second, the lingual half of the tooth is more fully developed, and therefore the lingual access extension typically is halfway up the lingual cusp incline.[56] The mandibular second premolar can have two lingual cusps, sometimes of equal size. When this occurs, the access preparation is centered mesiodistally on a line connecting the buccal cusp and the lingual groove between the lingual cusp tips. When the mesiolingual cusp is larger than the distolingual cusp, the lingual extension of the oval outline form is just distal to the tip of the mesiolingual cusp (Figs. 7-132 through 7-138).

Mandibular First Molar

The earliest permanent posterior tooth to erupt, the mandibular first molar seems to be the tooth that most often requires root canal treatment. It often is extensively restored, and it is subjected to heavy occlusal stress. Therefore the pulp chamber frequently has receded or is calcified. The tooth usually has two roots, but occasionally it has three, with two or three canals in the mesial root and one, two, or three canals in the distal root (Tables 7-24 and 7-25). The canals in the mesial root are the MB and ML canals; a middle mesial (MM) canal sometimes is present in the developmental groove between the MB and ML canals. The incidence of an MM canal ranges from 1%[215] to 15%.[76] The canals in the distal root include the distal canal (if only one canal is present) and the DB, DL, and middle distal (MD) canals (if more than one is present).[74] The orifices to these canals are connected by a developmental groove. Orifices to all canals usually are located in the mesial two thirds of the crown, and the pulp chamber floor is roughly trapezoid or rhomboid. Usually four pulp horns (MB, ML, DB, and DL) are present.

The presence of two separate distal roots is rare but does occur. In such cases the DL root is smaller than the DB root and usually more curved. Also, the DL root often has a sharp apical hook toward the buccal side that is not obvious on radiographs. The mesial root, the wider of the two roots, curves mesially from the cervical line to the middle third of the root and then angles distally to the apex. The buccal and lingual surfaces are convex throughout their length, whereas the distal surface of the mesial root and the mesial surface of the distal root have a root concavity, which makes the dentin wall very thin. Care must be taken to minimize instrumentation against these walls, because overzealous cutting of the concavity can lead to a strip perforation of the root.

The mesial canal orifices usually are well separated within the main pulp chamber and connected by a developmental groove. The MB orifice commonly is under the mesiobuccal cusp, whereas the ML orifice generally is found just lingual to the central groove. On occasion an MM canal orifice is present in the groove between the MB and ML orifices (Figs. 7-139 through 7-147). The clinician must always check for such an orifice after shaping and cleaning the main root canals. A bur is used to remove any protuberance from the mesial axial wall that would prevent direct access to the

developmental groove between the MB and ML orifices. The clinician should use magnification to explore this developmental groove carefully with the sharp tip of an endodontic explorer. If a depression or orifice is located, the groove can be troughed with ultrasonic tips, at the expense of the mesial aspect, until a small file can negotiate the canal. This is best accomplished with the DOM (see Fig. 7-141).

When only one distal canal is present, the orifice is oval buccolingually and the opening generally is located distal to the buccal groove. This orifice usually can be explored from the mesial with either an endodontic explorer or a small K-file. If the file tip takes a sharp turn in a distobuccal or distolingual direction, the clinician should search for yet another orifice; in rare cases an MD canal orifice is present.

If three root canals (MB, ML, and D) are present in this tooth, each is oval in the cervical and middle thirds of the root and round in the apical third. If two canals (DB and DL) are present in the distal root, they usually are more round than oval for their entire length. The mesial root canals usually are curved, with the greatest curvature in the MB canal. This canal can have a significant curvature in the buccolingual plane that may not be apparent on radiographs. Such a curvature usually can be detected with precurved pathfinder instruments.

Multiple accessory foramina are located in the furcation of the mandibular molars. These foramina usually are impossible to clean and shape directly; they are rarely seen, except occasionally on a posttreatment radiograph if they have been

filled with root canal sealer or thermoplastic filling material. Because sodium hypochlorite solutions can dissolve organic debris, the pulp chamber should be thoroughly exposed to allow the solution to reach the tiny openings. Fractures occasionally occur on proximal marginal ridges and extend down the root or under the lingual cusps.

The access cavity for the mandibular first molar typically is trapezoid or rhomboid regardless of the number of canals present. When four or more canals are present, the corners of the trapezoid or rhombus should correspond to the positions of the main orifices. Mesially the access need not invade the marginal ridge. Distal extension must allow straight-line access to the distal canal(s). The buccal wall forms a straight connection between the MB and DB orifices, and the lingual wall connects the ML and DL orifices without bowing.

A variation in root morphology is the presence of an extra distolingual root.[195] Usually this root has a type I canal configuration. It was found that two thirds of the first mandibular molars of a Chinese population possessed this variation.[250] Similarly, this distolingual root occurred in 4% of mandibular first molars of a Kuwait population.[154] These results confirm the observation that East Asian populations have more three-rooted mandibular first molars than other racial groups.[7]

Mandibular molars, mainly first molars, may also have an additional root located lingually or buccally. Although this is a rare occurrence in white populations it is more common in Asian populations.[212] The radix entomolaris (RE) is a supernumerary root located distolingually in mandibular molars, whereas the radix paramolaris (RP) is an extra root located mesiobuccally. Each root usually contains a single root canal. The orifice of the RE is located disto- to mesiolingually from the main canal or canals of the distal root; the orifice of the RP is located mesio- to distobuccally from the main mesial root canals. A dark line or groove from the main root canal on the pulp chamber floor leads to these orifices.[32] These anatomic variations present definite challenges to therapy because of their orifice inclination and root canal curvature. The canal can be straight, have a coronal curvature, or can have separate coronal and apical curvatures.[55]

Mandibular Second Molar

The mandibular second molar is somewhat smaller coronally than the first molar and tends to be more symmetrical. This tooth is identified by the proximity of its roots. The two roots often sweep distally in a gradual curve, with the apices close together. In some cases only one root is present. The degree of canal curvature and the configuration were studied in the mesial roots of 100 randomly selected mandibular first and second molars; 100% of the specimens showed curvature in both buccolingual and mesiodistal views.[48]

The pulp chamber and canal orifices of the mandibular second molar generally are not as large as those of the first molar. This tooth may have one, two, three, or four root canals (Table 7-26; Figs. 7-148 through 7-153). The two mesial orifices are located closer together. In some mandibular second molars with single or fused roots, a file placed in the mesiobuccal canal may appear to be in the distal canal. This happens because the two canals sometimes are connected by a semicircular slit, a variation of the C-shaped canal[134] (see Fig. 7-144, A) that often occurs in this tooth. The distal aspect of the mesial root and the mesial aspect of the distal root have concavities, which must be evaluated during cleaning and shaping procedures. The apices of this tooth often are close to the mandibular canal; therefore the clinician must take care not to allow instruments or filling material to invade this space, because paresthesia may result.

Continued

Mandibular Second Molar—cont'd

Mandibular second molars may have one to six canals, although the most prevalent configurations are two, three, and four canals (see Fig. 7-149). When three canals are present, the access cavity is similar to that for the mandibular first molar, although perhaps a bit more triangular and less rhomboid. The distal orifice is less often ribbon shaped buccolingually; therefore the buccal and lingual walls converge more aggressively distally to form a triangle. The second molar may have only two canals, one mesial and one distal, in which case the orifices are nearly equal in size and line up in the buccolingual center of the tooth. The access cavity for a two-canal second molar is rectangular, wide mesiodistally and narrow buccolingually. The access cavity for a single-canal mandibular second molar is oval and is lined up in the center of the occlusal surface.

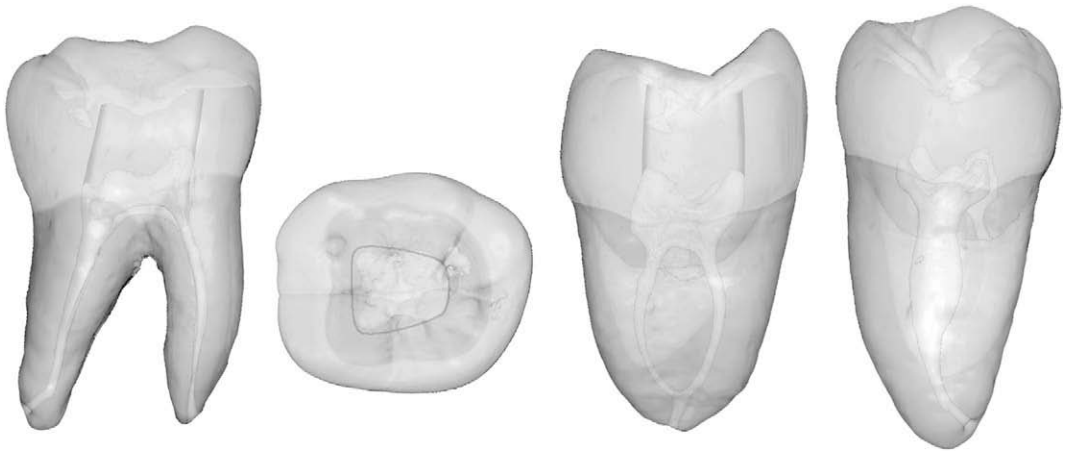

FIG. 7-148 Mandibular second molar. Average time of eruption, 11 to 13 years; average age of calcification, 14 to 15 years; average length, 19.8 mm. FIG. 7-152 Two canals with an accessory canal at the distal root apex.

FIG. 7-153 Fusion of mesial canals at the apex.

Mandibular Third Molar

The mandibular third molar is anatomically unpredictable and must be evaluated on the basis of its root formation. Fused short, severely curved, or malformed roots often support well-formed crowns. This tooth may have one to four roots and one to six canals (Table 7-27; Figs. 7-154 through 7-157). C-shaped canals also can occur. Most of these teeth can be successfully treated endodontically regardless of anatomic irregularities; however, the long-term prognosis is determined by the root surface volume in contact with bone. The clinician must weigh the benefit of treatment against the prognosis.

The anatomy of the mandibular third molar is unpredictable; therefore the access cavity can take any of several shapes. When three or more canals are present, a traditional rounded triangle or rhomboid shape is typical. When two canals are present, a rectangular shape is used. For single-canal molars, an oval shape is customary.

Teeth With C-Shaped Root Canal Systems

The main cause for C-shaped roots and canals is the failure of Hertwig's epithelial root sheath to fuse on either the buccal or lingual root surface. The C-shaped canal system can assume many variations in its morphology. The original classification[133] has been modified and has produced a more detailed description of C-shaped root and canal morphology. The "C" shape canal configuration can vary along the root depth so that the appearance of the orifices may not be good predictors of the actual canal anatomy.[64]

Category I (C1): The shape is an uninterrupted "C" with no separation or division (see Fig. 7-150, *A*).

Category II (C2): The canal shape resembles a semicolon resulting from a discontinuation of the "C" outline (see Fig. 7-150, *B*), but either angle α or β should be no less than 60 degrees.

Category III (C3): Two or three separate canals (see Fig. 7-150, *C* and *D*) and both angles, α and β, are less than 60 degrees.

Category IV (C4): Only one round or oval canal is in the cross-section (see Fig. 7-150, *E*).

Category V (C5): No canal lumen can be observed (is usually seen near the apex only) (see Fig. 7-150, *F*).

The C-shaped root canal system was first reported in 1979.[46] Most C-shaped canals occur in the mandibular second molar (Figs. 7-158 through 7-166), but they also have been reported in the mandibular first molar, the maxillary first and second molars, and the mandibular first premolar. Two investigators reported the first case of a C-shaped canal in a maxillary molar.[146] One study reported the incidence of C-shaped canal anatomy in maxillary first molars as 2 in 2175 (0.092%); this study also determined that the DB and palatal orifices were connected by a common groove (see Fig. 7-159, *B*).[34] Investigators who examined 309 Chinese maxillary second molars found C-shaped root canals in 4.9%.[248]

C-shaped mandibular molars are so named because of the cross-sectional morphology of their fused roots and their root canals. Instead of having several discrete orifices, the pulp chamber of a molar with a C-shaped root canal system is a single, ribbon-shaped orifice with an arc of 180 degrees or more. It starts at the mesiolingual line angle and sweeps around either to the buccal or the lingual to end at the distal aspect of the pulp chamber (see Fig. 7-159, *A*). Below the orifice, the root structure can show a wide range of anatomic variations. These can be classified into two basic types: those with a single, ribbonlike, C-shaped canal from orifice to apex, and those with three or more distinct canals below the usual C-shaped orifice. Fortunately, molars with a single swath of canal are the exception rather than the rule. More common is the second type, with discrete canals that take unusual forms.[46] Other investigators determined that C-shaped canals in mandibular second molars can vary in shape and number along the root length.[133] This makes cleaning, shaping, obturation, and restoration of these teeth difficult.

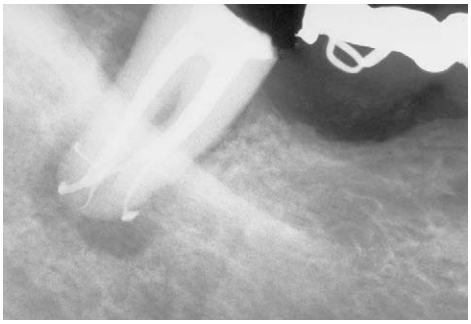

FIG. 7-163 Mandibular second molar with multiple foramina.

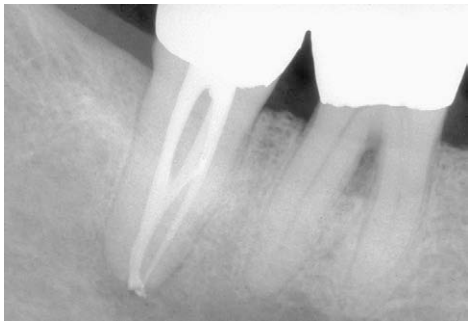

FIG. 7-164 Mandibular second molar with interconnecting canal anatomy.

One study reported a case of a mandibular first molar with a normal mesiolingual orifice and a C-shaped groove that ran continuously from the mesiobuccal orifice along the buccal wall to the distal canal orifice.[18] The groove ran continuously down the root to the apical third, where it divided into two canals. Other researchers reported a C-shaped groove in a mandibular first molar that extended from the DL to the DB orifice and across the buccal surface to the MB orifice.[26] The

FIG. 7-165 Pretreatment appearance of a mandibular first molar with a C-shaped canal.

FIG. 7-166 Root canal obturation showing the ribbonlike canal space. *(Courtesy Dr. Paulo Nogueira, São Paulo, Brazil.)*

ML orifice remained separate. Four separate apical foramina were noted. One investigator evaluated 811 endodontically treated mandibular second molars and found that 7.6% had C-shaped canals.[233] Several variants of the C-shaped canal morphology were noted, the most common being two or three canals that merged and exited as one canal.[233]

Significant ethnic variation can be seen in the incidence of C-shaped root canal systems. This anatomy is much more common in Asians than in the white population. Investigators in Japan[107] and China[247] found a 32% incidence of C-shaped canals. Others found the occurrence of C-shaped canals in a Chinese population to be 23% in mandibular first molars and 32% in mandibular second molars.[247] Another study found a 19% rate in Lebanese subjects[83] and 11% of mandibular second molars from a Saudi Arabian population.[5] Mandibular molars in a Burmese population were found to have C-shaped canals in 22% of teeth.[82] Another investigation found that 33% of Koreans had a C-shaped canal morphology in mandibular second molars.[183]

Four types of pulpal floors were found in mandibular second molars:

Teeth With C-Shaped Root Canal Systems—cont'd

Type I: A peninsula-like floor with continuous C-shaped orifice (see Fig. 7-160)

Type II: A buccal, striplike dentin connection between the peninsula-like floor and the buccal wall of the pulp chamber that separates the C-shaped groove into mesial (M) and distal (D) orifices. Sometimes the mesial orifice is separated into a mesiobuccal (MB) orifice and a mesiolingual (ML) orifice by another striplike dentin connection between the peninsula-like floor and the mesial wall of the pulp chamber (most common) (see Fig. 7-160)

Type III: Only one mesial, striplike dentin connection exists between the peninsula-like floor and the M wall, which separates the C-shaped groove into a small ML orifice and a large MB-D orifice. The MB-D orifice was formed by the merging of the MB orifice and the D orifice (second most common) (see Fig. 7-160)

Type IV: Non–C-shaped floors. One distal canal orifice and one oval or two round mesial canal orifices are present (least common) (see Fig. 7-160)

Not all C-shaped mandibular second molars with C-shaped canal systems have a C-shaped pulpal floor. This makes diagnosis difficult. However, it was determined radiographically that a tooth with a C-shaped canal system always has a fused root with a longitudinal groove in the middle of the root.[65] It was also found that there are three types of C-shaped canal systems in mandibular second molars (see Fig. 7-161).[72]

Type I (merging type): Canals merge to one main canal before exiting at the apical foramen

Type II (symmetrical type): Separated mesial and distal canals in each root, which exit as separate canals

Type III (asymmetrical type): Separated mesial and distal canals, with the distal canal having a long isthmus across the furcation area

The minimal wall thickness in the middle and apical parts of type III and in the apical part of type II makes these regions danger zones for canal enlargement procedures (see Fig. 7-162).[72]

Another study on mandibular molars found that there is a higher risk of root perforation at the thinner lingual walls of C-shaped canals during shaping and after canal preparation procedures. Both buccal and lingual canal walls were frequently narrower at the mesial locations.[38]

The access cavity for teeth with a C-shaped root canal system varies considerably and depends on the pulp morphology of the specific tooth. Teeth with C-shaped anatomy pose a considerable technical challenge; however, use of the DOM, sonic and ultrasonic instrumentation, and plasticized obturation techniques have made treatment successful.

CHAPTER OUTLINE

DIAGNOSTIC MATERIALS AND DEVICES
- Assessment of Pulp Sensibility
- Assessment of Pulp Vascularity
- Assessment of Cracks and Fractures
- Assessment of Images

ENDODONTIC INSTRUMENTS
- Hand Instruments
- Instruments for Cleaning and Shaping the Root Canal Space
- Devices for Periapical Débridement Through a Root Canal Access
- Devices for Measuring Root Canal Length
- Instruments for Root Canal Obturation
- Devices for Removing Root Canal Obstructions

MATERIALS FOR DISINFECTING THE PULP SPACE
- Chemomechanical Preparation
- Sodium Hypochlorite
- Chlorhexidine
- MTAD and Tetraclean
- Ethylenediamine Tetra-Acetic Acid
- Hydrogen Peroxide
- Iodine Potassium Iodide
- Choosing the Ideal Irrigant
- Intracanal Medication
- New Irrigation and Disinfection Techniques and Devices

ROOT CANAL FILLING MATERIALS
- Solid Materials
- Sealers and Cements
- Standards and Properties

DELIVERY SYSTEMS FOR ROOT CANAL OBTURATION MATERIALS
- Carrier-Based Systems
- Injection Techniques
- Rotary Techniques

TEMPORARY RESTORATIONS

LASERS
- Neodymium-Doped Yttrium Aluminum Garnet Lasers
- Erbium-Doped Yttrium Aluminum Garnet Lasers
- Diode Lasers
- Erbium/Chromium-Doped Yttrium Scandium Gallium Garnet Lasers

The past decades have seen many changes in the practice of endodontics, such as in materials, techniques, equipment, instrument design, and the types of metals used to manufacture endodontic instruments. However, the goals of nonsurgical endodontic therapy has not changed: "Root canal systems must be cleaned and shaped: cleaned of their organic remnants and shaped to receive a three-dimensional hermetic (fluid-tight seal) filling of the entire root canal space."[332]

DIAGNOSTIC MATERIALS AND DEVICES

Assessment of Pulp Sensibility

One of the greatest diagnostic challenges in clinical practice is the accurate assessment of pulp status. A variety of pulp testing approaches exist, and there may be confusion as to their validity or appropriateness in different clinical situations. When tests are evaluated, there are some terms that may lead to more definitive and possibly quantifiable endodontic diagnoses. These terms are *sensitivity,* the ability of a test to identify teeth with disease; *specificity,* the ability of a test to identify teeth without disease; and *predictive value,* the ability of a test to foretell what the diagnosis actually is.

Pulp stimulation with cold or heat is the oldest method of evaluating the pulp's health and its ability to respond to external stimulation, but evaluation of pulpal response must not be confused with vitality testing, which requires assessment of pulpal circulation.[140]

Cold Tests

Cold thermal testing causes contraction of the dentinal fluid within the dentinal tubules, resulting in a rapid outward flow of fluid within the patent tubules. This rapid movement of dentinal fluid results in hydrodynamic forces acting on the Aδ nerve fibers within the pulp-dentin complex, leading to a sharp

The authors acknowledge the excellent scholarship of Drs. Van Himel and John McSpadden in authoring previous editions of this chapter.

sensation lasting for the duration of the thermal test. A variety of cold tests may be employed; the major difference between them is the degree of cold applied to the tooth.[140]

A simple means of applying a cold stimulus to a tooth is to wrap a sliver of ice in wet gauze and place it against the buccal surface, comparing the reaction between the test tooth and a control tooth. Pencils of ice can be made by filling a plastic straw with water and freezing it in an upright position in a freezer.[352]

Ethyl chloride (−41° C) may be sprayed onto a cotton pledget, resulting in the formation of ice crystals (Fig. 8-1) prior to application to the tooth. Dichlorodifluoromethane (DDM) (−50° C) is a compressed refrigerant spray that can also be sprayed onto a cotton pledget for cold testing (Fig. 8-2). More recently, ozone-friendly non-chlorofluorocarbon sprays have been introduced in certain countries.

Another effective cold stimulus is frozen carbon dioxide (CO_2), also known as *dry ice* or *carbon dioxide snow* (−78.5° C). For testing purposes, a solid stick of CO_2 is prepared by delivering CO_2 into a custom-made plastic cylinder, and the stick is applied to the buccal surface of the tooth. This method is particularly effective when trying to assess teeth that have been restored with full-coverage metal restorations.[397] Rickoff et al.[314] reported that CO_2 snow applied to a tooth for 5 minutes did not jeopardize the health of the pulp, nor does it damage the surface of the enamel.[300] On the other hand, CO_2 may cause pitting of the surface of porcelain restorations when applied for as little as 5 seconds.[203] When testing with a cold stimulus, the advantage of refrigerant sprays and frozen carbon dioxide is that the cold stimulus does not go into a liquid phase but rather a gas phase. This allows testing to be specific to one tooth at a time, without cold water from melted ice stimulating adjacent teeth.

Ice-cold water is another useful and inexpensive test. The tooth being tested should be isolated with a rubber dam and then bathed with water from a syringe. Cold tests should be applied until the patient definitely responds or the stimulus has been applied for a maximum of 15 seconds.[121] One of the significant benefits of ice-water testing is that it can be used on any tooth regardless of the type of restoration that may be present. Overall, cold tests appear to be more reliable than heat tests,[93,341] and there is a general consensus that the colder the stimulus, the more effective the assessment of tooth innervation status.

Heat Test

Warm thermal testing is not employed as often as cold testing because most patients are more sensitive to cold stimuli, and warm thermal tests have been traditionally more difficult to perform. Heat testing can be undertaken using a stick of heated gutta-percha or hot water. A gutta-percha stick, preferably base-plate gutta-percha, is heated with a naked flame or an electric heater until it becomes soft and glistens.[149] It is then applied to the Vaseline-coated surface of the test tooth. It is purported that a tooth surface temperature as high as 150° C can be achieved with this technique[319]: gutta-percha softens at 65° C and may be heated in delivery devices up to 200° C. This test may be difficult to use on posterior teeth because of limited access. A further disadvantage is that excessive heating may result in pulp damage.[280] Prolonged heat application will result in biphasic stimulation of Aδ fibers initially, followed by the pulpal C fibers. Activation of C fibers may result in a lingering pain, therefore heat tests should be applied for no more than 5 seconds. However, inadequate heating of the gutta-percha stick could result in the stimulus being too weak to elicit a response from the pulp.[140]

The use of hot water, administered through an irrigating syringe under rubber dam isolation, has also been described as a means of thermal testing. Frictional heat may be generated by using a rubber cup intended for prophylaxis (without paste) against the buccal aspect of a tooth. The normal use of thermal tests on teeth has been shown not to be harmful to healthy pulp tissue.[170] The System B (SybronEndo, Orange, CA) allows dentists to set specific temperatures for warm thermal testing. After the surface of the tooth has been lubricated, a test tip can be attached to the handle of the System B and the temperature set at 150° F. The preheated tip is placed on the surface of the tooth, and the patient's response is evaluated.

One of the problems of testing with heat is that often a nonvital tooth increases in pain secondary to heat stimuli. In

the clinical situation whereby a patient reports pain to heat and relief with cold stimuli, the application of cold to individually selected teeth may eliminate the patient's tooth pain. Therefore, in these situations, the application of cold with relief of pain can be diagnostic for a nonvital pulp.

Electric Pulp Test

The objective of the electric pulp test (EPT) is to stimulate intact Aδ nerves in the pulpal-dentin complex by applying an electric current to the tooth surface. A positive result stems from an ionic shift in the dentinal fluid within the tubules, causing local depolarization and subsequent generation of an action potential from intact Aδ nerves.[292]

The electric pulp tester is a battery-operated instrument connected to a probe that is applied to the tooth under investigation. It functions by producing a pulsating electrical stimulus, the initial intensity of which should be set at a very low value to prevent excessive stimulation and discomfort. The intensity of the electric stimulus is then increased steadily at a preselected rate, and a note is made of the readout on the digital display when the patient acknowledges a warm or tingling sensation. The readout is not a quantitative measurement of pulp health; it simply provides evidence that the Aδ fibers are sufficiently healthy to function.[140]

Bipolar and monopolar are the two stimulating modes available. The bipolar mode is presumably more accurate because the current is confined to the coronal pulp, but most EPTs are still monopolar.[352]

The requirements of an EPT are an adequate stimulus, an appropriate application method, and careful interpretation of results (Fig. 8-3). Tooth isolation during EPT is essential. Drying the enamel, placement of an interproximal plastic strip, and use of a rubber dam can prevent the spread of electrical impulses to adjacent teeth or gingival tissue. Electric current can also be transferred between adjacent teeth through contacting metallic restorations.[64] A conducting medium should also be used to ensure that maximum current passes from the electrode to the tooth surface.[261] A laboratory study[247] concluded that the interface medium made no appreciable difference to either the voltage or the electric current transmitted. However, a more recent study did demonstrate that different media influence the responses gained from electric testing.[262]

FIG. 8-3 Electronic pulp tester. *(Courtesy SybronEndo, Orange, CA.)*

There are several considerations regarding optimal placement of the tester electrode. The response threshold is reached when an adequate number of nerve terminals are activated to attain what is termed a *summation effect*.[281] An area of high neural density should have a relatively fast and strong response and requires the least electric current. Therefore, the most desirable area of assessment in incisor teeth is at the incisal edge.[32] The tester should be applied on the tooth surface adjacent to a pulp horn, the area of highest nerve density within the pulp. This position equates to the incisal third region of anterior teeth and the mid-third region of posterior teeth. The threshold for response may be influenced by the thickness of the enamel and dentin overlying the pulp. Thus, the response threshold for healthy teeth may be lowest in incisors, slightly greater in premolars, and greatest in molar teeth. A recent study has revealed that the optimum site for tester electrode placement on molars is on the tip of the mesiobuccal cusp.[225]

Assessment of Pulp Vascularity

Vitality testing requires the measurement of pulpal blood flow. Several devices are used to evaluate circulatory changes rather than the neural integrity of the pulp, and a number of these have been used experimentally to evaluate pulpal health.

Crown Surface Temperature

An investigator[103] performed extensive research in the field of crown surface temperature. This pulp vitality technique is based on the hypothesis that vital teeth are warmer and will rewarm quicker after cooling than nonvital teeth. His experiments concluded that time/temperature curves comparing the warming of vital versus nonvital teeth were diagnostically informative.

Attempts to use color change of cholesteric liquid crystals as a diagnostic tool to measure crown temperature change[173] have also met with some success. And a more recent study using an infrared thermographic camera showed crown temperature patterns of nonvital teeth to be slower to rewarm than those of vital teeth.[320]

Transmitted Light Photoplethysmography

Transmitted light photoplethysmography (TLP) is a noninvasive technique used to monitor pulpal blood flow and has been successfully applied in animal and human studies. It has been suggested that TLP incurs less signal contamination from the periodontal blood flow than is the case for laser Doppler flowmetry (LDF).[227,268]

Laser Doppler Flowmetry

LDF was developed to assess blood flow in microvasculature systems such as the retina, mesentery, renal cortex, and skin.[171] It has recently been used in intact teeth in animals[137,139] and in man.[253,421] LDF utilizes a light beam (helium neon 632.8 nm) which is scattered by moving red blood cells.[421] Newer machines have varied the wavelength between 600 and 700 nm, depending on the light absorption properties of the tissue tested. This light beam undergoes a frequency shift according to the Doppler principle. The backscattered light is picked up by photodetectors and produces a signal that is proportional to the red cell flux (number of cells × average velocity). This can be used as a measure of pulpal blood flow, expressed as a percentage of full-scale deflection at a given gain. The

technique appears objective, noninvasive, and accurate. A growing number of reports indicate it is a method that can easily be adapted to the testing of a tooth and is promising as a pulp vitality tester. It is especially effective in young traumatized teeth with large pulps that do not respond well to other forms of sensitivity testing.[129,130,253,421]

Several studies have reported successful use of LDF to study human pulpal blood flow. The value of this method has been well documented, but its high cost and difficulty of use in clinical situations have prevented widespread use.

Pulse Oximetry

Pulse oximetry has been used to detect vascular integrity in the tooth.[335] The process measures oxygen saturation in external soft tissue. It has been suggested that it is capable of passing its signal through enamel and dentin. It may also be used on natural tooth structure. The device, as LDF, utilizes a probe that transmits red (640 mm) and infrared light through the tissue (received by a photodetector). Since oxygenated and deoxygenated hemoglobin absorb different amounts of each light, pulsating changes in blood volume cause periodic changes in the amount of light absorbed by the vascular bed before reaching the photodetector. To date, it has not been considered capable of judging pulp vitality in a manner that would allow the proper degree of sensitivity and specificity. It must again be stressed that LDF and pulse oximetry can only be used on natural tooth structure, never on restorations. When used clinically and having a possible response, a rubber dam should isolate the test teeth, and the gingival tissue below the dam should be blocked with an opaque substance (tin foil).

Xenon-133 Radioisotopes

Radioactive materials for measurement of pulpal blood circulation were previously used in the radiolabeled microsphere injection method.[191,192,396] A method utilizing a radiation probe with xenon-133 (^{133}Xe) radioisotope to differentiate between vital and pulpless teeth on the basis of blood supply has been found effective.[396] However, the use of radioactive materials is expensive, restricted on humans, and requires special licensing requirements. To this point, the most promising of these experimental methods are those using the measurement of light passing through or deflected from the blood in the pulp.

Dual Wavelength Spectrophotometry

Oximetry by spectrophotometry uses a dual wavelength light source (760 and 850 nm) to determine the oxygen saturation level of the pulpal blood supply. Preliminary tests on teeth were promising, since the blood oxygenation and volume could be detected.[284] The instrument might be useful not only in determining pulp necrosis but also the inflammatory status of the pulp. It shows promise as a pulp tester because it is noninvasive, objective, small, and portable.

Doppler techniques, pulse oximetry, and photoplethysmography are all used in medicine and in dental research. However, they have been less successfully applied to routine endodontic care, because the circulatory system of the pulp is encased in a rigid structure and therefore is difficult to study without the removal of hard tissue. Consequently, the need for an absolute rigid observation point in the Doppler technique and the interference of extrapulpal circulatory systems in pulse oximetry and photoplethysmography have limited the introduction of these methods to endodontic practice.

Assessment of Cracks and Fractures

Magnification

The introduction of the operative microscope marked outstanding progress in dentistry. Magnification improves the performance of clinical procedures, and the operating microscope has dramatically improved endodontic nonsurgical treatment and periradicular surgery. The use of the operating microscope and microsurgical instrumentation have resulted in greater precision in surgical procedures, less operative trauma, improved healing, better esthetic results, and more predictable treatments. Speed, control, comfort, and adjustment are other distinct advantages.

LOUPES

Magnification loupes attached to eyeglasses are relatively inexpensive, and the learning curve for their use is much shorter than for the microscope. However, there are several shortcomings to loupes compared to the operating microscope. Each loupe has a fixed magnification power (typically less than 4×) that cannot be increased or decreased. Most loupes have no integrated light source, although often they are employed with an accompanying headlamp system. There is no way to digitally document viewed images. The focus is adjusted through the movements of the clinician's head, creating postural positions that may not be ergonomic.

OPERATING MICROSCOPES

All microscope lenses are designed and installed in a telescopic system (Fig. 8-4). This means they are already focused to infinity. They send parallel beams of light to each eye, allowing the viewing of objects three dimensionally with an excellent depth impression.

Some characteristics of microscopes are: (1) wide range of magnification, (2) coaxial illumination that allows light to

FIG. 8-4 Zeiss Operating Microscope. (*Courtesy OperatingMicroscopes.com.*)

enter even the deepest areas of examination, (3) easy photographic and video capture documentation, (4) the capacity to make focus adjustments by moving the microscope or its parts, maintaining an ergonomic work position.

The major advantage of using light and magnification is the increased diagnostic potential. The microscope is an excellent tool for detecting cracks, additional canals, perforations, and the like.[252] It is important to clarify the difference between magnification and differentiation. *Magnification* is defined as viewing an object at a greater size; *differentiation* refers to making an object distinct or specialized. The microscope alone is very useful, but sometimes additional adjuncts must be employed for better differentiation. Methylene blue used in conjunction with magnification can add important information, especially for fracture detection. Additionally, some operating microscopes employ colored light sources which help in the differentiation between bone and root surfaces during apicoectomies.

Periodontal Probing

Periodontal probing is an essential part of the endodontic diagnostic process. The tooth should be evaluated interproximally and at every millimeter on both the buccal and lingual surfaces, with emphasis on the convex part of the root. Each furcation should also be explored with a periodontal or furcation probe. Periodontal probing is especially useful in helping to detect vertical root fractures (VRF). If the probe sinks abruptly into an isolated deep, narrow periodontal defect, the level of suspicion for a VRF increases. This is true especially when there is no evidence of periodontal disease associated with other areas of the tooth or adjacent teeth. If a VRF is suspected but cannot be directly visualized, magnification, illumination, and staining can be very helpful.

Elastic, plastic, periodontal probes (Premier, Plymouth Meeting, PA) (Fig. 8-5) have been advocated for better detection of defects associated with VRFs. A periodontal pocket associated with a VRF—in an otherwise periodontally intact tooth—differs from a common periodontal pocket by having a deep, narrow pocket with a small occlusal entrance. The flexibility of the plastic probes allows them to be introduced into pockets that may not permit the insertion of rigid metal probes (Fig. 8-6).

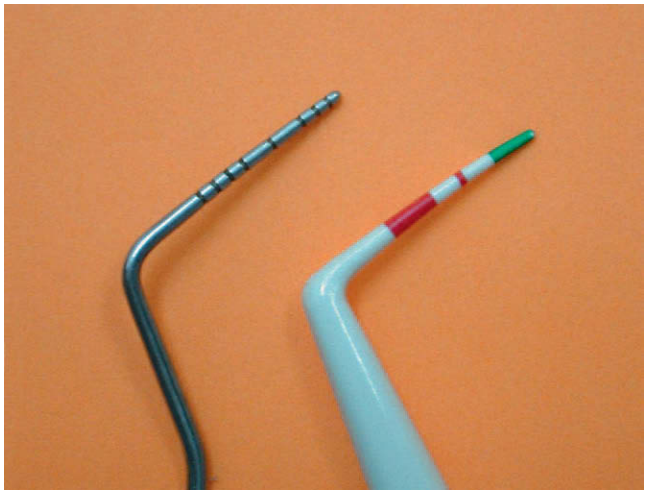

FIG. 8-5 Flexible periodontal probe (Premier, Plymouth Meeting, PA) and a conventional rigid metal probe.

Biting Tests

The Tooth Slooth (SybronEndo) (Fig. 8-7) has proved very useful for the differential diagnosis of various stages of incomplete crown fractures. The design of the device permits a chewing force to be applied selectively to one cusp at a time. When this selective force is applied to a cracked cusp of a vital tooth, the coronal dentin distorts, which is allowed by the crack and results in a painful response. This sensation is not present in other intact cusps of the same tooth. This device can be effective when cotton rolls or wooden sticks are not helpful.

Staining

Dyes can aid greatly in the diagnosis of either caries or fractures. Caries detectors have been used effectively to identify caries not otherwise evident with either visual inspection or traditional hand instruments. Methylene blue dye, India ink or iodine tincture have been very effective dyes used to diagnose the presence of crown or root fractures.[206]

Transillumination

Transillumination is the transmission of light through tissues of the body. A common example is the transmission of light

FIG. 8-6 A Premier periodontal probe in a narrow and deep pocket associated with VRF. Note the blanching that indicates the narrow nature of the pocket.

FIG. 8-7 Tooth Slooth. (*Courtesy Profession Results, Inc., www.toothslooth.com.*)

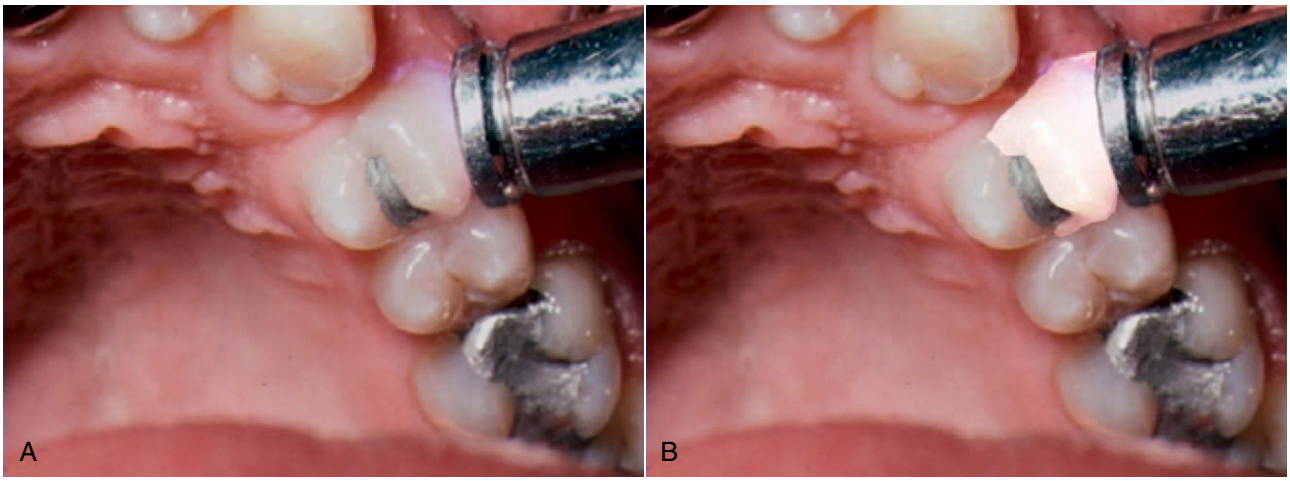

FIG. 8-8 A crack in the crown of a tooth, located by using a transilluminator.

through fingers, producing a red glow due to red blood cells absorbing all other colors of the light. Transillumination is an excellent technique for viewing caries, fractures, narrow root canal orifices, and other clinical entities. It is used by passing an intense light through the side of the tooth and can substantially enhance the clinician's diagnostic and treatment abilities. Healthy tooth structure has an index of light transmission greater than that of caries or calculus. A fracture line or a calcified root canal orifice also have a reduced ability to transmit light. Therefore, if an intense light is applied in direct proximity to a tooth, and other extraneous light is reduced, these clinical entities will appear as distinct dark areas in the otherwise bright structure (Fig. 8-8). The transilluminator tip is placed on either the facial or lingual surface of the tooth or the root, and the area can be viewed from the occlusal surface or the surface opposite the transilluminator. Direct vision or a dental mirror may be used for viewing, depending upon the area under examination. The exact placement of the transilluminator differs for caries, endodontics, fractures, and so forth.

The acceptance of transillumination as a diagnostic technique has been greatly enhanced by the availability of modern devices made expressly for this purpose.[118] These transilluminators use white light–emitting diode (LED) lamps to generate the necessary intense white light. The light is then transmitted to the working area, without heat, using a narrow fiberoptic rod or fiberoptic cables. An important feature is that a fiberoptic rod can be easily removed and autoclaved to avoid cross-contamination between patients. The small size and portability of these new devices enhances the convenient use of transillumination.

Assessment of Images

Radiographs

Radiography is an essential part of endodontic diagnosis. Modern technology is rapidly shifting toward digital filmless imaging and other new image-enhancing techniques (see online Chapter 29). Therefore the clinician must be well versed in this diagnostic field.

The radiographic examination should always be evaluated together with other diagnostic tests and clinical examination. Initial sensitivity tests can suggest which type of radiograph will be most advantageous. If a vital tooth is evaluated, a bitewing radiograph would be advantageous to detect caries or other potential causes of pulpal inflammation. If periapical disease is suspected by the previous tests, a periapical radiograph is indicated. All radiographs should be taken using holders that allow parallelism and standardization. If comparative radiographs will be necessary on a subsequent patient visit, it is useful to fabricate an individual impression material bite-block so that the angulation of follow-up radiographs will be as similar as possible. Extra oral radiographs, like occlusal or PAs, may also be useful in certain cases.

Radiography cannot directly detect pulpal inflammation, but caries or defective restorations seen on the radiograph may suggest pulpal inflammation. Condensing apical periodontitis is a near-pathognomonic sign of longstanding pulpitis. Also, the presence of an apical radiolucency of endodontic origin may be a good indication that necrosis or a necrotic zone is present in the pulp space.

The radiograph is one of the best means at our disposal for determining the existence of a chronic periapical condition. It is characterized by a rather well-defined radiolucent area, or dark shadow, which may or may not be exactly at the apex of the tooth.

Technology has advanced in the area of radiology to include F-speed or Insight conventional film, xeroradiography, digital radiography, subtraction radiography, phosphor images, ultrasound, and recently also cone-beam computed tomography (CBCT). But improvement in our ability to interpret periradicular/periapical pathosis is still debatable with some of these methodologies. Comparing xeroradiography and E-speed conventional film, investigators[22] reported no difference in the detection of periapical bone pathosis.

Another study[399] found that digitally subtracted images were more sensitive for identifying cortical and cancellous bone changes than conventional films. In an in vitro model, other investigators[90] found that subtraction radiography was capable of discriminating between health and disease. Still others[265] found that the progress of chronic apical periodontitis may be followed predictably by their subtraction methodology. Digital subtraction radiography may also be useful in the

evaluation of healing following endodontic therapy.[433] Another investigation[207] concluded that conventional film radiography performed slightly better for the detection of periapical bone lesions than direct digital radiography, and that image processing did not improve the observer performance.

Researchers[296] reported that cortical bone lesions were identified with greater accuracy than trabecular bone lesions, regardless of whether digital radiography or conventional films were used.

Another study[109] demonstrated that there was no significant difference in the accuracy of detecting artificially prepared periapical lesions between Schick CDR and Trophy RVGui DDR systems Their results using digital radiography were in agreement with Seltzer et al's.[341] finding using conventional radiography: artificially produced lesions were not radiographically observed unless the cancellous lesion extended to the junction of the cancellous and cortical bone.

Ultrasound

Coinvestigators[66] have introduced the potential of ultrasound real-time imaging in endodontics and found it able to distinguish between granulomas and cysts. This promising potential awaits further long-term investigations.

Cone-Beam Computed Tomography and Other Scans

CBCT (Fig. 8-9), ultrasound, and other emerging technologies seem to be very promising tools for determining a more accurate diagnosis of periradicular pathoses.[67,153,246,275] The reader is referred to Chapter 29 for further information about CBCT.

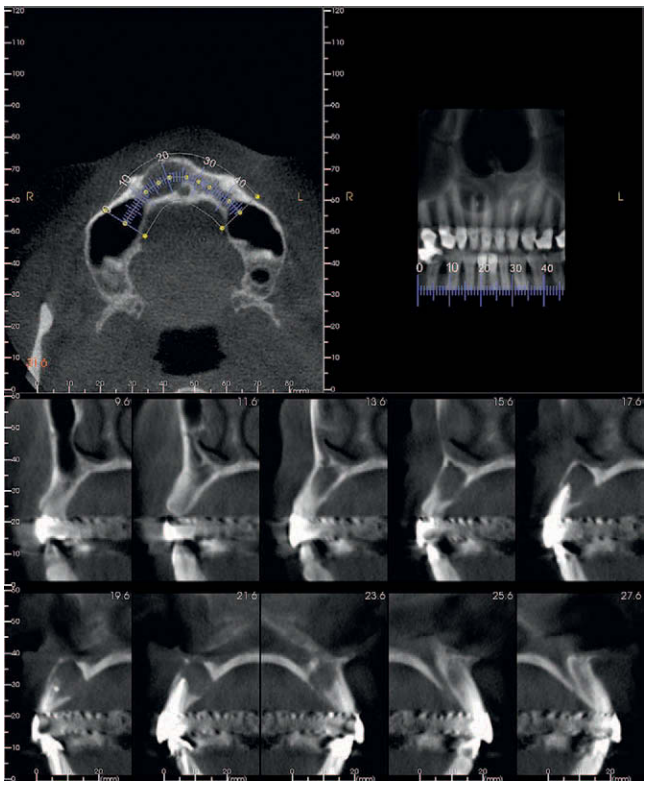

FIG. 8-9 CBCT example: These series of images show an ovoid radiolucent area in the anterior right maxilla. Both teeth 1.1 and 1.2 were endodontically treated; however, given the epicenter of the entity relative to the teeth, the radiolucent area was interpreted to be a keratocystic odontogenic tumor. *(Courtesy Dr. E. Lam.)*

ENDODONTIC INSTRUMENTS

Although most instruments used in general dentistry also can be used for endodontic therapy, some hand instruments are designed specifically for endodontic procedures. In addition, many different types of instruments have been designed for procedures performed inside the pulp space. These include manually operated instruments for root canal preparation, rotary and other engine-driven and energized instruments for root canal preparation, and instruments for root canal obturation.

Standardized specifications have been established to improve instrument quality. For example, the International Standards Organization (ISO) has worked with the Fédération Dentaire Internationale (FDI) through the Technical Committee 106 Joint Working Group (TC-106 JWG-l) to define specifications. These standards are designated with an ISO number. The American Dental Association (ADA) also has been involved in this effort, as has the American National Standards Institute (ANSI); these standards are designated with an ANSI number. However, new instrument designs have resulted in a need for reconsideration of the standards.

Two ISO standards pertain to endodontic instruments. ISO No. 3630-1 deals with K-type files (as does ANSI No. 28), Hedström files (ANSI No. 58), and barbed broaches and rasps (ANSI No. 63). ISO No. 3630-3 deals with condensers, pluggers, and spreaders (ANSI No. 71).

Hand Instruments

Traditional dental hand instruments have been modified for endodontic uses. A typical set of endodontic instruments might include a front-surface mouth mirror, a D-5 explorer, a D-16 endodontic explorer, cotton pliers, a spoon excavator, a series of pluggers, a plastic instrument, a hemostat, a periodontal probe, and a ruler. The endodontic explorer has two straight, very sharp ends that are angled in two different directions from the long axis of the instrument.

The mouth mirror should be a front-surface mirror, especially when magnifying loupes or an operating microscope are used. Several types of endodontic spoons are available. These spoons have a much longer offset from the long axis of the instrument (for better reach inside constricted pulp chambers) than regular dental spoons. The spoons are used to remove carious material and to excise pulp tissue; therefore, they should be kept well sharpened (Fig. 8-10). The cotton pliers should preferably be of the locking type that can securely hold gutta-percha cones when transferred from the dental assistant to the dentist's hand. The periodontal probe should be a flexible one (see Fig. 8-5). The exact type and number of instruments usually depend on the techniques used and clinician's preference.

Microinstruments

With the enhanced use of microscopes in endodontics, especially during apical surgery, many specially designed miniaturized instruments have been introduced. These include miniature mirrors, probes and pluggers (for details see Chapter 21).

Instruments for Cleaning and Shaping the Root Canal Space

The purposes of this section is to provide the principles necessary for the clinician to better understand the ideal design for current and future instruments. Most instructional materials mistakenly attempt to teach step-by-step techniques rather than explain the physics of the instruments. However, an increasing number of new products and their advocates have created confusion in the selection process. For this reason, the clinician must understand the basic mechanical, physical, and scientific principles of instrumentation (Box 8-1).

The two primary goals of root canal instrumentation are (1) to provide a biologic environment (infection control) conducive to healing and (2) to develop a canal shape receptive to obturation. Historically, most instruments used to shape the canal were designed to be used by hand. Recently, rotary instrumentation has gained considerable popularity and may be used in conjunction with hand instruments (Box 8-2). The information in the following sections should facilitate the most efficient use of rotary instruments, minimizing the chance of instrument or procedural mishaps and allowing the clinician to achieve ideal treatment results.

Group I: Manually Operated Instruments

Manually operated instruments are all instruments that are generically called *files*. Defining endodontic instruments by function, files are instruments that enlarge canals with reciprocal insertion and withdrawal motions. Reamers cut and enlarge canals with rotational motions. Before using either instrument, the clinician must make sure the canal is patent.

Files were first mass produced by the Kerr Manufacturing Co. of Romulus, Michigan, in the early 1900s, hence the name K-type file (or K-file) and K-type reamer (K-reamer). K-files and K-reamers originally were manufactured by the same process. Three or four equilateral, flat surfaces were ground at increasing depths on the sides of a piece of wire, producing a tapered pyramidal shape. The wire then was stabilized on one end, and the distal end was rotated to form the spiral instrument (Fig. 8-11). The number of sides and the number of spirals determine whether the instrument is best suited for filing or reaming. Generally, a three-sided configuration with fewer spirals is used for reaming; a three- or four-sided configuration with more spirals is used for filing.

Historically, root canal instruments were manufactured from carbon steel. Subsequently, the use of stainless steel greatly improved the quality of instruments. More recently, the introduction of the nickel-titanium (NiTi) alloy in the manufacture of endodontic instruments has resulted in significant improvements in canal shaping because of its increased flexibility compared to stainless steel (this metal is described later in the chapter).

BOX 8-1

Terminology for the Physical Properties of Instruments

Successful use of an instrument depends on the ways the material, design, and technique relate to the forces exerted on the instrument. The following terms quantify the actions and reactions to these forces.

Stress: The deforming force measured across a given area.

Stress concentration point: An abrupt change in the geometric shape of a file, such as a notch, which results in a higher stress level at that point than along the surface of the file where the shape is more continuous.

Strain: The amount of deformation a file undergoes.

Elastic limit: A set value representing the maximal strain that, when applied to a file, allows the file to return to its original dimensions. After the strain is removed, the residual internal forces return to zero.

Elastic deformation: The reversible deformation that does not exceed the elastic limit.

Shape memory: A condition that exists when the elastic limit is substantially higher than is typical for conventional metals. It allows an instrument to regain its original form after being deformed.

Plastic deformation: Permanent bond displacement, which occurs when the elastic limit is exceeded. The file does not return to its original dimensions after strain is removed.

Plastic limit: The point at which a plastic-deformed file breaks.

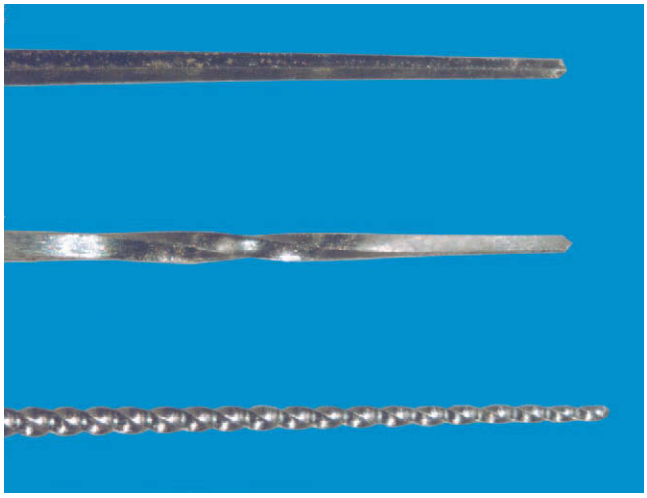

FIG. 8-11 The two ends of a blank, tapered pyramidal wire are stabilized *(top)* and then one end is rotated to create a spiral shape on the file's working surface *(middle)*. Multiple rotations produce the final spiral shape *(bottom)*. *(Courtesy John T. McSpadden, Lookout Mountain, GA.)*

BOX 8-2

Classification of Instruments Used for Cleaning and Shaping the Root Canal Space

Endodontic instruments for root canal preparation can be divided into six groups:

- **Group I:** Manually-operated instruments, such as barbed broaches and K-type and H-type instruments.
- **Group II:** Low-speed instruments with a latch-type attachment. Typical instruments in this group are Gates-Glidden (GG) burs and Peeso reamers. They are typically used in the coronal part of the canal and never used in a canal curvature.
- **Group III:** Engine-driven nickel-titanium rotary instruments. They consist of a rotating blade that can safely be operated in, and adapt itself to, curved root canals. Most engine-driven instruments available today belong to this group.
- **Group IV:** Engine-driven instruments that adapt themselves three-dimensionally to the shape of the root canal. Like other nickel-titanium instruments, they adapt to the shape of the root canal longitudinally but additionally they adapt also to the cross-section of the root canal. There is currently only one instrument in this group: the self-adjusting file (SAF; ReDent-Nova, Raanana, Israel).
- **Group V:** Engine-driven reciprocating instruments.
- **Group VI:** Ultrasonic instruments.

BARBED BROACHES AND RASPS

Dating from the early to mid-19th century, broaches and rasps were the earliest endodontic instruments used to extirpate the pulp and enlarge the canal (Fig. 8-12). Still used today, these instruments are manufactured by hacking a round, tapered wire with a blade to form sharp, projecting barbs that cut or snag tissue. Specifications have been set for both the barbed broach and the rasp (ANSI/ADA standard No. 63, ISO/FDI standard No. 3630/1).

A barbed broach does not cut or machine dentin; this instrument is mostly used to engage and remove soft tissue from the canal. It is also an excellent tool for removing cotton or paper points that have accidentally become lodged in the root canal.

K-TYPE INSTRUMENTS

The K-file and K-reamer are the oldest useful instruments for cutting and machining dentin (Fig. 8-13). They are made from a stainless steel wire that is ground to a tapered square or triangular cross-section and then twisted to create either a file or a reamer. A file has more flutes (see Components of a File) per length unit than a reamer.

K-type instruments are useful for penetrating and enlarging root canals. The instrument works primarily by compression-and-release destruction of the dentin surrounding the canal. Generally, a reaming motion (i.e., constant file rotation) causes less transportation than a filing motion (reciprocating or "watch-winding" file rotation).[406] (*Transportation* is the excessive loss of dentin from the outer wall of a curved canal in the apical segment. This procedural error can lead to perforation of the root canal system or an inability to negotiate the canal space apical to the canal transportation.) A stainless steel K-file can be precurved to a desired form to facilitate insertion and minimize transportation. Permanent deformation occurs when the flutes become wound more tightly or opened more widely (Fig. 8-14). When such deformation occurs, the instrument should no longer be used. Instruments fracture during clockwise motion after plastic deformation.[158,345] This occurs when the instrument becomes bound while the force of rotation continues. Interestingly, although the force required for failure is the same in both directions of rotation,[205,213] failure occurs in the counterclockwise direction at half the number of rotations required for failure in the clockwise direction. Therefore K-type instruments should be operated more carefully when pressure is applied in a counterclockwise direction.

H-TYPE INSTRUMENTS

An H-type instrument has spiral edges arranged to allow cutting only during a pulling stroke (Fig. 8-15). An example is a Hedström file. An H-type instrument is better for cutting than a K-type instrument, because it has a more positive rake angle (see Components of a File) and a blade with a cutting rather than a scraping angle. Bending a Hedström file results in points of greater stress concentration than occurs with K-type instruments. These concentration points can lead to the propagation of cracks and fatigue failure.[158] Clinically, fatigue happens without any external physical signs of stress, such as the flute changes seen in K-type instruments (see Fig. 8-14).

Currently all H-type instruments are ground from a tapered blank. Hedström files are formed by grinding a single continuous flute. Computer-assisted machining technology has allowed the development of H-type instruments with very complex forms. This process, called *multiaxis grinding,* allows adjustment of the rake angle, helix angle, multiple flutes, and tapers. H-files cut the canal wall when pulled or rotated clockwise; the file is relatively ineffective when pushed or rotated counterclockwise. Because the H-file generally has sharper edges than the K-file, it has a tendency to screw into the canal during rotation, particularly if the instrument's blades are nearly parallel. Awareness of screwing-in forces is important for avoiding instrument failure.

INSTRUMENT DESIGN MODIFICATIONS

K-files and H-files can be modified into numerous designs. Often the instruments can be improved for more effective instrumentation by changing the geometric dimensions, using computerized multiaxis grinding machines. For example, changing the cross-sectional geometry of a K-type instrument from square to rhomboid enhances the instrument's flexibility and rake angle. However, the possible geometries can complicate adherence to ISO and ANSI standards.

TIP DESIGN

Studies have shown that tip design can affect file control, efficiency, and outcome in the shaping of root canal systems.[266,267] The tip of the original K-file resembled a pyramid (see Fig. 8-13). Instrument tips have been described as *cutting, noncutting,* and *partially cutting,* although no clear distinction exists among the three types (Fig. 8-16).

The instrument tip has two functions: to guide the file through the canal and to enlarge the canal. A clinician who is unfamiliar with the tip design of a particular instrument is apt

to do either of the following: (1) transport the canal (if the tip is capable of enlarging the canal and remains too long in one position) or (2) encounter excessive torsion and break the file (if a noncutting tip is forced into a canal with a smaller diameter than the tip). Transportation of the original axis of the canal can occur by remaining too long in a curved canal with a tip that has efficient cutting ability.

The angle and radius of its leading edge and the proximity of the flute to its actual tip end determines the cutting ability of a file tip. Cutting ability and file rigidity determine the propensity to transport the canal. The clinician must keep in mind that as long as the file is engaged 360 degrees, canal transportation is unlikely to occur. Only with overuse does the file begin to cut on one side, resulting in transportation. Most instrumentation errors occur when the file tip is loose in the canal, which gives it a propensity to transport the canal.

A good beginner's rule is this: If the canal is smaller than the file, the prudent use of a cutting tip is more efficient. If the canal is larger than the tip, using a less-effective cutting tip can help prevent transportation (see Fig. 8-16). Much has been written about the importance of various sophisticated tip modifications to prevent such ledging, but little scientific evidence exists that any one design is better than another.[190,308,309,316,321]

METAL ALLOYS

The development of nitinol, an equiatomic alloy composed of nickel and titanium,[412] has proved a significant advancement in the manufacture of endodontic instruments. NiTi is called an *exotic metal* because it does not conform to the typical rules of metallurgy. Because it is a superelastic metal, the application of stress does not result in the usual proportional strain seen in other metals such as stainless steel. When stress is initially applied to NiTi, the result is proportional strain, but the strain remains essentially the same as the application of additional stress reaches a specific level, forming what is called a *loading plateau*. Eventually, of course, application of more stress results in more strain, which increases until the file breaks. This unusual property is the result of a molecular crystalline phase transformation. External stresses transform the austenitic crystalline form of NiTi into a martensitic crystalline structure that can accommodate greater stress without increasing the strain. As a result of its unique crystalline structure, a NiTi file has *superelasticity,* or the ability to return to its original shape after being deformed. Simply stated, NiTi alloys currently are the only readily available affordable materials with the flexibility and toughness for routine use as effective rotary endodontic files in curved canals.

Attempts to improve the NiTi alloy continue, and recent reports indicate that new NiTi alloys may be five times more flexible than currently used alloys.[186] Microscopic surface defects are considered a contributing factor for crack propagation and instrument fracture. Therefore, attempts to improve surface characteristics by electropolishing, surface coatings, and surface implantation have been used for this purpose.[216,310]

Group II: Low-Speed Rotary Instruments

Many types of rotary instruments are used during endodontic procedures. In addition to regular burs adapted for endodontics, various types of root canal reamers are used to shape the canal space, to place or remove root canal filling materials, or to prepare a post space.

FIG. 8-17 Gates-Glidden (GG) burs made of stainless steel. *(From Johnson WT:* Color atlas of endodontics, *St Louis, 2002, Saunders.)*

BURS

In addition to conventional burs, burs with extended shanks for low-speed contra-angle handpieces are useful for providing good visibility during deep preparation of the pulp chamber. This is particularly important when using an operating microscope when performing such procedures after access to the pulp chamber has been achieved. Straight-line access to the initial point of curvature traditionally has been accomplished using rotary instruments such as Gates-Glidden burs and Peeso instruments. These reamers are available in a 32-mm length and a 28-mm length for posterior teeth (Figs. 8-17, 8-18). Use of these instruments should be limited to the straight portion of the canal preparation. The risk of perforation with these instruments becomes a real possibility with attempts to instrument beyond the point of curvature or if the instruments are used to cut laterally. The risk of lateral cutting resulting in perforation is lower with Gates-Glidden burs than with the other instruments mentioned. This risk is especially pronounced on the furcation sides of mesial roots of molars. Gates-Glidden instruments are also available in nickel-titanium. The Peeso reamer is used mostly for post space preparation (Fig. 8-19).

Group III: Rotary Instruments for Canal Preparation

COMPONENTS OF A FILE

To make the best use of files, the clinician should be familiar with the parts of each file and understand how variations in design affect instrumentation (Fig. 8-20). The *taper* usually is expressed as the amount the file diameter increases each millimeter along its working surface from the tip toward the file handle. For example, a size #25 file with a #.02 taper would have a 0.27 mm diameter 1 mm from the tip, a 0.29 mm diameter 2 mm from the tip, and a 0.31 mm diameter 3 mm from the tip. Some manufacturers express the taper in terms of percentage (e.g., a #.02 taper is a 2% taper). Historically, as an

ISO standard, a file was fluted and tapered at 2% for 16 mm, but now files incorporate a wide variation of lengths and tapers of working surfaces. The ability to determine cross-sectional diameter at a given point on a file can help the clinician determine the file size in the point of curvature and the relative stress being placed on the instrument.

The *flute* of the file is the groove in the working surface used to collect soft tissue and dentin chips removed from the wall of the canal. The effectiveness of the flute depends on its depth, width, configuration, and surface finish. The surface with the greatest diameter that follows the groove (where the flute and land intersect) as it rotates forms the *leading (cutting) edge,* or the *blade* of the file. The cutting edge forms and deflects chips from the wall of the canal and severs or snags soft tissue. Its effectiveness depends on its angle of incidence and sharpness. If a surface projects axially from the central axis as far as the cutting edge between flutes, this surface is called the *land* (or sometimes the *marginal width*) (Figs. 8-21 and 8-22). The land touches the canal walls at the periphery of the file and reduces the tendency of the file to screw into the canal, reduces transportation of the canal, reduces the propagation of microcracks on its circumference, supports the cutting edge, and limits the depth of cut. Its position relative to the opposing cutting edge and its width determine its effectiveness. To reduce frictional resistance, some of the surface area of the land that rotates against the canal wall may be reduced to form the *relief* (Fig. 8-23). The angle the cutting edge forms with the long axis of the file, called the *helix angle,* augers debris collected in the flute from the canal. This angle is important for determining which file technique to use (see Fig. 8-23; Fig. 8-24).

If a file is sectioned perpendicular to its long axis, the *rake angle* is the angle formed by the leading edge and the radius of the file. If the angle formed by the leading edge and the surface to be cut (its tangent) is obtuse, the rake angle is said to be *positive* or *cutting*. If the angle formed by the leading edge and the surface to be cut is acute, the rake angle is said to be *negative* or *scraping* (Fig. 8-25). However, the rake angle may not be the same as the *cutting angle*. The cutting angle, or the *effective rake angle,* is a better indication of a file's cutting ability and is determined by measuring the angle formed by the cutting (leading) edge and the radius when the file is sectioned perpendicular to the cutting edge. If the flutes of the file are symmetric, the rake angle and the cutting angle are essentially the same.

The *pitch* of the file is the distance between a point on the leading edge and the corresponding point on the adjacent leading edge, or it may be the distance between corresponding

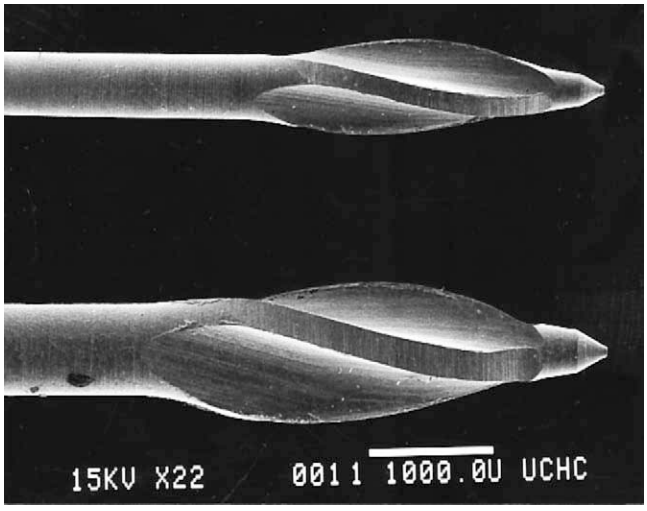

FIG. 8-18 Working part of a Gates-Glidden bur made of stainless steel. Note the rounded safety tip and the lack of sharp cutting edges. The instrument has a marginal land for centering the drill in the canal and to allow safer machining of the canal walls.

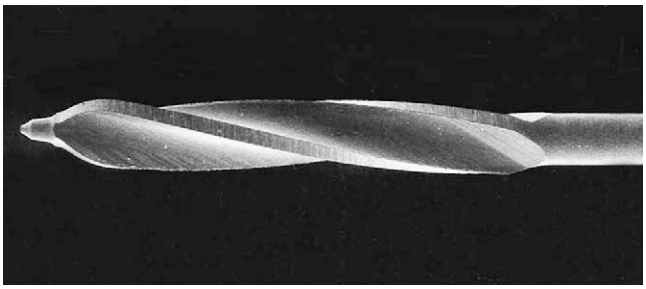

FIG. 8-19 Peeso Reamer (Union Broach, York, PA). Note the safety tip and marginal lands on the machining surfaces.

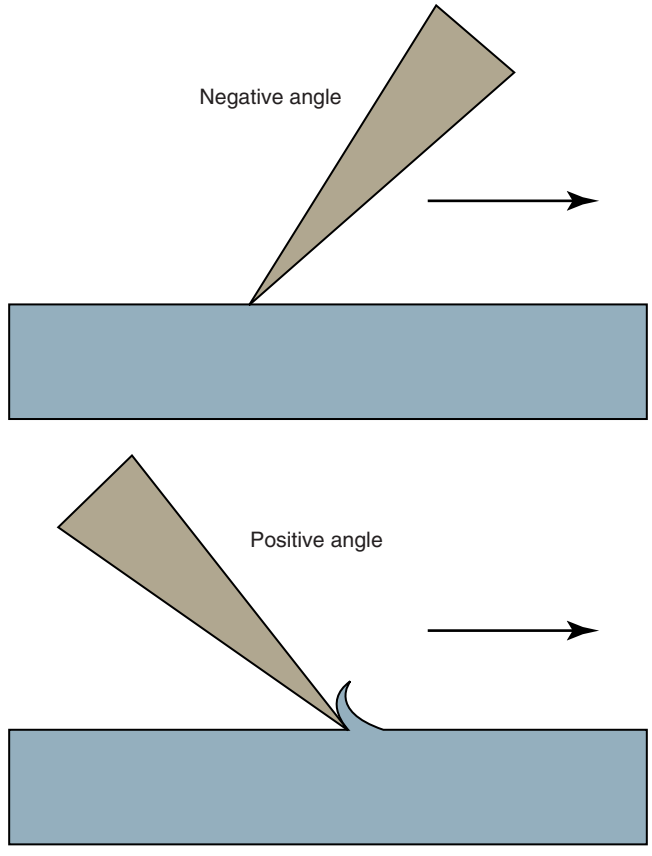

FIG. 8-25 Positive and negative rack angles. Negative angle results in scraping action; positive angle results in cutting action.

points within which the pattern is not repeated. The smaller the pitch or the shorter the distance between corresponding points, the more spirals the file has and the greater the helix angle. Most files have a variable pitch, one that changes along the working surface. Because the diameter increases from the file tip toward the handle, the flute becomes proportionately deeper, resulting in a *core taper* that is different from the *external taper*.

The cutting angles, helix angles, and external and core tapers may vary along the working surface of the file, and the

FIG. 8-26 Torque- and speed-controlled electric micromotor and handpiece (X-Smart Endodontic Motor). *(All rights owned by and used with permission from DENTSPLY International, Inc.)*

ratios of these quantities can vary between instruments of the same series. A change in any of these features can influence the file's effectiveness or its propensity for breakage as it progresses into the canal space; this can explain why some files act uncharacteristically compared with other files in the same series. In one study, investigators using electric and air-driven handpieces with rotary NiTi instruments found no significant difference in file distortion or breakage between the two handpieces at 150 revolutions per minute (rpm).[40] Other researchers have shown that the ability to select precise rpm[71] and torque[122] settings affects the efficiency and durability of instruments (Fig. 8-26). Determining and maintaining a file's proper rotational speed is more difficult with an air handpiece than with an electric handpiece. For this reason, the clinician would be wise to use an electric handpiece when instrumenting with rotary files. The popularity of electric handpieces among clinicians appears to support the conclusion that regardless of the design used for rotary NiTi instruments, an electric handpiece—rather than an air-driven handpiece—should be used because it allows precise speed and torque control (see Fig. 8-26).

INSTRUMENT DESIGNS

Design changes are made in endodontic instruments to help prevent procedural errors, increase efficiency, and improve the quality of canal shaping. Examples of instruments commonly used today are the ProFile and ProFile GT, the ProTaper, the Lightspeed LSX, the Quantec, the Twisted File (TF),[123,212] the RaCe, the EndoSequence, and the EZ-Fill SafeSider. For more information about these instruments and others, see Chapter 9. In many patients, the apical canal is larger than the largest file used at working length, so many design changes have been directed toward enabling the clinician to increase the size of the largest file used at working length. The following design components can be used to prevent excess stress on instruments.

1. The difference between the file's minimum and maximum diameters can be reduced so that the torque required for rotating the larger diameter does not exceed the plastic limit of the smaller diameter.
2. The space between the tip and the maximum diameter can be reduced so that the required torque does not exceed the ultimate strength of any part of the file.
3. A zero taper or nearly parallel and fluted working portion of the file can be provided for curved canals so that the apical portion of the canal can be enlarged without undue file stress and compression of debris.
4. The continuity of the blade engagement can be interrupted.
5. The number of flute spirals can be eliminated or reduced to the smallest number necessary to prevent excessive torque, which results from the accumulation of debris.
6. A means can be provided to complete the file function before the flutes fill with debris.
7. Any land width can be minimized to reduce abrasion on the canal surface.
8. The file can be given an asymmetric cross-section to help maintain the central axis of the canal.
9. The number of flutes with similar helix angles can be reduced. When helix angles are dissimilar, screwing-in forces are reduced; when flutes have no helix angles, screwing-in forces are eliminated.
10. Positive cutting angles can be incorporated to enhance the efficiency of canal enlargement.
11. Blades can be made appendages or projections from the file shaft rather than ground into the shaft.
12. Channels can be cut along the long axis of the file to facilitate its removal if it breaks.

Group IV: Engine-Driven Three-Dimensionally Adjusting Files

SELF-ADJUSTING FILE

The self-adjusting file (SAF; ReDent-Nova, Raanana, Israel) represents a new approach in file design and mode of operation.[260] The file is a hollow device, designed as a cylinder of thin-walled, delicate NiTi lattice with a lightly abrasive surface (Figs. 8-27 and 8-28). An initial glidepath is established with a #20 K-file to allow the insertion of the SAF file. The file is proposed to be compressed from its 1.5 mm diameter into dimensions equivalent to those of a #25 K-file (Fig. 8-29). It is operated with a modified KaVo handpiece (GENTLEpower 20LP with a 3LDSY head, KaVo Dental GmbH, Biberach/Riss, Germany) that generates in-and-out vibrations with 5000 vibrations per minute and 0.4 mm amplitude (Fig. 8-30). The overall concept is that the compressed file will adapts itself to the root canal walls, applying a uniform cutting action (see Fig. 8-28) gradually removing a uniform dentin layer from the canal walls.

As noted, the file is hollow, which allows for continuous irrigation through the file while operated in the root canal. The irrigant is delivered through a free-rotating hub to which a silicone tube is attached (see Fig. 8-30). Either a special irrigation unit (Fig. 8-31) (VATEA, ReDent-Nova, Raanana, Israel) or any appropriate dispenser-type unit may be used to deliver a constant flow of irrigant at 5 ml/min. This maintains a continuous flow of fresh, fully active irrigant that carries with its outflow tissue debris and the dentin powder generated by the file.[256]

One file is used throughout the procedure. It is initially compressed into the root canal (see Fig. 8-29) and gradually enlarges while cleaning and shaping the canal. The unique feature of this file is that it adapts to the shape of the canal not

FIG. 8-27 The SAF instrument. The instrument is made as a hollow, thin NiTi lattice cylinder that is compressed when inserted into the root canal and adapts to the canal's cross-section. It is attached to a vibrating handpiece. Continuous irrigation is applied through a special hub on the side of its shank. *(Courtesy ReDent-Nova, Raanana, Israel.)*

FIG. 8-30 The VATEA continuous irrigation unit used with the SAF instrument. The unit has two containers and provides a continuous flow (low pressure, 5 ml/min) of either irrigant (i.e., sodium hypochlorite and EDTA) through double silicon tubes that are connected to the hubs on the front of the device. It is controlled by finger-operated switches located on the handpiece. *(Courtesy ReDent-Nova, Raanana, Israel.)*

only longitudinally, as every NiTi file does, but also to the cross-section of the canal. Consequently, the basic shape of the root canal is preserved: a root canal with a round cross-section is enlarged to one with a similar but larger cross-section, whereas a flat root canal will be enlarged to a flat root canal of bigger dimensions (see Fig. 8-31). This unique feature of the SAF file makes it different from any other currently available file system.

Because it has no rigid metal core, the file is also extremely adaptable longitudinally. The inherent tendency to straighten curved root canals and transport their apical part to the outer side of the curvature, which is typical of most other file systems, is greatly avoided. The absence of a metal core also makes the SAF extremely resistant to fracture. File separation—a major problem with other NiTi files—has not been reported to occur, and mechanical failure (a rare occurrence if it happens) is

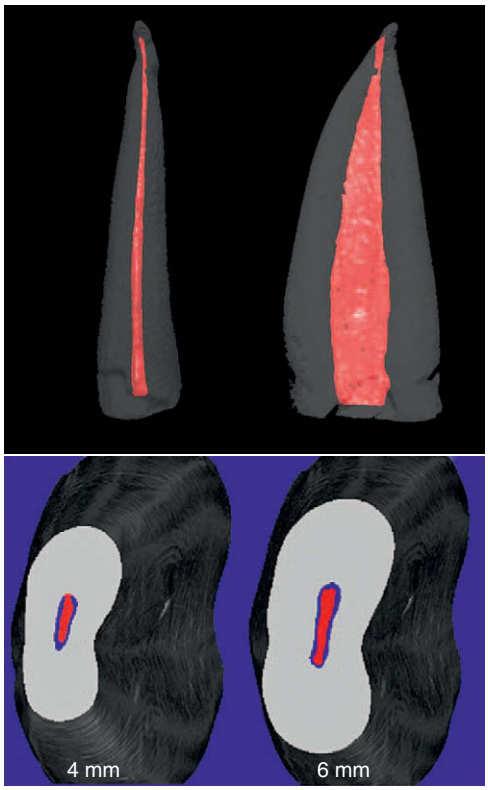

FIG. 8-31 A micro–computed tomography (microCT) analysis of the operation of the SAF instrument in a flat canal with extremely oval cross-section. *Upper:* Buccolingual and mesiodistal views of the root canal reconstructed from microCT. *Lower:* Cross-sections at 4 and 6 mm from the apex. *Red:* before, *blue:* after treatment. *(Courtesy ReDent-Nova, Raanana, Israel.)*

limited to local tears in the delicate NiTi lattice.[260] It is clear that this interesting conceptual device will be subjected to extensive independent study over the next few years.

Group V: Engine-Driven Reciprocating Instruments

ENDO-EZE RECIPROCATING FILES

The Giromatic handpiece, a rotary instrument in use since 1969, delivers 3000 quarter-turn reciprocating movements per minute. Rasps and barbed broaches are most often used in Giromatic handpieces, but K-type and H-type instruments also can be used. The Endo-Eze file system (Ultradent, South Jordan, UT) is a recently introduced addition for Giromatic handpieces. The set has four instruments that are designed to clean the middle third of the canal. The sizes and tapers are 0.10 #0.025 taper, 0.13 #0.35 taper, 0.13 #0.45 taper and 0.13 #0.06 taper. The use of stainless steel hand instruments is suggested for the apical third of the canal.

Group VI: Sonic and Ultrasonic Instruments

A radically different way of instrumenting root canals was introduced when clinicians became able to activate files by electromagnetic ultrasonic energy. Piezoelectric ultrasonic units are also available for this purpose (Fig. 8-32). These units activate an oscillating sinusoidal wave in the file with a frequency of about 30 kHz.

Two types of units, ultrasonic and sonic, are primarily available. Ultrasonic devices, which operate at 25 to 30 kHz, include the magnetostrictive Cavi-Endo (DENTSPLY Caulk, Milford, DE), the piezoelectric ENAC (Osada, Tokyo) (Fig. 8-33), the EMS Piezon Master 400 (Electro Medical Systems [EMS] Vallée de Joux, Switzerland), and the P5 Neutron (see Fig. 8-32) (Satelec, Merignac Cedex, France). Sonic devices, which operate at 2 to 3 kHz, include the Sonic Air MM 1500 (Micro Mega, Prodonta, Geneva, Switzerland), the Megasonic 1400 (Megasonic Corp, House Springs, MO), and the Endostar (Syntex Dental Products, Valley Forge, PA). Ultrasonic devices use regular types of instruments (e.g., K-files), whereas sonic devices use special instruments known as Rispi-Sonic, Shaper-Sonic, Trio-Sonic, or Heli-Sonic files.

Although similar in function, piezoelectric units have some advantages over the magnetostrictive systems. For example, piezoelectric devices generate little heat, so no cooling is needed for the electric handpiece. The magnetostrictive system generates considerable heat, and a special cooling system is needed in addition to the irrigation system for the root canal. The piezoelectric transducer transfers more energy to the file

than does the magnetostrictive system, making it more powerful. Working with no water cooling becomes essential when using an operating microscope, because the water spray may obstruct visualization.

The file in an ultrasonic device vibrates in a sinus wave–like fashion. A standing wave has areas with maximal displacement (i.e., antinodes) and areas with no displacement (i.e., nodes). The tip of the instrument exhibits an antinode. If powered too high, especially with no contact with the canal wall, the instrument may break because of the intense vibration. Therefore files must be used only for a short time, must remain passive within the canal, and the power must be controlled carefully. The frequency of breakage in files used for longer than 10 minutes may be as high as 10%, and the breakage normally occurs at the nodes of vibrations.[5]

Ultrasonic devices have proved very efficient for irrigating root canal systems. During free ultrasonic vibration in a fluid, two significant physical effects are observed: cavitation and acoustic streaming. During oscillation in a fluid, a positive pressure is followed by a negative pressure. If the file's tensile strength is exceeded during this oscillation of pressure gradients, a cavity is formed in the fluid in the negative phase. During the next positive-pressure phase, the cavity implodes with great force; this is *cavitation*. Under normal clinical conditions, the power of dental ultrasonic units is too low to create significant cavitation effects on the dentin walls. *Acoustic streaming* creates small, intense, circular fluid movement (i.e., eddy flow) around the instruments. The eddying occurs closer to the tip than in the coronal end of the file, with an apically directed flow at the tip. Acoustic streaming increases the cleaning effect of the irrigant in the pulp space through hydrodynamic shear stress. The increased amplitude that occurs with the smaller file sizes enhances the acoustic streaming.[6] This has proved valuable in the cleaning of root canals because conventional irrigation solutions do not penetrate small spaces well.

Acoustic streaming has little direct antimicrobial effect. Both cavitation and acoustic streaming are dependent on the free vibration of the file. The limits of the space in a root canal significantly inhibit the practical utility of ultrasonic devices for root canal cleaning. Depending on size and power, the file tip may have amplitudes that require a canal size of at least a #30 file through a #40 file for free oscillation. Any contact with the root canal walls dampens oscillation. As the contact with the canal wall increases, the oscillation is dampened and becomes too weak to maintain acoustic streaming. Using a small file size with minimal contact to the root canal wall provides optimal cleaning conditions.[7]

Ultrasonic devices have proved disappointing as instruments for improving the removal of dentin from the root canal walls. They do improve the ability to clean the pulp space (Fig. 8-34) and difficult-to-débride areas through acoustic streaming.[12,68,402,403] However, it is unclear whether this can be achieved during regular preparation when the file is actively dampened and little acoustic streaming takes place. Cleaning is further enhanced by the excellent irrigation systems some of the devices provide. Application of a freely oscillating file with sodium hypochlorite (NaOCl) irrigation for several minutes to aid pulp space disinfection is believed to be useful after complete biomechanical instrumentation of the pulp space.[361]

FIG. 8-34 Start-X ultrasonic tip #2; designed for working on the pulp chamber floor and walls when looking for 2MB canals. Note the surface texture of the instrument that allows long-lasting active surface. *(All rights owned by and used with permission from DENTSPLY International, Inc.)*

Sonic devices are more useful for true hard-tissue removal during root canal preparation. Because the files operate like a conventional handpiece, the file vibrations are less likely to be dampened by contact with the root canal walls. Therefore the special files used in these systems are true bulk dentin removers. New tip designs for piezoelectric ultrasonic units have also been found extremely effective in dentin removal in the pulp chamber and orifice of the canals (see Fig. 8-34).

National and International Standards for Instruments

As a result of concerns that arose nearly 45 years ago, efforts were made to standardize endodontic files and root filling materials. As mentioned previously, this resulted in an international standard for endodontic files, known in the United States as *ANSI standard No. 58* for Hedström files and *ANSI standard No. 28* for K-files (Table 8-1). The standards have several similarities, but some important differences exist. Fig. 8-35 shows the measurements dictated by the standards. The size designation is derived from the projected diameter at the tip of the instrument. This is an imaginary measurement and is not reflected in the real size of the working part of the instrument. The taper of the instruments is designed to be a 0.02 taper, namely a diameter-increase by .02 mm for each mm of length, starting at the tip. The working diameter is the product of the taper and the length of the tip. Three standard lengths are available at 21 mm, 25 mm, and 31 mm. The working part of the instrument must be at least 16 mm. As stated previously, tapers other than .02 and working parts of instruments less than 16 mm are now available and outside the standard.

This system of numbering files with at least 15 different sizes replaced the old, somewhat imperfect system that numbered the sizes from #1 through #6. Although the new standard

TABLE 8-1

Dimensions of Standardized K-File, H-File, and Gutta-Percha Cones (ANSI No. 28, 58, and 78*)

Size	D_0	D_{16}	Color
006	*0.06*	*0.38*	*No color assigned*
008	*0.08*	*0.40*	*No color assigned*
010	0.10	0.42	Purple
015	0.15	0.47	White
020	0.20	0.52	Yellow
025	0.25	0.57	Red
030	0.30	0.62	Blue
035	0.35	0.67	Green
040	0.40	0.72	Black
045	0.45	0.77	White
050	0.50	0.82	Yellow
055	0.55	0.87	Red
060	0.60	0.92	Blue
070	0.70	1.02	Green
080	0.80	1.12	Black
090	0.90	1.22	White
100	1.00	1.32	Yellow
110	1.10	1.42	Red
120	1.20	1.52	Blue
130	1.30	1.62	Green
140	1.40	1.72	Black

*Sizes in italics are for files that are commercially available but not covered by American National Standards Institute (ANSI) regulation No. 28 or No. 58. Colors are not required for instrument handles or gutta-percha cones, but the size must be printed on the handle. Tolerances are ± 0.02 ≥30 mm ± 2 mm.

includes many sizes, astute clinicians may include fewer instrument sizes for their special work habits.

In recent years, suggestions to change the numbering system for files with different sizes have been implemented by several manufacturers. One system has introduced "half" sizes in the range of #15 through #60, resulting in instruments in sizes #15, #17.5, #20, #22.5, and so on. Considering the fact that most manufacturers already are unable to size their instruments within the accepted range, the introduction of half sizes seems unnecessary. However, if standards are strictly adhered to, the use of half sizes seems more reasonable for instrument systems such as the LightSpeed, in which the strength of the instrument is such that full-size increments may generate stresses beyond the tolerance of the instrument. The standards are overdue for reevaluation in light of recent technologic changes.

Effectiveness and Wear of Instruments

Although the advertising literature is rich in claims of superiority of various file designs, few of these claims can be verified by well-designed studies in the peer-reviewed endodontic literature. No standards exist for either the cutting or machining effectiveness of endodontic files, nor have clear requirements been established for resistance to wear.

In any study of the effectiveness of an instrument, two factors must be investigated: (1) effectiveness in cutting or breaking loose dentin and (2) effectiveness in machining dentin. These two parameters are radically different. Methods exist for measuring machining, but currently no good method is available for measuring cutting. Some studies have attempted to evaluate cutting, but the methodologies have involved the use of a drilling motion with K-type instruments and at a speed higher than that used for clinical procedures.

Some studies of machining have evaluated the effectiveness of an instrument when used with a linear movement. These studies showed that instruments can differ significantly, not

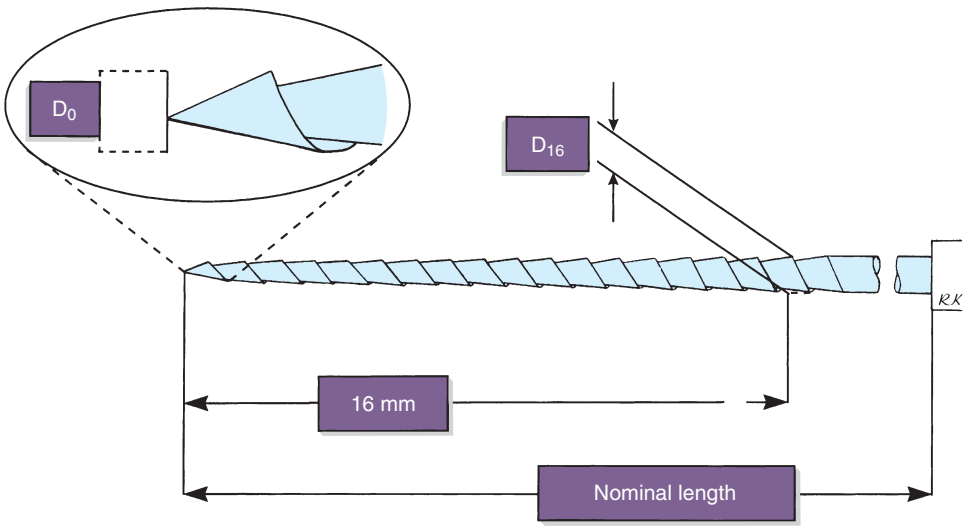

FIG. 8-35 Measuring points for American National Standards Institute (ANSI) and American Dental Association (ADA) regulations #28 and #58, which cover K-type and H-type instruments. The measuring point for the diameter of the instrument (size) is imaginary (D_0) and projects the taper of the instrument at the tip. Therefore an instrument with a short tip is more true to its size than an instrument with a long tip. D_{16} represents the diameter at the end of the working part, which must be at least 16 mm long.

only when comparing brands and types but also within one brand and type. For K-files, effectiveness varies 2 to 12 times between files of the same brand. The variation for Hedström files is greater, ranging from 2.5 to more than 50 times.[379] The greater variation among Hedström files is easy to understand because the H-file is the result of more individual grinding during manufacture than the conventional K-file, which is difficult to alter much during the manufacturing process. For example, during the grinding of a Hedström file, the rake angle can be modified to neutral or even slightly positive; this is impossible to achieve with a K-file. The Hedström file, therefore, is approximately 10 times more effective at removing dentin than the K-file.

In the machining process, the rake edge shaves off dentin that accumulates in the grooves between the rake edges. The deeper and larger this space, the longer the stroke can be before the instrument is riding on its own debris, making it ineffective. These design variations and the rake angle of the edges determine the effectiveness of a Hedström file. Of the hybrid files, the K-Flex (SybronEndo, Orange, CA) file, which is a modified K-file, shows variables similar to those of K-files. The Flex-R file (SybronEndo), which is a ground instrument, more closely resembles the H-files in its variation in effectiveness. It also is much more effective at substrate removal than the K-files but cannot measure up to the H-files' ability to machine.

Modern endodontic stainless steel instruments are fabricated from excellent metal alloys and have considerable resistance to fracture. The clinician who practices careful application of force and a strict program of discarding instruments after use should have few instrument fractures. Stainless steel files are so inexpensive that adequate cleaning and sterilization for reuse of files in sizes up to #60 may not be cost effective. If this is the case, files in the range up to #60 may be considered disposable instruments.

Devices for Periapical Débridement Through a Root Canal Access

The Apexum device (Apexum, Or-Yehuda, Israel) is currently the single representative of this group[258,259] (Fig. 8-36). It represents a totally different concept than that applied by most root canal cleaning and shaping systems. The goals of most current concepts are to maintain the original apical constriction by all means and to avoid any substantial overinstrumentation past the apical foramen. The Apexum concept requires widening the apical foramen to create an opening 330 µm in diameter by passing a #30 file 1 mm beyond the apex. This may represent some enlargement of the apical foramen in certain cases, but in other cases, the natural apical foramen diameter may be larger than this.[43] Further instrumentation with larger instruments (#40 or #45) to a length 1 mm short of the apical foramen are then used to recreate an artificial apical stop and constriction.

Two miniature devices are then used to débride the periapical tissues through the root canal access. The first is the Coarse Apexum Ablator, which is made from a prebent memory-shape NiTi wire encased in a NiTi tube that serves as its sheath (see Fig. 8-36). The instrument, still encased in its sheath, is inserted to the artificial apical stop. Then the inner wire is gently pushed through the apical foramen and into the periapical lesion.

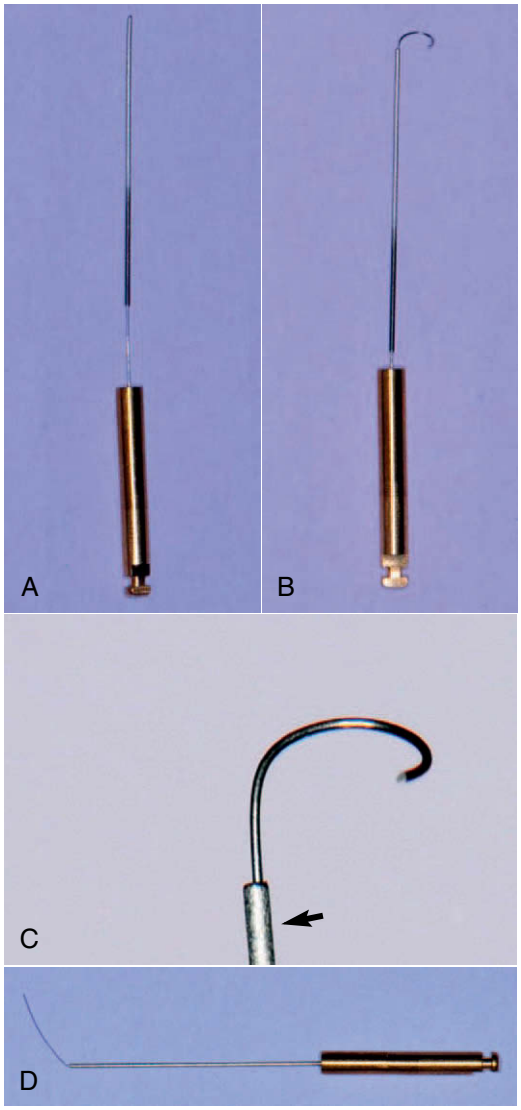

FIG. 8-36 Apexum device. **A,** The Coarse Apexum Ablator in its NiTi sheath (*arrow in C*). **B-C,** The active part was extruded and regained its preformed shape that allows it to rotate in the periapical lesion (250 rpm, 30 sec), mincing the soft tissue without engaging the walls of the bony crypt. **D,** The Fine Apexum Ablator, inserted into the lesion after the Coarse Apexum Ablator is removed; rotates at 7000 rpm for 30 seconds, turning the minced tissue into a thin suspension that can be washed out.[258,259] *(Courtesy Apexum, Or-Yehuda, Israel.)*

While in the periapical area, it regains its prebent shape (Figs. 8-37 and 8-38). It is then attached to a low-speed handpiece and rotated at 250 rpm for 30 seconds, thus coarsely mincing the periapical tissues. The first instrument is then removed, and the second instrument, the Fine Apexum Ablator, is inserted, passed through the apical foramen, and rotated at 7000 rpm for 30 seconds, turning the tissue into a thin suspension. The resulting suspension is then washed out coronally through the canal space using sterile saline solution delivered into the periapical area using a syringe and a thin, 30-gauge blunt needle.

The method is used as a supplementary treatment for enhancement the healing kinetics of periapical lesions for

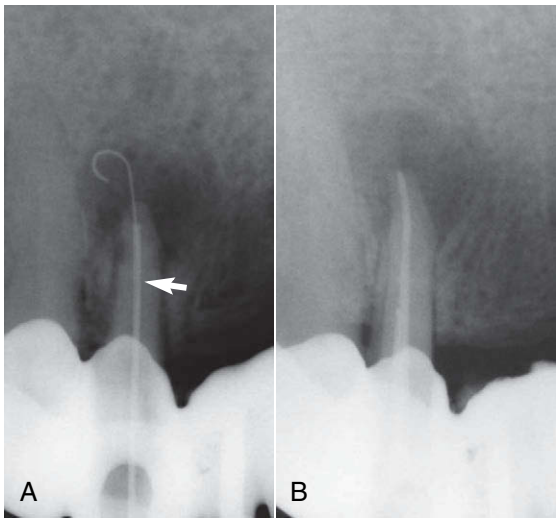

FIG. 8-37 Apexum in clinical use. **A,** The Coarse Apexum Ablator in a periapical lesion of an upper single rooted tooth. FIG. 8-39 Periapical healing after the Apexum procedure. **A,** Immediate postoperative radiograph. Note the periapical lesion. **B,** Three-month follow up. **C,** Six-month follow-up.[258] *(Courtesy Apexum, Or-Yehuda, Israel.)*

promoting faster healing (Fig. 8-39).[258,259] The Apexum procedure is applied only after completion of cleaning, shaping, and disinfection of the root canal and before root canal obturation. This interesting device will clearly be subjected to additional research over the next few years.

Devices for Measuring Root Canal Length

Radiographs, tactile sensation, the presence of bleeding on paper points, and knowledge of root morphology have been used to determine the length of root canal systems. Sunada[381]

developed the original electronic apex locator when he suggested that the apical foramen could be localized using a direct electric current. Currently the electronic apex locator is considered an accurate tool for determining working length.[114,115] One study reported that the use of electronic apex locators in a dental student clinic resulted in a higher quality of obturation length control and an overall reduction in the number of radiographs taken.[115] However, these devices must not be considered flawless, because several variables are known to affect their accuracy. For example, immature roots can present problems.[180] Once the roots mature (i.e., formed a narrow apical foramen) and the instruments are able to contact the canal walls, the electronic apex locator's accuracy greatly improves. Some investigators have found no statistical difference between roots with vital and necrotic tissue.[135,250] Because apical root resorption is prevalent in necrotic cases with long-standing apical lesions, these researchers also concluded that apical resorption does not have a significant effect on the accuracy of electronic apex locators.

Recently some clinicians have advocated the use of the electronically determined working length in lieu of working length estimations using the placement of a file in the canal and a radiograph. However, combined use of both of these techniques has been shown to result in greater accuracy.[95] Furthermore, radiographs may also add essential anatomic information that may be missed if electronic apex locators are used exclusively.

The first two generations of electronic apex locators were sensitive to the contents of the canal and irrigants used during treatment. The development of an algorithm called the *ratio measurement method* distinguished the third generation of apex locators.[197] To arrive at this method, the impedance of the canal was measured with two current sources of different frequencies, and a quotient was determined using the electrical potentials proportional to each impedance.[197] This study found that electrolytes did not have a significant effect on the accuracy of the unit. Some third-generation apex locators are the Endex Plus, or Apit, (Osada, Los Angeles, CA),[141] the Root ZX (Fig. 8-40) (J. Morita, Kyoto, Japan),[114,211] and the Neosono Ultima EZ (Satelec, Mount Laurel, NJ). The Endex Plus device uses 1 and 5 kHz and provides apex location based on subtraction. The Root ZX emits currents at frequencies of 8 and 0.4 kHz and provides apex location based on the resulting quotient.

A fourth-generation apex locator was introduced with the Elements Diagnostic Unit (see Fig. 8-44), the Apex Locator (SybronEndo), and the Bingo 1020/Ray-X4 (Forum Engineering Technologies, Rishon Lezion, Israel). The Bingo uses only one of its two frequencies at a time (8 Hz or 400 Hz). According to the manufacturer, the Elements unit (which operates at frequencies of 0.5 and 4 kHz) compares the resistance and capacitance information to a database to determine the distance between the file and the apex. When the file tip reaches the area of the apical foramen, the apex locator emits a signal.

Recently, miniaturized electronic apex locators were introduced by SybronEndo (Fig. 8-41) and MedicNRG, Kibutz Afikim, Israel (the Apex NRG[277,278]) (Fig. 8-42).

An apex locator typically has four parts: (1) the lip clip, (2) the file clip, (3) the instrument itself, and (4) a cord connecting the other three parts. A display indicates the advancement of the file toward the apex (see Fig. 8-40).

FIG. 8-40 Root ZX apex locator with lip clip and file holder. *(Courtesy J. Morita USA, Irvine, CA.)*

FIG. 8-41 SybronEndo mini apex locator. *(Courtesy SybronEndo, Orange, CA.)*

These electrical instruments are generally safe, but manufacturers' instructions state that they should not be used on patients with pacemakers without consulting the patient's cardiologist.[30,113] When connected directly to cardiac pacemakers in vitro, four of five electronic apex locators did not interfere with the function of the pacemaker.[126]

Instruments for Root Canal Obturation

After the root canal has been properly cleaned and enlarged, the space is obturated with a manufactured material. A number of obturation methods are practiced, but lateral and vertical compactions are the two most common. Many specialized

FIG. 8-42 NRG miniature electronic apex locator. *(Courtesy Medic-NRG, Kibutz Afikim, Israel.)*

*The cones are pointed. The diameters 3 mm (D_3) and 16 mm (D_{16}) from the tip are prescribed. Tolerance is ± 0.05 mm, and length is ≥30 mm ± 2 mm. *XF*, Extra-fine; *FF*, fine-fine; *MF*, medium-fine; *FM*, fine-medium; *M*, medium; *ML*, medium-large; *L*, large; *XL*, extra-large.

instruments are available for every type of method. Spreaders and pluggers are the significant instruments for obturation. The spreader is a tapered, pointed instrument intended to displace gutta-percha laterally for insertion of additional accessory gutta-percha cones. The plugger is similar but has a blunt end. In smaller sizes, the spreader and plugger are often used interchangeably. These instruments are available with handles or as finger-held instruments. The instruments with handles are potentially dangerous because the tips of the working ends are offset from the long axes of the handles. This results in strong lateral wedging forces on the working ends if the instruments are not operated carefully. The risk of vertical damage to the root is greatly reduced with finger spreaders and pluggers. Each clinician must choose the appropriate spreader and plugger according to personal working preferences. Standardized instruments are available with the same taper as the files (e.g., #.02). Considering the greater taper of standardized accessory gutta-percha cones (Table 8-2), nonstandardized spreaders with a larger taper sometimes may be used to better accommodate the gutta-percha.

When using spreaders and accessory gutta-percha cones, the accessory cone selected must reach the depth of the penetration of the spreader. To accomplish that, the accessory cone must be *thinner* and/or with a *smaller taper* than the spreader used. If accessory cones which do not reach that depth are used, the procedure will result in voids at the apical end of each spreader penetration, leading the operator to an illusion that the root canal is properly obturated.

In recent years, spreaders and pluggers have become available in nickel-titanium. NiTi spreaders have been shown to reach deeper into canals than the stainless steel type when #.02 tapered gutta-percha is used in canals with a curvature of more than 20 degrees. When #.04 taper gutta-percha was used, the NiTi spreaders were more effective regardless of the degree of curvature.[424]

Heat carriers are used for vertical-compaction obturation techniques. Traditionally, heat carriers are handled similarly to pluggers. They are used to transfer heat to the gutta-percha in the root canal, allowing apical and lateral displacement of the gutta-percha. Electrical heat carriers are more common today, either as independent units such as Touch 'n Heat and System B (SybronEndo, Orange, CA) (Fig. 8-43), or incorporated into multifunctional systems such as Elements (Fig. 8-44) (SybronEndo). Recently, battery-charged, handheld heat carriers were introduced, such as the vibrating heat carrier DownPack[67] (Hu-Friedy, Chicago, IL) (Fig. 8-45) or HotTip (Fig. 8-46) (Discus Dental, Culver City, CA). These devices can be heated to controlled levels with a self-contained cordless unit.

FIG. 8-45 DownPack: hand-held heating and vibrating unit for warm gutta-percha compaction. *(Courtesy Hu-Friedy, Chicago, IL.)*

A Lentulo spiral may be used for placement of the sealer, cement, and calcium hydroxide ($Ca[OH]_2$) dressings. The Lentulo spiral is a safe instrument if used correctly but if used carelessly, it may engage the wall of the root canal and break. It must be operated clockwise in the handpiece, inserted not rotating to working length, then retracted 1 to 2 mm to make

FIG. 8-46 "HotTip": hand-held heating unit for warm gutta-percha compaction. *(Courtesy Discus Dental LLC; Culver City, CA.)*

sure it is free to rotate without engaging the canal walls. It should be started and rotated at a slow speed while being gradually withdrawn from the root canal. This instrument effectively drives the paste into the root canal. However, for optimal effect, the spiral must be as large as possible so that the paste is forced forward as the material is squeezed between the canal walls and the spiral. Endodontic files, paper points, and syringes also are commonly used to apply sealer in the root canal system, but they are all less effective than a Lentulo spiral if filling a root canal entirely with sealer is desired.

Devices for Removing Root Canal Obstructions

There are many devices available for removing natural and manufactured obstructions from within the canal. Please see Chapter 25 for details on these devices.

MATERIALS FOR DISINFECTING THE PULP SPACE

Chemomechanical Preparation

To increase the efficacy of mechanical preparation and bacteria removal, instrumentation must be supplemented with active irrigating solutions. *Irrigation* is defined as washing out a body cavity or wound with water or a medicated fluid. *Aspiration* is defined as the process of removing fluids or gases from the body with a suction device.

The objectives of irrigation are both mechanical and biologic. The mechanical objective involves flushing out debris, lubricating the canal, and dissolving organic and inorganic tissue. The biologic function of the irrigants is related to their antimicrobial effect.

Irrigation Hydrodynamics

The effectiveness of root canal irrigation in terms of debris removal and eradication of bacteria depends on several factors: penetration depth of the needle, diameter of the root canal, inner and outer diameter of the needle, irrigation pressure, viscosity of the irrigant, velocity of the irrigant at the needle tip, and type and orientation of the needle bevel (Box 8-3).[181]

The size and length of the irrigation needle relative to the canal space dimension is of utmost importance for the effectiveness of proper irrigation. If the external diameter of the needle is too large or rigid, it may inhibit introduction of the irrigant into the more apical extent of the root canal or into areas of curved canals. The internal diameter of the needle correlates to the necessary pressure for moving the syringe plunger and the velocity at which the irrigant is expressed. Narrow needles require more pressure of the plunger and will extrude the irrigant with higher velocity than large needle diameters. Although a needle with a larger internal diameter

BOX 8-3

Ideal Characteristics of an Endodontic Irrigant[58,149,390]

The ideal irrigant should:

1. Be an effective germicide and fungicide.
2. Be nonirritating to the periapical tissues.
3. Remain stable in solution.
4. Have a prolonged antimicrobial effect.
5. Be active in the presence of blood, serum, and protein derivates of tissue.
6. Have low surface tension.
7. Not interfere with repair of periapical tissues.
8. Not stain tooth structure.
9. Be capable of inactivation in a culture medium.
10. Not induce a cell-mediated immune response.
11. Be able to completely remove the smear layer, and be able to disinfect the underlying dentin and its tubules.
12. Be nonantigenic, nontoxic, and noncarcinogenic to tissue cells surrounding the tooth.
13. Have no adverse effects on the physical properties of exposed dentin.
14. Have no adverse effects on the sealing ability of filling materials.
15. Have convenient application.
16. Be relatively inexpensive.

will extrude the irrigant with a larger volume over time, the irrigant cannot be introduced as deeply. Moser and Heuer[276] measured the pressure necessary for activation of the plunger in different sizes and types of irrigation needles. They determined lower pressure was necessary for irrigation with larger needle diameter sizes (23 to 24 gauge) compared with smaller diameter sizes (24 to 30 gauge). However, larger needles placed at a greater distance from the apex were less efficient during irrigation than smaller diameter needles placed closer to the apex.[174] Common injection needles have an external diameter of 0.40 mm (27 gauge), but special irrigation tips with external diameters of 0.30 mm (30 gauge) are available as well (Table 8-3). To improve safety of irrigation and prevent apical extrusion of the irrigant, some of these needles release the solution through lateral openings and have a closed, safe-ended tip (Fig. 8-47). The Stropko Flexi-Tip (30 gauge) needle is fabricated out of NiTi to improve its flexibility and penetration into curved canals.

Sodium Hypochlorite

NaOCl is the most commonly used irrigating solution. It is an excellent antibacterial agent, capable of dissolving necrotic tissue, vital pulp tissue, and the organic components of dentin and biofilms.[343]

NaOCl solution, commonly known as *bleach,* is frequently used as a disinfectant or a bleaching agent. It is the irrigant of choice in endodontics, owing to its efficacy against pathogenic organisms and pulp digestion, and satisfies most of the preferred characteristics stated earlier.

History

Hypochlorite was first produced in 1789 in Javelle, France, by passing chlorine gas through a solution of sodium carbonate. The resulting liquid, known as "Eau de Javelle" or "Javelle water" was a weak solution of NaOCl. However, this process was not very efficient, and alternate production methods were sought. One such method involved the extraction of chlorinated lime (known as *bleaching powder*) with sodium carbonate to yield low levels of available chlorine. This method was

commonly used to produce hypochlorite solutions for use as a hospital antiseptic that was sold under the trade names "Eusol" and "Dakin's solution." NaOCl as a buffered 0.5% solution was recommended for the irrigation of wounds during World War I by Dakin.[74] Coolidge[69] later introduced NaOCl to endodontics.

Mode of Action

Please see Chapter 9 for further information on this subject.

Allergic Reactions to Sodium Hypochlorite

Although few reports have been published[101,156] on allergic-like reactions to NaOCl, real allergies to NaOCl are unlikely to occur, since both sodium and chlorine are essential elements in the physiology of the human body. Nevertheless, hypersensitivity and contact dermatitis may occur in rare cases. In cases of hypersensitivity to NaOCl, chlorhexidine should not be used either (because of its chlorine content). Use of an alternative irrigant with high antimicrobial efficacy, such as iodine potassium iodide, should be considered, assuming there is no known allergy to the irrigant. Irrigants such as alcohol or tap water are less effective against microorganisms and do not dissolve vital or necrotic tissue. $Ca(OH)_2$ could be used as a temporary medicament because it dissolves both vital and necrotic tissue.[10,161]

Increasing the Efficacy of Hypochlorite Preparations

One alternative approach to improving the effectiveness of hypochlorite irrigants in the root canal system[439] could be to increase the temperature of low-concentration NaOCl solutions, which improves their immediate tissue-dissolution capacity. Furthermore, heated hypochlorite solutions remove organic debris from dentin shavings more efficiently. The antimicrobial properties of heated NaOCl solutions have also been evaluated. The bactericidal rates for NaOCl solutions are more than doubled for each 5° C rise in temperature in the range of 5° C to 60° C. This was corroborated in a recent study[359] using steady-state planktonic *Enterococcus faecalis* cells. A temperature rise of 25° C increased NaOCl efficacy by a factor of 100. The capacity to dissolve human dental pulp using 1% NaOCl at 45° C was found to be equal to that of a 5.25% solution at 20° C. Additionally, the systemic toxicity of preheated low concentrations of NaOCl irrigants should be less than that of a more concentrated unheated solution. However, there are no clinical studies available at this point to support the use of heated NaOCl.

In this context, it should also be noted that time is a factor that has gained little attention in endodontic studies. Even fast-acting biocides such as NaOCl require an adequate working time to reach their potential. Chlorine, which is responsible for the dissolving and antibacterial capacity of NaOCl, is unstable and consumed rapidly during the first phase of tissue dissolution, probably within 2 minutes.[268] Continuous replenishment of the irrigant is essential, especially since rotary root canal preparation techniques have expedited the shaping process. The optimal time a hypochlorite irrigant needs to remain in the canal system is an issue yet to be resolved.

Chlorhexidine

History

Chlorhexidine (CHX) was developed more than 50 years ago at Imperial Chemical Industries in England and first marketed in the United Kingdom in 1953 as an antiseptic cream.[104] Since 1957 it has been used for general disinfection purposes and the treatment of skin, eye, and throat infections in both humans and animals.[104,231]

Molecular Structure

CHX belongs to the polybiguanide antibacterial family, consisting of two symmetric four-chlorophenyl rings and two bisguanide groups connected by a central hexamethylene chain. CHX is a strongly basic molecule and is stable as a salt. CHX digluconate salt is easily soluble in water.[147]

Mode of Action

CHX is a wide-spectrum antimicrobial agent, active against gram-positive and gram-negative bacteria as well as yeasts.[81] Owing to its cationic nature, CHX is capable of electrostatically binding to the negatively charged surfaces of bacteria,[72] damaging the outer layers of the cell wall and rendering it permeable.[165,178,179]

Depending on its concentration, CHX can have both bacteriostatic and bactericidal effects. At high concentrations CHX acts as a detergent; by damaging the cell membrane, it causes precipitation of the cytoplasm and thereby exerts a bactericidal effect. At low sublethal concentrations, CHX is bacteriostatic, causing low molecular-weight substances (i.e., potassium and phosphorous) to leak out without the cell being irreversibly damaged. It also can affect bacterial metabolism in several other ways, such as abolishing sugar phosphotransferase system (PTS) transport activity and inhibiting acid production in some bacteria.[25]

Substantivity

Due to the cationic nature of the CHX molecule, it can be absorbed by anionic substrates such as the oral mucosa.[237,240] CHX has the ability to bind to proteins such as albumin, present in serum or saliva, pellicle found on the tooth surface, salivary glycoproteins, and mucous membranes.[317,398] This reaction is reversible.[169] CHX can also be adsorbed onto hydroxyapatite and teeth. Studies have shown that the uptake of CHX onto teeth is also reversible. This reversible reaction of uptake and release of CHX leads to substantive antimicrobial activity and is referred to as *substantivity*. This effect depends on the concentration of CHX. At low concentrations of 0.005% to 0.01%, a stable monolayer of CHX is adsorbed and formed on the tooth surface, which might change the physical and chemical properties of the surface and may prevent or reduce bacterial colonization. At higher concentrations (>0.02%), a multilayer of CHX is formed on the surface, providing a reservoir of CHX which can rapidly release the excess into the environment as the concentration of CHX in the surrounding environment decreases.[97]

The antibacterial substantivity of three concentrations of CHX solution (4%, 2%, and 0.2%) after 5 minutes of application has shown a direct relationship between the concentration of CHX and its substantivity.[271] On the contrary, Lin et al.[226] attributed the substantivity of CHX to its ability to adsorb onto

the dentin during the first hour. They stated that it is only after the saturation point is reached after the first hour that the antimicrobial capability of CHX increases with time. Furthermore, Komorowski et al.[199] revealed that a 5-minute application of CHX did not induce substantivity, so dentin should be treated with CHX for 7 days. Taken together, it seems that residual antimicrobial activity of CHX in the root canal system remains for up to 12 weeks.

Cytotoxicity

In the medical field, CHX is normally used at concentrations between 0.12% and 2.0%. According to Löe,[231] at these concentrations, CHX has a low level of tissue toxicity, both locally and systemically. In another report, when 2% CHX was used as a subgingival irrigant, no apparent toxicity was noted on gingival tissues.[232,369] Moreover, CHX rinses have been reported to promote the healing of periodontal wounds.[14] Based on these reports, Jeansonne et al.[184] assumed that the periapical tissues would be as tolerant to CHX as gingival tissues. In two studies when CHX and NaOCl were injected into subcutaneous tissues of guinea pigs and rats, an inflammatory reaction developed; however, the toxic reaction from CHX was less than that of NaOCl.[289,432] Furthermore, when CHX was applied as a rinse in the extraction sites of the third molars on the day of surgery and several days after, it was reported to reduce the incidence of alveolar osteitis.[56] There are only a few reports in the literature of allergic and anaphylactic reactions to CHX.[127,286]

Conversely, some studies have reported unfavorable effects of CHX on the tissues. Hidalgo and Dominguez[168] demonstrated that CHX is cytotoxic to some lines of cultured human skin fibroblasts. Recently the behavior of osteoblastic human alveolar bone cells in the presence of CHX and povidone iodine (PI) has been investigated. It has been reported that CHX has a higher cytotoxicity profile than povidone iodine.[49] Faria et al.[105] also demonstrated that CHX injected in the hind paw of mice could induce severe toxic reactions. They reported that CHX induced apoptosis at lower concentrations and necrosis at higher concentrations when added to cultured L929 fibroblast cells.

Another interesting observation has recently been reported whereby the byproduct of combining CHX with NaOCl is the formation of toxic breakdown products such as parachloroaniline (PCA) that may have a negative impact on tissues.[26] The toxicity level of CHX on periapical tissues when applied in the root canals, especially with other irrigants, merits further investigation.

Chlorhexidine Application in Endodontics

CHX has been extensively studied as an endodontic irrigant and intracanal medication, both in vivo[20,228,239,293] and in vitro.* In vitro, CHX has at least as good or even better antimicrobial efficacy than $Ca(OH)_2$.[354] Notably, 2% CHX was very effective in eliminating a biofilm of *E. faecalis*.[223] In vivo, it inhibits experimentally induced inflammatory external root resorption when applied for 4 weeks.[228] In infected root canals, it reduces bacteria as effectively as $Ca(OH)_2$ when applied for 1 week.[20] Unlike $Ca(OH)_2$, CHX has substantive antimicrobial activity that, if imparted onto the root dentin, has the potential to prevent bacterial colonization of root canal walls for prolonged periods of time.[184,199] This effect depends on the concentration of CHX, but not on its mode of application, which may be as a liquid, gel, or controlled-release device.[27]

*References 24, 27, 28, 184, 199, and 217.

Chlorhexidine as an Endodontic Irrigant

CHX in liquid and gel form has been recommended as an irrigant solution, and its different properties have been tested in several studies, both in vitro[137] and in vivo.* Many investigations have conducted studies on the antibacterial effectiveness of CHX in different concentrations. It has been demonstrated that 2% CHX as an irrigant has a better antibacterial efficacy than 0.12% CHX in vitro, so the antibacterial efficacy of CHX evidently depends on its concentration level.[28] Since NaOCl is still the most commonly used irrigant, the antibacterial efficacy of CHX has been compared to that of NaOCl. The results from these studies are inconclusive, but in general, no significant difference between the two solutions has been reported. Unlike NaOCl, CHX lacks a tissue-dissolving property. Therefore, NaOCl is still considered the primary irrigating solution in endodontics.

The cleanliness of root canals by CHX in gel and liquid forms was evaluated using scanning electron microscopy in two separate experiments. In an in vitro study, the canals treated with 2% CHX gel were cleaner than those treated with 2% CHX liquid or 5.25% NaOCl, and it was suggested that the mechanical action of the gel might have facilitated the cleansing of the canals. Another in vitro study showed that the 2% CHX liquid was inferior to 2.5% NaOCl in cleaning the canals.[431]

The antibacterial effectiveness of CHX in infected root canals has been investigated in several studies. Investigators[315] reported that 2.5% NaOCl was significantly more effective than 0.2% CHX when the infected root canals were irrigated for 30 minutes with either of the solutions.

In a controlled and randomized clinical trial, the efficacy of 2% CHX liquid was tested against saline using culture technique. All the teeth were initially instrumented and irrigated using 1% NaOCl. Then either 2% CHX liquid or saline was applied as a final rinse. The authors reported a further reduction in the proportion of positive cultures in the CHX group. Their results showed a better disinfection of the root canals using CHX compared to saline as a final rinse.[437]

In a recent study, the antibacterial efficacy of 2% CHX gel was tested against 2.5% NaOCl in teeth with apical periodontitis, with the bacterial load assessed using real-time quantitative polymerase chain reaction (RTQ-PCR) and colony forming units (CFU). The bacterial reduction in the NaOCl group was significantly greater than the CHX group when measured by RTQ-PCR. Based on culture technique, bacterial growth was detected in 50% of the CHX-group cases compared to 25% in the NaOCl group.[405] On the other hand, another study based on this culture technique revealed no significant difference between the antibacterial efficacy of 2.5% NaOCl and 0.12% CHX liquid when used as irrigants during the treatment of infected canals.[356,357]

Chlorhexidine as an Intracanal Medication

CHX in liquid, gel, or in a controlled-release device has been suggested as an alternative intracanal medication to replace $Ca(OH)_2$. This has been the focus of many in vitro[78,199,217,354]

*References 99, 208, 220, 356, 357, 386, 405, and 437.

and in vivo studies.* The results of in vitro experiments were mostly in favor of CHX regardless of its mode of application. The results have also demonstrated the potential antibacterial substantivity of CHX in the root canals.

Researchers[155] developed an experimental model using dentin powder particles to investigate the possible inactivation of some antibacterial medicaments when they come in contact with dentin. The medicaments tested were $Ca(OH)_2$, 1% NaOCl, 0.5% and 0.05% CHX acetate, and different concentrations of iodine potassium iodide (IKI). They showed that dentin powder had inhibitory effects on all medicaments tested. The effect was dependent on the concentration of the medicament and the duration of contact. The effect of $Ca(OH)_2$ was totally abolished by the presence of dentin powder. The effect of 0.05% CHX and 1% NaOCl was reduced but not totally eliminated by the presence of dentin. No inhibition could be measured when full-strength solutions of CHX and IKI were used.

Contradicting results have been reported when evaluating the effect of different intracanal medications on sealing of the root canals. In an in vitro study using extracted human teeth, all root canals, after 10 days of intracanal medication, were obturated and then tested for microbial leakage. The root canals medicated with CHX gel demonstrated less resistance against bacterial leakage compared to the root canals medicated with $Ca(OH)_2$.[23] In contrast, Wuerch et al.[430] found no significant difference in leakage between the canals medicated with CHX and $Ca(OH)_2$ and reported that 2% CHX gel and $Ca(OH)_2$ paste did not adversely affect the apical seal of the root canal system.

In a human ex vivo model, the antibacterial efficacy of 0.2% CHX liquid applied for 24 hours was tested against a saline solution. After extraction, the infected teeth were endodontically treated using CHX or saline for irrigation and then further medicated with either of the solutions. Samples were obtained and evaluated using culture technique at each treatment step. In both groups, the numbers of bacteria were decreased after instrumentation and irrigation of the canals. However, after 24 hours of medication, it was reported that the numbers of bacteria were further decreased in the CHX group, in contrast to the saline group, where an increase was noted.[78] CHX may also have an effect on reduction of inflammatory external root resorption caused by infection. Lindskog et al.[228] assessed the therapeutic effect of a 4-week intracanal application of CHX gel on inflammatory root resorption in replanted infected teeth of monkeys. They reported that the extent of inflammatory resorption was significantly reduced compared to nonmedicated teeth, suggesting that CHX may be a useful adjunct in the management of inflammatory root resorption.

These in vitro and animal studies suggest that CHX has the potential to replace $Ca(OH)_2$ as an intracanal medicament, but the limitations of the in vitro experiments make the conclusions obtained difficult to extrapolate to actual clinical situations. In vivo human experiments are therefore required to test the efficacy of CHX as an intracanal medication.

Compared to the number of in vitro studies, very few in vivo studies have been conducted to assess the effectiveness of CHX as an intracanal medication. An in vivo investigation[20] assessed the antibacterial efficacy of three different intracanal medications: camphorated paramonochlorophenol, $Ca(OH)_2$, and 0.12% CHX liquid by applying them for 1 week in single-rooted teeth of patients. Using a culture method, it was reported that the proportions of positive cultures were not significantly different among the tested medications, but they were slightly lower in teeth medicated with CHX (0.12%) liquid than those medicated with camphorated paramonochlorophenol or $Ca(OH)_2$.[20]

Another in vivo study evaluated the antibacterial effectiveness of 2% CHX liquid as an intracanal medication in teeth with apical periodontitis.[293] The results showed a moderate increase in bacterial counts during a medication period of 7 to 14 days that was similar to outcomes seen and reported for $Ca(OH)_2$ by Peters et al.[301] It was speculated that the CHX liquid may have partially escaped from the apical foramen, and that the higher-viscosity gel form might have been better suited as an intracanal medication.[293]

However, a different study[239] demonstrated that intracanal medication with $Ca(OH)_2$, 2% CHX gel, or a mixture of $Ca(OH)_2$/CHX applied for 7 days did not reduce the bacterial concentration beyond what was achieved after chemomechanical preparation using 1% NaOCl. The results were not significantly different among the medication groups. Similar results were found by other investigators,[238] where after a randomized controlled trial of 30 patients, they concluded that a final rinse with MTAD (*m*ixture of *t*etracycline, *a*cid, and *d*etergent) and intracanal application of 2% CHX gel did not reduce bacterial counts beyond levels achieved by chemomechanical preparation using NaOCl.

Chlorhexidine and Calcium Hydroxide

During the last few years, researchers have studied the combination of $Ca(OH)_2$ and CHX, with the concept that their antimicrobial properties interact in a synergistic fashion that enhances their efficacy. The high pH of $Ca(OH)_2$ was unaffected when combined with CHX.[26] However, the results have not been conclusive. Some in vitro studies have reported an improved antibacterial action when both agents were combined,[28,102,438] while other studies reported conflicting results.[157]

Recent animal studies have evaluated the tissue reactions to the mix of $Ca(OH)_2$/CHX, showing that the combination exerts good antimicrobial properties[364] and improves healing of the periapical tissues. In vivo studies have shown that the mix is at least as good as both agents applied separately in necrotic teeth with apical periodontitis,[239] as well as in previously treated cases with persistent apical periodontitis. A more recent study utilizing a CHX-based protocol of 0.12% CHX as an irrigant followed by a 7-day intracanal medication of $Ca(OH)_2$/0.12% CHX has shown promising results. The authors concluded that chemomechanical canal shaping using 0.12% CHX solution as an irrigant significantly reduced the number of intracanal bacteria, but it failed to render the canals bacteria free. Further intracanal medication with a $Ca(OH)_2$/CHX paste significantly improved the results by reducing the number of bacteria.[353] Taken together, it seems that the usefulness of mixing $Ca(OH)_2$ with CHX remains unclear and controversial.

Chlorhexidine and Coronal Penetration of Bacteria

Because of its antimicrobial substantivity, it seems that CHX preparations delay entry of bacteria through the coronal

*References 20, 70, 83, 98, 228, 239, 293, and 441.

portion of the tooth into the root canal system. A laboratory study[138] investigated the time required for recontamination of the root canal system of teeth with coronal restorations medicated with $Ca(OH)_2$, 2% CHX gel, or a combination of both. The canals without a coronal restoration but medicated with CHX showed recontamination after an average time of 3.7 days, the group with $Ca(OH)_2$ after 1.8 days, and the group with CHX + $Ca(OH)_2$ after 2.6 days. The canals medicated with CHX and restored with intermediate restorative material (IRM) showed recontamination within 13.5 days, the group with $Ca(OH)_2$ + IRM after 17.2 days, and the group with CHX + $Ca(OH)_2$ + IRM after 11.9 days. The group with no medication but restored with IRM showed recontamination after an average time of 8.7 days. There were statistically significant differences between the groups ($P < 0.05$). All groups without a coronal restoration were recontaminated significantly more quickly than those restored with IRM, except those teeth that had a restoration but no medicament. The groups with intracanal medication and a coronal restoration were not significantly different from each other.

An ex vivo study[408] assessed coronal dye penetration of extracted human teeth after root canal treatment using 1% NaOCl, 1% NaOCl + 17% ethylenediamine tetra-acetic acid (EDTA), 2% CHX gel, 2% CHX gel + 1% NaOCl and distilled water. Results revealed that the least dye penetration occurred with 1% NaOCl + 17% EDTA and 2% CHX gel. NaOCl, distilled water, and 2% CHX gel + 1% NaOCl had more dye penetration with a significant difference compared with NaOCl + 17% EDTA and 2% CHX gel and compared with one another.

Lambrianidis and colleagues[210] have shown that viscous irrigants, including those containing CHX gluconate, were less soluble substances that can leave residue on root canal surfaces and potentially affect root canal obturation. The efficiency of removing $Ca(OH)_2$/CHX gel, $Ca(OH)_2$/CHX solution and $Ca(OH)_2$/saline pastes with the use of instrumentation and irrigation with NaOCl and EDTA solutions has been assessed. None of the techniques used in this study removed the interappointment root canal medicaments effectively. Overall, $Ca(OH)_2$/CHX (gel) paste was associated with significantly larger amount of residue, whereas the $Ca(OH)_2$/CHX mixture was associated with less residue than the other two medicaments. Overall, because of its substantivity, CHX as an intracanal medicament/irrigant may delay the coronal recontamination of the root canal system.

Interaction Between CHX, NaOCl, and EDTA

A suggested clinical protocol[439] for treating dentin prior to root canal obturation consists of irrigation with NaOCl to dissolve the organic components, irrigation with EDTA to eliminate the smear layer, and irrigation with CHX to increase the antimicrobial spectrum of activity and impart substantivity. Although such a combination of irrigants may enhance the overall antimicrobial effectiveness,[208] possible chemical interactions between the irrigants must be considered. Some studies have reported the occurrence of color change and precipitation when NaOCl and CHX are combined[26,439] (Fig. 8-48). Furthermore, concerns have been raised that the color change may have some clinical relevance because of staining, and the resulting precipitate might interfere with the seal of the root obturation. The formation of a precipitate could be explained by the acid-base reaction that occurs when NaOCl and CHX

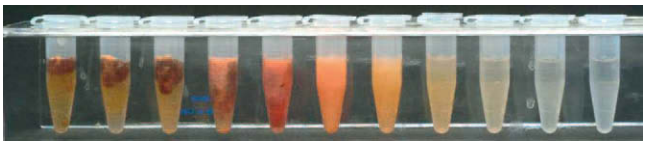

FIG. 8-48 Color change and precipitation occur when NaOCl and CHX are combined.

are mixed together. CHX, a dicationic acid, has the ability to donate protons. NaOCl is alkaline and can accept protons from the dicationic acid. This proton exchange results in the formation of a neutral and insoluble substance referred to as the *precipitate*.[26] Basrani et al.[26] evaluated the chemical nature of this precipitate and reported that there was an immediate reaction when 2% CHX was combined with NaOCl, even at the low concentration (0.023%). They found that the amount of PCA directly increased with the increasing concentration of NaOCl. PCA has been shown to be toxic in humans with short-term exposure, resulting in cyanosis, which is a manifestation of methemoglobin formation. In another study, the effect on root dentin and dentinal tubules was evaluated subsequent to irrigating root canals with a combination of NaOCl and CHX. They concluded that the NaOCl/CHX precipitate tends to occlude the dentinal tubules and suggested that until this precipitate is studied further, caution should be exercised when irrigating with both NaOCl and CHX. In summary, the combination of NaOCl and CHX causes color changes and formation of a neutral and possibly toxic insoluble precipitate that may interfere with the seal of the root obturation. Alternatively, the canal can be dried using paper points before the final CHX rinse.[439]

The combination of CHX and EDTA produces a white precipitate, so a group of investigators[311] did a study to determine whether the precipitate involves the chemical degradation of CHX. The precipitate was produced and redissolved in a known amount of dilute trifluoroacetic acid. Based on the results, CHX was found to form a salt with EDTA rather than undergoing a chemical reaction.

Dentin Bonding of Chlorhexidine

During the last 2 decades, chemical and technical advances have contributed to increases in resin-dentin bond strength. However, the premature loss of bond strength is one of the problems that still affects adhesive restorations[270] and markedly reduces their durability.[54,80,117] Researchers[53] evaluated the effect of CHX on resin-dentin bond stability ex vivo. They concluded that autodegradation of collagen matrices can occur in resin-infiltrated dentin, but this may be prevented by the application of a synthetic protease inhibitor such as CHX.[53] Because of its broad-spectrum matrix metalloproteinase (MMP)-inhibitory effect, CHX may significantly improve resin-dentin bond stability.

Allergic Reactions to Chlorhexidine

CHX, although reported to be a relatively safe solution, may induce allergic reactions. The sensitization rate has been reported in several studies to be approximately 2%.[202] One case of an anaphylactic shock was reported after the application of 0.6% CHX to intact skin that had signs of a rash following a minor accident.[15] Further allergic reactions such as anaphy-

FIG. 8-49 BioPure MTAD. *(Courtesy DENTSPLY Tulsa Dental, Tulsa, OK.)*

laxis, contact dermatitis, and urticaria have been reported following direct contact to mucosal tissue or open wounds.[92,303,340,363] There are no publications reporting allergic reactions following root canal irrigation with CHX.[181]

MTAD and Tetraclean

Recently, MTAD (Fig. 8-49) and Tetraclean, two new irrigants based on a mixture of antibiotics, citric acid, and a detergent, have been developed. MTAD is the first irrigating solution created which is capable of removing the both the smear layer and disinfecting the root canal system.[392] It is a mixture of 3% doxycycline hyclate, 4.25% citric acid, and 0.5% polysorbate-80 (Tween 80) detergent.[392] Commercially available as BioPure MTAD (DENTSPLY Tulsa Dental, Tulsa, OK), it is mixed as a liquid and powder prior to use. MTAD has been recommended in clinical practice as a final rinse after completion of conventional chemomechanical preparation.*

Tetraclean (Ogna Laboratori Farmaceutici, Muggio, Italy) is another combination product similar to MTAD. The two irrigants differ in the concentration of antibiotics (doxycycline 150 mg/5 ml for MTAD and 50 mg/5 ml for Tetraclean) and the kind of detergent (Tween 80 for MTAD, polypropylene glycol for Tetraclean).

Mode of Action

There is no detailed information on the exact mechanism of action of MTAD in the removal of the smear layer and the killing of bacteria. In most studies, its effect on the smear layer is attributed to the existence of doxycycline and citric acid. These two components in solution have been separately reported as being effective in the removal of the smear layer.[163] Its antibacterial effect is mostly attributed to the doxycycline, an isomer of tetracycline. Tetracyclines—including tetracycline HCl, minocycline, and doxycycline—are broad-spectrum antibiotics that are effective against a wide range of microorganisms. Tetracycline is a bacteriostatic antibiotic which exerts its effect through the inhibition of protein synthesis. According to Torabinejad et al.,[393] this property may be advantageous because in the absence of bacterial cell lysis, antigenic byproducts (i.e., endotoxin) are not released. In high concentrations, tetracycline may also have a bactericidal effect. The role of citric acid in killing bacteria is not well known. Tween 80, the other component of MTAD, seems to have limited antibacterial activity, yet it may increase the antibacterial effect of some substances by directly affecting the bacterial cell membrane. It may also facilitate the penetration of MTAD into dentin. On the contrary, Tween 80 may also be a nutrient for some bacteria, and it may inactivate the antibacterial properties of some disinfecting agents such as CHX and povidone iodine. Doxycycline, citric acid, and Tween 80 together may have a synergistic effect on the disruption of the bacterial cell wall and on the cytoplasmic membrane.

*References 29, 31, 346, 347, 392, and 393.

Surface Tension

According to Grossman and Meiman,[150] low surface tension is one of the ideal characteristics of an irrigant. Lower surface tension may help by allowing the irrigant to penetrate better into the dentinal tubules and inaccessible areas of the root canal system.[388]

To be more effective in debris removal and to penetrate more readily into the root canal system, irrigants must be in contact with the dentin walls. The closeness of this contact is directly related to its surface tension.[133] Irrigants with a low surface tension are more suitable as endodontic irrigants. To decrease the surface tension, Tween 80 has been added to the MTAD solution.

Smear Layer Removal

In two studies, the efficacy of MTAD or EDTA in the removal of the smear layer was confirmed, but no significant difference between these two solutions was reported.[389,390]

Antibacterial Efficacy

Reported results regarding the antibacterial properties of MTAD are conflicting. The studies measuring zones of inhibition on agar plates have shown consistently that MTAD was an effective antibacterial agent against *E. faecalis*.[73,201,393] Tay et al.[389,390] also found larger zones of bacterial inhibition using dentin cores irrigated with MTAD compared to NaOCl-irrigated dentin cores. When they applied MTAD to dentin that was already irrigated with 1.3% NaOCl, however, they noticed a contradictory result: the diameters of the zones of inhibition were significantly smaller than those of MTAD alone but comparable to those irrigated with 1.3% NaOCl alone. They concluded that the antimicrobial effect of MTAD was lost due to oxidation of the MTAD by NaOCl.

A study using extracted human teeth contaminated with saliva showed that MTAD was more effective than 5.25% NaOCl in disinfection of the teeth.[347] In contrast, Krause et al.,[201] using bovine tooth sections, showed that 5.25% NaOCl was more effective than MTAD in disinfection of dentin discs inoculated with *E. faecalis*.

In another study performed on extracted human teeth inoculated with *E. faecalis,* a protocol of 1.3% NaOCl followed by 5 minutes of MTAD was more effective in the disinfection of canals than a protocol of 5.25% NaOCl followed by 1 minute of 17% EDTA and then 5 minutes of 5.25% NaOCl as a final rinse.[347] In a series of studies, MTAD has failed to show superior antibacterial efficacy against bacterial biofilms. Bacteria collected from the teeth of patients diagnosed with apical periodontitis were grown as a biofilm on hemisections of root apices. MTAD was an effective antibacterial agent in this model, but it was unable to completely disrupt the bacterial biofilm, compared to 6% NaOCl. NaOCl (5.25%) was the most

effective irrigant against a biofilm of *E. faecalis* generated on cellulose nitrate membrane filters, whereas the bacterial load reduction using MTAD was not significant.[134] The results of testing antibacterial efficacy of medicaments obtained from in vitro studies should be analyzed with caution. They may be influenced by factors such as the test environment, bacterial susceptibility, and the different methodologies used to evaluate the results.[354]

In vivo Clinical Trial

With the exception of one study[394] that evaluated the effect of MTAD on postoperative discomfort, there have been no other in vivo studies to address the other characteristics of MTAD. Malkhassain et al.[238] in a clinical controlled trial of 30 patients reported that the final rinse with MTAD did not reduce the bacterial counts in infected canals beyond levels achieved by chemomechanical preparation using NaOCl alone.

Protocol for Use

The clinical protocol for the use of MTAD *was developed on the basis of a pilot project*.[346] The results of this project showed consistent disinfection of the infected root canals could occur after chemomechanical preparation using 1.3% NaOCl as a root canal irrigant followed by a 5-minute rinse of MTAD.

Ethylenediamine Tetra-Acetic Acid

EDTA is often suggested as an irrigation solution because it can chelate and remove the mineralized portion of the smear layer (Fig. 8-50). It is a polyaminocarboxylic acid with the formula $[CH_2N(CH_2CO_2H)_2]_2$. This colorless, water-soluble solid is produced on a large scale for many applications. Its prominence as a chelating agent arises from its ability to sequester di- and tricationic metal ions such as Ca^{2+} and Fe^{3+}. After being bound by EDTA, metal ions remain in solution but exhibit diminished reactivity.

History

The compound was first described in 1935 by Ferdinand Munz, who prepared the compound from ethylenediamine and chloroacetic acid. Today, EDTA is mainly synthesized from ethylenediamine (1, 2-diaminoethane), formaldehyde (methanal), and sodium cyanide.

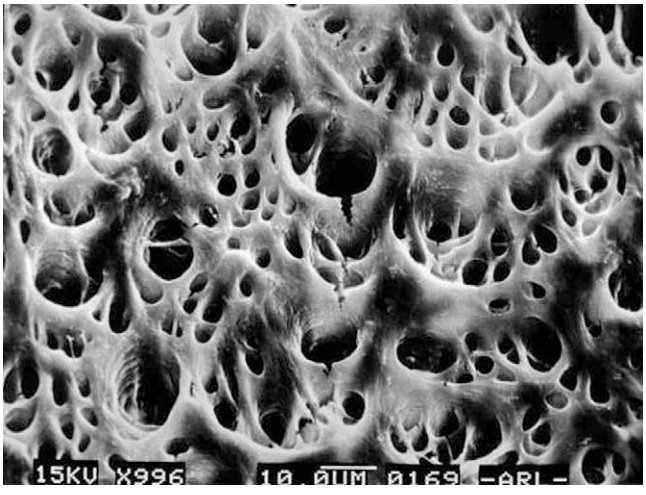

FIG. 8-50 Scanning electron microscope (SEM) image of root canal dentin exposed to 2 minutes of EDTA.

Mode of Action

On direct exposure for extended time, EDTA extracts bacterial surface proteins by combining with metal ions from the cell envelope, which can eventually lead to bacterial death.

Applications in Endodontics

EDTA alone normally cannot remove the smear layer effectively; a proteolytic component (e.g., NaOCl) must be added to remove the organic components of the smear layer.[136] Commercial products with such combinations are available. Endo-Dilator N-Ø (Union Broach, York, PA) is a combination of EDTA and a quaternary ammonium compound. Such an irrigation fluid has a slight detergent effect in addition to the chelating effect. Two newer irrigating solutions, MTAD (discussed earlier) and Smear Clear (SybronEndo), have recently been studied. Smear Clear is a clear, odorless, water-soluble solution containing water, 17% EDTA salts, a cationic surfactant (cetrimide), and anionic surfactants.

EDTA is normally used in a concentration of 17% and can remove the smear layers when in direct contact with the root canal wall for less than 1 minute. The decalcifying process is self-limiting. For root canal preparation, EDTA has limited value alone as an irrigation fluid. Since it is capable of decalcifying up to 50 µm, it can open up an occluded, very fine canal. This depth, added from two opposite canal walls, will result in a 100-µm opening, equivalent to the tip of a #010 file.

Although citric acid appears to be slightly more potent at similar concentration than EDTA, both agents show high efficiency in removing the smear layer. In addition to their cleaning ability, chelators may detach biofilms adhering to root canal walls.[151] This may explain why an EDTA irrigant proved to be highly superior to saline in reducing intracanal microbiota despite the fact that its antiseptic capacity is relatively limited.[151] Although never shown in a randomized clinical trial, an alternating irrigating regimen of NaOCl and EDTA may be more efficient in reducing bacterial loads in root canal systems than NaOCl alone. Antiseptics such as quaternary ammonium compounds (EDTAC) or tetracycline antibiotics (MTAD) have been added to EDTA and citric acid irrigants, respectively, to increase their antimicrobial capacity. The clinical value of this, however, is questionable. EDTAC shows similar smear-removing efficacy as EDTA, but it is more caustic.

Interaction of EDTA and NaOCl

Investigators[146] studied the interactions of EDTA with NaOCl. They concluded that EDTA retained its calcium-complexing ability when mixed with NaOCl, but EDTA caused NaOCl to lose its tissue-dissolving capacity, with virtually no free chlorine detected in the combinations. Clinically, this suggests that EDTA and NaOCl should be used separately. In an alternating irrigating regimen, copious amounts of NaOCl should be administered to wash out remnants of the EDTA.

Hydrogen Peroxide

Hydrogen peroxide (H_2O_2) has been used as an endodontic irrigant for years, mainly in concentrations ranging between 3% and 5%. It is active against bacteria, viruses, and yeasts.

Hydroxy free radicals (•OH) destroy proteins and DNA. The tissue-dissolving capacity of H_2O_2 is clearly lower than that of NaOCl.[330] When used in combination with NaOCl, bubbling will occur as a result of nascent oxygen being released through the chemical reaction between these two liquids. Generally this is no longer recommended as a routine irrigant.

Iodine Potassium Iodide

IKI, used as a solution of 2% iodine in 4% potassium iodide, has been proposed and is used as an endodontic disinfectant because of its excellent antibacterial properties and low cytotoxicity. However, it may act as a severe allergen[306] and also stains dentin.[330]

Choosing the Ideal Irrigant

Although iodine is less cytotoxic and irritating to vital tissues than NaOCl and CHX,[370,371] it has a higher risk of causing an allergic reaction.[306] The same is true for quaternary ammonium compounds. Sensitivities to hypochlorite and CHX are rare.[439]

Of all the currently used substances, NaOCl appears to be the most ideal because it covers more of the requirements for endodontic irrigant than any other known compound. Hypochlorite has the unique capacity to dissolve necrotic tissue and the organic components of the smear layer. It kills sessile endodontic pathogens organized in biofilms and in dentinal tubules as efficiently as CHX or iodine at comparable concentration.[290,373,401] Inactivation of endotoxin by hypochlorite has been reported, but the effect is minor compared to that of a $Ca(OH)_2$ dressing.

Intracanal Medication

When treatment cannot be completed in one appointment [see Chapters 4 and 15], the surviving intracanal bacteria often proliferate between appointments.[47,415] To curtail bacterial regrowth and possibly even improve bacterial suppression, an intracanal medication can be advantageous. Interappointment antimicrobial medication acts to inhibit proliferation and further eliminate surviving bacteria, as well as minimize ingress through a leaking restoration.

Phenolic Preparations

Phenol (C_6H_5OH), or carbolic acid, is one of the oldest antimicrobial agents used in medicine. Despite the severe toxicity of phenolic preparations, derivatives of phenol, such as paramonochlorophenol (C_6H_4OHCl), thymol ($C_6H_3OHCH_3C_3H_7$), and cresol ($C_6H_4OHCH_3$), remain available. One survey noted a decrease in the use of classic phenolic intracanal medicaments with a corresponding increase in the use of $Ca(OH)_2$ or no medication.[128]

Phenol is a nonspecific protoplasm poison that has an optimal antibacterial effect at 1% to 2%. Many dental preparations use much too high a concentration of phenol (e.g., in the range of 30%). At such a concentration, the antimicrobial effect in vivo is lower than optimal and of very short duration.[254]

Derivatives of phenol are stronger antiseptics and toxins than phenol. Phenolic compounds are often available as camphorated solutions. Camphoration results in a less toxic phenolic compound because it slows the release of toxins to the surrounding tissues.

Studies in vitro have shown that phenol and phenol derivatives are highly toxic to mammalian cells, and their antimicrobial effectiveness does not sufficiently balance their toxicity.[370,371] Phenols are ineffective antiseptics under clinical conditions.[46,96]

Formaldehyde

Formaldehyde, used as formocresol, has been used extensively in endodontic therapy despite its high toxicity and mutagenic and carcinogenic potential.[221] The formaldehyde component of formocresol may vary substantially between 19% and 37%. Tricresol formalin, another formaldehyde preparation, contains 10% tricresol and 90% formaldehyde. All of these preparations have a formaldehyde content well above the 10% normally used for fixation of pathologic specimens. Formaldehyde is volatile and releases antimicrobial vapors when applied to a cotton pellet for pulp chamber disinfection. All formaldehyde preparations are potent toxins with an antimicrobial effectiveness much lower than their toxicity.[371,372]

There is no clinical reason to use formocresol as an antimicrobial agent for endodontic treatment, based on what is known at this time. The alternatives are better antiseptics with significantly lower toxicity.

Halogens

Chlorinated solutions have been used for many years to irrigate root canals. They are also used as an intracanal dressing in the form of chloramine-T, an *N*-chloro tosylamide sodium salt. Iodine, in the form of IKI, is a very effective antiseptic solution with low tissue toxicity. IKI is an effective disinfectant for infected dentin and can kill bacteria in infected dentin in 5 minutes in vitro.[324] IKI releases vapors with a strong antimicrobial effect. The solution can be prepared by mixing 2 g of iodine in 4 g of potassium iodide; this mixture then is dissolved in 94 ml of distilled water. Tincture of iodine (5%) has proved to be one of the few reliable agents for disinfection of rubber dam and tooth surfaces during the preparation of an aseptic endodontic workfield.[272]

Calcium Hydroxide

Hermann introduced[166,167] the use of $Ca(OH)_2$ in endodontics in 1920. Although its use was well documented for its time, the clinical applications over the next 25 years were not well known. Its use in root canal treatment as an intracanal medication has been associated with periradicular healing and few adverse reactions. Its use in root canal treatment was promoted by a series of papers[46,48] documenting the antibacterial efficacy of $Ca(OH)_2$ in human root canals. Subsequent studies substantiated these reports,[290,360] and the routine use of $Ca(OH)_2$ as an interappointment intracanal medicament became widespread.[327]

$Ca(OH)_2$ cannot be categorized as a conventional antiseptic, but it kills bacteria in the root canal space. The value of $Ca(OH)_2$ in endodontic treatment of necrotic, infected teeth is now well documented. $Ca(OH)_2$ normally is used as slurry of $Ca(OH)_2$ in a water base. At body temperature, less than 0.2% of the $Ca(OH)_2$ is dissolved into Ca^{++} and OH^- ions. Because $Ca(OH)_2$ needs water to dissolve, water should be used as the vehicle for the $Ca(OH)_2$ paste. In contact with air, $Ca(OH)_2$ forms calcium carbonate ($CaCO_3$). However, this is an extremely slow process and of little clinical significance. $Ca(OH)_2$ paste, with a significant amount of calcium carbonate, feels granular because the carbonate has a very low solubility.

$Ca(OH)_2$ is a slow-acting antiseptic. Direct-contact experiments in vitro show that a 24-hour contact period is required for complete killing of enterococci.[324,360] Another study of 42 patients found that NaOCl canal irrigation reduced the bacteria level by only 61.9%, but use of $Ca(OH)_2$ in the canals for 1 week resulted in a 92.5% reduction.[350] These researchers concluded that $Ca(OH)_2$ should be used in infected cases to more predictably obtain disinfection.

In addition to killing bacteria, $Ca(OH)_2$ has the extraordinary ability to hydrolyze the lipid moiety of bacterial lipopolysaccharides (LPS), thereby inactivating the biologic activity of the lipopolysaccharide and reducing its effect.[322,323] This is a very desirable effect because dead cell wall material remains after the bacteria have been killed and can continue to stimulate inflammatory responses in the periradicular tissue.

$Ca(OH)_2$ may be mixed with sterile water or saline; this formula is also available commercially from a number of manufacturers in sterile, single-dose packages (e.g., Calasept [J.S. Dental, Ridgefield, CT]; Calcijet [Centrix, Shelton, CT]; and DT Temporary Dressing, [Global Dental Products, North Bellmore, NY]) (Fig. 8-51). The mixture should be thick to carry as many $Ca(OH)_2$ particles as possible. This slurry is best applied with a Lentulo spiral. For maximum effectiveness, the root canal must be filled homogeneously to the working length. Saturated $Ca(OH)_2$ solution mixed with a detergent is an effective antimicrobial agent suitable for irrigation.

Limitations of Calcium Hydroxide

There are some concerns regarding the use of $Ca(OH)_2$. The handling and proper placement of $Ca(OH)_2$ present a challenge to the average clinician.[233,358] Also, the removal of $Ca(OH)_2$ is frequently incomplete, resulting in a residue covering 20% to 45% of the canal wall surfaces, even after copious irrigation with saline, NaOCl, or EDTA.[211] Residual $Ca(OH)_2$ can shorten the setting time of zinc oxide eugenol–based endodontic sealers.[243] Most notably, it may interfere with the seal of the root filling and compromise the quality of treatment. An additional concern is that $Ca(OH)_2$ is not totally effective against several endodontic pathogens, including *E. faecalis* and *Candida albicans*.[416] Recently the ability of $Ca(OH)_2$ to completely eradicate bacteria from the root canal has been questioned. For example, in vitro studies have shown that dentin can inactivate the antibacterial activity of $Ca(OH)_2$,[155,307] and one clinical study[301] has shown that the number of bacteria-positive canals actually increased after $Ca(OH)_2$ medication. Other studies have also indicated that $Ca(OH)_2$ could not predictably eliminate bacteria or that cultures changed from negative to positive after $Ca(OH)_2$ placement.[301,415]

When different studies report inconsistent results, a systematic review and meta-analysis technique can clarify conflicting research data and the current state of knowledge regarding specific issues. Therefore, based on the current best available evidence, $Ca(OH)_2$ has limited effectiveness in eliminating bacteria from human root canals when assessed by culture techniques. The quest for better antibacterial protocols and sampling techniques must continue to ensure that bacteria can be been reliably eradicated prior to obturation.

Chlorhexidine

CHX is also used as an intracanal medication and has already been discussed extensively under its own heading.

Ledermix

Ledermix (Lederle Pharmaceuticals, Wolfratshausen, Germany) is a corticosteroid-antibiotic paste. Medicaments such as Ledermix paste have been recommended as routine intracanal medicaments. Ledermix paste has been advocated as an initial dressing, particularly if the patient presents with endodontic symptoms.

Schroeder developed the material that is now commercially marketed as Ledermix paste.[339] Ledermix paste contains triamcinolone acetonide as an antiinflammatory agent, at a concentration of 1%. When the Ledermix materials and other similar corticosteroid-containing formulations were commercially released, there was a considerable amount of opposition to their use.[195]

Ledermix paste is a nonsetting, water-soluble paste material for use as root canal medicament or as a direct or indirect

FIG. 8-51 Calcijet is a calcium hydroxide prefilled, easy-to-use, single-dose syringe system. Centrix NeedleTube cartridges can be used for direct syringe injection into the root canal. *(Courtesy Centrix, Shelton, CT.)*

pulp capping agent. The release and dentin diffusion characteristics of triamcinolone from Ledermix paste when used as a root canal medicament have been investigated under different conditions.[1-3] These studies show that triamcinolone is released from Ledermix paste in the root canal and can reach the systemic circulation via diffusion through dentinal tubules, lateral canals, and the apical foramen. After the first 24 hours, 30% of the triamcinolone was released. By the end of 14 weeks, the remaining 70% had been released.

Immediate intracanal placement of Ledermix has been studied for replanted teeth, because it has been shown to inhibit root resorption after extended dry time. In a recent study done in dogs, the groups treated with Ledermix, triamcinolone and demeclocycline had significantly more favorable healing and more remaining root structure than the group filled with gutta-percha and sealer (positive control).[57]

The Triple-Antibiotics Paste

The triple-antibiotics regimen, composed of metronidazole, ciprofloxacin, and minocycline, was first tested[328] for its effectiveness against *Escherichia coli*–infected dentin in vitro. The same research group also tested its bactericidal efficacy against microbes from carious dentin and infected pulp. They found that the mixture of antibiotics is sufficiently potent to eradicate the bacteria.[391] The clinical effectiveness of the triple-antibiotic paste in the disinfection of immature teeth with apical periodontitis has been reported.[425] One potential concern of using an intracanal antibiotic paste is that it may cause bacterial resistance. Additionally, intracanal use of minocycline can cause tooth discoloration, creating potential cosmetic complications.

Bioactive Glass

Research is underway in the use of bioactive glass as an intracanal medicament. In one study,[440] the glass used was composed of 53% SiO_2 (w/w), 23% Na_2O, 20% CaO, and 4% P_2O_5 and was prepared from reagent-grade Na_2CO_3, $CaHPO_4$, $2H_2O$, $CaCO_3$, and Belgian sand. When used in root canals, bioactive glass was found to kill bacteria, but the mechanism of action was not pH related, and dentin did not seem to alter its effect. Some new obturating materials (e.g., Resilon [Pentron Clinical Technologies, Wallingford, CT]) contain bioactive glass.

New Irrigation and Disinfection Techniques and Devices

Other than conventional irrigation, additional techniques for endodontic disinfection have been proposed and tested, including laser systems and gaseous ozone. Recently several new devices for endodontic irrigation and/or disinfection have been introduced, among which are the EndoActivator System (DENTSPLY Tulsa Dental Specialties, Tulsa, OK), passive ultrasonic irrigation, EndoVac (Discus, Culver City, CA), the Safety-Irrigator (Vista Dental Products, Racine, WI), the self-adjusting file (ReDent, Raanana, Israel), photoactivation disinfection, and ozone. These new devices use pressure, vacuum, oscillation, and/or a combination with suction. For most of these devices and techniques, no data exists on the clinical efficacy, risk, frequency, and intensity of apical irrigant extrusion or the problems encountered with the use of negative pressure or oscillation.

EndoActivator

The EndoActivator System uses safe, noncutting polymer tips in an easy-to-use subsonic handpiece to quickly and vigorously agitate irrigant solutions during endodontic therapy (Fig. 8-52).

In a recent study,[84] the safety of various intracanal irrigation systems was analyzed by measuring the apical extrusion of irrigant. They concluded that EndoActivator had a minimal, although statistically insignificant, amount of irrigant extruded out of the apex when delivering the subsonic activation of the irrigant into the pulp chamber and canal. Manual, ultrasonic, and Rinsendo (Dürr Dental, Bietigheim-Bissingen, Germany) groups had significantly greater amount of extrusion compared with EndoVac and EndoActivator.

Passive Ultrasonic Activation

Ultrasonic devices were first introduced in endodontics by Richman.[312] Ultrasonically activated files have the potential to prepare and débride root canals mechanically. The files are driven to oscillate at ultrasonic frequencies of 25 to 30 kHz. They operate in a transverse vibration, setting up a characteristic pattern of nodes and antinodes along their length.[413,414] Unfortunately, it proved difficult to control the cutting of dentin during ultrasonic preparation, which resulted in apical perforations and irregular canal shapes.[235,380]

However, it has been shown that ultrasonically driven files are effective for the irrigation of root canals. Two types of ultrasonic irrigation have been described in the literature[6,420]: one where irrigation is combined with simultaneous ultrasonic instrumentation (UI) and another without simultaneous instrumentation, called *passive ultrasonic irrigation* (PUI). During UI, the file is intentionally brought into contact with the root canal wall. UI has been shown to be less effective in removing simulated pulp tissue from the root canal system or smear layer from the root canal wall than PUI. This can be explained by a reduction of acoustic streaming and cavitation.[6] Because the root canal anatomy is complex,[302] an instrument

FIG. 8-52 EndoActivator system. *(Courtesy DENTSPLY Tulsa Dental Specialties, Tulsa, OK.)*

will never contact the entire root canal wall.[429] Thus, UI could result in uncontrolled cutting of the root canal wall without effective cleaning.

Passive ultrasonic irrigation was first described by Weller et al.[420] The term *passive* does not adequately describe the process, since it is in fact active. When it was first introduced, the term *passive* related to the noncutting action of the ultrasonically activated file. PUI relies on the transmission of acoustic energy from an oscillating file or smooth wire to an irrigant in the root canal. The energy is transmitted by means of ultrasonic waves and can induce acoustic streaming and cavitation of the irrigant.[6] After the root canal has been shaped to the master apical file (irrespective of the preparation technique used), a small file or smooth wire (for example, size #15) is introduced in the center of the root canal, as far as the apical region. The root canal is then filled with an irrigant solution, and the ultrasonically oscillating file activates the irrigant. Since the root canal has already been shaped, the file or wire can move freely, and the irrigant can penetrate more easily into the apical part of the root canal system,[204] with the cleaning effect being more significant.[235] Using this noncutting methodology, the potential to create aberrant shapes within the root canal are reduced to a minimum. A file larger than a #15 or #20 will only oscillate freely in a wide root canal. A #25 file may in fact produce less acoustic streaming than a #15 and #20 file.[6] Consequently, using a file larger than a #20 may be considered fundamentally different from the basic principle of PUI. The cleaning efficacy of PUI implies the effective removal of dentin debris, microorganisms (planktonic or in biofilm), and organic tissue from the root canal. Because of the active streaming of the irrigant, its potential to contact a greater surface area of the canal wall will be enhanced.

If ultrasonic activation of the hypochlorite irrigant is to be used, it appears important to apply the ultrasonic instrument after canal preparation has been completed. A freely oscillating instrument will cause more ultrasound effects in the irrigating solution than a counterpart that binds to canal walls.[318] In addition, ultrasonic files can cause uncontrolled cutting of the canal walls, especially if used during preparation.[380] Therefore, it appears best to insert a slim, noncutting instrument in a controlled fashion after canal preparation.[402,403] As of recently, smooth wires fitting to an ultrasonic device have been commercially available. However, objective guidelines regarding their risks and benefits have not been ascertained.[439]

EndoVac

EndoVac is a combined irrigation/evacuation system. The irrigant is extruded from the system with pressure at the root canal orifice. The evacuator, a microcannula, extends to the apical region of the root canal; the dimensions of the needle are size #55 with a 2% taper. High-volume suction from the dental unit results in negative apical pressure and thus passively sucks the irrigant from the orifice to the apical part of the root canal, which is passively evacuated from the canal space. Apical extrusion of the irrigant will probably be reduced, since the canal is irrigated with negative (as opposed to positive) pressure.[283] There is little research to demonstrate this device is safe and effective when there is an open (immature) apex or in cases where there is a pathologic perforating root resorption.

A similar device has been presented by Fukumoto et al.[119,120] The irrigant is delivered by a needle (outer diameter 0.41 mm, inner diameter 0.19 mm) and a tubing pump (Masterflex, Cole Palmer Instruments, Vernon Hills, IL) to the coronal or middle part of the root canal and aspirated by a second needle (outer diameter 0.55 mm, inner diameter 0.30 mm), which is introduced into the apical part of the root canal. The aspiration pressure is −20 kPa. The irrigant is flushed from the coronal to the apical part of the root canal and there finally suctioned. This technique in an in vitro experiment on teeth with resected apices resulted in significantly less overextrusion of irrigant than a conventional irrigation technique with the needle tip placed 2 mm short of the apex. When the needle was placed 3 mm from the apex, the results did not significantly differ (Figs. 8-53 to 8-56).

Safety-Irrigator

The Safety-Irrigator is an irrigation/evacuation system that apically delivers the irrigant under positive pressure through a thin needle containing a lateral opening, and evacuates the solution through a large needle at the root canal orifice. As of this printing, no information on its safety or efficacy is available (Fig. 8-57). Absent clear evidence of safety and efficacy through peer-reviewed literature, the reader is advised to use caution in choosing an irrigating device.

Self-Adjusting File

The SAF was recently introduced primarily as an endodontic file (discussed at length earlier under Instruments for Cleaning and Shaping the Root Canal Space). It should also be considered as an irrigation device since the file is hollow, which allows for continuous irrigation. The irrigant is delivered through a free-

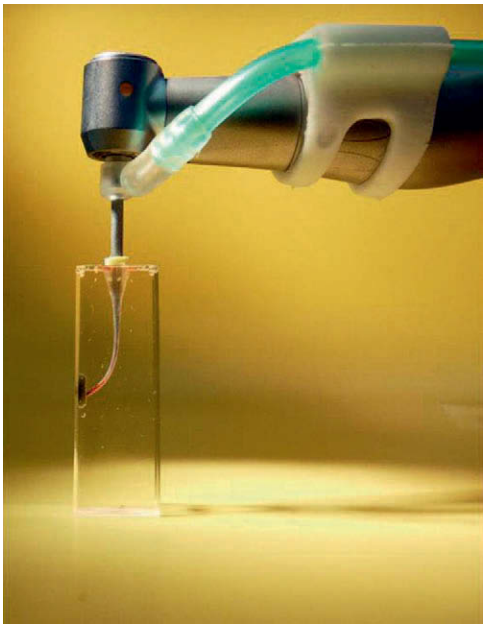

FIG. 8-58 The self-adjusting file (SAF; ReDent-Nova, Raanana, Israel). The hollow endodontic file is used also as a continuous irrigation device throughout the cleaning and shaping of the root canal. *(Courtesy ReDent-Nova, Raanana, Israel.)*

rotating hub to which a silicone tube is attached (Fig. 8-58). Either a special irrigation unit (see Fig. 8-30) (VATEA, ReDent, Raanana, Israel) or any physio-dispenser-type unit may be used to deliver a constant flow of irrigant at 5 ml/min. This maintains a continuous flow of fresh, fully active irrigant, facilitating an outflow of tissue debris and dentin powder that is generated by the file use. No positive pressure is thought to be created in the canal during this continuous irrigation procedure. The open metal lattice allows the irrigant to escape freely, minimizing the risk of irrigant transportation beyond the apical foramen.[260] The replacement of irrigation fluid in the apical part of curved canals is demonstrated in Fig. 8-59. Further research on this device is underway.

HealOzone

Ozone (also known as triatomic oxygen or trioxygen) is a naturally occurring compound consisting of three oxygen atoms. It is found in nature in the form of a gas in the stratosphere at a concentration of 1 to 10 ppm, being continually created from and destroyed into molecular O_2. The reliable microbiologic and metabolic properties of ozone, in either the gaseous or aqueous phases, make it a useful disinfectant with a wide range of activity. Ozone, in the gaseous or aqueous phase, has been shown to be a powerful and reliable antimicrobial agent against bacteria, fungi, protozoa, and viruses. It is generally accepted that the oxidant potential of ozone induces the destruction of cell walls and cytoplasmic membranes of bacteria and fungi. During this process, ozone attacks glycoproteins, glycolipids, and other amino acids and inhibits the enzymatic control system of the cell. This results in increased membrane permeability, the key element of cell viability, leading to immediate functional cessation. The ozone molecules then readily enter the cell and cause the microorgan-

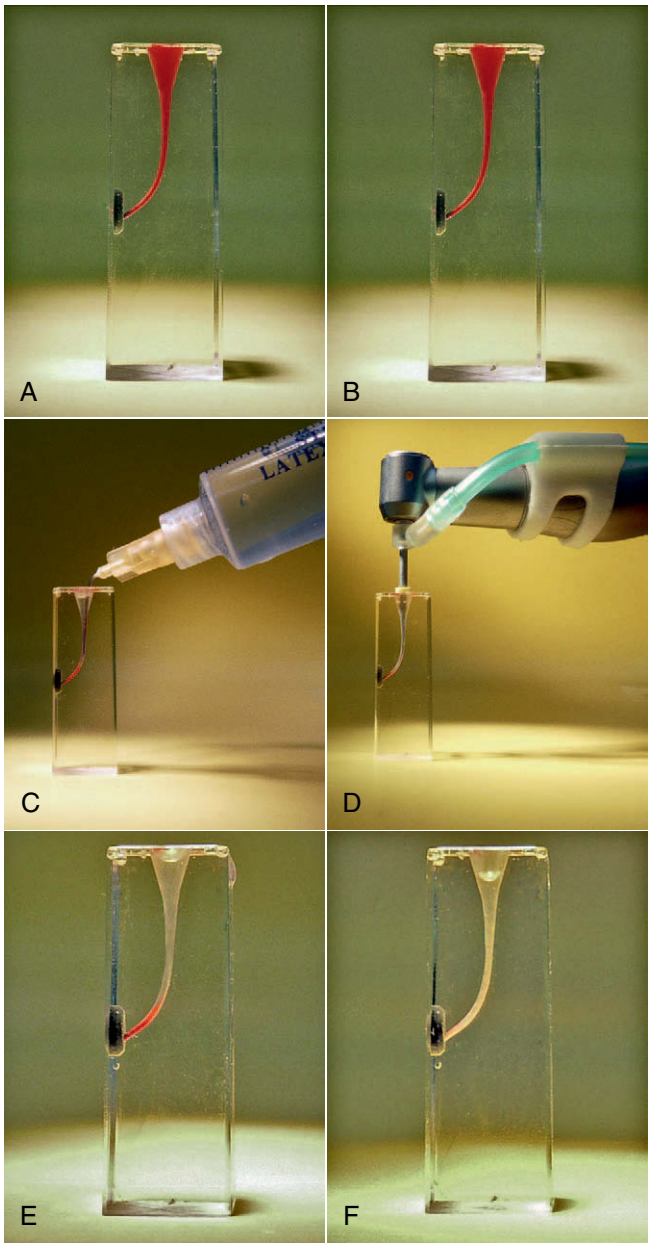

FIG. 8-59 Replacement of irrigation fluid in the apical part of curved canals. Transparent training blocks were filled with colored liquid **(A-B).** The canal was rinsed with either 20 ml of water using a syringe **(C)** or using the SAF instrument with a continuous flow of an equal amount of water **(D).** The short needle was unable to replace the liquid beyond the curve **(E),** but the SAF irrigation did it effectively **(F).**[260]

ism to die. Ozone can also attack many biomolecules, such as the cysteine, methionine, and histidine residues of proteins. By oxidizing the biomolecules featured in dental diseases, ozone has a severely disruptive effect on cariogenic bacteria, resulting in the elimination of acidogenic bacteria. The strongest naturally occurring acid—produced by acidogenic bacteria during cariogenesis—is pyruvic acid. Ozone can decarboxylate this acid to acetic acid. It has been shown that remineralization of incipient carious lesions can be encouraged when the production of acetic acid, or other high *p*Ka acids found in resting plaque, buffers plaque fluid.[245]

E.A. Fisch (1899–1966) was the first dentist to use ozonated water in his practice and introduced it to the German surgeon Erwin Payr (1871–1946) who used it from that time forward in surgery. He reported his results at the 59th Congress of the German Surgical Society in Berlin (1935). In dental surgery, ozonated water was used to promote hemostasis, enhance local oxygen supply, and inhibit bacterial proliferation. Theoretically, ozone can reduce the bacterial count in active carious lesions and therefore may temporarily arrest the progression of caries, resulting in preventing or delaying the need for tooth restorations.[313] For review on ozone use in dentistry see Azarpazhooh and Limeback.[17]

Ozone in Endodontics

Four in vitro studies[100,164,279,282] were identified investigating the bactericidal effect of ozone compared to 2.5% NaOCl, the standard irrigation solution in endodontics. The results of these studies[164,279,282] are controversial. The hazards of ozone when used in endodontics have not been investigated. Care should be taken with regard to the patient's and the dentist's exposure to the gas. Fig. 8-60 shows ozone equipment with a special tip for intracanal application.

Superoxidized Water

Superoxidized water,[152] also called electrochemically activated water[241,365] or oxidative potential water,[162,344] is saline that has been electrolyzed to form superoxidized water, hypochlorous acid, and free chlorine radicals. It is available as Sterilox (Sterilox Technologies, Radnor, PA). This solution is nontoxic to biologic tissues yet able to kill microorganisms. The solution is generated by electrolyzing saline solution, a process no different than that used in the commercial production of NaOCl.[116] The difference, however, is that the solution accumulating at the anode is harvested as the anolyte and that at the cathode as the catholyte. These solutions display properties that are dependent upon the strength of the initial saline solution, the applied potential difference, and the rate of generation. The technology that allows harvesting of the respective solutions resides in the design of the anode and the cathode and originates either in Russia (electrochemically activated water) or Japan (oxidative potential water).[240,241] Although the solutions bear different names, the principles in the manufacturing process are probably the same.

The use of superoxidized water is sparse in the endodontic literature but shows early promise. The solutions from both technologies have been tested for their ability to débride root canals,[162,241] remove smear layer,[344,365] and kill bacteria[172] and bacterial spores.[234] Results are favorable, while also showing biocompatibility with vital systems.[183]

Anolyte and catholyte solutions generated from one such technology (Radical Waters Halfway House 1685, S. Africa) have shown promise as antibacterial agents against laboratory-grown, single-species biofilm models.[132] Such solutions have been recommended as suitable for removing biofilms in dental unit water lines[240] and have even been marketed for this purpose. Cautious clinicians may prefer to wait for more studies to demonstrate safety and efficacy under ordinary clinical setting conditions before adopting newer, less tested irrigating solutions.

Photoactivation Disinfection

Photodynamic therapy (PDT) or light-activated therapy (LAT) may have endodontic applications because of its antimicrobial effectiveness.[159] In principle, the strategy utilizes a selectively accumulated or endogenously produced photosensitizer (photoactive compound). The activation of photosensitizer molecules by a specific wavelength of light produces deleterious chemical entities that kill bacteria. The strong oxidizer generated during the process can act on multiple targets in a microbial cell, resulting in membrane damage, enzyme inactivation, and genomic and plasmid DNA damage, resulting in instantaneous death. In addition, the light-activated killing of bacteria has a wide spectrum of antimicrobial activity with a minimal chance of giving rise to a resistant microbial population, making it an ideal disinfectant. Fighting biofilm-mediated localized human infections is one of the potential medical applications of LAT.[410] The principal agent involved in bacterial killing is the oxygen-based free radical.[159] Unlike systemic therapeutic agents, LAT has the advantage of dual selectivity. Only those cells which have selectively accumulated the photosensitizer or possessing endogenously produced photosensitizers will be affected upon irradiation. Separately, the low-intensity light and the nontoxic photosensitizer generally used in LAT are harmless. In addition, the use of an optic fiber helps in directing the irradiation to the intended site of application. Studies have highlighted the possibility of killing antibiotic-resistant strains of pathogenic bacteria using LAT.[409,411] Because of the wide spectrum of antimicrobial activity, instant bacterial killing, and ability to target biofilm bacteria, the application of LAT-based regimens has great promise in root canal disinfection.[400] However, a thorough knowledge about the behavior of the photosensitizer and the physicochemical characteristics of the microenvironment prevailing in the root canal system is necessary for disinfection to be effectively achieved. In advanced stages of infection with mineralized biofilms, it may be necessary to do a minimal mechanical preparation of the root canal prior to LAT to achieve maximum disinfection.

IntraLight Ultraviolet Disinfection

Ultraviolet (UV) light is widely used for disinfection purposes. IntraLight (InterLight, Or-Yehuda, Israel) consists of an intracanal UV illuminator shaped with dimensions of an endodontic file, which allows uniform circumferential illumination of the root canal walls with 254 nm UV light. In a recent in vitro study,[255] root canals were infected with *E. faecalis* bacteria that

were allowed to grow and establish a biofilm on the root canal walls. Treatment with 5% NaOCl for 10 minutes failed to result in negative cultures in 53% of the canals. Similar results were reported by others.[255,257] An additional illumination of the canal walls with 254 nm UV light (300 mJ/cm^2) rendered 96% of the canals free of cultivable bacteria. A wide range of bacteria are sensitive to 254 nm UV light, including those that are resistant to $Ca(OH)_2$.[257] The device is used as a supplemental disinfection after NaOCl irrigation in the canal. Otherwise, bacteria in the inner layers of thick biofilms may be protected from the UV light, which is absorbed by bacteria in the outer layers.[257]

ROOT CANAL FILLING MATERIALS

Solid Materials

After the root canal system has been appropriately prepared, it must be obturated with a material capable of completely preventing communication between the oral cavity and the periapical tissue wound. Materials used for this purpose should be compatible with healing. This is achieved by attempting to seal the root canal system at both its coronal and apical ends, as well as throughout the canal system, to seal the openings of accessory canals. Apical and intracanal obturation blocks the exit to the periradicular tissues from organisms that have survived in the root canal after cleaning and shaping. Coronal obturation prevents reinfection of the pulp space from the oral environment. The required physical and biologic properties make the selection of obturation material critical. The materials commonly used for root canal fillings normally can be divided into a solid phase and a cementing medium (i.e., a sealer).

Gutta-Percha

Gutta-percha is the most commonly used root canal filling material. It is a linear crystalline polymer that melts at a set temperature, with a random but distinct change in structure resulting. (See Chapter 10 for further discussion of the physical properties of gutta-percha.) It occurs naturally as 1,4-polyisoprene and is harder, more brittle, and less elastic than natural rubber.

The crystalline phase has two forms, the alpha phase and the beta phase. The forms differ only in the molecular repeat distance and single-bond form. The alpha form is the material that comes from the natural tree product. The processed, or beta, form is used in gutta-percha for root fillings.[333] When heated, gutta-percha undergoes phase transitions. The transition from beta phase to alpha phase occurs at around 115° F (46° C). An amorphous phase develops at around 130° F to 140° F (54° C to 60° C). When cooled very slowly (i.e., 1° F per hour), gutta-percha crystallizes to the alpha phase. Normal cooling returns the gutta-percha to the beta phase. Gutta-percha cones soften at a temperature above 147° F (64° C).[139,333] These cones can easily be dissolved in chloroform and halothane and dissolve less in turpentine or xylene.

Modern gutta-percha cones that are used for root canal fillings contain only about 20% gutta-percha (Box 8-4). The major component is zinc oxide (60% to 75%). The remaining 5% to 10% consists of various resins, waxes, and metal sulfates. Antiseptic gutta-percha with various antimicrobial agents has been suggested, and several studies are available concerning the effect of these additives (see Medicated Gutta-Percha).

BOX 8-4

Composition of Gutta-Percha for Endodontic Use

Gutta-percha (19%–22%)
Zinc oxide (59%–79%)
Heavy metal salts (1%–17%)
Wax or resin (1%–4%)

Because gutta-percha cannot be heat sterilized, other decontamination methods must be used. The most practical method is to disinfect the gutta-percha in NaOCl before use. This can be done in 1 minute if the cone is submerged in a 5% solution of NaCOl.[342] However, after this disinfection and before its use for obturation, it is imperative that the gutta-percha be rinsed in ethyl alcohol to remove crystallized NaOCl; such crystals may impair the obturation seal.[349]

Obturation with gutta-percha normally requires some form of compaction pressure, but real compression of gutta-percha is practically impossible.[333] Pressure applied during root canal filling procedures does not compress gutta-percha, but rather compacts the gutta-percha cones to obtain a more three-dimensionally complete fill of the root canal system.

After heating, while cooling, there is a slight shrinkage of approximately 1% to 2% when the gutta-percha has solidified. Prevention of shrinkage is practically impossible in vertical warm compaction.[139,334] Careful control of the temperature during warm compaction is crucial to prevent focal areas of unnecessarily high temperatures. Better temperature control is available with electrically controlled heating devices as the Touch 'n Heat, System B, Elements units (SybronEndo, Orange, CA), or the recently introduced vibrating heat carrier, Down-Pack[67] (Hu-Friedy, Chicago, IL), or HotTip (Discus Dental, Culver City, CA), all of which are more commonly used for this purpose (see Figs. 8-41 through 8-44).

Gutta-percha oxidizes with exposure to air and light and eventually becomes brittle.[198,242] It should be stored in a cool, dry place (e.g., a refrigerator) for better shelf life. Methods of "rejuvenating" aged gutta-percha have been suggested.[189]

Gutta-percha cannot be used as the sole filling material; it lacks the adherent properties necessary to seal the root canal space. Therefore, a sealer (cement) is always needed for the final seal. (See the following sections on sealers.)

Manufacturers now supply gutta-perch cones in tapers matching the larger tapered rotary instruments (#.02, #.04, and #.06) (Fig. 8-61). An international standard has been accepted for gutta-percha cones, based on similar size and taper standards set forth for the endodontic files (ANSI No.78) (see Table 8-1). The tolerance is much less stringent for gutta-percha compared to files. An endodontic file must be manufactured with a tolerance of +0.05 mm. Consequently, with the same size instrument and gutta-percha cone, a difference in diameter of 0.07 mm (more than one file size) is possible (see Table 8-2 for gutta-percha cone sizes).

Gutta-percha has been extensively investigated as a root canal filling material in animals and has been proven biocompatible. Compared with sealers used for root canal obturation,

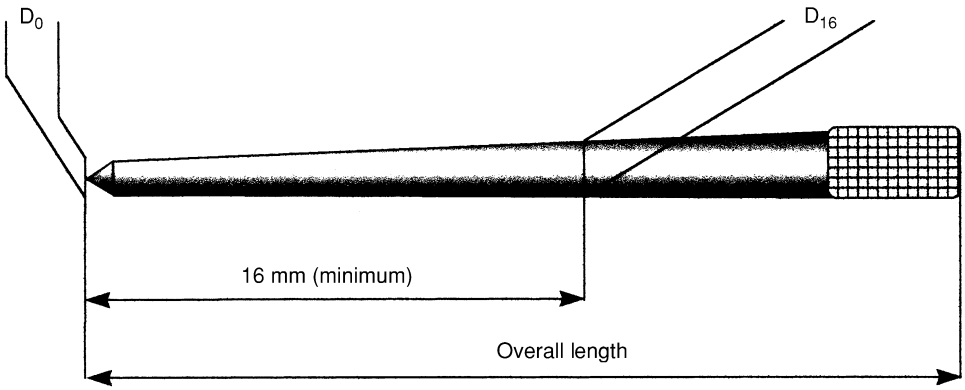

FIG. 8-61 Measurement points for gutta-percha cones as determined by ADA and ANSI standard #78.

it clearly has the lowest tissue toxicity. When compared to Resilon, both materials were equally biocompatible.[38] After subcutaneous implantation, gutta-percha normally becomes surrounded by a defined capsule rich in cells but without a significant number of inflammatory cells, although some macrophages are present.[37,288,362] Results from more sensitive assays in vitro support the in vivo results, suggesting that gutta-percha used for root canal fillings has a low toxicity.[295] Nevertheless, gutta-percha in the form of very small particles induces an intensive foreign body reaction, with massive accumulation of mononucleated and multinucleated macrophages.[362] This is not surprising, since materials that are normally considered inert (e.g., Teflon) cause similar reactions when presented to the tissues as an irregular surface or particle.[50]

Resilon

Resilon (Pentron Clinical Technologies, Wallingford, CT), a thermoplastic, synthetic, polymer-based root canal filling material, was developed in an attempt to create an adhesive bond between the solid-core material and the sealer. It is designed to be used with Epiphany (Pentron Clinical Technologies), a new resin sealer with a bonding capacity to dentin. Resilon can be supplied in the same ISO sizes and shapes (cones and pellets) as gutta-percha. The manufacturer has stated that it can be used with any current root canal obturation technique (lateral compaction, thermoplasticized, carrier, injection). When manufactured in cones, Resilon's flexibility is similar to that of gutta-percha. Based on polyester polymers, Resilon contains bioactive glass and radiopaque fillers (bismuth oxychloride and barium sulfate) with a filler content of approximately 65%. It can be softened with heat or dissolved with solvents such as chloroform. This characteristic allows the use of current retreatment techniques for nonhealing cases. Because it is a resin-based system, it is compatible with current restorative techniques in which cores and posts are placed with resin bonding agents (Figs. 8-62 to 8-64).[348]

Coated Gutta-Percha

Gutta-percha is now available that may achieve bonding between the solid core and a resin sealer. The uniform layer is placed on the gutta-percha cone by the manufacturer. When the material comes in contact with the resin sealer, a resin bond is formed. The manufacturer claims that this will inhibit leakage between the solid core and the sealer. The technique calls for use of EndoRez sealer (Ultradent, South Jordan, UT) with this new solid-core material (Fig. 8-65). The material with a resin sealer was compared with gutta-percha for microleakage. The results indicated a bonding between core and sealer resulting in far less microleakage than gutta-percha.[348] Another study tested the apical sealer of methacrylate-coated gutta-percha, and it caused the least amount of leakage.[445]

Medicated Gutta-Percha

The melding of an antibacterial substance to a gutta-percha cone or other solid-core obturation materials may have utility in preventing root canal therapy failures due to coronal or apical microleakage. In an early study, $Ca(OH)_2$ and CHX combined with zinc oxide and eugenol were found effective against the test organisms studied.[305] It is interesting to note that gutta-percha and Resilon appear to have no antibacterial or antifungal effects in and of themselves. When tested against five common organisms found in necrotic root canal systems, both materials proved not to be effective.

Several studies have attempted to examine gutta-percha cones which were formed with various antibacterial and antifungal preparations. In one study,[42] gutta-percha was impregnated with either CHX or $Ca(OH)_2$ and tested against eight organisms commonly found in infected root canal systems. CHX demonstrated inhibition against all organisms studied, while $Ca(OH)_2$ did not inhibit any of the same organisms. The antimicrobial effect of gutta-percha cones containing a mixture of both CHX and $Ca(OH)_2$ was found superior when compared the antimicrobial effectiveness of either substance when tested separately.[291] Another study testing CHX or $Ca(OH)_2$ with gutta-percha found CHX to be significantly more effective when tested in cultures of gingival fibroblasts.[383] When epithelial tumor cells and gingival fibroblasts were used to test gutta-percha cones containing either CHX or $Ca(OH)_2$, CHX samples showed significantly lower protein synthesis. Both tested materials induced cell growth–specific alterations.[422]

Early studies of medicated gutta-percha examined the use of iodoform in the solid-core material. While inhibitory against some pathogens, it was not inhibitory for all organisms.[351] A later study showed no differences between iodoform and regular gutta-percha samples in delaying microleakage of *E. faecalis*.[59] Gutta-percha discs impregnated with iodoform or other iodine combinations were tested against usual root canal system pathogens. Medicated gutta-percha inhibited all

bacterial growth for 24 hours and was statistically more effective than regular gutta-percha.[35]

When tetracycline impregnation was compared to iodoform-medicated gutta-percha cones and Resilon and tetracycline discs, the impregnated cones inhibited growth for all species tested.[251] Tetracycline integrated with gutta-percha inhibited all test organisms when compared to conventional gutta-percha.[36]

Although effective in the cited studies, medicated gutta-percha cones are not used on a regular basis. More testing must be done to investigate their toxicity, antibacterial and antifungal potentials, and potential for allergic reactions.

Sealers and Cements

Endodontic Sealers

The sealer plays an important role in the root canal filling. It fills all the space the solid-core material is unable to fill because of the solid core's physical limitations. A good sealer adheres strongly to the dentin and the core material. The sealer also must have cohesive strength to hold the obturation material together. Sealers ideally should be antimicrobial, which would be an important role in the success of root canal therapy. Sealers usually are made of a mixture that hardens through a chemical reaction. This reaction normally includes the release of toxic material, which makes the sealer less biocompatible. In general, the sealer is the critical component when the toxicity of material is assessed.

The sealer must have some degree of radiopacity to be visible on adequately exposed radiographs. Additives used to enhance radiopacity are silver, lead, iodine, barium, and bismuth. Compared with gutta-percha cones, most sealers have a slightly lower radiopacity and can be distinguished from gutta-percha alone or in combination with the sealer. A variety of sealers are available, and the clinician must be careful to evaluate all characteristics of a sealer before selecting one (Fig. 8-66, *A-F*).

Zinc Oxide Eugenol Cements

Many endodontic sealers are simply zinc oxide eugenol (ZnOE) cements that have been modified for endodontic use. The mixing vehicle for these materials is mostly eugenol. The powder contains zinc oxide that has been finely sifted to enhance the flow of the cement. The setting time is adjusted to allow for adequate working time. These cements easily lend themselves to the addition of chemicals; paraformaldehyde was sometimes added for antimicrobial and mummifying effects, germicides for antiseptic action, rosin or Canada balsam for greater dentin adhesion, and occasionally corticosteroids for suppression of inflammatory reactions. However, the use of formaldehyde is completely unacceptable, given the possibility of its circulation to other body tissues and organs. Corticosteroids are generally not included in sealers in the United States; it appears that their effect is limited by the amount contained in the preparation.[176]

Zinc oxide is a valuable component of the sealer. It is effective as an antimicrobial agent. The incorporation of rosins containing resin acids in sealers initially may have been for the adhesive properties.[148] Rosins (i.e., colophony), which are derived from a variety of conifers, are composed of approximately 90% resin acid. Resin acids are amphophilic, with the carbon group being lipophilic, affecting the lipids in cell membranes. Thus the resin acids have a strong antimicrobial effect that in mammalian cells is expressed as cytotoxicity. The resin acids work similarly to quaternary ammonium compounds by increasing the cell membrane permeability of affected cells. Although toxic, the combination of zinc oxide and resin acids overall may be beneficial. Under certain conditions, resin acids may react with zinc, forming a resin acid salt (i.e., resinate). This matrix-stabilized zinc resinate is only slightly soluble in water,[249] so ZnOE cements with resin components are less soluble than regular ZnOE cements.

The antimicrobial action of zinc oxide in both gutta-percha cones and many sealers create a low-level but long-lasting antimicrobial effect. In one study, a ZnOE sealer had a statistically significant larger mean zone of inhibition than three $Ca(OH)_2$ sealers.[264] When a new preparation of ZnOE sealer (Fill Canal) was tested, it showed large zones of inhibition against all microorganisms tested.[355]

The setting of ZnOE cements is a chemical process combined with physical embedding of zinc oxide in a matrix of zinc eugenolate. The particle size of the zinc oxide, pH, and the presence of water regulate the setting and other additives

that might be included in special formulas. The formation of eugenolate constitutes hardening of the cement, and $Ca(OH)_2$ accelerates this action, so canal systems containing $Ca(OH)_2$ must be well irrigated before obturation. Free eugenol always remains in the mass and acts as an irritant.

Several of the companies producing ZnOE root canal cements have been replaced by new companies, resulting in new names for older preparations such as Rickerts sealer, Procosol, and Wach's sealer. Fill Canal (Ligas Odontologicas, Sao Paulo, Brazil), Tubli-Seal (SybronEndo), and Pulp Canal Sealer (SybronEndo) are three successors to the original ZnOE cements and have been recently investigated. *E. faecalis* is a highly resistant organism found in necrotic root canal systems. That organism was exposed to two ZnOE sealers, Roth's 811 and Kerr EWT. Roth's exhibited the largest zone of inhibition.[263] Sultan, a ZnOE sealer, was one of the three most potent bacterial-growth inhibitors (*E. faecalis*).[61,304,353] When *Candida albicans* was used as the test organism, a ZnOE preparation demonstrated the largest zone of inhibition.[269] A direct contact test determined that the virulence of endodontic pathogens determine response to sealers.[298]

Historically, formaldehyde was commonly mixed into endodontic sealers, but formaldehyde is a dangerous additive to any sealer; it adds to the already toxic effect of eugenol and prevents or delays healing. Chapters 11 and 27 further discuss why potential major liabilities exist for any dentist who unwisely chooses to use formaldehyde or paraformaldehyde during endodontic therapy.

Chloropercha

Chloropercha was another type of sealer used for many years. It is made by mixing white gutta-percha (i.e., alba) with chloroform. This allowed gutta-percha root filling to fit better in the canal. However, chloropercha has no adhesive properties and is no longer used as an obturation material in root canal therapy. The use of chloroform has been sharply curtailed for many years because of its demonstrated toxicity.[436] In endodontics, the amounts normally used are insignificant and cause no detectable health hazard.[39,60,338] Nevertheless, the clinician must take prudent steps to reduce vaporization during use, because chloroform is highly volatile. When used to soften gutta-percha during revision of old root fillings, the chloroform should be dispensed through a syringe and hypodermic needle and only passively expressed into the area of the pulp chamber. For other uses, the exposure time, amount used, and chloroform surface exposed should be kept to a minimum.

Some chloroform substitutes, such as halothane and turpentine, are in use. Compared to chloroform, halothane is less effective at softening gutta-percha, is similarly hepatotoxic, and has a higher local toxicity (Table 8-4). For these reasons, halothane is not a good substitute. Turpentine is not carcinogenic but is reported to cause allergic reactions.[52,395] It has a high local toxicity and dissolves gutta-percha poorly. Therefore, no good substitute exists for the use of chloroform in endodontic procedures. With careful workplace hygiene, little risk is associated with the occasional use of minute amounts of chloroform in preparing customized master cones or when performing endodontic retreatments, provided no federal or state laws are violated.[21,244]

Calcium Hydroxide Sealers

Several $Ca(OH)_2$-based sealers are now commercially available, such as Sealapex (Sybron Endo), RealSeal (Sybron Endo) Apexit and Apexit Plus (Ivoclar Vivadent). These sealers are promoted as having therapeutic effects because of their $Ca(OH)_2$ content (Box 8-5). The antimicrobial effect of $Ca(OH)_2$ is thought to occur because of its ability to release hydroxyl ions and by having a high pH.[297] Short-term direct contact tests have shown Sealapex and Apexit to be mildly effective antimicrobial agents.

These sealers also have poor cohesive strength.[325] No evidence supports the contention that a $Ca(OH)_2$ sealer provides any advantage for root canal obturations or has any of the desirable biologic effects of $Ca(OH)_2$ paste. In a study of diffusion of hydroxyl ions into surrounding dentin after root filling with Sealapex and Apexit, no traces were found in teeth filled with Apexit. Some hydroxyl ions could be detected in the dentin close to the root filling with Sealapex.[378] In vivo

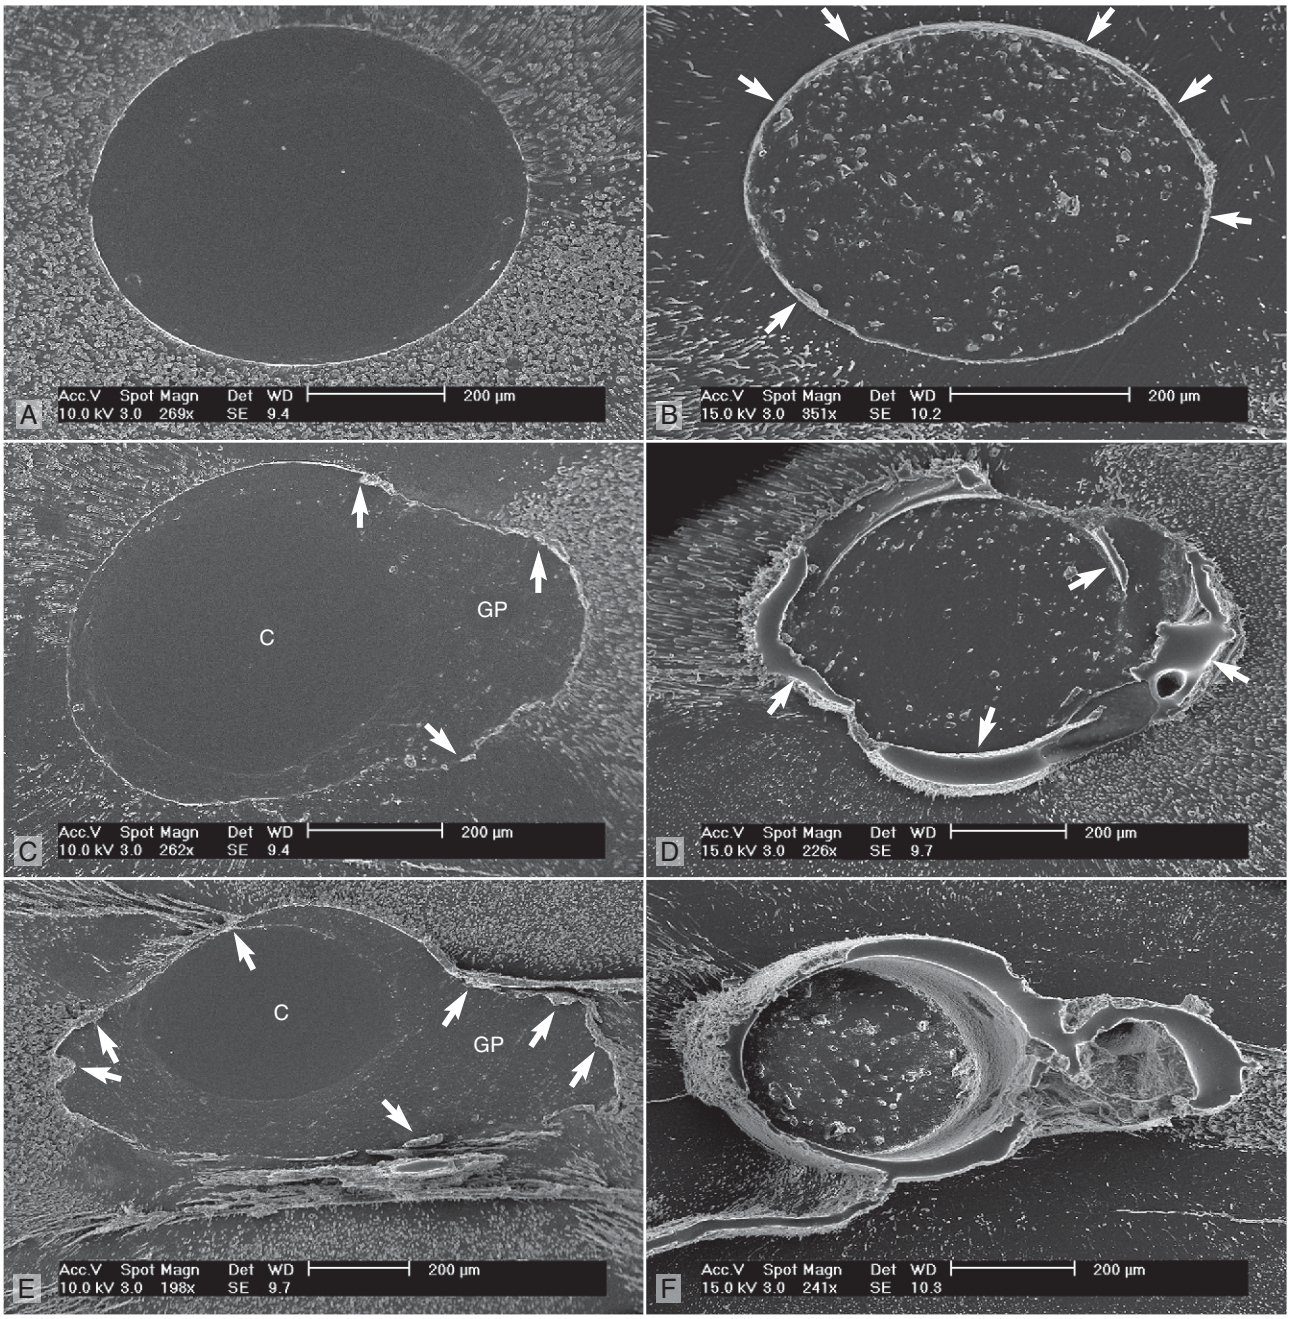

FIG. 8-66 Scanning electron microscope replicas comparing Resilon/Epiphany and Thermafil/AH Plus in variously shaped root canal systems. Impressions of the sectioned canals were taken with an ultraflow viscosity polyvinylsiloxane (PVS), and the replicas were directly examined. They are negative impressions of gaps, with PVS impression material flowing into the gaps. When the impression material was removed, a gap would appear as a flap of PVS material sticking out of the impression. All leaflets of PVS gaps appear blunt and stick out from the regions that represent root-filling material *(arrows)*. Two views of each canal morphology are shown. **A,** Thermafil/AH Plus (×269), round, narrow canal shape. **B,** Resilon/Epiphany (×351), round, narrow canal shape. **C,** Thermafil/AH Plus (×198), wider, irregular canal shape. **D,** Resilon/Epiphany (×241), wider, irregular canal shape. **E,** Thermafil/AH Plus (×198), narrow, ribbon-like (rotary instrument) shape. **F,** Resilon/Epiphany (×241), narrow, ribbon-like, (rotary instrument) shape. *(Courtesy Dr. Franklin Tay, Medical College of Georgia, Augusta, GA.)*

studies of Sealapex and CRCS (Coltene Whaledent, Altstätten, Switzerland) have demonstrated that these sealers easily disintegrate in the tissue, and both cause chronic inflammation.

Many studies have been conducted on various classes of root canal sealers, including $Ca(OH)_2$. The majority of these studies report that *all sealers leak*.[85] $Ca(OH)_2$ appears to be effective in formation of dentin bridges when used as a direct capping material,[4,107] which may indicate its ability to encourage formation of root-end hard tissue. It also appears to demonstrate acceptable antimicrobial activity. Success was seen at the same levels observed for mineral trioxide aggregate.[387]

TABLE 8-4

Toxic Effect of Gutta-Percha Solvents on L929 Cells In Vitro*

Time	Control	Chloroform	Halothane	Turpentine
AIR EVAPORATION				
Fresh Mix	7.2 ± 0.7	94.4 ± 3	102.5 ± 7.5	87.3 ± 2.2
1 day	10.1 ± 0.4	11.3 ± 1.8	12.6 ± 0.9	66.6 ± 5.3
7 days	9.5 ± 0.4	11.6 ± 0.9	14.8 ± 1	12.5 ± 2.8

1 day	10.1 ± 0.4	89.1 ± 6.7	103.9 ± 9	71.8 ± 4.7
7 days	9.5 ± 0.4	11.6 ± 5.8	10.1 ± 2.8	64.2 ± 3.9

*Gutta-percha (2.5 g) was dissolved in chloroform, halothane, or turpentine (5 ml). The cell injury was measured as mean percentage of release of ^{51}Cr (M ± SD) at various times after mixing. The solvents were allowed to evaporate in air or through a liquid layer. The higher the release, the higher the toxicity. (From Barbosa SV, Burkard DH, Spångberg LSW: Cytotoxic effect of gutta-percha solvents. *J Endod* 20:6, 1994.)

BOX 8-5

Composition of Calcium Hydroxide Sealers: Sealapex, CRCS, and Apexit*

Sealapex

Base
- Calcium hydroxide (25%)
- Zinc oxide (6.5%)

Catalyst
- Barium sulfate (18.6%)
- Titanium dioxide (5.1%)
- Zinc stearate (1%)

CRCS

Powder
- Calcium hydroxide
- Zinc oxide
- Bismuth dioxide
- Barium sulfate

Liquid
- Eugenol
- Eucalyptol

Apexit

Base
- Calcium hydroxide (31.9%)
- Zinc oxide (5.5%)
- Calcium oxide (5.6%)
- Silicon dioxide (8.1%)
- Zinc stearate (2.3%)
- Hydrogenized colophony (31.5%)
- Tricalcium phosphate (4.1%)
- Polydimethylsiloxane (2.5%)

Activator
- Trimethyl hexanedioldiasalicylate (25%)
- Bismuth carbonate basic (18.2%)
- Bismuth oxide (18.2%)
- Silicon dioxide (15%)
- 1,3-Butanedioldisalicylate (11.4%)
- Hydrogenized colophony (5.4%)
- Tricalcium phosphate (5%)
- Zinc stearate (1.4%)

*Proportions are unavailable for CRCS and incomplete for Sealapex.

Despite the favorable responses seen in the cited study, the results must be considered ambivalent and variable. Adhesion of the sealer to the prepared dentin wall and the solid-core obturation material also is a consideration. There is no creditable information that states that $Ca(OH)_2$ sealers in and of themselves provide adhesive forces. One study does state that use of an erbium-doped yttrium aluminum garnet (Er:YAG) laser does increase the adhesiveness of $Ca(OH)_2$ sealers.[27]

Polymers

Polymers are macromolecules composed of 10,000 or more atoms. Rubber has a polymeric structure based on a repeating isoprene (monomer). Polymeric molecules, discovered in nature (rubber), have led to synthetic analogs with a variety of properties and applications, such as adhesives (root canal sealers). While it is more convenient to discuss polymer sealers according to their classification or type, it may be more meaningful to describe them according to their ability to act in a particular manner based on what or how each group of sealers' characteristics are when used, such as their adhesiveness, sealing ability, and similar properties.

When considering the adhesiveness of a sealer, it must have the ability to adhere to both the prepared dentin wall and the solid-core obturation material used. As such, adhesiveness becomes very important in the material's ability to seal the prepared root canal system from coronally and apically, since the preparation procedures appear unable to sterilize the root canal space and at most may only disinfect the system.

Other significant sealer considerations include their biocompatibility, radiopacity, cytotoxicity, and bond strength.

Most of the newer sealers are polymers, including AH26 and AH Plus (DENTSPLY Caulk), Epiphany (Pentron Clinical Technologies), and EndoRez (Ultradent).

AH26

AH26 is an epoxy resin that was initially developed as a single obturation material. Because of its positive handling characteristics, it has been extensively used as a sealer. It has a good flow, seals well to dentin walls, and has sufficient working time.[224] Like most sealers, AH26 is very toxic when freshly prepared.[295] Earlier research indicated that AH26 toxicity was limited and principally caused by release of small traces of formaldehyde.[34,176] However, recent studies using more modern methods of analysis indicate that the sealer's mechanism for induced cytotoxicity may be due to activation of COX-2 in RNA gene expression,[175] leading to decreases in iNOS protein expression,[215] and the synergistic effects of root canal sealers on LPS induces COX-2 expression by macrophage cells.[214] Toxicity may decline rapidly during setting, and after 24 hours the cement may have one of the lowest toxicities of endodontic sealers.[187] A new formulation of AH26 is AH Plus. This is a two-paste mixing system that assures a better mixture and does not release formaldehyde upon setting.[63,218] It is more radiopaque and has a shorter setting time (approximately 8 hours), lower solubility, and a better flow compared with AH26. One study demonstrated that AH Plus had a lower short- and long-

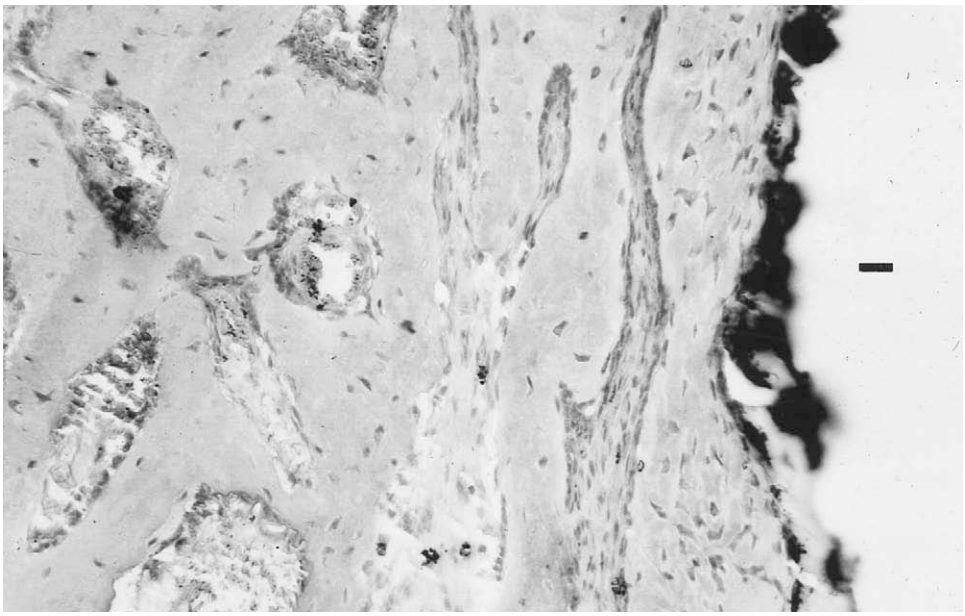

FIG. 8-67 AH26 implant in the mandible of a guinea pig 12 weeks after implantation. Bone has grown up and integrated with the implant. Remnants of the implant, which was lost during histologic preparation, can be seen as a black area at the top of the image. Complete healing was observed without signs of inflammation.

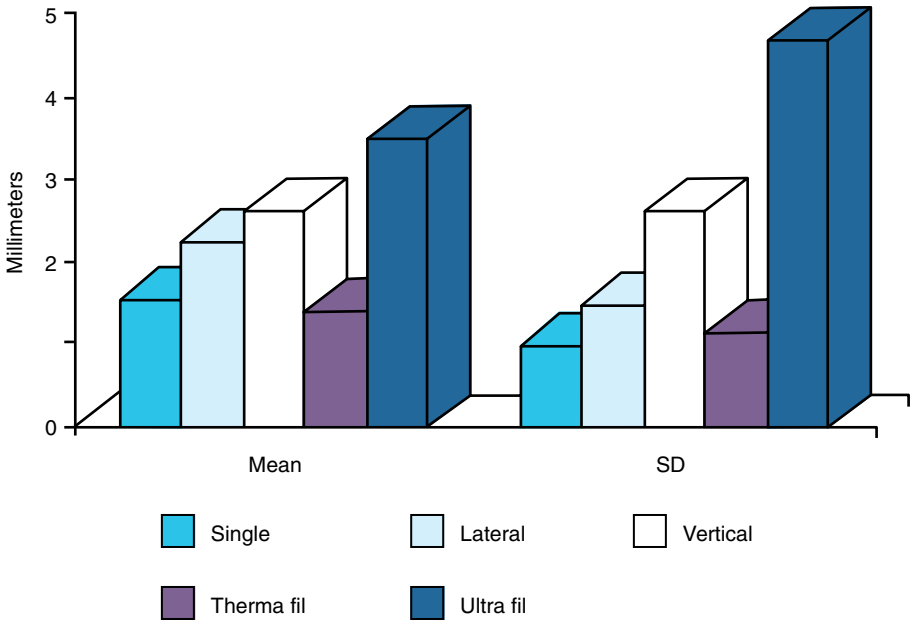

FIG. 8-68 Comparison of dye penetration after various obturation methods using AH26 sealer. The dye was delivered with a vacuum method, and penetration was measured as millimeters of leakage. The single cone technique and use of ThermaFil resulted in the least leakage, followed by lateral compaction, vertical compaction, and use of UltraFil. The standard deviation is high, as is common for leakage studies, reflecting the variability in the obturation method. The less complicated the obturation method, the lower the standard deviation.[69]

term toxicity level and was less genotoxic than AH26 (Figs. 8-67 and 8-68).[16,222]

Epiphany

Epiphany is a dual curable dental resin composite sealer composed of BisGMA, ethoxylated BisGMA, UDMA, and hydrophilic difunctional methacrylates with fillers of $Ca(OH)_2$, barium sulfate, barium glass, and silica. The total filler content of the sealer is approximately 70% by weight. Biocompatibility has been demonstrated both in vitro and in vivo, resulting in approval by the U.S. Food and Drug Administration. Epiphany was designed for use with Resilon instead of gutta-percha, although it can also be used with either core material. Unlike other resin sealers, this system's sealer requires a self-etch primer before placement of the resin sealer.[348] The newest iteration of the sealer utilizes a self-etching injectable paste that bonds to the prepared dentin walls and the solid-core material. Although not without controversy, used with Resilon cones, the subsequent obturated canal system may be fracture resistant.[182,423]

EndoRez

EndoRez is a UDMA resin-based root canal sealer with hydrophilic properties that allow good penetration into dentinal tubules. In addition to its biocompatibility,[442,445] it offers good radiopacity. EndoRez is as radiopaque as gutta-percha, which simplifies radiographic interpretation (Fig. 8-69).[444] The system includes a sealer, solid cores (resin-coated gutta-percha) and an accelerator and does not rely on heat to soften the material or pluggers to exert pressure to move the core apically. Much like Resilon/Epiphany, the bonding to both the dentin and solid core is thought to make the completed obturation resistant to fracture.[160]

Glass Ionomer Cement

Glass ionomer cements have been introduced as endodontic sealers (Ketac-Endo [ESOE]) and are known to cause little tissue irration,[443] with low toxicity in vitro. Questions remain about the quality of the seal achieved with Ketac-Endo, because dentin and sealer adhesive failures have been observed.[77] Some investigators have expressed concern about glass ionomers' solubility compared with other sealers.[331]

Silicon-Base Sealer

RoekoSeal (Roeko, Langenau, Germany) is a polydimethylsiloxane-based root canal sealer. One in vitro study comparing it with eugenol-based Sealapex or $Ca(OH)_2$-based Kerr's Pulp Canal Sealer concluded that RoekoSeal was less cytotoxic.[8] It has adequate solubility properties.[331] When its resistance to coronal and apical leakage was compared with that of AH26, no significant difference was observed.[61] With both sealers, removal of the smear layer improved the coronal and apical seal. Roeko recently introduced another version of its silicone sealer, GuttaFlow. It comes in a unidose capsule and is injected after mixing. The silicone is mixed with gutta-percha powder to form what the company calls a "two-in-one" cold filling system. GuttaFlow and RoekoSeal have recently been examined for spreadability on dentin and gutta-percha surfaces and compared to Roth 801 and AH26 sealers. Use of a sufficient load during lateral compaction is necessary for RoekoSeal and GuttaFlow to satisfactorily wet gutta-percha and dentin.[200] Microleakage and sealing ability also have been tested. When RoekoSeal and GuttaFlow were compared to other sealers, leakage patterns were found to be similar to other sealers.[75] GuttaFlow showed similar leakage results when used with lateral compaction or System B techniques, but it demonstrated expanding capacity over time compared to compacted gutta-percha and AH26 over a 12-month period.[200] When GuttaFlow was compared to two single-cone obturation systems, it was found that the apical seal was as effective as AH Plus used with vertical compaction.[274] However, in a dual-chamber leakage model with *Streptococcus mutans* as a biologic marker, thermoplasticized gutta-percha with AH Plus using vertical compaction was more effective in minimizing bacterial leakage.[273] Evaluating the long-term sealing ability of GuttaFlow compared to Epiphany, PCS, and AH Plus, GuttaFlow and Epiphany allowed less fluid movement.[41]

Sealers Containing Formaldehyde

A large group of endodontic sealers and cements had substantial paraformaldehyde additives. Some of the more common brands were Endomethasone, Riebler's paste (Amubarut; Wera Karl, Biensingen, Germany), and N2 (Indrag-Agsa, Bologne,

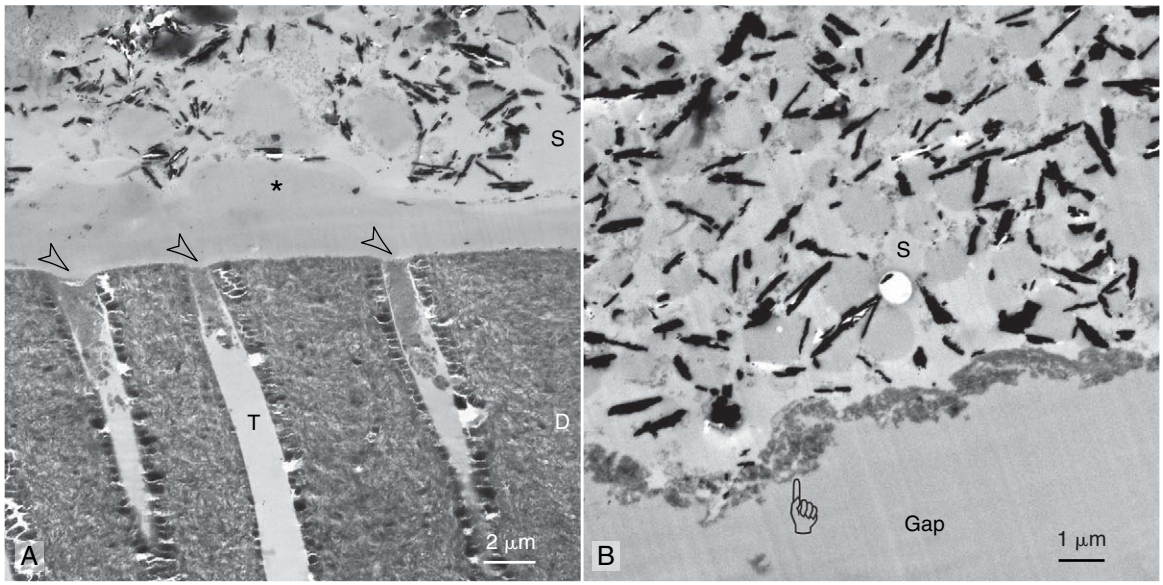

FIG. 8-69 Transmission electron microscope image illustrates the application of EndoRez sealer to smear layer–covered dentin (created by Profile nickel-titanium instruments) following use of 6.15% NaOCl initial rinse and sterile distilled water as final rinse. (Manufacturer recommends use of EDTA as final rinse.) **A,** A gap (asterisk) seen between the sealer (S) and radicular dentin (D). Smear plugs *(open arrowheads)* retained along orifices of dentin tubules (T). The smear layer was originally loosely attached to the canal wall dentin surface. EndoRez was applied to canal walls after NaOCl and distilled water irrigation, the resin portion of EndoRez (fillers) did not penetrate the loosely arranged smear layer particles. **B,** During polymerization of EndoRez, shrinkage stresses pulled the smear layer *(pointer)* away from the dentin, resulting in the smear layer being attached to sealer (S). Italy). All of these sealers have essentially the same toxicity. N2 is also known as *RC-2B* or the *Sargenti technique*. Historically, it has been heavily commercialized. There are no creditable studies available as to establish this material's use clinically. (Chapter 11 presents a more comprehensive discussion.) There are no clinical conditions to justify the use of these pastes.

N2 is basically a ZnOE sealer. Its composition has varied extensively over the years. The significant amount of lead oxide and smaller amount of organic mercury that were formerly major toxic components are often missing in more recent formulations. However, N2 still contains unacceptable amounts of formaldehyde.[44] Because it contains 6% to 8% paraformaldehyde (and sometimes hydrocortisone and prednisolone), it loses substantial volume when exposed to fluid. It also absorbs more than 2% of fluid during the first week in situ.

N2 is extremely toxic in experiments in vitro and in animal experiments. The tissue reaction normally observed is a coagulation necrosis within a very short time. The coagulated tissue is altered to such an extent that it cannot undergo any repair for months because it is impregnated with formaldehyde. With time, the formaldehyde may be washed out of the necrotic tissue, allowing either bacteria to be established in the necrosis or, if the blood supply is adequate, repair to take place.

The Interstate Commerce Commission of the U.S. Government has banned the transport of N2 across state lines, effectively halting the sale of these types of sealers. Please read Chapters 11 and 27 to gain a fuller understanding of the legal consequences of using these unacceptable pastes in unwary patients.

Standards and Properties

Physical Properties

Endodontic sealers are listed under ANSI/ADA specification number 57, Endodontic Sealing Material 2000 (reaffirmed 2006). This specification is for material used in endodontics within the tooth to seal the root canal space. This specification in an adoption of ISO6876:2001. ANSI/ADA Standard 57 outlines various test methods for evaluation of the physical properties of endodontic sealer-filling materials. Sealers are classified into two categories, depending on the intended use: type I materials are intended to be used with core materials; type II materials are intended for use with or without core material or sealer. Type I materials are divided into three classes. Class 1 includes materials in the form of powder and liquid that set through a nonpolymerizing process; class 2 includes materials in the form of two pastes that set through a nonpolymerizing process; class 3 includes polymer and resin systems that set through polymerization. The subclasses for type II materials are the same as for type 1 materials, except that metal amalgams are also included. ANSI/ADA No. 57 describes testing methods for working time, setting time, flow, film thickness, solubility, and disintegration; it also establishes a specific requirement for radiodensity. The tests for endodontic core materials include determinations of the material's dimensions, brittleness, and flow. A separate ANSI/ADA standard (No. 78) examines prefabricated metallic or polymeric-based cones used in obturation procedures. Despite the standard's often detailed requirements, significant disagreement exists on the ideal properties of endodontic sealers and fillers, so most of these expectations are guidelines that have not significantly affected the industry.

Biologic Properties

ANSI/ADA No. 41 recommends protocols for biologic evaluation of dental materials. This document covers recommended standard practices for biologic evaluation of the safety of materials used in dentistry and is not intended for use in the evaluation of pharmacologically active medicaments. This document outlines recommended test protocols for various dental materials, including certain guidelines for endodontic filling materials. These methods include general toxicity assessments (LD_{50}), cytotoxicity assessments in vitro, sensitization assays, mutagenicity assays, implantation tests, and usage tests. It was last updated in 2006. Several test methods are presented for each of these factors, depending on the type of material.

Root canal filling materials generally are toxic, and none fulfills the expectations set forth in ANSI/ADA No. 41. However, the methods described in this specification can be used to distinguish more toxic materials. Less toxic materials produce a less intense or shorter chemical insult to the remaining apical pulp or apical periodontium. If the wound area is free of bacteria when the initial chemical necrosis occurs, as results from sealers containing paraformaldehyde, tissue repair should occur as the initial irritant declines in intensity. Some tissue irritation may occur as a result of phagocytosis of particles of the material, but an expanding lesion would not develop.[362]

Endodontic sealers other than those that contain paraformaldehyde should not be implicated as the cause of a periradicular bone lesion. If the tissue in the apical root area is not sterile due to infection within the root canal system, presence of sealer should not cause a chemically induced periradicular necrosis. Thus, materials that cause extensive tissue necrosis inside the root canal may become vehicles for the development of failure of endodontic treatment. This supports the idea that treatment should focus on the proper application of asepsis and antisepsis, and that materials that are as biocompatible as possible should be used.

Sealers and cements are the very toxic component of gutta-percha root filling techniques. Therefore, the clinician must take great care in selecting materials and must have an understanding of what each material contributes to a disease process. ZnOE cements have a significant drawback in their release of free eugenol and loss of volume during the hydrolysis that takes place after setting. This is somewhat mitigated by its change into a relatively inert eugenolate substance within 24 to 48 hours. Several of the polymer materials have high toxicity during the polymerization phase but may become practically inert when polymerized. Sealers with inclusions of dissolvable components, such as $Ca(OH)_2$, lose these components in the tissue, resulting in compromise of the integrity of the obturation.

DELIVERY SYSTEMS FOR ROOT CANAL OBTURATION MATERIALS

The search for a more simplified and proficient obturation technique has led to the development of many new hybrid materials. Differences focus on alternative systems for introducing the solid-core material into the root canal system while

maintaining length control. The newer methods currently in use vary considerably. Most hybrid obturation methods require modification of the outline of the root canal preparation. One hybrid preparation technique involves the use of a rotating instrument that spins in the opposite direction of normal rotations and feeds the obturation material into the canal system instead of moving it out of the system. For optimal results, the clinician must consider technique variations before attempting a hybrid obturation method. A comparison of the more commonly practiced obturation methods, using an objective and sensitive vacuum dye penetration method, failed to show any major difference in the quality of the obturation.[69] However, dye penetration techniques have come into question in recent years. Other evaluation methods, such as dye extraction and fluid filtration techniques, seem to produce more consistent and credible data.[51]

The introduction of new materials, techniques, and delivery systems is challenging basic beliefs and concepts previously thought to be standard. For example, use of a single cone of gutta-percha with sealer historically has been considered unacceptable. However, with the introduction of new technology for cleaning and shaping and the development of innovative sealer delivery systems, a paradigm shift may be occurring toward improved canal preparation to receive more flowable sealers and a single insertion of a core material. To validate the long-term success of any of the obturation techniques, clinical studies to support evidence-based practice must be one of the goals of endodontic research.

Carrier-Based Systems

ThermaFil, ThermaFil Plus, ProTaper, and GT Obturators (DENTSPLY Tulsa Dental, Tulsa, OK) are obturation systems in which alpha-phase gutta-percha is preapplied to a flexible solid central carrier (Fig. 8-70). The gutta-percha obturator is heated in a proprietary heater (ThermaPrep Plus Oven, DENTSPLY Tulsa Dental) (Fig. 8-71) to the appropriate softness, and after the placement of canal sealer, the obturator is placed into the canal. These devices are available with a plastic, stainless steel, or titanium carrier core. In one study, ThermaFil demonstrated a greater percentage of canal obturation than either System B compaction or lateral compaction.[76] If necessary, the plastic core material can be softened with chloroform or heated using a System B[428] for easy removal. These obturators offer an alternative method of obturation with gutta-percha.

SimpliFill (Discus, Culver City, CA) (Fig. 8-72) is an obturation system designed to be used with the LightSpeed instrumentation system. The technique is based on a presized plug (5 mm long) of gutta-percha or Resilon which is attached to the end of a metal carrier. After sealer has been placed, the appropriate size SimpliFill is placed to working length, and the carrier is removed, leaving the apical segment obturated and the coronal segment open. Sealer is then injected with a syringe into the coronal segment, and a single cone (gutta-percha or Resilon) or post is inserted. In a study of coronal microbial leakage, an apical plug of SimpliFill in combination with FiberFill (Pentron Clinical Technologies, Wallingford, CT) in the coronal segment of canals was found to have significantly less leakage than lateral, vertical, and Obtura III (SybronEndo, Orange, CA) compaction techniques.[348] A later study found that SimpliFill samples demonstrated the most complete coverage in both coronal and apical sections when compared to

FIG. 8-70 ThermaFill obturators. Currently, obturators are provided to fit many of the individual types of files used in the canal. vertical compaction, Obtura III, System B and ThermaFil Plus.[177]

Injection Techniques

Several techniques have been described for introducing gutta-percha into the root canal system after the gutta-percha has been plasticized with heat. The Obtura system (Fig. 8-73) is currently the most commonly used injection delivery system for gutta-percha.[385] It dispenses a heavy form of gutta-percha heated to a high temperature. Although the temperature of the gutta-percha in the Obtura III injection gun is as high as 302° F to 338° F (150° C to 170° C), the temperature of the extruded material may range from 140° F (60° C) to 280° F (138° C).[89] When the Obtura III was compared to the System B heat source using different heat points, neither exceeded an increase of 10° C at any root level monitored.[382] Intracanal temperatures after delivery, measured with intracanal thermocouples, have ranged from 107.6° F to 192.2° F (42° C to 89° C). Periodontal injuries have been reported after excessive heat during endodontic treatment of teeth in the ferret and the dog.[329] Recent studies testing the Obtura III found a 10° C increase in the mandibular anterior teeth in vitro,[229] less temperature rise than when a gutta-percha carrier was combined with an injectable gutta-percha.[230] Shrinkage of gutta-percha in these injectable gutta-percha systems does not appear to be different from the shrinkage of normally heated gutta-percha. When plasticized by heat, gutta-percha has a volume loss of approximately 2% after cooling.[145]

Rotary Techniques

Frictional heat also can be used to soften gutta-percha. This was first suggested with the introduction of the McSpadden Compactor device (DENTSPLY Maillefer). This technique has undergone many variations, with the development of several compaction instruments. The heat generated may exceed safe levels compared to other heat compaction techniques.[329] One such device, Quickfil (J.S. Dental, Ridgefield, CT), has the ability to obturate root canals comparable to lateral compaction.[62] Volumetric changes in the gutta-percha after friction heat compaction are similar to other types of gutta-percha compactions using heat. The major observed problem was the inability of the heated gutta-percha to fill the entire canal system due to the presence of sealer in the apical third of the preparation. Rotary techniques, although still used by practitioners, have become less popular in many instances with the introduction of the new solid-core resin polymer sealers.

Heating Systems

Although not injectable systems, Touch 'n Heat and System B (SybronEndo, Orange, CA), are involved with the placement and removal of gutta-percha from root canal systems using heat. Touch 'n Heat delivers a heated, pointed probe into a mass of gutta-percha, removing the material in small increments and down packing with pluggers after each removal. The gutta-percha is warmed approximately 5 mm ahead of the heating probe, and at a distance of 5 mm from the measured end of the master cone, a final down packing is made to move the remaining mass to the apex. The System B device is an outgrowth of the Touch 'n Heat and attempts to remove the greater bulk of gutta-percha to within 5 mm of the apex in one heated mass. These techniques are often combined with an injectable technique of obturation.

TEMPORARY RESTORATIONS

If endodontic therapy cannot be completed in one visit, the pulp space must be closed with a temporary restoration. The same is true whenever a root canal procedure is completed. This restoration must provide a satisfactory seal to prevent bacteria and fluids in the oral cavity from contaminating the pulp space. The restoration must have enough structural strength to withstand the masticatory forces and retain the occlusal seal. A literature search identified 28 materials that have been tested between 2000 and 2009 (Box 8-6). The most common such materials are IRM (DENTSPLY Caulk), TERM (DENTSPLY Caulk), Cavit (3M ESPE St. Paul, MN.) and Coltosol (Coltene Whaledent). IRM is a reinforced zinc oxide cement available as a powder-liquid mix in single-dose mixing capsules. Cavit is a premixed material composed of zinc oxide, calcium sulfate, glycol, and polyvinyl acetate, polyvinyl chloride, and triethanolamine. It sets upon contact with water. TERM is a filled composite resin that is light activated. When Cavit, IRM, TERM and Fermit (Ivoclar Vivadent, Schaan, Lichtenstein) (the latter two being light-cured preparations) were compared over a 21-day period, Cavit was found to be more resistant to leakage at 7 days.[19,88] Coltosol and IRM were tested against two resins, and results showed they sealed statistically better than the resins. Coltosol is a non-eugenol preparation delivered by syringe.[435] In another study,[442] coronal microleakage was evaluated after thermocycling, comparing Cavit, IRM, and a polycarboxylate cement (Ultratemp Firm).

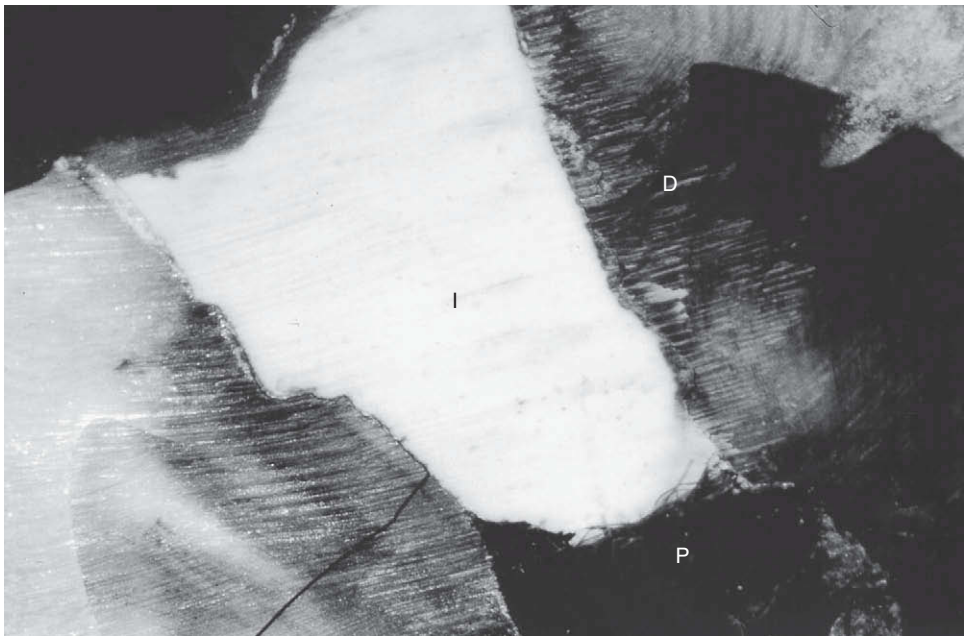

FIG. 8-74 Temporary filling of IRM (white I). The dye has penetrated the margins and dyed the content of the pulp chamber (P). The dentin (D) has been stained by the dye penetrating the margins.

Zinc phosphate cement
Z100 (Composite resin)

There was no statistically significant marginal microleakage between the three; IRM also absorbed the dye into the bulk of the material. IRM has extensive marginal leakage of fluid, whereas Cavit seems to absorb fluid into the entire body of the restoration.[18,209] These findings are surprising; however, because of its eugenol content, IRM may provide a bacterial barrier but allow leakage of other liquid substances (Figs. 8-74 and 8-75). Therefore, if Cavit or other types of relatively soft temporary cements are used, they must be placed at a thickness of at least 4 to 5 mm.[419] If a more robust temporary restoration is required for longer than 1 week, the soft cement must be covered with a harder cement such as IRM, glass ionomer cement, or resin.

The temporary coronal seal of endodontically treated teeth will not prevent coronal leakage if left for long time periods.[19] The interval between sealing the canal system and placing the core buildup is possibly more important than the material used. In a Colleagues for Excellence newsletter, the American Association of Endodontists stated that "restoration … should commence as soon as possible after RCT."[65] Whenever possible, the bonded core buildup should be placed at the obturation appointment.

LASERS

Lasers are among the alternative methods used in endodontic treatment. Various laser wavelengths have properties that may be useful when applied to access cavity preparation, cleaning and shaping of root canal systems, and three-dimensional obturation procedures. The use of lasers for endodontics is becoming more predictable with the development of different wavelengths and radially emitting probes. One of the greatest strengths in using laser irradiation is its ability to cause a change in the hard tissue of the root canal space dentin. The change occurs in the morphology and physical aspects of dentin by melting and resolidifying dentin in a manner that closes the orifices of the dentinal tubules, which may harbor microorganisms and other organic pulpal remnants. However, this strength also turns out to be laser irradiation's greatest weakness. This occurs because of the dentin's location, con-

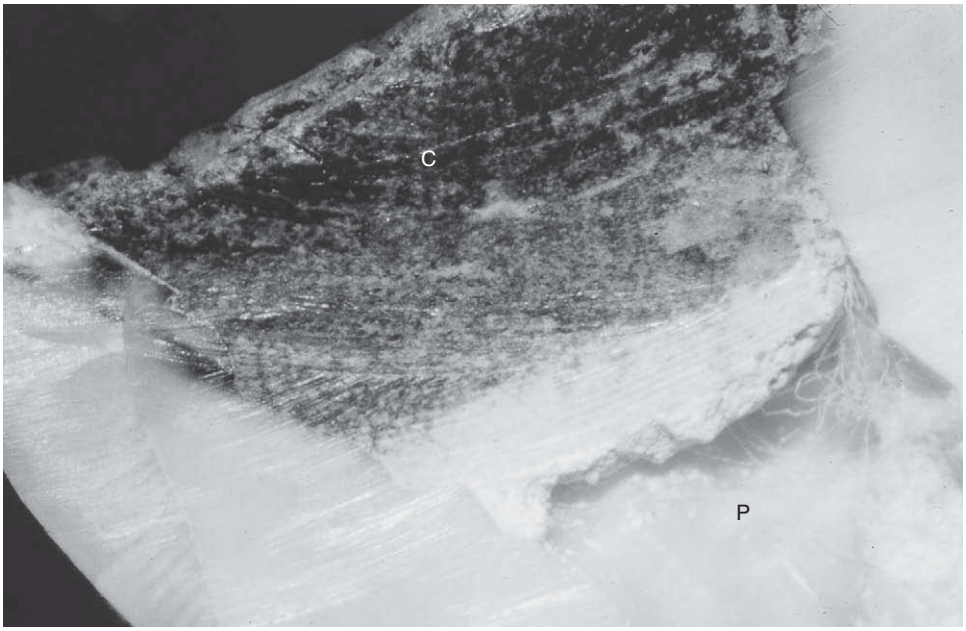

FIG. 8-75 Temporary filling with Cavit. Dye has been absorbed into the body of the restoration *(C)* but has not penetrated to the pulp chamber *(P)*, which is filled with white cotton. The inner part of the Cavit is unstained.

fined to a space that is curved and cylindrical that cannot be viewed in a manner where the changes can be identified or visualized, such as can occur in cavity preparation procedures. A further weakness is the amount of energy needed to effect change of internal morphology. Intertubular dentin surfaces are in the shape of calcospherites rather than the relatively flat surfaces seen in extratubular coronal dentin, which can be easily visualized and affected by the laser. The amount of energy required for intertubular procedures generates increased temperatures that may cause harm to the attachment apparatus (cementum, periodontal ligament, and alveolar bone).

Dental lasers currently in use operate in several areas of the electromagnetic spectrum, including the infrared, visible, and ultraviolet ranges.[374,375] Each laser wavelength in a particular range allows the device to target various tissues and carry out different procedures. Carbon dioxide (CO_2) is highly absorbed by tissues with high water content, and neodymium-doped yttrium aluminum garnet (Nd:YAG) can be absorbed by vascular tissues, having greater effect on gingiva and dental pulp tissue, respectively.

Early attempts using lasers to carry out cleaning and shaping functions were less than successful. The Nd:YAG laser used a contact probe that simulated a hand instrument, but it was composed of a fused silica (glass); it could not be precurved and could not be seen radiographically if it separated within the root canal system. In addition, the probe emitted energy at its end rather than radially over a 360-degree range. The result was a preparation that was neither fully clean nor shaped. Other lasers used noncontact probes that emitted the laser beams through a system of mirrors in an articulated arm (wave guide with CO_2). Their lack of contact with the dentin walls of the root canal system precluded a sense of touch available to the operator.[194,248]

Neodymium-Doped Yttrium Aluminum Garnet Lasers

Several laser systems are now available that appear to be useful in root canal system preparation. Necessary to the success of these procedures is an understanding of the effects of irradiation on the morphology of the inner dentin walls. Nd:YAG lasers have been extensively studied in the past several years. A study showed that at increased power, the system produced globular formations and melting and glazing typical of earlier studies with this wavelength.[326] The same group found that root canal systems treated with NaOCl and EDTA with Nd:YAG irradiation demonstrated partial obliteration of dentin tubules and removal of smear layer.[106] When an Nd:YAG laser was compared to a diode laser, scanning electron microscope (SEM) images showed fusion and resolidification of the dentin surface, more evident with the Nd:YAG group, but the diode group had more uniform changes.[79] The erbium/chromium-doped yttrium scandium gallium garnet (Er,Cr:YSGG) laser has also been extensively studied over the past several years since its inception, but to date, the studies have not demonstrated the same results seen with older laser systems. Improvement in the use of these systems will lead to a device that accomplishes all the requirements of a well-cleaned and shaped system and aid in three-dimensional obturation.[294]

More recent investigations have indicated that lasers are effective when used in infected root canal systems. When patients were treated using a step-back technique, half the teeth were treated with the Nd:YAG laser using NaOCl and H_2O_2 irrigants. Tenderness to percussion was less at 1 week and 3 months in the laser-treated groups compared to controls.[196]

Removal of filling materials and broken files in retreatment cases is often difficult but effective if temperatures are con-

trolled.[434] A recent study compared the removal of gutta-percha using two solvents with an Nd:YAG system, which raised root surface temperatures 4° C.[407] Laser energy alone was found to be effective, whereas solvents did not appreciably improve removal.

Dentin exposed to the Nd:YAG laser was evaluated using five different irrigation solutions. The surfaces of the teeth were examined using a SEM, while dispersive x-ray fluorescence spectrometry assessed mineral content. Calcium levels and calcium/phosphorus ratios decreased significantly with NaOCl solutions, suggesting changes at the molecular level. Surface examination showed that the lowest scores for root cleaning occurred with the use of EDTA and the Nd:YAG laser.[154] The use of the Nd:YAG laser has been suggested as a more efficient way of handling this procedure. A study using the Nd:YAG laser using a flexible quartz fiber probe which is able to be concentrated in a specific area was used to remove gutta-percha and Sealapex or AH26 and was compared to use of Gates-Glidden drills and K-files. Results showed that the use of laser ablation was significantly shorter than conventional methods.[11]

Erbium-Doped Yttrium Aluminum Garnet Lasers

Together with removal of obturation materials, lasers have been used in attempts to alter the dentin surfaces of root canal systems to create greater sealer adhesion. Single-rooted teeth were tested using an Nd:YAG laser. Black ink was used in one test group as an initiator, with two groups lased without ink. Controls were not exposed to laser energy. Results demonstrated leakage in all groups at both coronal and apical test areas.[82] Using an Er:YAG laser, extracted teeth were tested to determine whether increased adhesion occurred between ZnOE and resin sealers. The resin-based sealer (Sealer 26) adhered better to dentin prepared with and without laser exposure than ZnOE-based sealers.[367] Increasing the frequency and use of EDTA increased adhesion when a resin sealer was used with either an Nd:YAG laser or Er:YAG laser.[368] When a 980-nm diode laser was tested, bond strength again increased for the resin sealer (AH26) but did not affect adhesion of Epiphany sealer.[9]

When India ink was used to absorb energy to cause an effect, the Nd:YAG laser was found to remove smear layer and reduce apical leakage in extracted, obturated human teeth.[144] Others found the same results, showing that this laser wavelength was useful for reducing apical leakage in obturated root canal systems.[55,236] The Nd:YAG laser was also used to seal the dentin surface after apicoectomy ex vivo.[143,376,377]

The use of laser energy in endodontics receiving the most attention relates to cleaning and shaping (instrumentation) and laser-assisted endodontic procedures involving the use of laser irradiation within the confines of the root canal system. As noted earlier, this may cause increased temperatures extending to the outer root surface of the tooth and lead to damage to the attachment apparatus. An Er,Cr:YSGG laser used to instrument the root canal system walls for 7 seconds found average rises of temperature on the outer root surfaces were less than 8° C. An 810-nm diode laser recorded temperatures at less than 7° C when energy input was alternated with periods of no energy input. A 910-nm diode laser recorded differing temperatures depending on what area of the root canal system was being affected. Highest temperatures were found in the apical third but were judged not to be in the range harmful to the attachment apparatus. An 810-nm diode laser was able to melt dentin, which resolidified and closed tubular orifices. Temperature rise was reported to be in the range of 1.6° C to 8.6° C, below those temperatures that would adversely affect the PDL.[74]

The permeability of root dentin is an important consideration in endodontic therapy, and the laser has been suggested as a means of removing smear layer and melting and solidifying the walls of the preparation. Comparison of the Nd:YAG device to an Er:YAG laser showed that the former had lessened radicular dentin permeability with various irrigation regimens.[45] An in vitro study using extracted teeth that were inoculated with *E. coli* and *E. faecalis* found that Nd:YAG, Ho:YAG (holmium-doped yttrium aluminum garnet), and Er:YAG lasers eliminated 99% of the organisms without causing unfavorable temperature increases at the settings used.[110]

Temperature rise is an important consideration in the use of any laser energy. One study used 20 extracted human teeth and an Er:YAG laser at two irradiation intensities with water spray.[193] A temperature increase of less than 6° C was recorded at the apical third and less than 4° C in the midportion of the root, suggesting that the thermal effect on periodontal tissues may be minimal.

Although no widespread agreement exists on the need to remove the smear layer in root canal preparations, the Er:YAG laser has proved effective at accomplishing this task. An Er:YAG laser was compared with a CO_2 laser for ability to remove the smear layer.[384] A comparison was also made with NaOCl, H_2O_2, and EDTA irrigation regimens. The Er:YAG laser was found to be the most effective of these methods at removing the smear layer. A more recent study, using radially emitting probes with Er:YAG and Er,Cr:YSGG lasers, increased the action of EDTA in removing thick, artificially created smear layers.[131] An associated study found that the use of a radial-firing tip and Er,Cr:YSGG laser was a suitable tool for the elimination of microorganisms and removal of smear layer from root canal systems. A study in modification of root canal dentin found that by varying the electromagnetic wavelength, Er:YAG energy induced different modifications to the root canal surface, which may have some utility in preparation procedures.[91]

Sterilization of root canal systems has continued to be an aim of successful endodontic therapy. Chemical and other liquid medicaments have been utilized alone or in combination in an attempt to sterilize these systems, with no lasting effect. The idea of removing smear layer appears to be necessary in sterilization, and lasers have been suggested for that use and altering the intracanal dentin through melting and resolidification, causing closure of dentinal tubule orifices. An Er:YAG laser was used in posterior dogs' teeth that were necrotic with chronic periradicular lesions. Group 1 was treated by biochemical preparation, and group 2 was also bioprepared but with laser irradiation. Teeth were sampled for anaerobes, aerobes, and total colony-forming units (CFU) 7 days post treatment. Results showed increased CFU for all microorganisms and significant reduction of anaerobes in group 1 and anaerobes and total CFU in group 2.[219] Using an

Er:YAG laser, other investigators[404] found statistically similar results between laser-treated and conventionally treated groups. One study found that treatment with an Er:YAG laser showed effective antimicrobial action against *E. coli* and *Staphylococcus aureus*.[337] The results were significantly better than those achieved with NaOCl. More recently, lasers were found to be effective against *Candida albicans* and four other test organisms. However, 70% of specimens lased 3 mm short of the apex remained infected.[299]

Diode Lasers

New laser systems using diodes are now available. In the presence of methylene blue or other dyes, diode lasers activate the dyes and cause photochemical reactions that produce reactive oxygen species. The process is termed *photoactivated disinfection* (PAD) and has the potential to eradicate persistent endodontic infections in cases where conventional methods may be unsuccessful. When used against four common root canal microorganisms *(Fusobacterium nucleatum, Peptostreptococcus micros, P. intermedia, Streptococcus intermedius),* significantly higher numbers were killed. When pathogens in planktonic phase and *E. coli* biofilms were sensitized with methylene blue and treated with red light, all organisms were eliminated. When energy levels were raised, 97% of *E. faecalis* was also eliminated. Other studies resulted in the conclusion that the use of photoactivated disinfection resulted in maximum elimination of microorganisms, especially *E. faecalis*.*

However, when comparing teeth treated conventionally, using rotary instrument NaOCl and EDTA versus the added use of Er:YAG laser system, neither method eliminated infection.[185] An in vitro study using the Er:YAG laser system found that it was effective against six of the bacterial species examined. The numbers of viable cells in the biofilms were significantly decreased with atrophic changes in bacterial cells and biofilm density.[285] When an Nd:YAG laser was used to kill microorganisms seeded on dentin discs with three endodontic pathogens, bacterial eradication occurred. However, when microcolonies were found in biofilms, bacterial eradication was reduced.

Erbium/Chromium-Doped Yttrium Scandium Gallium Garnet Lasers

The Nd:YAG system was found to be more effective than the Er,Cr:YSGG laser, with the former demonstrating a reduction of 97% and 98% of organisms.[417] Researchers[94] found the Er,Cr:YSGG system to be less effective than a 3% solution of NaOCl, with the latter inhibiting growth of *E. faecalis* in all root canal systems tested. A later study found that the same system eliminated bacteria and smear layer debris in root canals, with only moderate elevation of temperature on the outer root surfaces.[336] Others have demonstrated the same results when comparing the Er,Cr:YSGG system to NaOCl, using a radically emitting laser probe for 2 minutes; 99.7% bacterial reduction occurred with the laser.[142] A high-powered 810-nm diode laser was used to examine the ability to achieve disinfection in deep layers of dentin. A group of 10 extracted teeth were treated with rotary files, 0.5% NaOCl, 17% EDTA, and irradiated, with a second group treated the same but without laser exposure. A third group was treated only with saline irrigation. Results showed 100% and 98.3% disinfection when compared with the control group.[86] However, few of the investigators cited were willing to call the effects *sterilization* as opposed to *disinfection*. There are also differences in results that appear to be dependent on wavelength. *Therefore, the use of lasers still remains somewhat controversial for use in sterilization of root canal systems.*

Laser irradiation has been used in the preparation of root-end restorations. The root-end areas prepared with burs expose dentinal tubules, which may allow leakage of microorganisms and their byproducts. When preparations using an Er:YAG laser were compared to an Nd:YAG laser and high-speed burs, the lasers demonstrated lower infiltration indices than high-speed burs.[287] In a similar study, results determined that a transversely excited atmospheric pressure (TEA) CO_2 laser and an Er:YAG laser showed clean, smooth root-end preparation surfaces with sealed tubules and a reduction of permeability to methylene blue dye.[143] An Er:YAG laser was compared to root-end ultrasonic preparation using three filling materials (MTA, Super EBA, IRM). The laser-treated areas demonstrated lower microleakage values for all three materials.[188] When comparing use of a low-speed bur and an Er,Cr:YSGG laser for reverse root-end preparations using cyanoacrylate and MTA as filling materials, MTA and laser samples presented significantly higher permeability rates.[426] Alternating Er:YAG and Nd:YAG irradiation preparations with high-speed hand piece preparation showed no differences between either group exposed to lasers and no differences between bur preparations in microleakage percentages.[13] Diode lasers are available at much lower costs than other systems and can also be used for root-end preparations. Groups treated with a 980-nm laser were compared to non-laser groups, demonstrating absence of smear layer and reduced leakage when compared with nonlased teeth.[418] However, *when used in combination with MTA for reverse filling, the laser radiation did not improve apical sealing.*[87]

Laser energy may prove useful for treating diseases of the root canal system and periradicular regions, but years of successful endodontic care have demonstrated the value of several already proven methods. Until independently supported, reproducible studies are published in peer-reviewed journals—wherein findings match present marketing claims—the reader is advised to exercise prudent caution before embracing these newer laser technologies.

SUMMARY

An explosion in knowledge and technology has created an exciting time in the specialty of endodontics. New instruments and materials seem to appear faster than clinicians can learn about the preceding versions. This has created an educational challenge for practitioners, universities, and manufacturers, requiring a greater degree of cooperation among these groups than ever before. Clinicians should only use those instruments and materials that have been shown safe and effective by independent studies.

- Concepts and Strategies

CANAL PREPARATION TECHNIQUES
- Hand Instrumentation
- Rotary Instrumentation
- Other Systems

CANAL CLEANING TECHNIQUES
- Irrigation Modes and Devices
- Eradication of Microorganisms
- Smear Layer Management

FRAMEWORK FOR ROOT CANAL TREATMENT

Clinical endodontics encompasses a number of treatments, but perhaps the most important is treating pulps and root canal systems (with or without periradicular pathosis of pulpal origin) so that patients can retain their natural teeth in function and esthetics. The treatment of traumatic dental injuries and prophylactic treatment of vital pulps to maintain vitality are different from pulpectomies in which root canal instrumentation is required. However, endodontic therapy essentially is directed toward one specific set of aims: to cure or prevent periradicular periodontitis.[429]

Routine orthograde root canal treatment is a predictable and usually highly successful procedure, both in relatively straightforward (Fig. 9-1) and more difficult cases (Figs. 9-2 and 9-3). In recent studies and reviews, favorable outcome rates of up to 95% were reported for the treatment of teeth diagnosed with irreversible pulpitis[39,99,139]; favorable outcome rates of up to 85% were reported for necrotic teeth.[98,140,303,311]

To date, many treatment modalities, including nickel-titanium rotary instruments, have not been shown to have a statistically relevant impact on treatment outcomes.[303] This poses a real problem in the age of evidence-based therapy, because a new therapeutic technique should provide a better result than standard procedures in clinical tests. The small number of relevant prospective clinical studies is only partly offset by numerous in vitro experiments. This chapter includes pertinent information from such studies, as well as results from our own experiments, because rotary nickel-titanium instruments have become widely used adjuncts in root canal treatment.

Pathophysiology of Endodontic Disease

Many prospective and peritreatment factors have been suggested as links to favorable treatment outcomes in endodontic therapy. Such factors include the patient's age and gender, the position of the tooth in the arch, extension of the root canal filling, and the use of certain interappointment dressings, such as calcium hydroxide [$Ca(OH)_2$]. The presence of a periradicular osseous lesion (i.e., "apical periodontitis") appears to be a relevant prognostic factor that reduces the likelihood of a favorable outcome for root canal treatment; however, lesion size by itself is not an indication for endodontic surgery (see Chapter 22). Fig. 9-4 shows two cases in which large osseous lesions were treated by orthograde approaches. At recall appointments, the teeth were asymptomatic, and a reduction in lesion size was evident in both cases.

Some may question whether lesions such as the ones in Fig. 9-4 are in fact cysts. Several studies have demonstrated that lesion size shows little correlation with the incidence of radicular cysts.[55,222,275,279] Only histologic examination can prove whether a radiolucency is in fact a cyst. True cysts are believed to heal only after surgical enucleation,[278] whereas the noncystic majority of apical processes heal predictably by orthograde endodontic treatment without surgery. An orthograde approach, therefore, appears to be beneficial in clinically asymptomatic cases and should include recall appointments at appropriate intervals (see Chapter 14).

If clinical symptoms persist or begin after endodontic therapy, surgery may be performed in addition to orthograde root canal treatment. In the case shown in Fig. 9-5, a large

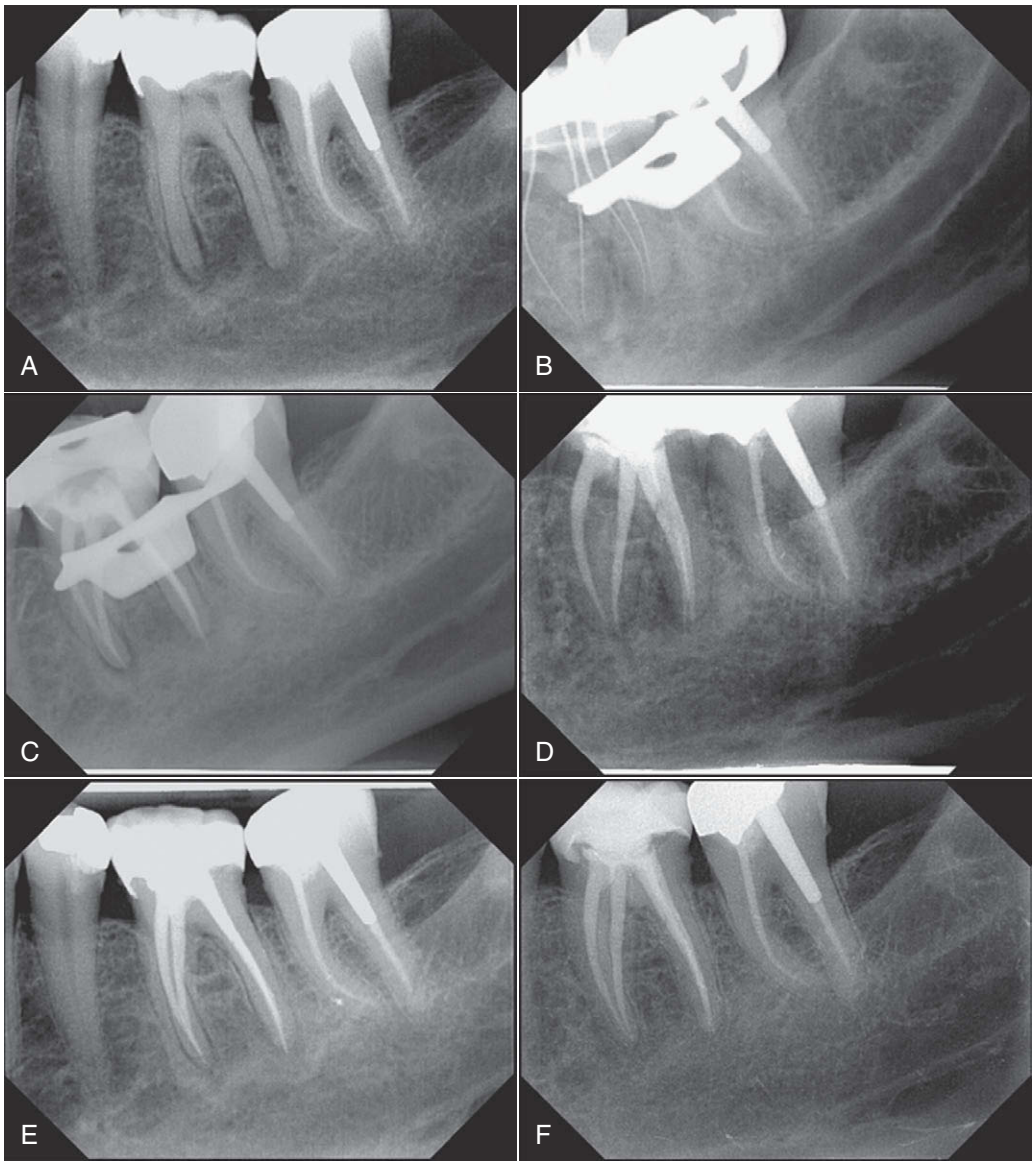

FIG. 9-1 Effect of routine root canal treatment of a mandibular molar. **A,** Pretreatment radiograph of tooth #19 shows radiolucent lesions adjacent to both mesial and distal root apices. **B,** Working length radiograph shows two separate root canals in the mesial root and two merging canals in the distal root. **C,** Posttreatment radiograph after shaping of root canal systems with nickel-titanium rotary files and obturation with thermoplasticized gutta-percha. **D,** Six-month recall radiograph after restoration of tooth #19 with an adhesively inserted full ceramic crown; some periradicular bone fill can be seen. **E,** One-year recall radiograph shows evidence of additional periradicular healing. **F,** Five-year recall radiograph; tooth not only is periapically sound but also clinically asymptomatic and fully functional.

lesion that extended into the maxillary sinus and nasal cavity was treated surgically 1 week after orthograde therapy of teeth #7 and #8, which included removal of two instrument fragments. The lesion was completely enucleated during surgery, and a tissue biopsy specimen was submitted for histologic processing; the lesion was diagnosed as a radicular cyst. As expected in this case, the patient reported discomfort after surgery. This supports the preference for a nonsurgical approach whenever possible.

When root canal therapy is part of a comprehensive treatment plan, a favorable outcome for the root canal portion is a prime requirement. Extended bridgework and removable dentures depend on healthy periradicular tissues, just as they depend on healthy marginal and apical periodontal tissues. Fig. 9-6 presents a case in which a removable denture seemed unavoidable at the first examination. After extractions and root canal therapy were performed, small-unit, fixed partial dentures were placed. These reconstructions remain fully functional and allow this patient to benefit from the natural dentition.

In summary, orthograde root canal treatment has a high degree of predictability both in normal and complex cases. Some limitations exist, but the potential for a favorable outcome is significant. As indicated previously, the shaping and cleaning procedures performed as part of root canal treatment are directed against microbial challenges to the root canal system.[170]

FIG. 9-2 Root canal treatment in a case of apical and interradicular pathosis. **A,** Pretreatment radiograph of tooth #19 shows an interradicular lesion. **B-C,** Posttreatment radiographs after root canal preparation and obturation. Note the lateral canal in the coronal third of the root canal. **D-E,** Two-month recall radiograph suggests rapid healing. *(Courtesy Dr. H. Walsch.)*

Microorganisms can breach dental hard-tissue barriers through several avenues, the most common being dental caries (Fig. 9-7).[327]

Dental Anatomy

Pulpal reactions may be observed as soon as the *diffusion barrier* (the remaining dentin thickness) is sufficiently permeable for bacteria or their toxins to affect the pulp[56] (see Fig. 9-7). Under experimental conditions, pulpal inflammation can be detected only a few hours after topical application of bacterial components to exposed dentin.[46,286] In an established lesion, a bacterial ecosystem evolves, with synergisms and antagonisms among the microorganisms (see Chapter 15). These interactions play an important role in the course of the disease when intraradicular biofilms develop and bacteria invade dentinal tubules.[236] Two key factors initiate and modify inflammatory reactions such as the development of microabscesses in subodontoblastic regions: the penetration of bacterial components and the release and diffusion of inflammatory mediators.

The stereotypic pulpal defense reaction is hard-tissue deposition (Fig. 9-8 and see Fig. 9-7) by primary and secondary odontoblasts.[56] Hard tissue is laid down as a response to a stimulus (*reactionary* or *reparative dentinogenesis*) and thus takes place within a defined spatial relationship to that stimulus, occurring slightly apical to the lesion.

Hard-tissue deposition is a natural event with aging[451] (*secondary dentinogenesis*), which creates a higher degree of treatment difficulty in older patients.[452] Clinicians note a radiographically detectable decrease in the size of the pulp space that occurs most often in the coronal regions but also can be seen in the more apical areas. This condition is not a contraindication to orthograde endodontic therapy, but it does require additional attention to clinical procedures such as preenlargement and prebending of hand files (discussed later in this chapter).

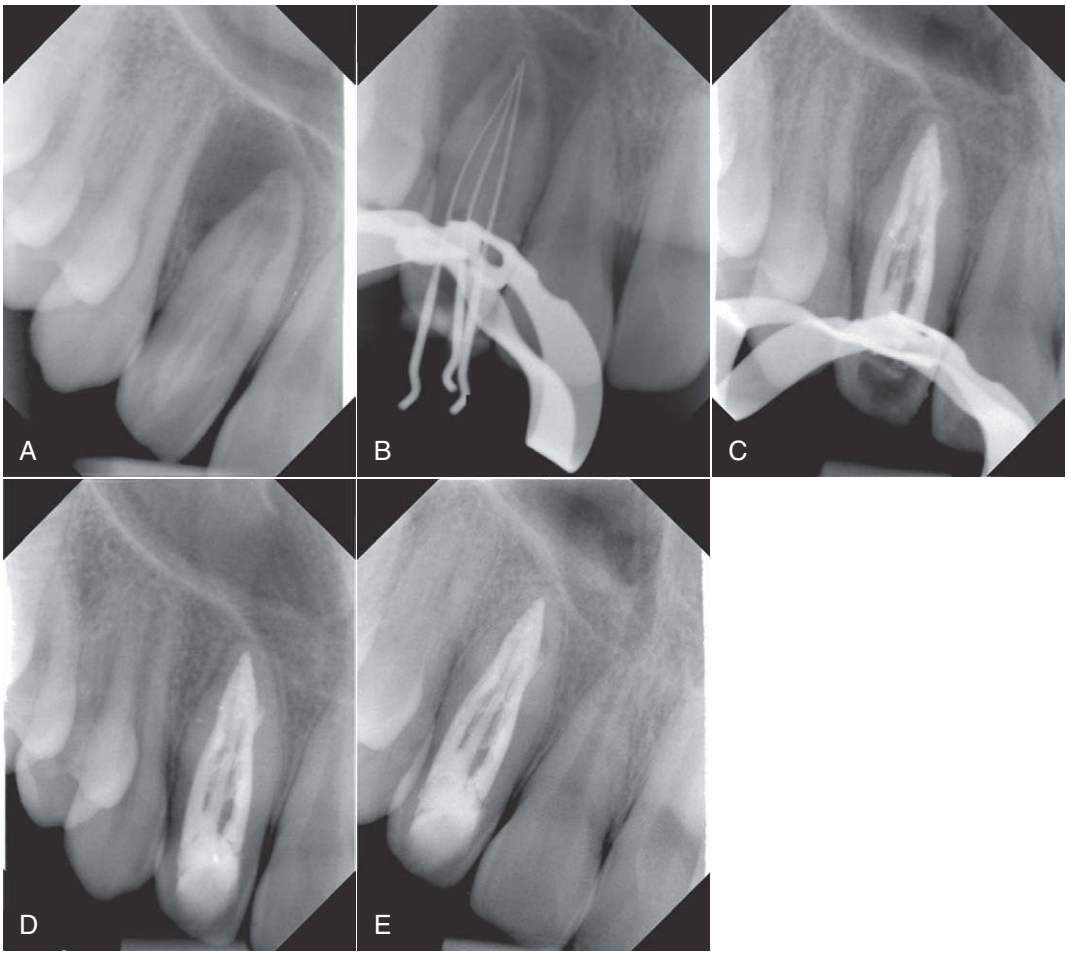

FIG. 9-3 Root canal treatment in a case with unusual and complicated anatomy. **A,** Pretreatment radiograph of tooth #7 in a 12-year-old boy shows a substantial periradicular lesion and evidence of additional radicular anatomy (i.e., a dens-in-dente type II, according to Oehlers' classification).[285] **B,** Working length radiograph shows three separate root canals. **C,** Posttreatment radiograph 2½ months after shaping of the root canal systems with a nickel-titanium rotary system aided by ultrasonically activated K-files and dressing with calcium hydroxide four times for about 2 weeks each. Note the substantial periradicular bone fill. **D,** One-year recall radiograph shows evidence of periradicular healing. **E,** Two-year recall radiograph shows sound periradicular tissues.

The process of *calcific metamorphosis* is a response to traumatic injury.[22] It is characterized by a reduction in the size of both the radicular and coronal pulp spaces. Conversely, teeth with signs of hard-tissue deposition caused by bacterial attack show an initial reduction of pulp space size coronally, which may involve the pulp chamber and canal orifices (see Fig. 9-7). This situation calls for meticulous preparation of an access cavity and preenlargement of canal orifices in a nondestructive manner. Depending on the timing of inoculation and the number of microbes, hard-tissue deposition also may occur more apically.[215]

Reparative dentin may form a diffusion barrier sufficient for the pulp to recover, depending on the severity of the bacterial challenge and the capability of the defense mechanisms.[242] Unfortunately, no consensus exists on the best therapy to allow this recovery to occur.[47] Further into the disease progress, and if the carious lesion persists, bacteria may be present in sufficient concentrations to induce pulpal inflammation. This is triggered by molecular signals (e.g., cytokines) released from cells such as macrophages and neutrophils well before microbes are actually present intrapulpally (see Chapter 15). At this stage, with a diagnosis of reversible pulpitis, endodontic treatment may be avoidable, provided the source of the irritants is removed.

To deliver adequate endodontic therapy, the clinician must understand that apical periodontitis is the endpoint of a disease flow that in most cases originates coronally, either with carious lesions or a traumatized pulp (see Fig. 9-7). As stated previously, opportunistic bacteria may invade dental hard tissue, and their byproducts eventually may reach the pulp space (see Chapter 15). Host response factors, such as the recruitment of neutrophil granulocytes and local development of neurogenic inflammation, act against microbial invasion, but this line of defense may succumb to the challenge if the carious defect is not repaired. Then, after microabscesses form, circulation changes occur; coronal and subsequently radicular pulp may become nonperfused and thus necrotic.

At various points in this process, bacterial factors such as lipopolysaccharides and peptidoglycans[201] can reach periapical tissues through apical and accessory foramina. Zones of bone resorption (appearing as radiolucencies) may develop, depending on the balance between microbial virulence factors and

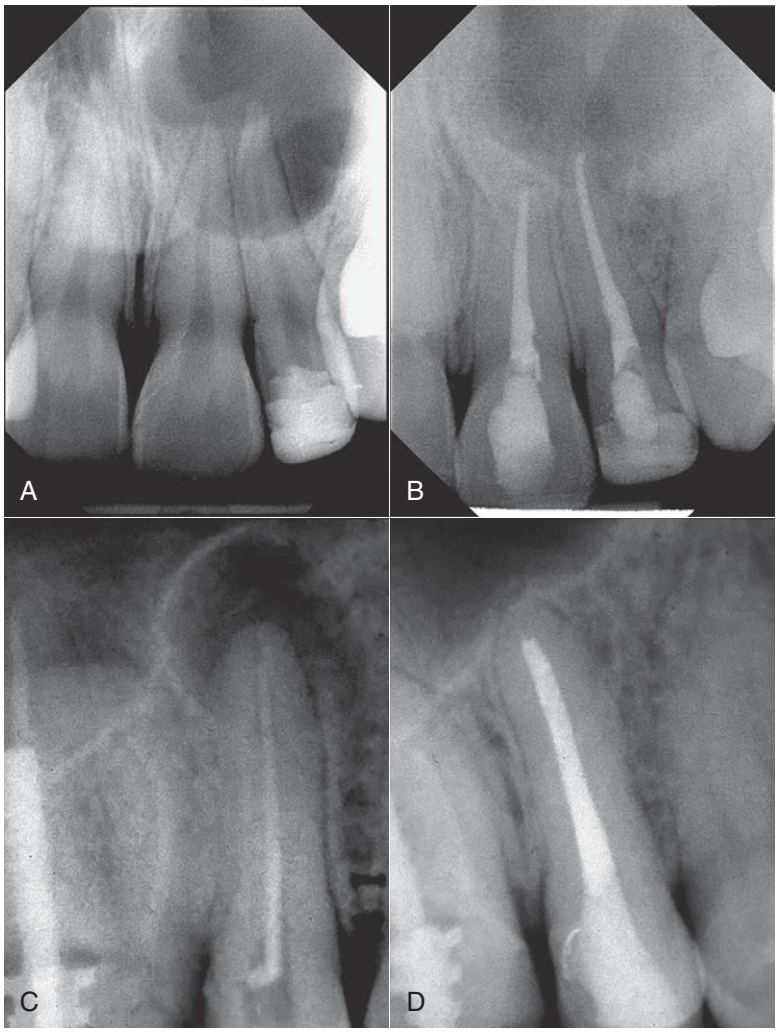

FIG. 9-4 Potential of root canal treatment in cases of substantial periradicular destruction. **A,** Pretreatment radiograph of teeth #8 and #9 shows a large lesion. Neither tooth responded to cold tests. **B,** Two-year follow-up radiograph shows bone fill. The canals were shaped with rotary and hand instruments, and obturation was performed using laterally compacted gutta-percha with AH Plus as the sealer. **C,** Pretreatment radiograph of tooth #4, which has a previously filled root canal; a large periradicular lesion and insufficient obturation can be seen. **D,** Two-year posttreatment radiograph shows evidence of bony healing after nonsurgical retreatment. (***A-B*** *courtesy Dr. M. Zehnder;* ***C-D*** *courtesy Dr. F. Paqué.)*

host defenses.[402] The development of apical periodontitis is associated with a significantly less encouraging prognosis after orthograde endodontic treatment.[99,387,389]

One school of thought emphasizes the importance to successful endodontic therapy of cleaning and filling lateral and accessory canals.[337,458] Clinical radiographs of beautifully performed cases support this position; the contribution of accessory canals to lesion development in certain cases seems highly likely (see Fig. 9-2). However, this pathogenesis depends on the volume of accessory canals and the amount of bacteria harbored in them. Another subject of controversy is the clinical importance and mechanisms of dentinal tubule infection[235,236,300] with bacteria and fungi (Fig. 9-9).

In most cases, lesions are associated with the main root canal systems (see Figs. 9-1 and 9-3 to 9-5) and form periapically around the main foramina. The main canal unquestionably has the highest bacterial load, and important studies link reduction of the viable intracanal bacterial load to favorable outcomes for endodontic therapy.[207,299,387] A primary aim of all endodontic procedures, and most notably of cleaning and shaping, is to remove canal contents, specifically infective microorganisms and necrotic tissues.[2]

Clinical Objectives

A wide spectrum of possible strategies exists for attaining the goal of removing the canal contents and eliminating infection. Investigators[244] introduced a minimally invasive approach to removing canal contents and accomplishing disinfection that did not involve the use of a file: the noninstrumentation technique.[137] This system consisted of a pump, a hose, and a special valve that was cemented into the access cavity (Fig. 9-10, *A*) to provide oscillation of irrigation solutions (1% to 3% sodium hypochlorite[3]) at a reduced pressure. Although several in vitro studies[243,245,246] demonstrated that canals can be cleaned and subsequently filled using this system (see Fig. 9-10, *B* and *C*), preliminary clinical results have not been as convincing (see Fig. 9-10, *D*).[27]

At the opposite end of the spectrum is a treatment technique that essentially removes all intraradicular infection through extraction of the tooth in question (see Fig. 9-10, *C*). Almost invariably, periradicular lesions heal after extraction of the involved tooth.

Clinical endodontic therapy takes place somewhere along this spectrum of treatment strategies. This is reflected in some of the controversies that surround the cleaning and shaping

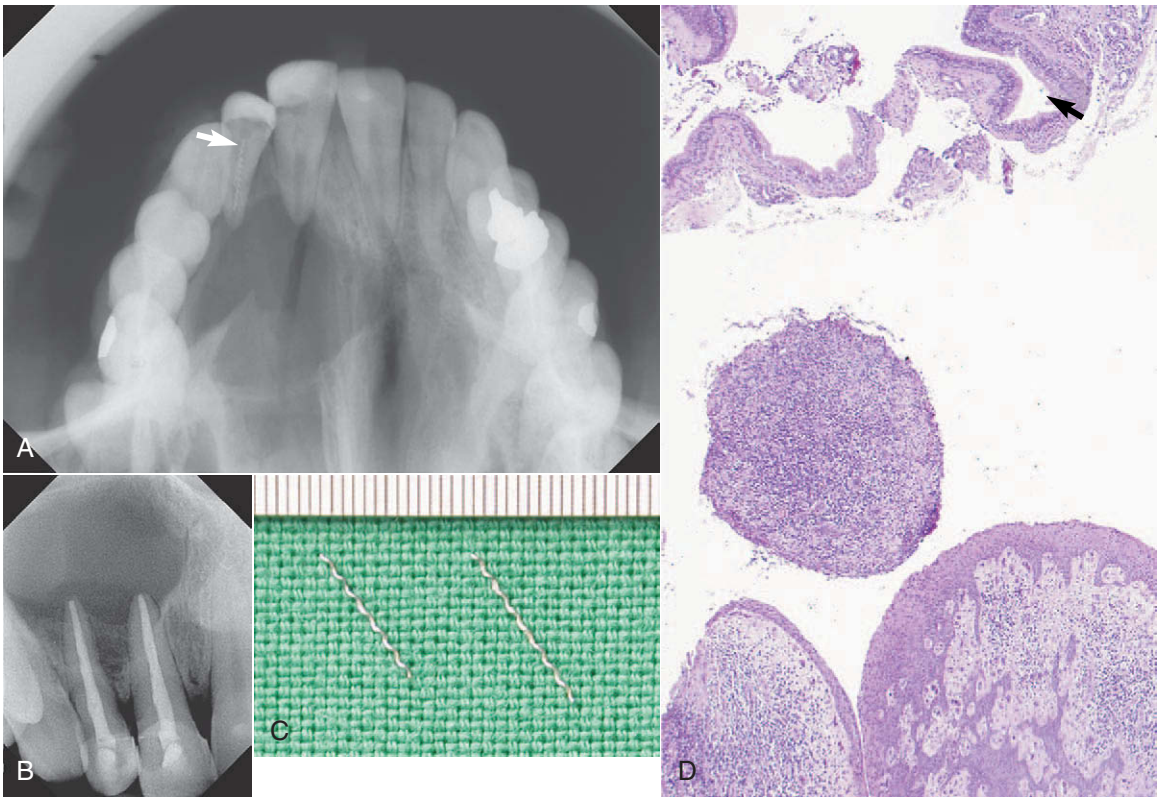

FIG. 9-5 Possibilities and limitations of orthograde endodontic therapy. In this case, a large lesion in the right maxilla was enucleated and histologically diagnosed as a radicular cyst. **A,** Pretreatment occlusal plane radiograph shows a large periradicular lesion in the right maxilla, as well as two separated instruments in tooth #7 *(arrow)*. **B,** Posttreatment periapical radiograph of tooth #7 and necrotic tooth #8, which were obturated after calcium hydroxide dressings had been placed for 2 weeks. Obturation was done with laterally compacted gutta-percha and Roth's 801 sealer. **C,** Two lentulo spiral fragments removed from tooth #7 (ruler gradation is 0.5 mm). **D,** Histologic slide shows both respiratory epithelium *(arrow)* and squamous epithelial lining and inflammatory cells, supporting the diagnosis. *(**C** Courtesy Dr. I. Hegyi.)*

process, such as how large the apical preparation should be and what are the correct diameter, length, and taper.[204]

The foundation of the endodontic treatment plan is an adequate diagnostic process (see Chapter 1), which includes obtaining diagnostic radiographs from various angles. Also, the restorability and periodontal status of teeth to be treated endodontically must be determined. In some cases, buildups or crown lengthening is required for preendodontic restoration to allow proper isolation, create pulp chambers that retain irrigants, and facilitate interappointment temporary restorations. In many cases, the existing restoration may have to be removed so an adequate diagnosis can be made and the immediate cause of endodontic treatment can be assessed.[1]

Once the decision has been made to initiate endodontic treatment, the clinician must integrate his or her knowledge of dental anatomy, immunology, and bioengineering science with clinical information. The intent of this chapter is to assist clinicians with that task and to provide a much-condensed background in radicular anatomy, pulpal pathophysiology, and nickel-titanium metallurgy.

Endodontic therapy has been compared to a chain, wherein the chain is only as strong as each individual link. For the purposes of this chapter, shaping and cleaning of the root canal system is considered a decisive link, because shaping determines the efficacy of subsequent procedures. It includes mechanical débridement, the creation of space for the delivery of medicaments, and optimized canal geometries for adequate obturation.[301] These tasks are attempted within a complex anatomic framework, as recognized in the early 20th century by Walter Hess[183] (Fig. 9-11) (see Chapter 7).

Unfortunately, canal preparation results are adversely affected by the highly variable root canal anatomy.[12,13,188,274,308] This fact is especially true for conventional hand instruments and to a lesser degree for most nickel-titanium rotary instruments.[50,301] Therefore the radicular anatomy is briefly reviewed as it pertains to cleaning and shaping.

Root canal curvature can be assessed clinically from radiographs, preferably taken from various angles. However, it is well documented that curves in the mesiodistal plane often are greater than those in the more readily accessible buccal-lingual plane.[103,312] In vitro, a full account of three-dimensional canal anatomy can be seen with interactive micro–computed tomographic (μCT) reconstructions (Figs. 9-12 and 9-13).

The clinician must understand the five commonly encountered canal paths: canals that merge, curve, recurve, dilacerate, or divide.[337] All five situations are risk factors for file breakage and should be carefully evaluated, as is done for more basic considerations such as the estimated canal length, position of the primary curve, canal diameter, and apical topography.

Early anatomic studies[162,163,219] evaluated the position and topography of the apical foramina and the position of the apical constriction. These studies found that the *physiologic*

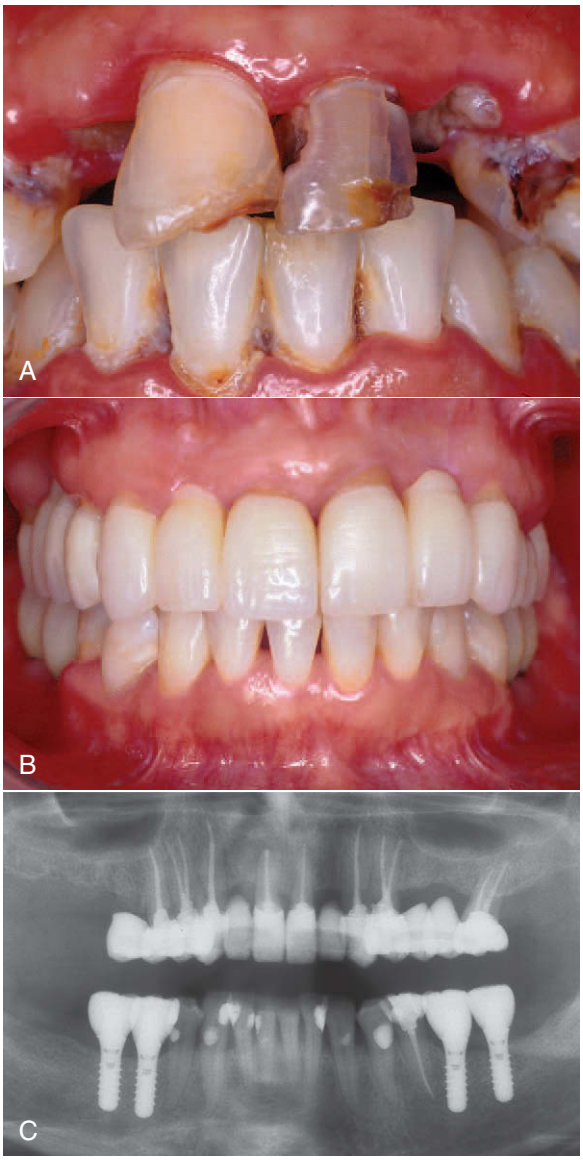

FIG. 9-6 Root canal therapy as part of a comprehensive treatment plan. The patient, who was recovering from intravenous drug addiction, requested restorative dental treatment. Because of extensive decay, several teeth had to be extracted, and nine teeth were treated endodontically. Root canal treatment was aided by nickel-titanium rotary instruments, and obturation was done with lateral compaction of gutta-percha and AH26 as the sealer. Microsurgical retrograde therapy was performed on tooth #8, and the distobuccal root of #14 had to be resected. Metal-free adhesively luted restorations were placed, and missing mandibular teeth were replaced by implants. **A,** Pretreatment intraoral status, showing oral neglect. **B,** Posttreatment intraoral status at 4-year follow-up, showing fully functional, metal-free, tooth-colored reconstructions. **C,** Panoramic radiograph at 4-year recall shows sound periradicular tissues in relation to endodontically treated teeth. *(Restorations done by Dr. Till N. Göhring.)*

foramen, or *canal terminus,* was located up to 1 mm coronal to the *anatomic apex,* or *root tip.* This observation has been confirmed by later studies.[123,267]

Clinically, the landmark detected from radiographs (the *radiographic apex*) does not necessarily coincide with the anatomic apex because of projection artifacts. Taken together, these observations suggest that shaping to the radiographic apex is likely to produce overinstrumentation past the apical foramen, with possible clinical sequelae of posttreatment pain and inoculation of microorganisms into periapical spaces.[45,47,126,168]

Foramen diameter was also an issue in both early[162,219] and more recent studies.[68,123,267,403] The smallest canal diameter, called the *apical constriction,* was located 0.5 to 0.7 mm coronal to the canal terminus.[162,219] A wide range of diameters has been reported in that region, from 0.2 to about 1 mm[68,210-212,219,267]; the concept of a single apical constriction has also been challenged.[123] Moreover, studies have shown that clinicians usually underestimate apical dimensions.[461] Clearly the apical anatomy presents the clinician with major challenges (Fig. 9-14), such as apically dividing canals, nonround cross sections, and delta-like configurations. In addition, canal cross sections that are wide buccolingually[458] are difficult to instrument with rotary techniques.

The clinician must choose the strategies, instruments, and devices to deal with these challenges and control the preparation shape, length, and width precisely. This allows the clinician to use endodontic therapy to address acute (Fig. 9-15) and chronic (Fig. 9-16) forms of the disease processes described previously. Recall radiographs taken at appropriate intervals will demonstrate longevity and favorable outcomes (see Figs. 9-1 to 9-4, 9-6, and 9-16) if clinical objectives are maintained (Box 9-1).

BOX 9-1

Basic Objectives in Cleaning and Shaping

The primary objectives in cleaning and shaping the root canal system are to:

- Remove infected soft and hard tissue
- Give disinfecting irrigants access to the apical canal space
- Create space for the delivery of medicaments and subsequent obturation
- Retain the integrity of radicular structures

CLEANING AND SHAPING: TECHNICAL ISSUES

Because several technical issues arise with the instruments and devices used for cleaning and shaping, a short review of these products is provided here (also see Chapter 8). A vast array of instruments, both handheld and engine-driven, are available for root canal preparation. Up to the last decade of the past century, endodontic instruments were manufactured from stainless steel. With the advent of nickel-titanium,[370] instrument designs began to vary in terms of taper, length of cutting blades, and tip design. Files traditionally have been produced according to empiric designs, and most instruments still are devised by individual clinicians rather than developed through an evidence-based approach. Similar to the development of composite resins in restorative dentistry, the development of new files is a fast and market-driven process. With new versions rapidly becoming available, the clinician may find it difficult to pick the file and technique most suitable for an individual case. Clinicians must always bear in mind that all

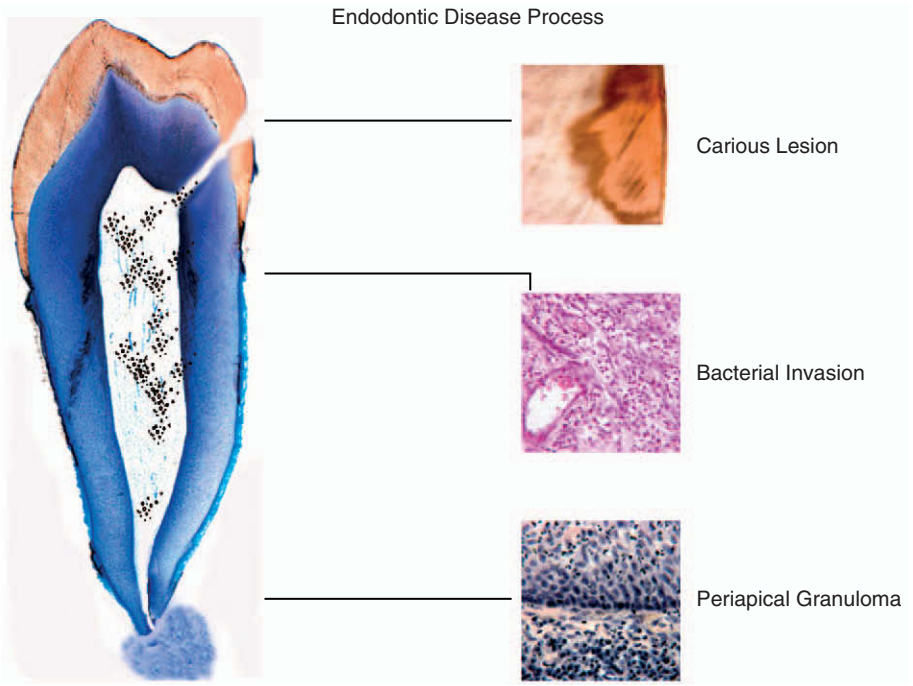

FIG. 9-7 Schematic representation of the progression of pulpal disease and the development of periradicular pathosis. A carious lesion leads to contact of toxins and microbes with the coronal pulp, resulting in inflammation and infection. The stereotypic defense reaction of dental pulp then occurs: hard-tissue deposition. This reaction may lead to repair or to additional hard-tissue deposition (e.g., as calcific metamorphosis). The next step may be formation of microabscesses, changes in circulation during inflammation, and ultimately progression of infection into the radicular pulp space. Finally, periradicular osseous lesions may develop if the bacterial challenge persists. *(Courtesy Professor H.-U. Luder and T. Häusler.)*

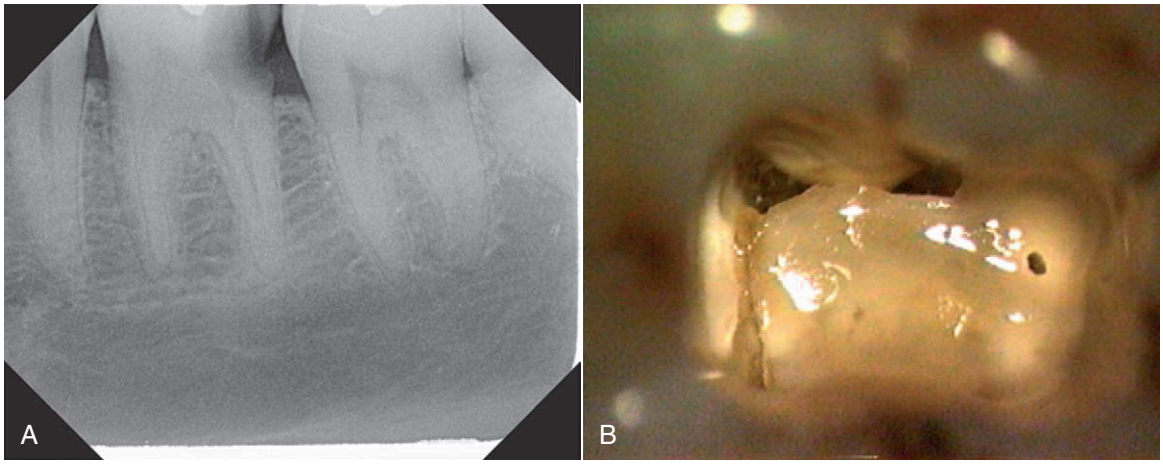

FIG. 9-8 Evidence of coronal hard-tissue deposition. **A,** Periapical radiograph of tooth #19 shows evidence of reduced coronal and radicular pulp space. **B,** Intraoral photograph, taken through an operating microscope (×25), of access cavity of the tooth shown in **A;** note the calcific metamorphosis.

file systems have benefits and weaknesses. Ultimately, clinical experience, handling properties, usage safety, and case outcomes, rather than marketing or the inventor's name, should decide the fate of a particular design.

Hand and Engine-Driven Instruments

Hand instruments have been in clinical use for almost 100 years, and they still are an integral part of cleaning and shaping procedures. A norm established by the American Dental Association (ADA) and the International Standards Organization (ISO)[21,117] sets the standards for broaches, K-type files and reamers, Hedström files, and paste carries; however, the term *ISO-normed instruments* currently is used mainly for K-files (Fig. 9-17). One important feature of these instruments is a defined increase in diameter of 0.05 or 0.1 mm, depending on the instrument size (Fig. 9-18).

Broaches

Barbed broaches are produced in a variety of sizes and color codes. They are manufactured by cutting sharp, coronally angulated barbs into metal wire blanks. Broaches are intended to remove vital pulp from root canals, and in cases of mild inflammation, they work well for severing pulp at the constriction level in toto. The use of broaches has declined since the advent of nickel-titanium rotary shaping instruments, but broaching occasionally may be useful for expediting proce-

dures and removing materials (e.g., cotton pellets or absorbent points) from canals.

K-Files

K-files were manufactured by twisting square or triangular metal blanks along their long axis, producing partly horizontal cutting blades (Fig. 9-19). Noncutting tips, also called *Batt tips,* are created by grinding and smoothing the apical end of the instrument (see Fig. 9-19). Investigators introduced a modified shape, the Flex-R file, which was manufactured fully by grinding so that the transitional angles were smoothed laterally between the tip and the instrument's working parts.[335] Similar techniques are required to manufacture NiTi K-files[413] such as the NiTi-Flex (DENTSPLY Maillefer, Ballaigues, Switzerland). NiTi K-files are extremely flexible and are especially useful for apical enlargement in severe apical curves. They can be precurved, but only with strong overbending; this subjects the file to excess strain and should be done carefully. Because of their flexibility, the smaller NiTi files (sizes up to #25) are of limited use.

Cross-sectional analysis of a K-file reveals why this design allows careful application of clockwise and counterclockwise rotational and translational working strokes. ISO-normed K- and Hedström files are available in different lengths (21, 25, and 31 mm), but all have a 16-mm-long section of cutting flutes (see Fig. 9-17). The cross-sectional diameter at the first rake angle of any file is labeled D_0. The point 1 mm coronal to D_0 is D_1, the point 2 mm coronal to D_0 is D_2, and so on up to D_{16}. The D_{16} point is the largest diameter of an ISO-normed instrument. Each file derives its numeric name from the diameter at D_0 and is assigned a specific color code (see Fig. 9-17).

Another aspect of ISO files is the standard taper of 0.32 mm over 16 mm of cutting blades, or 0.02 mm increase in diameter per millimeter of length (#.02 taper) (see Fig. 9-17). Thus a size #10 instrument has a diameter of 0.1 mm at D_0 and a corresponding diameter of 0.42 mm at D_{16} [0.1 mm + (16 × 0.02 mm)]. For a size #50 instrument, the diameters are 0.5 mm at D_0 and 0.82 mm at D_{16}.

The tip size increases by 0.05 mm for file sizes #10 to #60; for sizes #60 to #140, the absolute increase is 0.1 mm (see Fig. 9-18). Recalculation of these diameter increments into relative steps (in percentages) reveals dramatic differences: the step from size #10 to #15 is 50%, whereas the increase from size #55 to #60 is less than one fifth of that change (see Fig. 9-18).

In very small files (sizes #6 to #10), the problem is partly resolved by several key points: (1) apical dimensions are such that a size #6 file does not significantly remove dentin other than in severely calcified cases; (2) a size #8 file taken 0.5 to 1 mm long to establish patency (discussed later in the chapter) contacts the desired endpoint of the preparation with a diameter approaching the tip size of a #10 file; (3) similarly, placing a size #10 file just minutely through the foramen eases the way for passive insertion of the subsequent #15 file to full length.[337]

The ISO specifications inadvertently complicated the cleaning and shaping of root canal systems. The ISO-normed design is a simplification that has specific disadvantages, and it may explain the clinical observation that enlarging from size #10 to #15 is more difficult than the step from size #55 to #60. The introduction of Golden Medium files (DENTSPLY Maillefer), which have tip sizes between the ISO-stipulated diameters, seemed to solve the problem. However, their use is not that important clinically, because the approved machining tolerance of ± 0.02 mm negates the intended advantage. Moreover, although ± 0.02 mm tolerance is stipulated by the ISO norm (see Fig. 9-17), most manufacturers do not adhere to it.[208,365,404,487]

A subsequent modification involved tips with a constant percentage of diameter increments, the Series 29. The first ProFile instruments (DENTSPLY Tulsa Dental, Tulsa, OK, USA) followed this design, with a nominal diameter increase of 29%. This sizing pattern creates smaller instruments that carry less of a workload. However, the intended advantage is offset by larger diameters, because the 29% increase between successive files is actually greater than the percentage change found in the ISO file series.

Hedström Files

Hedström files are milled from round, stainless steel blanks. They are very efficient for translational strokes,[355] but rotational working movements are strongly discouraged because of the possibility of fracture. Hedström files up to size #25 can be efficiently used to relocate canal orifices and, with adequate

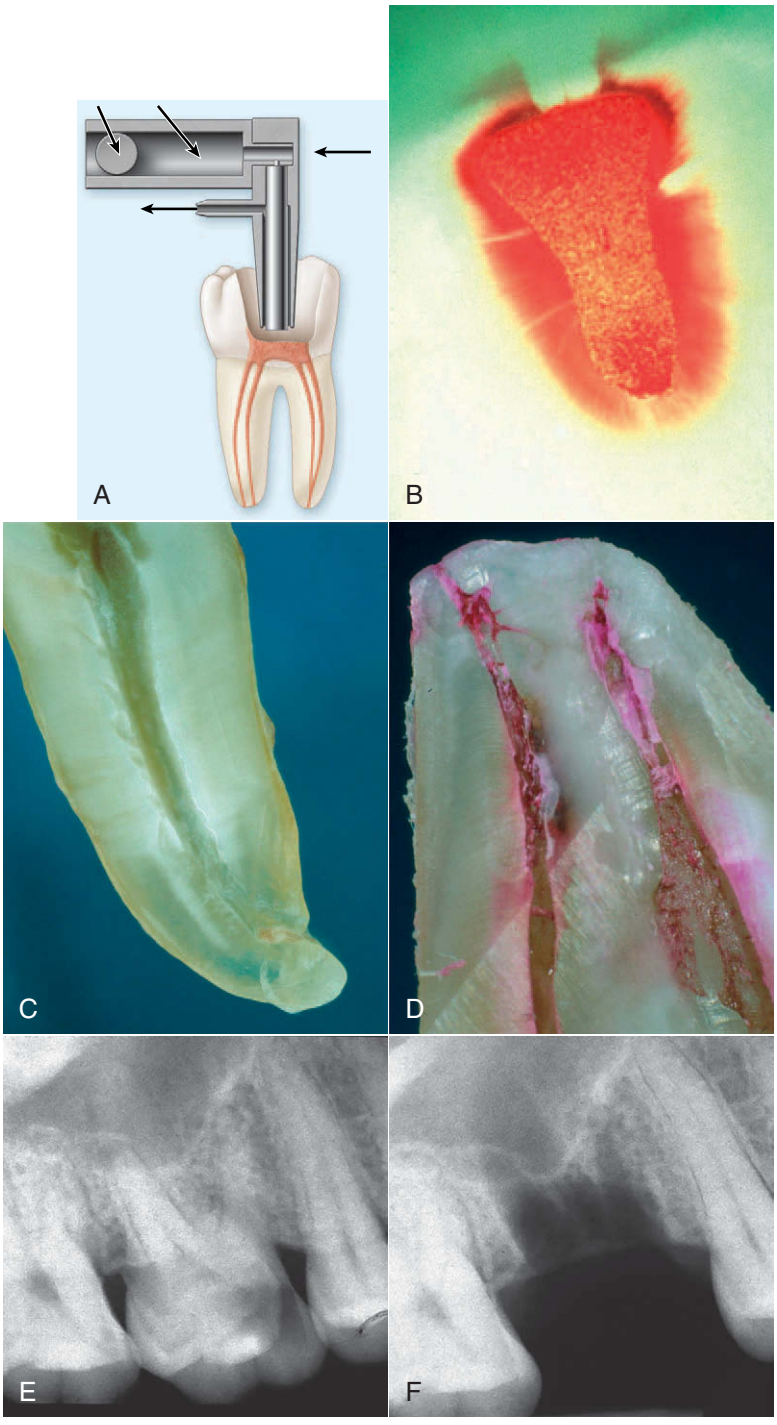

FIG. 9-10 Spectrum of strategies for accomplishing the primary aim of root canal treatment: elimination of infection. **A,** Schematic diagram of minimally invasive therapy using the noninstrumentation technique (NIT). **B,** Example of teeth cleaned in vitro using NIT. Lussi; **C-D** courtesy Professor T. Attin; **E-F** Courtesy Dr. T. Kaya.)*

filing strokes, to remove overhangs. Similarly, wide oval canals can be instrumented with Hedström files as well as with rotary instruments. On the other hand, overzealous filing can lead to considerable thinning of the radicular wall and strip perforations (Fig. 9-20). As with stainless steel K-files, Hedström files should be single-use instruments.[397]

Gates-Glidden Drills

Gates-Glidden (GG) drills are important instruments that have been used for more than 100 years without noteworthy design changes. These instruments, especially the nickel-titanium FlexoGates model (DENTSPLY Maillefer),[151] usually work well for preenlargement of coronal canal areas.[114,261] However, when misused, GG drills can dramatically reduce radicular wall thickness.[149,197,239]

GG instruments are manufactured in a set and numbered 1 to 6 (with corresponding diameters of 0.5 to 1.5 mm); the number of rings on the shank identifies the specific drill size. GG instruments are available in various lengths and made by several manufacturers. Each instrument has a long, thin shaft

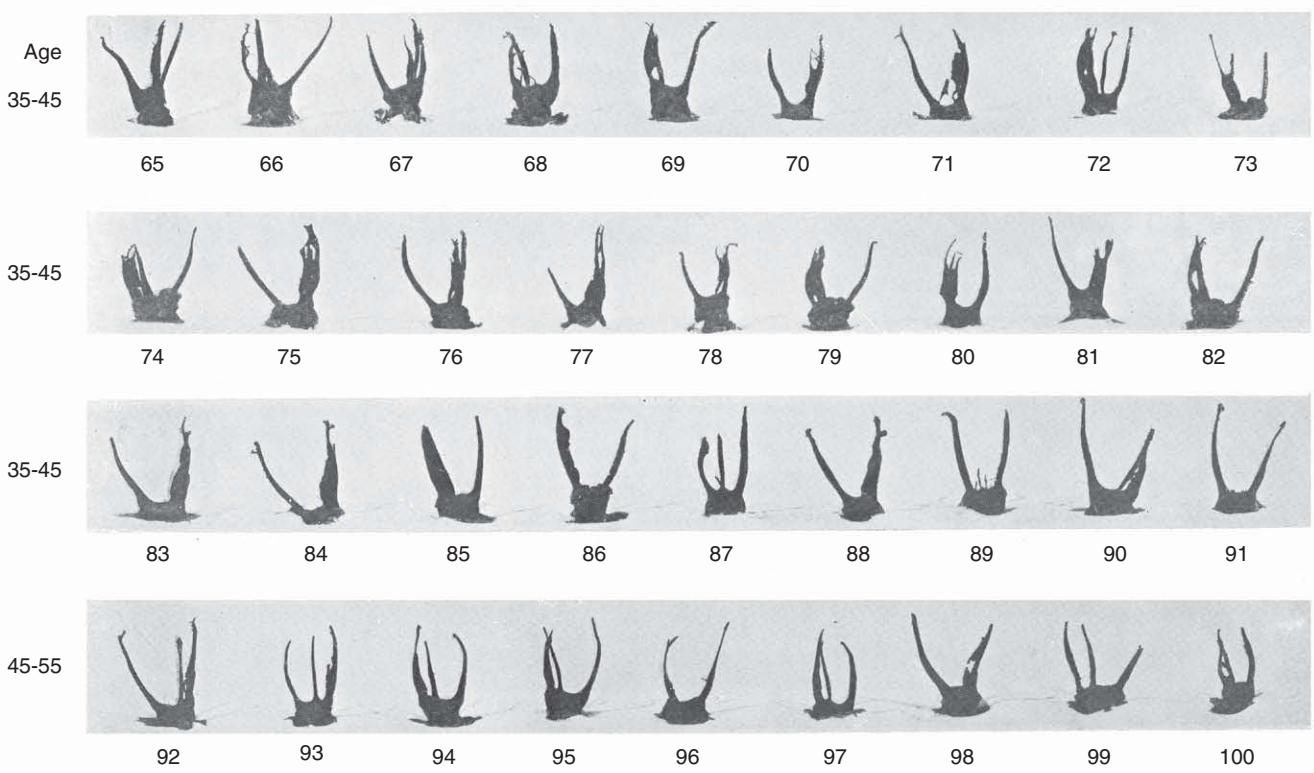

FIG. 9-11 Panel of 36 anatomic preparations of maxillary molars from the classic work by Professor Walter Hess of Zurich. with parallel walls and a short cutting head. Because of their design and physical properties,[66] GG drills are side-cutting instruments with safety tips; they can be used to cut dentin as they are withdrawn from the canal (i.e., on the outstroke).[337] Used this way, their cutting action can deliberately be directed away from external root concavities in single-rooted and furcated teeth.[4] GG instruments should be used only in the straight portions of the canal, and they should be used serially and passively.[424]

Two procedural sequences have been proposed: with the step-down technique, the clinician starts with a large drill and progresses to smaller ones; conversely, with the step-back

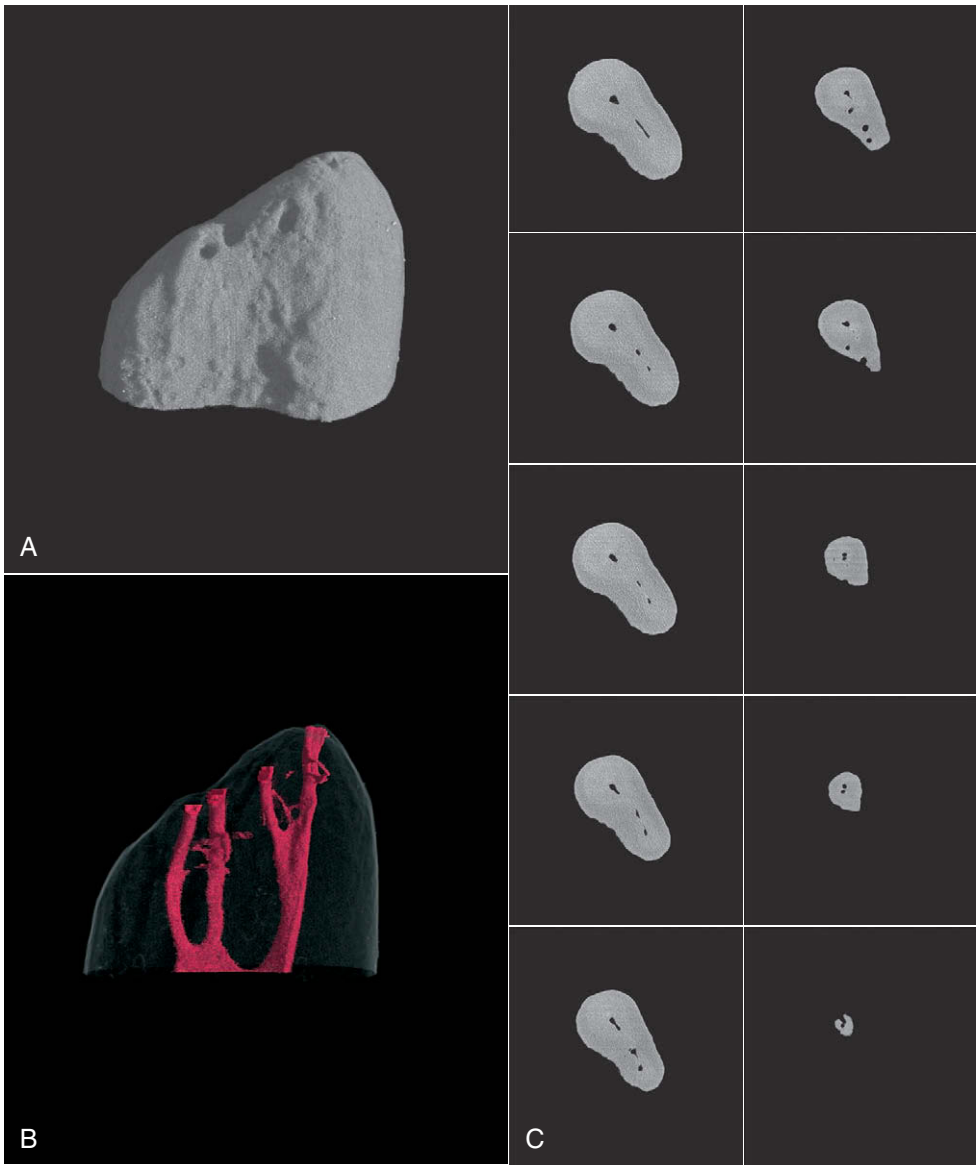

FIG. 9-14 Micro–computed tomographic scan of anatomy of the apical 5 mm of a mesiobuccal root (8 µm resolution). **A-B,** Three-dimensional reconstruction of outer contour and root canal systems. **C,** Cross sections 0.5 mm apart.

technique, the clinician starts with a small drill and progresses to larger ones. With the step-down approach, the clinician must select a GG instrument with a diameter that allows introduction into the respective orifice and progression for about 1 mm. The subsequent smaller instruments progress deeper into the canal until the coronal third has been preenlarged. This technique efficiently opens root canal orifices and works best when canals exit the access cavity without severe angulations. Opened orifices simplify subsequent cleaning and shaping procedures and help establish a smooth glide path from the access cavity into the root canal system.

With the step-back approach, a small GG instrument is introduced into the canal, and dentin is removed on the outstroke. This process is repeated with the next larger GG instrument, which is again worked shorter than the preceding smaller one. In this way, the coronal third of the root canal is enlarged and dentin overhangs are removed.

As stated earlier, when used adequately, GG instruments are inexpensive, safe, and clinically beneficial tools. High revolutions per minute (rpm), excessive pressure, an incorrect angle of insertion, and the use of GG instruments to aggressively drill into canals have resulted in mishaps such as strip perforation. Also, cyclic fatigue may cause GG instruments to fracture when used in curved canal areas, and the short cutting heads may fracture with high torsional loads. Gates-Glidden drills may be used safely and to their fullest potential at 750 to 1500 rpm. As with nickel-titanium rotary instruments, GG drills work best when used in electric gear reduction handpieces rather than with air motors.

Nickel-Titanium Rotary Instruments

Since the early 1990s, several instrument systems manufactured from nickel-titanium (NiTi) have been introduced into endodontic practice. The specific design characteristics vary,

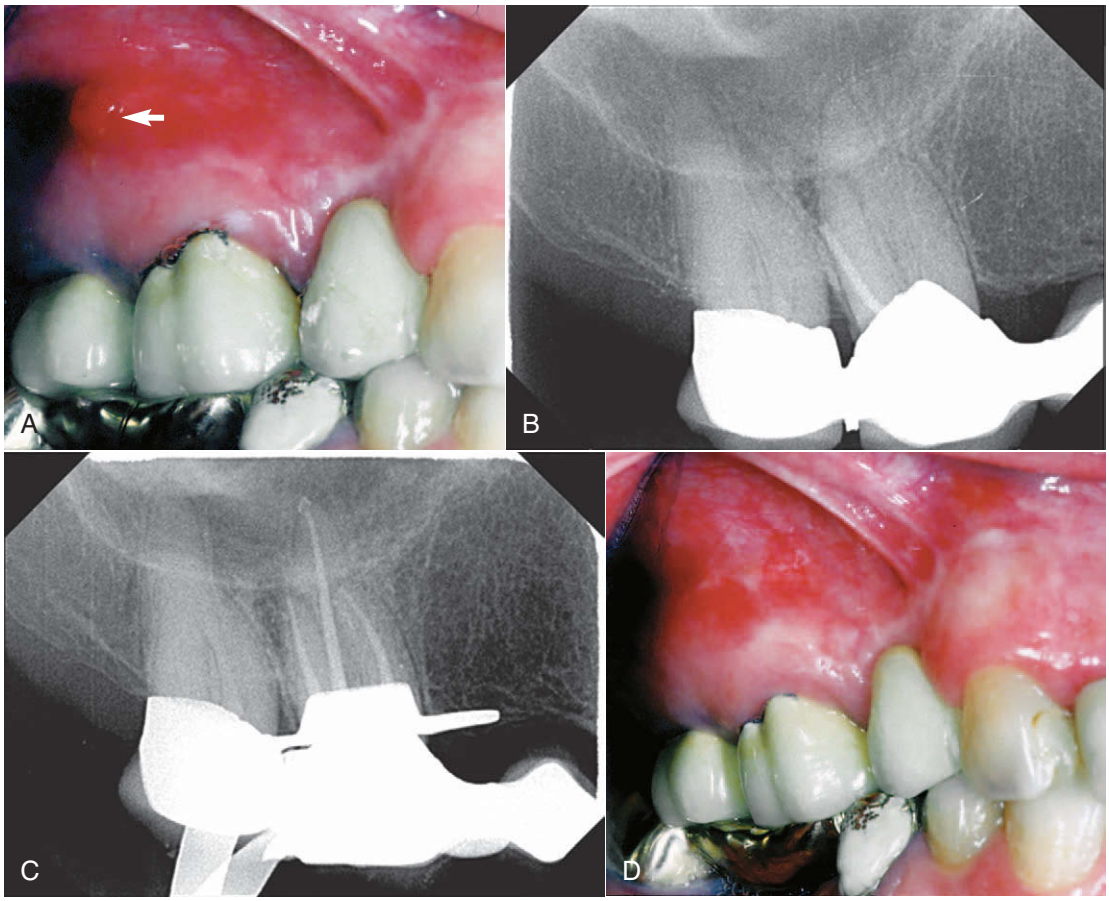

FIG. 9-15 Sinus tract as a sign of a chronic apical abscess and effect of routine root canal treatment. **A,** Intraoral photograph of left maxillary region with draining sinus tract *(arrow)* periapical to tooth #14. **B,** Pretreatment radiograph with gutta-percha point positioned in the sinus tract, pointing toward the distobuccal root of #14. **C,** Finished root canal fillings after 2 weeks of calcium hydroxide dressing. **D,** Intraoral photograph of the same region as in **A,** showing that the sinus tract had closed by the time obturation was performed.

such as tip sizing, taper, cross section, helix angle, and pitch (Fig. 9-21). Some of the early systems have been removed from the market or play only minor roles; others, such as ProFile (DENTSPLY Tulsa Dental, DENTSPLY Maillefer), are still widely used. New designs continually are produced, but the extent to which clinical outcomes (if any) will depend on design characteristics is difficult to forecast.[303]

Most of the instruments described in this section are manufactured by a grinding process, although some are produced by laser etching and others by plastic deformation under heating. Precision at the surface quality is not really at a high level, whereas the tolerances are. Surface quality also is an important detail (see Fig. 9-21), because cracks that arise from superficial defects play a role in instrument fracture.[16] Superficial defects such as metal flash and rollover are common in unused NiTi instruments.[125,251,489]

Attempts have been made to improve surface quality by electropolishing the surface and coating it with titanium nitride.[325,353] The latter process also seems to have a beneficial effect on cutting efficiency.[353]

In essence, two properties of the NiTi alloy are of particular interest in endodontics: superelasticity (Fig. 9-22) and high resistance to cyclic fatigue (discussed later). These two properties allow continuously rotating instruments to be used successfully in curved root canals. Many variables and physical properties influence the clinical performance of NiTi rotaries.[218,302,370,413]

Much of what is known about NiTi instruments, including reasons for instrument fracture[33] and instrument sequences, has been gleaned from clinical practice. In vitro research continues to clarify the relationship between NiTi metallurgy and instrument performance, but already NiTi rotary instruments have become an important adjunct in endodontics.[301]

NiTi rotary instruments have substantially reduced the incidence of several clinical problems (e.g., blocks, ledges, transportation, perforation), but they are also believed to fracture somewhat more easily than hand instruments. This does not by itself predispose a case to posttreatment disease; rather, a retained instrument fragment limits access of disinfecting irrigants to the root canal system, possibly impeding sufficient elimination of microorganisms.[172]

The following sections describe the instruments most widely used in the United States and Europe for root canal preparation. Most basic strategies apply to all NiTi rotary instruments, regardless of the specific design or brand. However, three design groups need to be analyzed separately: group I, the LightSpeed; group II, rotary instruments with #.04 and #.06 tapers, which includes the ProFile and many other

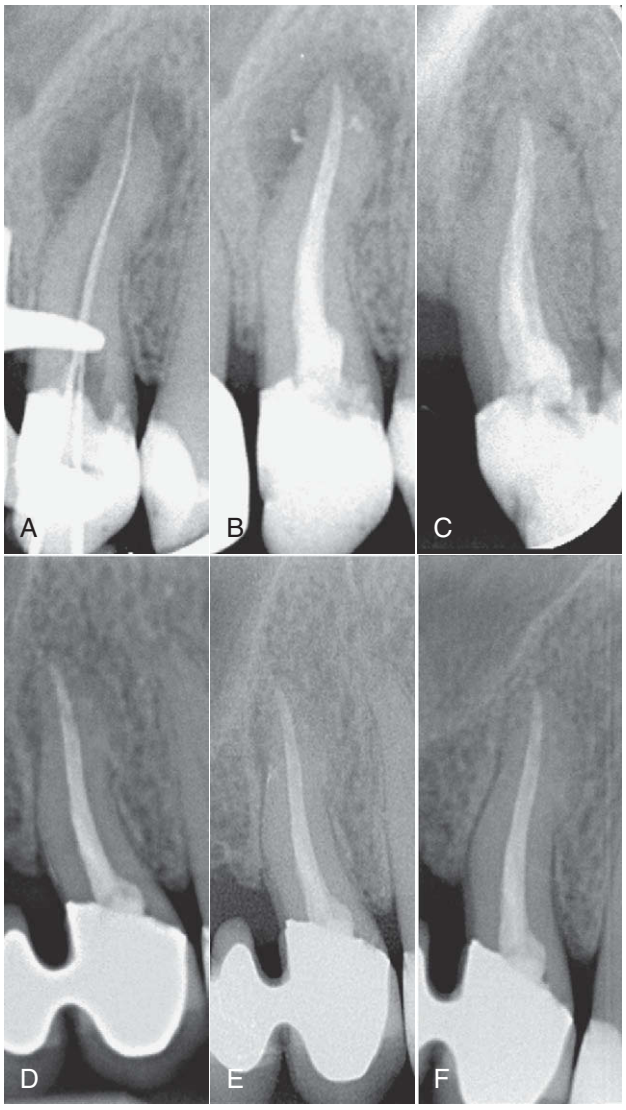

FIG. 9-16 Relationship of radicular anatomy and endodontic disease as shown by filled accessory canals. **A,** Working length radiograph of tooth #13 shows lesions mesially and distally but not apically. **B,** Posttreatment radiograph shows the accessory anatomy. **C,** Six-month recall radiograph before placement of the restoration. **D,** Two-year recall radiograph after resection of the mesiobuccal root of tooth #14 and placement of a fixed partial denture. models; and group III, rotary instruments with specific design changes, such as the ProTaper (DENTSPLY Maillefer) and RaCe (FKG, La Chaux-de-Fonds, Switzerland).

LightSpeed and LightSpeed LSX Instruments

The LightSpeed file, developed by Dr. Steve Senia and Dr. William Wildey in the early 1990s and now also known as *LS1*, was introduced as an instrument different from all others because of its long, thin noncutting shaft and short anterior cutting part. The same design principles apply to the recently developed LSX instrument (Discus Dental, Culver City, CA, USA) (Fig. 9-23) that is manufactured not by milling but by stamping. A full set consists of 25 LightSpeed LS1 instruments in sizes #20 to #100, including half sizes (e.g., 22.5, 27.5); LSX does not have half sizes, and a set includes sizes #20 to #80.

The recommended working speed for LS1 instruments is 1500 to 2000 rpm and for LSX, 2500 rpm. Both variants should be used with minimal torque,[32] owing to the thin shaft.[120]

Cross sections of LightSpeed LS1 cutting parts show three round excavations, the U-shape design common to many earlier NiTi instruments, whereas the LSX is shaped like a flat chisel in cross section (see Fig. 9-23). Because of the thin noncutting shaft, both types of LightSpeed instruments are considerably more flexible than any other instrument on the market. In addition, cyclic fatigue is lower than with all other instruments, allowing the use of higher rpm speeds. All LightSpeed instruments feature a noncutting tip.

Because of their design, LightSpeed LS1 and LSX require specific instrumentation sequences to produce canal shapes amenable to root canal filling. The current recommendation calls for an apical 4-mm zone to be prepared to a cylindrical, nontapered shape. This section may then be filled with the proprietary SimpliFill system (Discus Dental). Different sequences are required for lateral compaction or other filling techniques.

The original LightSpeed is a widely researched NiTi rotary instrument,[49,319,321,375,415,416] and most reports have found that the system has a low incidence of canal transportation and preparation errors. Loss of working length was also minimal in most of these studies. Data regarding the LSX are sparse. One report found similar shaping abilities for LSX and LightSpeed LS1 assessed with a double-exposure technique.[196]

ProFile

The ProFile system (DENTSPLY Tulsa Dental) was introduced by Dr. Ben Johnson in 1994. In contrast to the LightSpeed instrument with its thin, flexible shaft, ProFile instruments have increased tapers compared with conventional hand instruments. The ProFile system was first sold as the "Series 29" hand instruments in .02 taper, but it soon became available in .04 and .06 taper (Fig. 9-24). The tips of the ProFile Series 29 rotary instruments had a constant proportion of diameter increments (29%). Because of the nonstandardized diameters, obturation was performed with nonstandardized gutta-percha cones, using either lateral compaction or thermoplastic obturation of gutta-percha (see Chapter 10). Later, another ProFile series with ISO-sized tips (DENTSPLY Maillefer) was developed and marketed in Europe. This set was believed to better accommodate standardized gutta-percha cones, which are predominantly used in Europe. Subsequently, instruments with even greater tapers and 19-mm lengths were introduced, and a .02 variant was added.

Cross sections of a ProFile instrument show a U-shape design with radial lands and a parallel central core. Lateral views show a 20-degree helix angle, a constant pitch, and bullet-shaped noncutting tips. Together with a neutral or slightly negative rake angle, this configuration facilitates a reaming action on dentin rather than cutting. Also, debris is transported coronally and is effectively removed from the root canals.

The recommended rotational speed for ProFile instruments is 150 to 300 rpm, and to ensure a constant rpm level, the preferred means is electrical motors with gear reduction rather than air-driven motors.

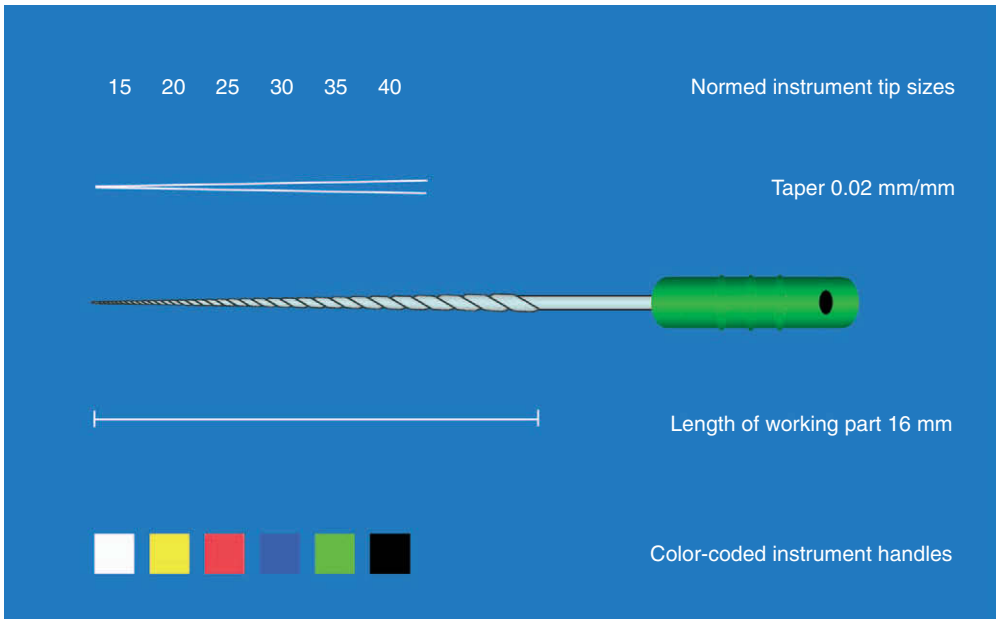

FIG. 9-17 Schematic drawing of an ISO-normed hand instrument size #35. Instrument tip sizing, taper, and handle colors are regulated by the ISO/ANSI/ADA norm.

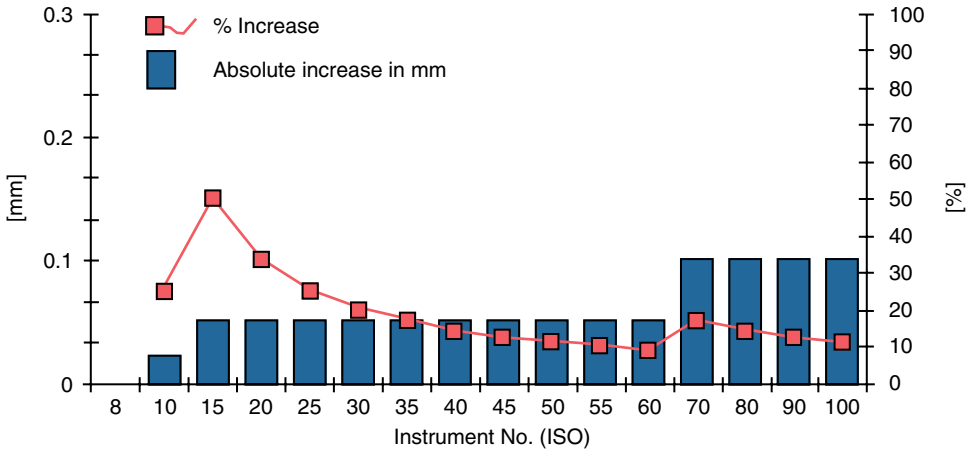

FIG. 9-18 Increase in tip diameter in absolute figures and in relation to the smaller file size. Note the particularly large increase from size #10 to size #15.

ProFile instruments shaped canals without major preparation errors in a number of in vitro investigations.[72,73,417,418] A slight improvement in canal shape was noted when size .04 and .06 tapered instruments were used in an alternating fashion.[71] Loss of working length did not exceed 0.5 mm[71-73,417,418] and was not affected by the use of .06 tapered instruments.[71] Comparative assessments in vitro suggested that ProFile prepared mesial canals in mandibular molars with less transportation than K3 and RaCe.[14]

A very recent addition to the ProFile family of instruments is the Vortex (DENTSPLY Tulsa Dental). The major change lies in the non-landed cross section, whereas tip sizes and tapers are similar to existing ProFiles. Manufactured using M-Wire, Profile Vortex also have varying helical angle to counteract the tendency of non-landed files to thread into the root canal. At this point, comparatively little clinical or experimental data are available for ProFile Vortex.

GT and GTX Files

The Greater Taper, or GT file, was introduced by Dr. Steve Buchanan in 1994. This instrument also incorporates the U-file design and was marketed as ProFile GT. The system was first produced as a set of four hand-operated files and later as engine-driven files. The instruments came in four tapers (.06, .08, .10, and .12), and the maximum diameter of the working part was 1 mm. This decreased the length of the cutting flutes and increased the taper. The instruments had a variable pitch and an increasing number of flutes in progression to the tip; the apical instrument diameter was 0.2 mm. Instrument tips were noncutting and rounded (Fig. 9-25); these design principles are mostly still present in the current incarnation, the GTX instrument. The main differences are the NiTi alloy type used (M-Wire, manufactured by SportsWire, Langley, OK) and a different approach to instrument usage, emphasizing the use of the #20 .06 rotary.

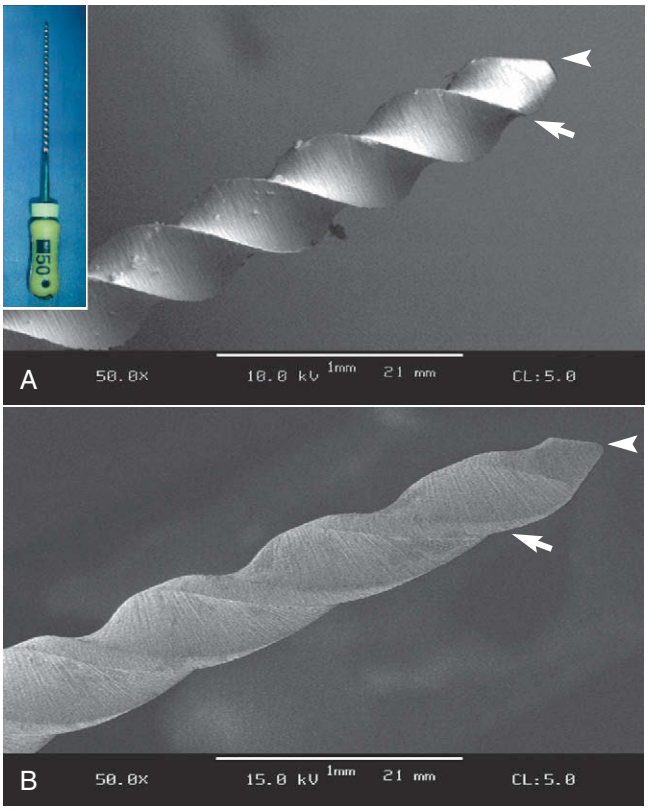

FIG. 9-19 Flute geometry and tip configuration of a hand file *(insert)* and a NiTi rotary instrument. **A,** K-file with sharp cutting edges *(arrow)* and Batt tip *(arrowhead)*. **B,** GT rotary file with rounded, noncutting tip *(arrowhead)*, smooth transition, and guiding radial lands *(arrow)*.

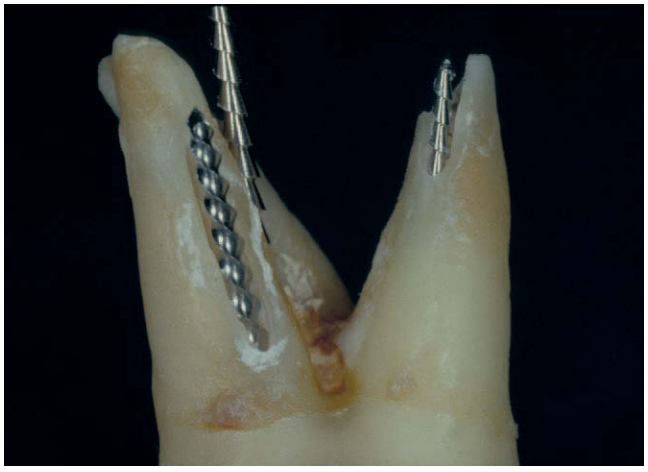

FIG. 9-20 Result of an overenthusiastic attempt at root canal treatment of a maxillary second molar with large stainless steel files. Multiple strip perforations occurred; consequently, the tooth had to be extracted.

The GTX set currently includes tip sizes 20, 30, and 40, in tapers ranging from .04 to .010 (see Fig. 9-25). The recommended rotational speed for GT and GTX files is 300 rpm, and the instrument should be used with minimal apical force to avoid fracture of the tip.

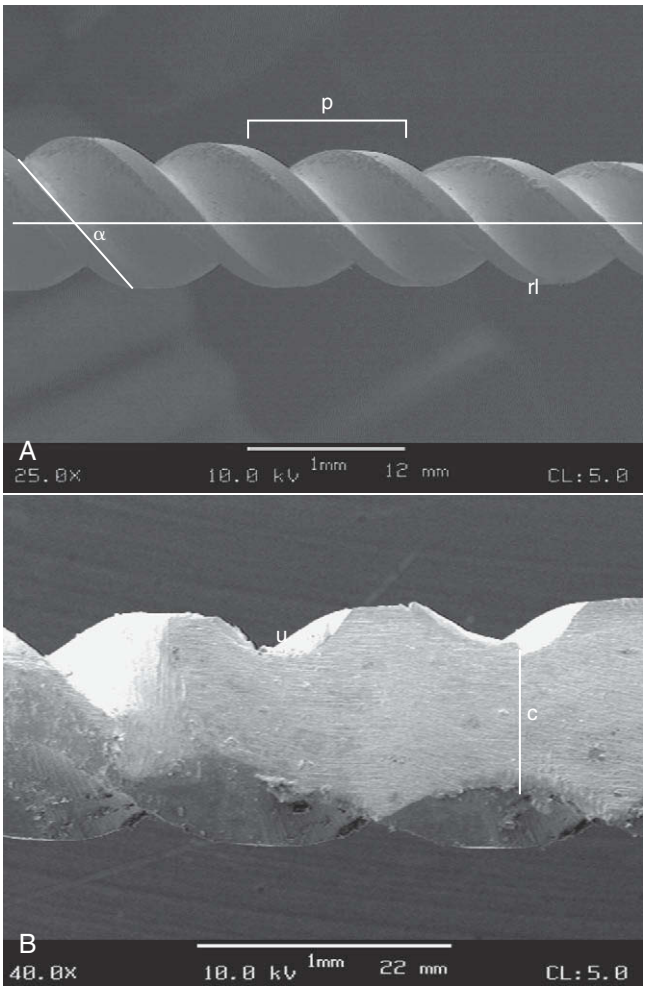

FIG. 9-21 Design characteristics of nickel-titanium rotary instruments. **A,** Lateral view showing the details of the helix angle, pitch *(p)*, and the presence of guiding areas, or radial lands *(rl)* (scanning electron micrograph [SEM], ×25). **B,** Ground working part of the instrument in **A,** showing U-shaped excavations and the dimension of the instrument core *(c)*.

Studies on GT files found that the prepared shape stayed centered and was achieved with few procedural errors.[149,178,310,316,479] A shaping assessment using µCT showed that GT files machined statistically similar canal wall areas compared with ProFile and LightSpeed preparations.[310] These walls were homogeneously machined and smooth.[294,479]

HERO 642, Hero Shaper

First-generation rotary systems had neutral or slightly negative rake angles. Several second-generation systems were designed with positive rake angles, which gave them greater cutting efficiency. HERO instruments (MicroMega, Besançon, France) are an example of a second-generation system; the original system known as *HERO 642* has now been replaced by HERO Shaper, with very little difference in the instrument design.

Cross sections of HERO instruments show geometries similar to those of an H-file without radial lands (Fig. 9-26). Tapers of .02, .04, and .06 are available in sizes ranging from #20 to #45. The instruments are relatively flexible (the acronym

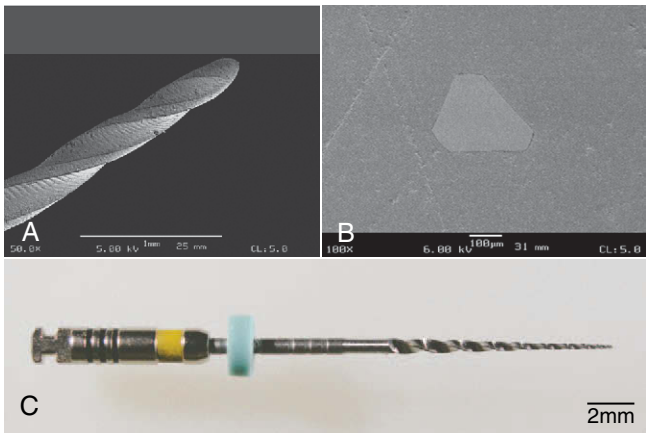
HERO stands for *h*igh *e*lasticity in *ro*tation) but maintain an even distribution of force into the cutting areas.[430,431] HERO instruments have a progressive flute pitch and a noncutting passive tip, similar to other NiTi rotary systems. The instruments are coded by handle color.

Research with HERO files indicates a shaping potential similar to that of the FlexMaster[189] (DENTSPLY VDW, Munich, Germany) and the ProFile,[147] although in one study the HERO induced more changes in cross-sectional anatomy.[157] HERO instruments also were found to cause some aberrations when used in simulated canals with acute curves[414] but were safer than Quantec SC instruments (SybronEndo, Orange, CA).[193] More recently, HERO Shapers were found to have a better centering ability compared to RaCe instruments in resin blocks.[28] Comparing earlier HERO 642 and current HERO Shaper rotaries, no differences were found assessing cross sections before and after shaping in a modified Bramante technique.[84]

ProTaper Universal

The ProTaper system is based on a unique concept and originally comprised just six instruments: three shaping files and three finishing files. This set is now complemented by two larger finishing files and a set designed for retreatment procedures. The instruments were designed by Dr. Cliff Ruddle, Dr. John West, and Dr. Pierre Machtou. In cross section, ProTaper shows a modified K-type file with sharp cutting edges and no radial lands (Fig. 9-27); this creates a stable core and sufficient flexibility for the smaller files. The cross section of finishing files F3, F4, and F5 is slightly relieved for increased flexibility. A unique design element is varying tapers along the instruments' long axes. The three shaping files have tapers that increase coronally, and the reverse pattern is seen in the five finishing files.



Shaping files #1 and #2 have tip diameters of 0.185 mm and 0.2 mm, respectively, 14-mm-long cutting blades, and partially active tips. The diameters of these files at D_{14} are 1.2 and 1.1 mm, respectively. The finishing files (F1-F5) have tip diameters of 0.2, 0.25, 0.3, 0.4, and 0.5 mm, respectively, between D_0 and D_3, and the apical tapers are .07, .08, .09, .05, and .04, respectively. The finishing files have rounded noncutting tips.

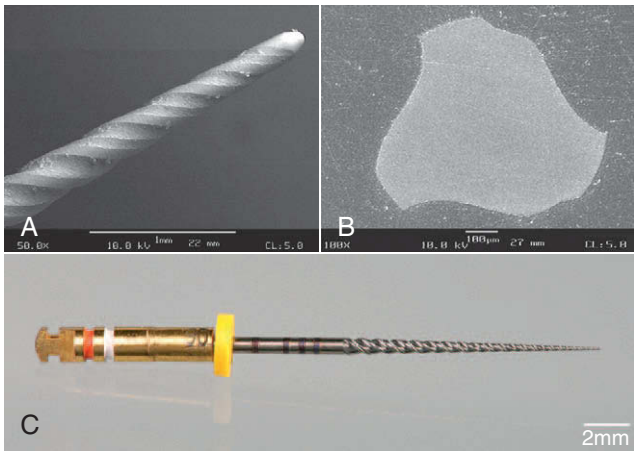
The convex triangular cross section of ProTaper instruments reduces the contact areas between the file and the dentin. The greater cutting efficiency inherent in this design has been safely improved by balancing the pitch and helix angle, preventing the instruments from inadvertently threading into the canal. The instruments are coded by colored rings on the handles. ProTaper instruments can be used in gear reduction electrical handpieces at 250 to 300 rpm, in accordance with universally recognized guidelines. Two usage characteristics have been recommended for ProTaper. The first is the preparation of a glide path, either manually[298] or with special rotary instruments.[52] An enlargement to a size approaching the subsequent rotaries' tips prevents breakage and allows assessment of the canal size.[298] The second specific recommendation is the use of a more lateral "brushing" working stroke. Such a stroke allows the clinician to direct larger files coronally away from danger zones and counteract any "threading-in" effect.[58] Both usage elements should be considered good practice for other instruments, particularly more actively cutting ones.[314]

In a study using plastic blocks, the ProTaper created acceptable shapes more quickly than GT rotary, ProFile, and Quantec instruments[479] but also created somewhat more aberrations. This was recently corroborated comparing preparations of mesial root canals in mandibular molars ex vivo with ProTaper Universal to Alpha (Brasseler Komet, Lemgo, Germany).[440] In a comparison of ProTaper and K3 instruments (SybronEndo, Orange, CA), Bergmans et al.[48] found few differences, with the exception of some transportation by the ProTaper into the furcation region. A study using µCT showed that the ProTaper created consistent shapes in constricted canals, without obvious preparation errors, although wide canals may be insufficiently prepared with this system.[308] It has been recommended that ProTaper be combined with less tapered, more flexible rotaries to reduce apical transportation.[199]



K3

In a sequence of constant development by their inventor, Dr. McSpadden, the Quantec 2000 files were followed by the Quantec SC, the Quantec LX, and the current K3 system (all by SybronEndo). The overall design of the K3 is similar to that of the ProFile and the HERO in that it includes instruments with .02, .04, and .06 tapers. The most obvious difference between the Quantec and K3 models is the K3's unique cross-sectional design (Fig. 9-28): a slightly positive rake angle for greater cutting efficiency, wide radial lands, and a peripheral blade relief for reduced friction. Unlike the Quantec, a two-flute file, the K3 features a third radial land to help prevent threading-in.

In the lateral aspect, the K3 has a variable pitch and variable core diameter, which provide apical strength. This complicated design is relatively difficult to manufacture, resulting in some metal flash (see Fig. 9-28).

Like most other instruments, the K3 features a round safety tip, but the file is about 4 mm shorter than other files (although it has the same length of cutting flutes) because of the Axxess handle. The instruments are coded by ring color and number.

Tested in vitro, K3's shaping ability seems to be similar to that of the ProTaper[48] and superior to that achieved with hand instruments.[357] More recently, when curved canals in lower molars were shaped to a size #30 .06,[14] K3 had less canal transportation in a modified Bramante model than RaCe but more than ProFile.

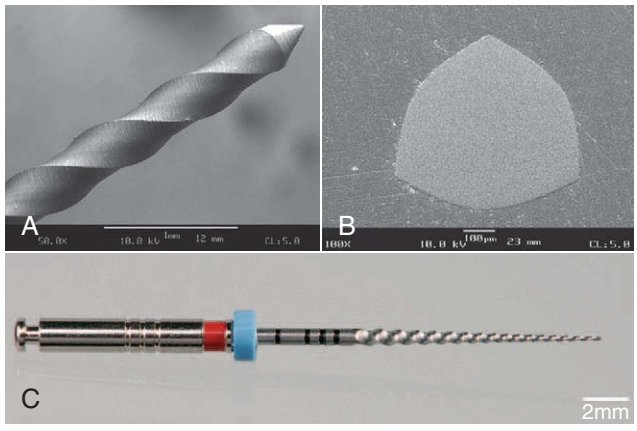
FlexMaster

The FlexMaster file system currently is unavailable in the United States. It also features .02, .04, and .06 tapers. The cross sections (Fig. 9-29) have a triangular shape, with sharp cutting edges and no radial lands. This makes for a relatively solid instrument core and excellent cutting ability. The overall manufacturing quality is high, with minimal metal flash and rollover.

FlexMaster files have rounded, passive tips; the tip diameters are 0.15 to 0.7 mm for size .02 instruments and 0.15 to 0.4 mm for size .04 and .06 files (see Fig. 9-29). In addition to the standard set, the Intro file, which has a .11 taper and a 9-mm cutting part, is available. The instruments are marked with milled rings on the instrument shaft, and the manufacturer provides a system box that indicates sequences for narrow, medium-size, and wide canals.

Several studies indicate that the FlexMaster allows centered preparations in both constricted and wider canals[188] and that it performed on par with other systems.[189,455] Clinical studies confirmed that the FlexMaster showed superior shaping characteristics compared with K-files.[358] Also, novice dental students were able to shape plastic blocks successfully with the FlexMaster after a short training period.[392,393] Tested in a well-described model of simulated canals, FlexMaster instruments led to few aberrations but took longer than preparation with RaCe files.[263] Moreover, FlexMaster appeared to be less effective than RaCe in removing dye from the walls of simulated canals prepared to size #30 but were more effective than ProFile.[362]

RaCe, Bio Race

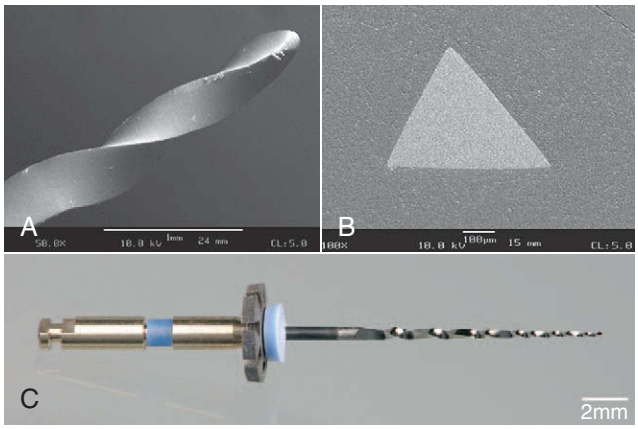


The RaCe has been manufactured since 1999 by FKG and was later distributed in the United States by Brasseler (Savannah, GA). The name, which stands for *reamer with alternating cutting edges,* describes just one design feature of this instrument (Fig. 9-30). Light microscopic imaging of the file shows flutes and reverse flutes alternating with straight areas; this design is aimed at reducing the tendency to thread the file into the root canal. Cross sections are triangular or square for #.02 instruments with size #15 and #20 tips. The lengths of cutting parts vary from 9 to 16 mm (see Fig. 9-30).

The surface quality of RaCe instruments has been modified by electropolishing, and the two largest files (size #35, #.08 taper and size #40, #.10 taper) are also available in stainless steel. The tips are round and noncutting, and the instruments are marked by color-coded handles and milled rings. RaCe instruments have been marketed in various packages to address small and large canals; recently they are sold as BioRaCe, purportedly to allow preparations two larger sizes, with an emphasis on the use of .02 tapered instruments.

Few results of in vitro experiments comparing RaCe to other contemporary rotary systems are available[359,360]: canals in plastic blocks and in extracted teeth were prepared by the RaCe with less transportation from the original curvature than occurred with the ProTaper.[359] In a separate study, ProTaper and RaCe performed similarly when canals were prepared to an apical size #30.[293] When preparing to a size #40, RaCe prepared canals rapidly and with few aberrations or instrument deformities.[324] The newer BioRaCe instrument sequences attempt to utilize .02 tapered instruments to promote larger apical sizes; this is also possible in a hybrid technique.

EndoSequence



The Sequence rotary instrument is produced by FKG in Switzerland and marketed in the United States by Brasseler. This is another instrument that adheres to the conventional

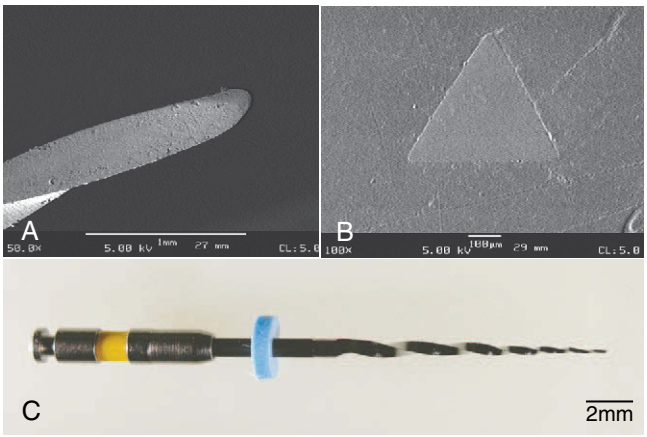
length of the cutting flutes, 16 mm, and to larger tapers, .04 and .06, to be used in a crown-down approach. The overall design, including the available tapers and cross sections, is thus similar to many other files (Fig. 9-31), but the manufacturer claims that a unique longitudinal design called *alternating wall contact points* (ACP) reduce torque requirements and keep the file centered in the canal. Another feature of the Sequence design is an electrochemical treatment after manufacturing, similar to RaCe files, that results in a smooth, polished surface. This is believed to promote better fatigue resistance, hence a rotational speed of 600 rpm is recommended for EndoSequence.[214]

Twisted File

In 2008, SybronEndo presented the first fluted NiTi file (Fig. 9-32, *A*) manufactured by plastic deformation, a process similar to the twisting process that is used to produce stainless steel K-files. According to the manufacturer, a thermal process allows twisting during a phase transformation into the so-called R-phase of nickel-titanium. The instrument is currently available with size #25 tip sizes only, in taper .04 up to .12.



The unique production process is believed to result in superior physical properties; indeed, early studies suggested significantly better fatigue resistance of size #25 .06 taper Twisted File compared to K3 instruments of the same size and size #20 .06 GTX.[146] Moreover, as determined by bending tests according to the norm for hand instruments, ANSI/ADA No. 28 (ISO 3630), Twisted Files size #25 .06 taper were more flexible than ProFiles of the same size.[145]

The manufacturer recommends a conventional crown-down technique after securing a glide path with a size #15 K-file. Specifically, for a "large" canal, tapers .10 to .06 should be used, and in a "small" canal, tapers .08 to .04 are recommended. Although early reports suggest that the Twisted File is clinically resistant to fatigue, there are no reports available at this point that show improved healing outcomes compared to other rotary files.

The preceding descriptions covered only a limited selection of the most popular and widely used rotary instruments on the market. New files are continually added to the armamentarium, and older systems are updated. This is partly the reason for the scarcity of clinical outcome studies at this point.

To summarize, most systems include files with tapers greater than the #.02 stipulated by the ISO norm. The LightSpeed LS1 and LSX are different from all other systems; the ProTaper, RaCe, and Twisted File have some unique features; and most other systems have increased tapers. Minor differences exist in tip designs, cross sections, and manufacturing processes, but the clinical effects of these modifications currently are unknown. Even in vitro, tests have only begun to identify the effect of specific designs on shaping capabilities,[50,192,301] and differences in clinical outcomes in regard to these design variations appear to be minimal.[165,303,358]

Physical parameters governing rotary root canal preparation are crucial because NiTi rotary files are felt to have an increased risk of fracture compared with K-files. In a study using plastic blocks, as many as 52 ProFile Series 29 instruments became permanently deformed.[417] Three fractures were reported in a subsequent study on ISO-norm ProFile size #.04 instruments, and three other instruments were distorted.[73] An even higher fracture incidence was shown in a study on rotary instruments used in plastic blocks in a specially designed testing machine.[412]

These findings were supported by two studies in which high fracture incidences were reported for LightSpeed and Quantec rotary instruments used in a clinical setting.[33,345]

On the other hand, a retrospective clinical study suggest similar outcomes with and without retained instrument fragments[400]; moreover, others' experiences suggest that the number of rotary instrument fractures is lower than previously estimated.[116,213,460] Removal of such fragments is possible in many situations, but there is also the potential for further damage (e.g., perforation) rather than successful removal.[405,453]

Consequently, a benefit-versus-risk analysis should be carried out prior to attempts to remove NiTi instrument fragments, addressing the reasons and the clinical consequences of instrument fracture.

Physical and Chemical Properties of NiTi Alloys

During the development of the equiatomic nitinol alloy (55% [by weight] nickel and 45% [by weight] titanium), a shape memory effect was noted; this was attributed to specific thermodynamic properties of the new alloy.[75] The alloy sparked interest in dental research because of its "shape recovery" property after passage through critical temperatures.[100] Some researchers envisioned the manufacture of nondulling rotary instruments from an alloy called *60-nitinol*. However, NiTi wire was found to be difficult to bend into clamp retainers.[100]

Subsequently, researchers thought that the superelastic properties of 55-nitinol might prove advantageous in endodontics, and the first hand instruments produced from 55-nitinol were tested (Fig. 9-33).[445] That study found that size #15 NiTi instruments were two to three times more flexible than stainless steel instruments. Nickel-titanium instruments showed superior resistance to angular deflection; they fractured after 2½ full revolutions (900 degrees) compared to 540 degrees for stainless steel instruments (see Fig. 9-33, C).

Furthermore, hardly any plastic deformation of cutting flutes was recorded when an instrument was bent up to 90 degrees,[445] and forces required to bend endodontic files to 45 degrees were reduced by 50% with NiTi.[370] In the latter study,

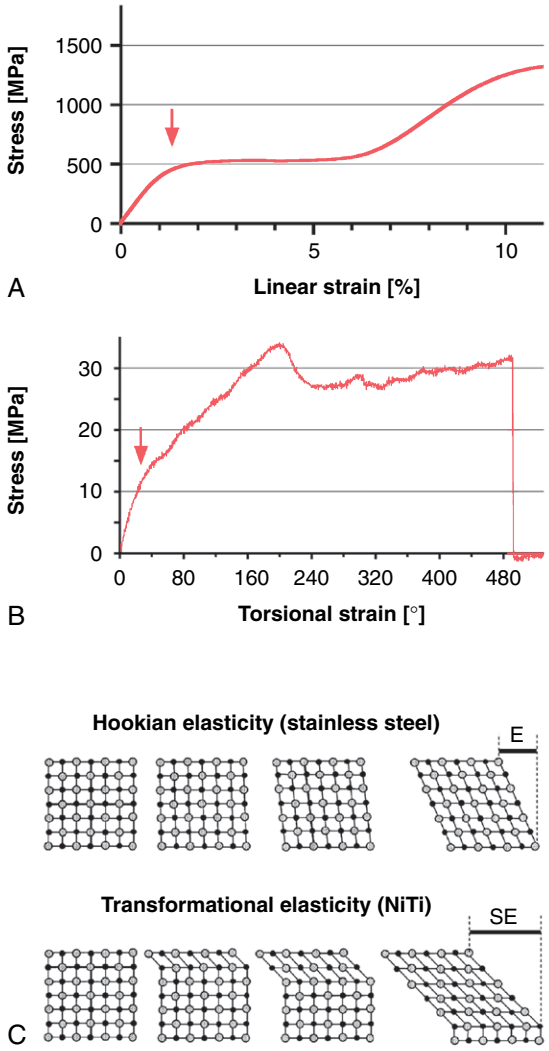

FIG. 9-33 Stress-strain behavior of nickel-titanium alloy. **A,** Schematic diagram of linear extension of a NiTi wire. **B,** Torque to failure test of a size #60, #.04 taper ProFile NiTi instrument. Note the biphasic deformation, indicated by arrows in **A-B. C,** Comparison of stainless steel and nickel-titanium crystal lattices under load. Hookian elasticity accounts for the elastic behavior *(E)* of steel, whereas transformation from martensite to austenite and back occurs during the superelastic *(SE)* behavior of NiTi alloy. *(**C** modified from Thompson SA: An overview of nickel-titanium alloys used in dentistry.* Int Endod J *33:297-310, 2000.)*

the authors speculated that heat, probably during sterilization cycles, could even restore the molecular structure of used NiTi files, resulting in an increased resistance to fracture.

Specific properties of NiTi can be explained by specific crystal structures of the austenite and martensite phases of the alloy.[413] Heating the metal above 212° F (100° C) may lead to a phase transition, and the shape memory property forces the instrument back to a preexisting form. Likewise, linear deforming forces are shunted into a stepwise transition from an austenitic to a martensitic lattice, and this behavior leads to a recoverable elastic response of up to 7% (see Fig. 9-33, A).

However, graphs such as those shown in Fig. 9-33, B are generated when larger NiTi instruments are subjected to angular deflection until failure. Such graphs show different results for stainless steel instruments, which produce a relatively steep stress-strain curve with less than 1.3% recoverable deformation.[413] As stated previously, the superelastic behavior of NiTi also dictates the production of NiTi instruments, which are usually milled.

Similarly to phase transformations induced by strain, heating and cooling NiTi can also result in conformational changes.[179,265] Thermal conditions during the production of the raw wire can be used to modify its properties—most importantly, its flexibility.

Recently, such a thermal process was harnessed to allow twisting of raw NiTi material into the shape of a nonlanded rotary instrument (Twisted File, SybronEndo). This process is believed to respect the grain structure of the material better and does not introduce milling marks or other surface irregularities.

Typically, NiTi instruments may have characteristic imperfections such as milling marks, metal flashes, or rollover.[125,370,426,445] Some researchers have speculated that fractures in NiTi instruments originate at such surface imperfections.[16,237]

Surface irregularities may also provide access to corrosive substances, most notably sodium hypochlorite (NaOCl). Some studies have suggested that chloride corrosion may lead to micropitting[344] and possibly subsequent fracture in NiTi instruments.[174] Not only immersion in various disinfecting solutions for extended periods (e.g., overnight) produced corrosion of NiTi instruments and subsequent decreased torsional resistance,[284,394] but for ProTaper,[51] RaCe, and ProFile[309] instruments, also short-term immersion. Other authors, however, did not find a corrosion-related effect on K3[35] or ProFile[257] instruments. Regular cleaning and sterilization procedures do not seem to affect NiTi rotary instruments.[231,266,406] In one study, only limited material loss occurred when NiTi LightSpeed instruments were immersed in 1% and 5% NaOCl for 30 to 60 minutes.[78] Corrosion of NiTi instruments used in the clinical setting, therefore, might not significantly contribute to fracture except when the instruments are immersed in warmed NaOCl for longer than 60 minutes. Although sterilization procedures per se do not have an impact on NiTi integrity,[184,266,326,377,442,489] there is an ongoing discussion over the impact of other aspects of clinical usage on the mechanical properties of NiTi rotaries. Most likely, clinical usage leads to some changes in the alloy, potentially work-hardening,[15] depending on the amount of torsional load the instrument was subjected to.

Over the last 4 years, several manufacturers have begun to utilize electropolishing, a process that removes surface irregularities such as flash and burr marks. It is believed to improve material properties, specifically fatigue and corrosion resistance; however, the evidence for both these claims is mixed. One study[24] found an extension of fatigue life for electropolished instruments, others found no improvement of fatigue resistance of electropolished instruments.[76,94,182] Still other researchers[59] suggested a change in cutting behavior with an increase of torsional load after electropolishing. Corrosion resistance of electropolished NiTi rotaries is also controversial. One study[62] found superior corrosion resistance for electropolished RaCe instruments, whereas another study[309] found similar corrosion susceptibility for RaCe and non-

electropolished ProFile instruments. A recent review[374] points out difficulties in assessing NiTi properties by conventional corrosion tests, since they do not take deformation and consequent surface deformation into account.

Fracture Mechanisms

In general, instruments used in rotary motion break in two distinct modes, torsional and flexural.[302,345,433] Torsional fracture occurs when an instrument tip is locked in a canal while the shank continues to rotate, thereby exerting enough torque to fracture the tip. This also may occur when instrument rotation is sufficiently slowed in relation to the cross-sectional diameter. In contrast, flexural fracture occurs when the cyclic loading leads to metal fatigue. This problem precludes the manufacture of continuously rotating stainless steel endodontic instruments, because steel develops fatal fatigue after only a few cycles.[370] NiTi instruments can withstand several hundred flexural cycles before they fracture,[173,227,321,433,475] but they still can fracture in the endodontic setting after a low (i.e., below 10,000) number of cycles.[92]

Repeated loading and cyclic fatigue tests for endodontic instruments are not described in pertinent norms. Initially, rotary instruments such as Gates-Glidden burs and Peeso reamers were tested with a superimposed bending deflection.[66] In GG burs, a 2-mm deflection of the instrument tip resulted in fatigue lifespans ranging from 21,000 revolutions (size #1 burs) to 400 revolutions (size #6 burs).[66] In another study, stainless steel and NiTi hand files were rotated to failure in steel tubes with an acute 90-degree bend and an unspecified radius.[370] Under these conditions, size #40 stainless steel instruments fractured after fewer than 20 rotations, whereas various NiTi files of the same size withstood up to 450 rotations.

Cyclic fatigue was also evaluated for ProFile size #.06 instruments using a similar device.[474,475] The number of rotations to failure for unused control instruments ranged from 1260 (size #15 files) to 900 (size #40 files). These scores did not change when the instruments were tested under simulated clinical conditions such as repeated sterilization and contact with 2.5% NaOCl. Subsequently, control instruments were compared with a group of instruments used in the clinical setting in five molar cases[474]; again, no significant differences were found in resistance to cyclic fatigue.

One study[173] used a different testing method involving tempered metal cylinders with radii of 5 mm and 10 mm that produced a 90-degree curve. They reported fatigue fractures for size #15, #.04 taper ProFile instruments after about 2800 cycles with the 10 mm cylinders. In size #40, #.04 taper ProFile instruments, fractures occurred after about 500 cycles with the 5-mm cylinders. In comparison, size #15, #.06 taper ProFile instruments also failed after about 2800 revolutions with the 10-mm cylinders, but failure occurred in size #40, #.06 taper ProFile specimens after only 223 cycles with the 5-mm cylinders.

Rotary NiTi instruments with larger tapers and sizes consistently fractured after fewer rotations,[313] and although the radius of the curves was halved, fatigue-life was reduced by 400%. Another investigation[173] reported similar results for selected HERO instruments, and their findings were confirmed by other tests on GT rotary instruments. Size #20, #.06 taper GT files failed after 530 rotations in a 90-degree curve with a 5-mm radius; size #20, #.12 taper GT files failed after 56 rotations under the same conditions.[306]

Reuse of rotary instruments depends on safety, specifically on assessment of fatigue and also the potential to properly clean NiTi surfaces.[34,61,284,289,376,394,396,427] Specific instruments perform differently in this regard, since fatigue depends more on the amount of metal in cross section at the point of stress concentration[159,425] than on the specifics of instrument design.[93]

On the other hand, manufacturers claim that their instrument has been equipped with design elements that render it more fatigue resistant. For example, LightSpeed LSX is manufactured without a milling process. However, no data have been published regarding its fatigue resistance. GTX is manufactured from a novel NiTi alloy, M-Wire, to increase its fatigue resistance.[203] However, investigators[216] could not confirm these findings. Similarly, another study[223] did not find the Twisted File, which is not milled and hence believed to be fatigue resistant,[146] to perform better than conventionally manufactured ProFile rotaries. Another feature, electropolishing (see earlier) does not appear to confer a significantly increased fatigue resistance to EndoSequence[223,328] and RaCe.[425,427,471] One possible reason for these variable outcomes are the different testing environments used in vitro[95]; clinically, even greater variability is to be expected.

Attempts have been made to use tests according to norms and specifications described for stainless steel hand instruments such as K-files and Hedström files,[117] since no comparable norms exist for instruments used in continuous rotary motion. Consequently, a number of models have been devised to assess specific properties of NiTi rotary instruments, including torque at failure, resistance against cyclic fatigue, and others (Fig. 9-34). These systems can simultaneously assess torque at failure, working torque axial force, and cyclic fatigue (Fig. 9-35).

According to the norms mentioned previously, torque at failure is recorded with the apical 3 mm of the instrument firmly held in the testing device while the instrument's handle is rotated. A wide variety of rotary NiTi endodontic instruments have been tested in this way. For example, ProFile NiTi

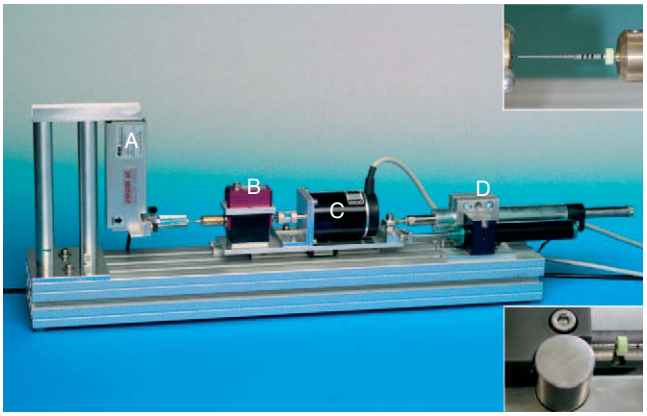

FIG. 9-34 Testing platform for analysis of various factors during simulated canal preparation with rotary endodontic instruments. Labeled components are a force transducer **(A),** a torque sensor **(B),** a direct-drive motor **(C),** and an automated feed device **(D).** For specific tests, a cyclic fatigue phantom or a brass mount compliant with ISO No. 3630-1 *(inserts)* may be attached.

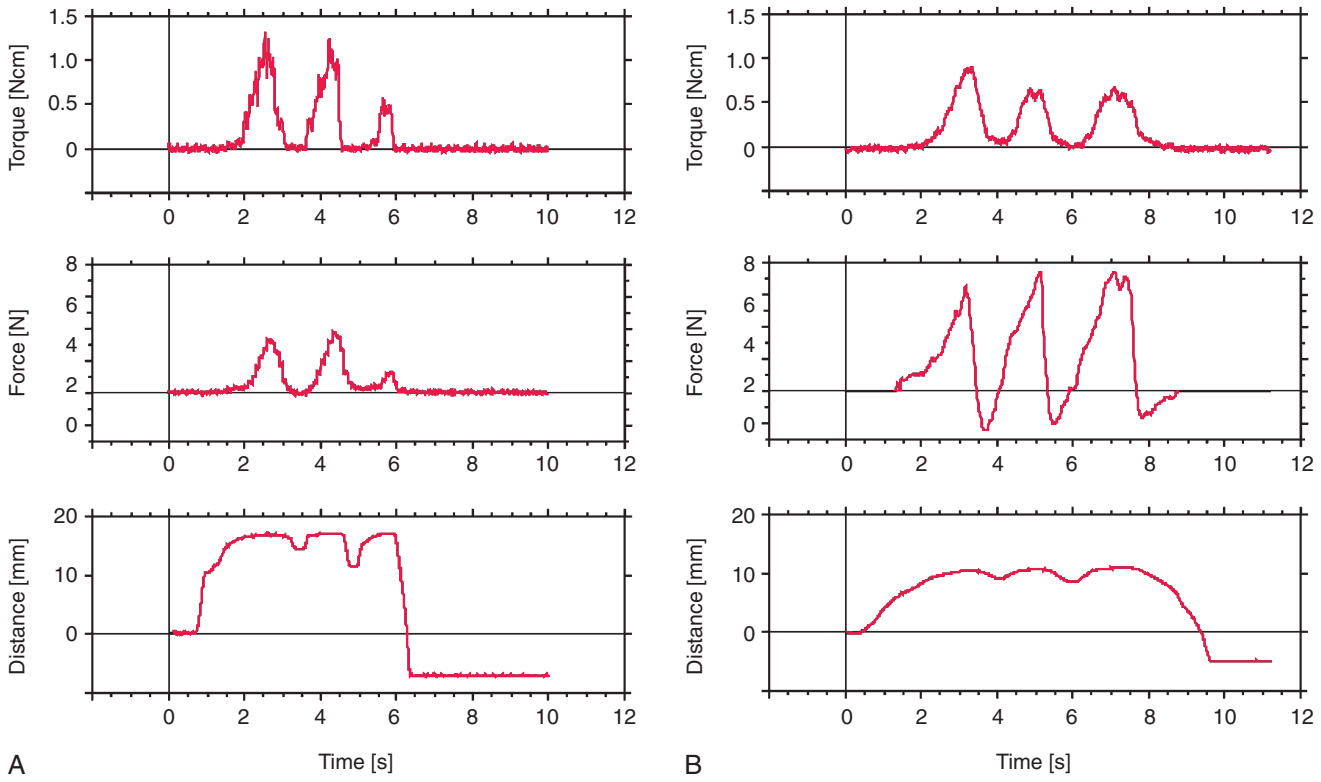

FIG. 9-35 Physical factors (torque, axial force, and insertion depth) that affect root canal instrumentation documented with a torque-testing platform. **A,** ProFile size #45, #.04 taper used in a mildly curved canal of a single-rooted tooth, step-back after apical preparation to size #40. **B,** FlexMaster size #35, #.06 taper used in a curved distobuccal canal of a maxillary first molar, crown-down during the initial phase of canal preparation.

rotary files in ISO sizes #25, #30, and #35 (#.04 taper) fractured at 0.78, 1.06, and 1.47 Ncm, respectively.[406]

Investigators[407] reported similar scores when instruments were forced to fracture in plastic blocks with simulated curved canals. In a different setup, GT rotary instruments (size #20, #.06 taper to size #20, #.12 taper) fractured at 0.51 and 1.2 Ncm, respectively.[306] These values are somewhat lower than recent data obtained from the same but slightly modified torque bench,[209] pointing towards the importance of experimental conditions for torque and fatigue measurements.

Compared with NiTi instruments with tapered flutes, LightSpeed instruments had lower torques to fracture (0.23 to 2 Ncm[254]). No such data are currently available for Lightspeed LSX.

When analyzing clinical factors involved in instrument fracture, one must consider both torsional load and cyclic fatigue[345] (Fig. 9-36). However, these are not separate entities, especially in curved canals.[63] Working an instrument with high torque may lower resistance to cyclic fatigue.[142] Conversely, cyclic prestressing has been shown to reduce the torsional resistance of ProTaper finishing files,[433] as well as K3[30] and MTwo[313] (DENTSPLY VDW, Munich, Germany). Also, cyclic fatigue occurs not only in the lateral aspect when an instrument rotates in a curved canal but also axially when an instrument is bound and released by canal irregularities.[54]

The torque generated during canal preparation depends on a variety of factors, and an important one is the contact area.[57] The size of the surface area contacted by an endodontic instrument is influenced by the instrumentation sequence or by the use of instruments with different tapers.[364] A crown-down approach is recommended to reduce torsional loads (and thus the risk of fracture) by preventing a large portion of the tapered rotating instrument from engaging root dentin (known as *taper lock*).[57,476]

The clinician can further modify torque by varying axial pressure, because these two factors are related[364] (see Fig. 9-35). In fact, a light touch is recommended for all current NiTi instruments to avoid forcing the instrument into taper lock. The same effect might occur in certain anatomic situations, such as when canals merge, dilacerate, and divide.

The torsional behavior of NiTi rotary endodontic instruments cannot be described properly without advanced measurement systems and a new set of norms. However, the clinician must be able to interpret correctly the stress-strain curves for all rotary NiTi instruments used in the clinical setting to be able to choose an appropriate working torque and axial force.

Motors and Devices

Newer motors have been developed for rotary instruments since the simple electric motors of the first generation in the early 1990s (Fig. 9-37, *A*). Electric motors with gear reduction are more suitable for rotary NiTi systems because they ensure a constant rpm level; however, they also deliver torques much higher than those required to break tips. Some authors believe that torque-controlled motors (see Fig. 9-37, *B* to *D*), which

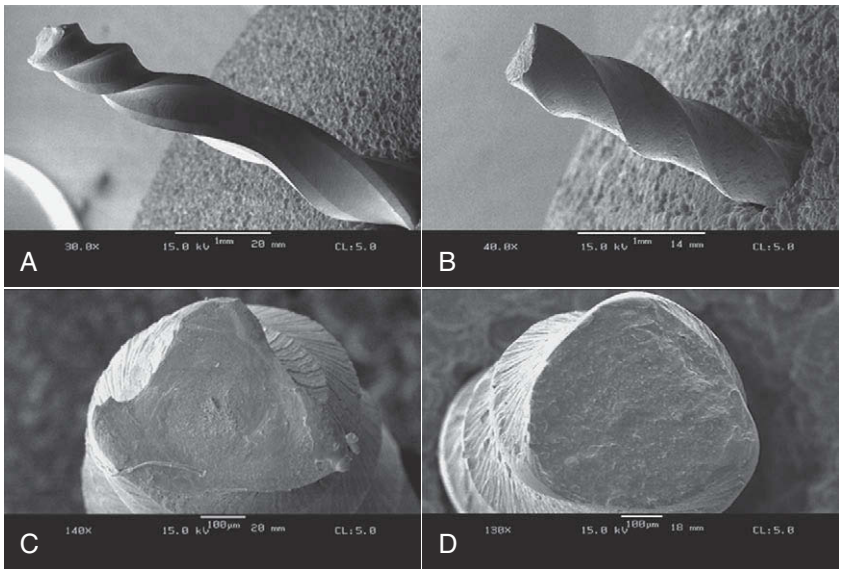

FIG. 9-36 Scanning electron micrographs of deformed or separated nickel-titanium rotary instruments. **A,** Lateral view of a ProTaper F3 instrument after application of torsional load (×25). **B,** Lateral view of a size #35, #.04 taper FlexMaster instrument after more than 500 rotations in a 90-degree curve with a 5-mm radius (see Figure 9-31) (×30). **C,** Cross section of the ProTaper instrument in **A.** Note signs of ductile fracture near center of the instrument core (×140). **D,** Cross section of FlexMaster instrument in **B** (×100).

FIG. 9-37 Examples of motors used with rotary nickel-titanium endodontic instruments. **A,** First-generation motor without torque control. **B,** Fully electronically controlled second-generation motor with sensitive torque limiter. **C,** Frequently used simple torque-controlled motor. **D,** Newest-generation motor with built-in apex locator and torque control.

have been used for several years, increase operational safety.[143] However, others have suggested that torque-control motors may be helpful mainly to inexperienced clinicians.[476] These motors probably do not reduce the risk of fracture caused by cyclic fatigue, and even if the torque is below the fracture load at D_3, a fracture at a smaller diameter (D_2) is still possible.

To complicate matters further, an obvious differential exists between torque at failure at D_3 and the working torque needed to operate an instrument effectively (Fig. 9-38 and Box 9-2).[58,187,302,307,346] In many cases, the working torque is greater than the torque required to fracture the instrument's tip. However, the tip will not break if a passive glide path has been verified.

This differential is especially large with files with a taper equal to or greater than #.06; therefore, these files are rather ineffective in most torque-controlled motors. Most motors allow adjustment of torque for the instrument used, either with a key or a system card that is inserted into the box.

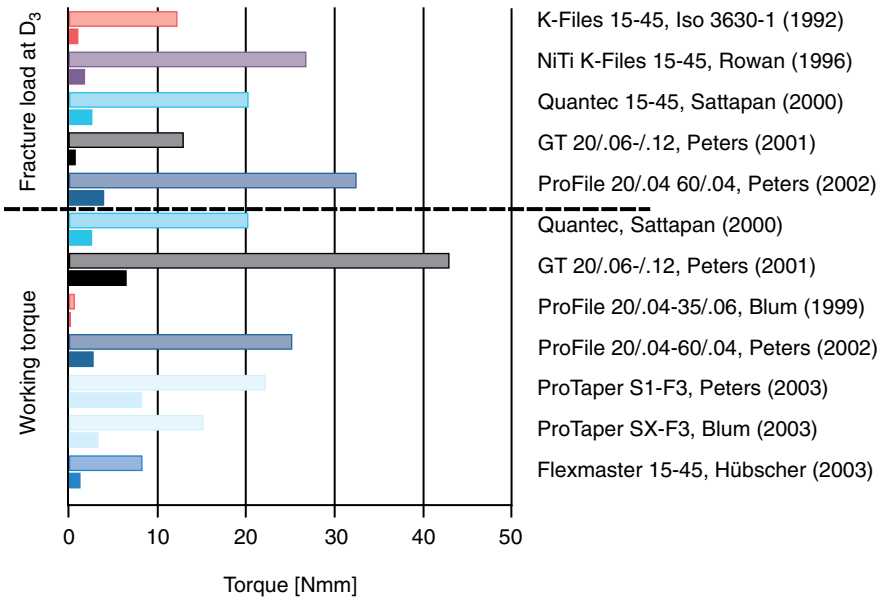

FIG. 9-38 Diagram comparing fracture loads at D_3 *(upper section of graph)* to torques occurring during preparation of root canals *(lower section of graph)*. Filled columns represent the largest file in each set, and open columns show the scores of the most fragile file (see text and Box 9-3 for details).

BOX 9-2

Instrument Breakage With Torsional Load (MacSpadden Factor)

For rotary instrument tips, susceptibility to breakage is governed by the quotient of torque needed to fracture divided by working torque. Simply put, the larger the value, the safer the file.

BOX 9-3

Factors Governing the Potential for Nickel-Titanium Rotary Instrument Fractures

- Clinician's handling (most important)
- Combination of torsional load, bending, and axial fatigue
- Root canal anatomy
- Manufacturing process and quality

One way to mitigate problems with continuous rotation (e.g., taper lock, fatigue fracture) is to return to oscillation. One researcher[472] has recently described such an approach. Based on experiments evaluating the maximal rotational angle before plastic deformation for the selected instrument, he recommends ProTaper F2, a forward angle of 144 degrees, followed by a reverse rotation of 72 degrees. This cycle continues at 400 rpm until working length is reached. Preliminary experiments and clinical results are encouraging, but more research is needed to optimize motor settings and instrument selection for this approach.

Other factors that may influence the incidence of fracture in motor-driven NiTi rotary instruments are lubrication, specific instrument motion, and speed of rotation. It cannot be overemphasized that NiTi rotary instruments should be used only in canals that have been flooded with irrigant. Although lubricants such as RC-Prep (Premier, Norristown, PA) and Glyde (DENTSPLY Maillefer) have also been recommended, their benefit may be restricted to plastic blocks,[23] rather than relevant when rotary instruments engage dentin surfaces.[60,304] In fact, because of chemical interactions between NaOCl and ethylenediamine tetra-acetic acid (EDTA),[161] alternating irrigants and using lubricants that contain EDTA may even be counterproductive. Moreover, no data have been produced linking the use of lubricants to reduction of torque during clinical root canal preparation.

For instrument motion, most manufacturers usually recommend a pecking, up-and-down motion. This not only prevents threading in of the file, it is also believed to distribute stresses away from the instrument's point of maximum flexure where fatigue failure would likely occur.[227,321] However, such in-and-out movements did not significantly enhance the lifespan of ProFile size #.04 or GT rotary instruments rotated around a 5-mm radius cylinder with a 90-degree curve.[302,305] Furthermore, large variations were noted in the lengths of the fractured segments,[187,433] which suggests that ductile fractures may originate at points of surface imperfections.

Rotational speed may also influence instrument deformation and fracture. Some studies indicated that ProFile instruments with ISO-norm tip diameters failed more often at higher rotational speed,[119,141] whereas other studies did not find speed to be a factor.[113,206]

Clinicians must fully understand the factors that control the forces exerted on continuously rotating NiTi instruments (Box 9-3). To minimize the risk of fracture and prevent taper lock, they should not try to force motor-driven rotary instruments in an apical direction. Similarly, acute apical curves limit the use of instruments with higher tapers because of the risk of cyclic fatigue. The incidence of instrument fracture can be reduced to an absolute minimum if clinicians use data from well-designed torque and stress studies. Adequate procedural strategies, a detailed knowledge of anatomic structures, and specific instrumentation sequences may also improve shaping results. Moreover, in a well-controlled study, clinical outcomes were statistically similar comparing teeth with and without retained instrument fragments.[400] This was true irrespective of

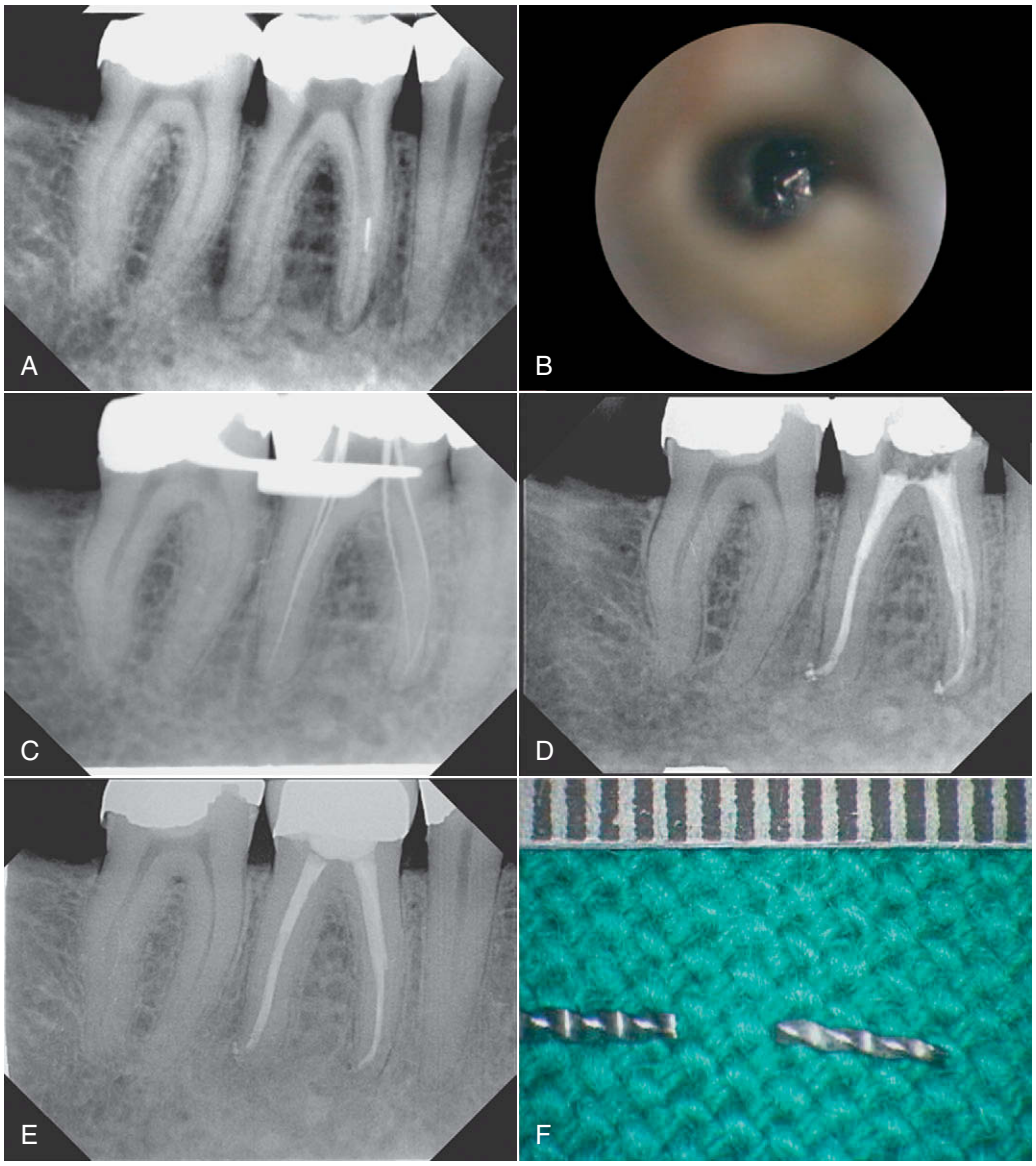

FIG. 9-39 Removal of a separated NiTi instrument from a mesiolingual canal of a mandibular molar. **A,** Fragment located in the middle third of the root. **B,** Clinical aspect of the fragment after enlargement of the coronal third of the root canal with modified Gates-Glidden drills, visualized with an operating microscope (×25). **C,** Radiograph taken after removal of the fragment; four hand files have been inserted into the canals. **D,** Final radiograph shows slight widening of the coronal third of the mesiolingual canal and fully sealed canal systems. A full crown was placed immediately after obturation. **E,** Recall radiograph 5 years after obturation shows sound periradicular tissues. **F,** Removed fragment and separated file (gradation of ruler is 0.5 mm).

the pretreatment diagnosis; as stated before, this underlines the importance of a detailed case assessment before removal of a retained instrument fragment is attempted.

Specific procedures have been developed for removing fractured instruments from root canals (Fig. 9-39); these are discussed in detail elsewhere in this book (see Chapter 25). Most of those methods require the use of additional equipment, such as a dental operating microscope and ultrasonic units. However, the best way to deal with instrument fracture is prevention. An understanding of the anatomy of the root canal system, together with a clear plan for selecting, sequencing, and using shaping instruments, can certainly help prevent procedural mishaps.

Disinfectants, Dentin Surface Modifiers, and Lubricants

Studies have demonstrated conclusively that mechanical instrumentation cannot sufficiently disinfect root canals, regardless of whether stainless steel[80] or NiTi[112] instruments are used (Fig. 9-40). Irrigation solutions are required to eradicate microbiota, and over time, a variety of chemicals have been promoted for this purpose. The ideal irrigant or combination of irrigants kills bacteria, dissolves necrotic tissue, lubricates the canal, removes the smear layer, and does not irritate healthy tissues.[153,191] Some formaldehyde-containing materials are no longer recommended for clinical use, but many irrigating solutions and varying concentrations of commonly used

Messer.)*

materials are described in the literature. Some solutions used in the past were sterile saline, alcohol, hydrogen peroxide, NaOCl, and detergents (e.g., quaternary ammonium compounds, chlorhexidine, citric acids, and EDTA).[399] The following section describes current irrigation solutions and gives some recommendations for their clinical use.

Sodium Hypochlorite

NaOCl encompasses many desirable properties of a main root canal irrigant and has therefore been described as the most ideal of all available rinsing agents.[268,481] NaOCl has been in use for almost a century.[111,446] A 0.5% solution of NaOCl was used effectively during World War I to clean contaminated wounds.[111] In the endodontic field, NaOCl possesses a broad-spectrum antimicrobial activity against endodontic microorganisms and biofilms (Table 9-1), including microbiota difficult to eradicate from root canals, such as *Enterococcus, Actinomyces,* and *Candida* organisms.[175,320,338,481]

NaOCl dissolves organic material such as pulp tissue and collagen. If the organic portion of a smear layer is dissolved in NaOCl, and bacteria inside the main root canal, lateral canals, and dentinal tubules—if in direct contact with the irrigant—are destroyed, then to a minor degree, endotoxins may be eliminated.[256,444]

During endodontic therapy, NaOCl solutions are used at concentrations ranging from 0.5% to 6%. In infected dentin blocks, a 0.25% solution of NaOCl was sufficient to kill *Enterococcus faecalis* in 15 minutes; a concentration of 1% NaOCl required 1 hour to kill *Candida albicans*.[368] In infected extracted teeth, Ruff et al.[338] found that a 1-minute application of 6% NaOCl and 2% chlorhexidine were equally effective in eliminating microorganisms and statistically significantly superior to MTAD and 17% EDTA in eliminating *Candida albicans* infections.

Lower concentrations (e.g., 0.5% or 1%) dissolve mainly necrotic tissue.[482] Higher concentrations allow better tissue dissolution but dissolve both necrotic and vital tissue, which is not always a desirable effect. In some cases, full-strength NaOCl (6%) may be indicated, but although higher concentrations may increase antibacterial effects in vitro,[477] enhanced clinical effectiveness has not been demonstrated conclusively for concentrations stronger than 1%.[399]

Commercially available household bleach (Clorox, The Clorox Company, Oakland, CA) contains 6.15% NaOCl, has an alkaline pH of 11.4, and is hypertonic.[399,482] Some authors recommend dilution of commercially available NaOCl with 1% bicarbonate instead of water to adjust the pH to a lower level.[111,399] Others do not see any reduction of the aggressiveness on fresh tissue by buffering NaOCl and recommend diluting solutions of NaOCl with water to obtain less concentrated irrigation solutions.[383,482]

NaOCl only minimally removes dentin debris or smear layers (Fig. 9-41). Therefore, some authors recommend concurrent use of demineralizing agents to rid the root canal surface of a postinstrumentation smear layer and thus enhance cleaning of difficult-to-reach areas, such as dentinal tubules and lateral canals.[81,283] When using NaOCl over extended periods of time during treatment, it should be mentioned that NaOCl seems to have an undesired side effect on the flexural strength of dentin. One study[252] investigated the influence of irrigants on flexural strength of dentin bars and concluded that a 24-minute exposure time to a 2.5% hypochlorite solution caused a significant drop in flexural strength, while the modulus of elasticity was not altered during this time. Other authors discovered a lowering of both flexural and elastic strength after 2-hour submersion of dentin bars in NaOCl.[11,164] The loss of calcium ions appears to be both dependent on NaOCl concentration (5% showing the greatest amount of decalcification) and time of exposure.[351]

Chlorhexidine

Chlorhexidine (CHX) is a broad-spectrum antimicrobial agent effective against gram-negative and gram-positive bacteria (see Table 9-1). It has a cationic molecular component that attaches to negatively charged cell membrane areas, causing cell lysis.[26,156] CHX as a mouth rinse and periodontal irrigant has been used in periodontal therapy, implantology, and cariology for many years to control dental plaque.[130,232] Its use as an endodontic irrigant[40,96,131,181,454] is based on its substantivity and long-lasting antimicrobial effect, which arises from binding to hydroxyapatite. However, it has not been shown to have more superior clinical properties than NaOCl. In fact, an in situ disinfection study suggests no additive effect on typical endodontic flora.[259]

TABLE 9-1

Efficacy of Various Irrigants in Deactivating Microorganisms*

	NaOCl	CHX	IPI	MTAD	$Ca(OH)_2$
ENTEROCOCCI	**1 min** of 6% solution reduced biofilm by 7-8 orders of magnitude[459] **15 min** at 0.25% in contaminated dentin blocks[482] **30 min** at 0.5% and **2 min** at 5.25% in direct contact with bacteria[322]	**7 days** of 0.5% dressing resulted in complete killing in dentin blocks up to full depth of 950 μm[330] **24 hours** to reduce cultured bacteria below detection limit[318] and **5 min** when in direct contact with bacteria[122]	**24 hours** for iodine (2%) in potassium iodide (4%) resulted in complete killing in dentin blocks up to a depth of 700 μm[384] **1 hour** to reduce bacteria under 0.1% and **24 hours** below detection limit; however, loss of activity through dentin powder[317]	**5 min** application resulted in no growth on infected dentin[373] **MTAD** as efficient as 5.25% NaOCl in cultures[423]	**24 hours** to reduce cultured bacteria below detection limit, but inhibited by dentin powder, hydroxyapatite, and serum albumin[318] Showed little effect on *Enterococcus faecalis*[50] Complete killing in dentin blocks up to full depth of 950 μm[385] **7 days** of $Ca(OH)_2$ in 0.5% chlorhexidine acetate dressing resulted in complete killing in dentin blocks up to full depth of 950 μm[385]
***ACTINOMYCES* ORGANISMS**	**1 min** at 1% solution[37] **10 sec** at 0.5% in direct contact with bacteria[322]	No growth directly after rinsing with 2% CHX in patients with necrotic pulps and/or apical granuloma[127] **3 days** for 2% CHX to eliminate *Actinomyces israelii* from all samples of infected dentin[41]	After **60 days,** 25% of *Actinomyces israelii*–infected root canal walls and dentinal tubules in vitro treated with IKI still showed bacterial growth[41]	**ND**	After **60 days,** 50% of *Actinomyces israelii*–infected root canal walls and dentinal tubules in vitro treated with calcium hydroxide still showed bacterial growth[41]
***CANDIDA* ORGANISMS**	**1 hour** at 1% or 5% solution on root dentin with smear layer[368] **30 sec** for both the 0.5% solutions to kill all cells in culture[449] **1 min** of 6% solution: no growth[338]	**1 hour** at 0.12% on root dentin with smear layer[368] **10 sec** at 0.5% solution in direct contact with bacteria[322] **5 min** at 0.5% solution to kill all yeast cells and **1 hour** at 0.05% solution; less effective than IKI and NaOCl[449]	**30 sec** for both 2% and 4% solution to kill all cells in culture; 0.2% and 0.4% as effective as 0.5% CHX[449] **1 min** of 2% solution: no growth[338]	Not effective against *C. albicans* after 5 min exposure[338]	After **1 hour** and **24 hours,** only a small reduction of CFU observed[449] Not effective against *C. albicans* after 5 min exposure[338]

*Effects achieved by killing through antimicrobial action.

$Ca(OH)_2$, Calcium hydroxide; *CHX,* chlorhexidine acetate; *IKI,* iodine potassium iodide; *MTAD,* BioPure MTAD (*m*ixture of *t*etracycline, *a*cid, and *d*etergent); *NaOCl,* sodium hypochlorite; *ND,* not determined.

When compared to CHX as an irrigant, it was found that hypochlorite significantly more often achieved negative cultures than CHX.[333] When used as combination, NaOCl and CHX did not improve the antimicrobial activity of CHX against tested microorganisms.[443]

Some researchers found that CHX had significantly better antibacterial effects than $Ca(OH)_2$ when tested on cultures.[230] Combinations of CHX and $Ca(OH)_2$ are available and show antimicrobial activity against obligate anaerobes, the combination in some studies augmenting the antibacterial effect of either medicament on certain species.[315,385] However, 2% CHX gel alone was more effective than its combination with $Ca(OH)_2$ against several tested microorganisms in other investigations.[155,248] Medicaments containing 2% CHX have the ability

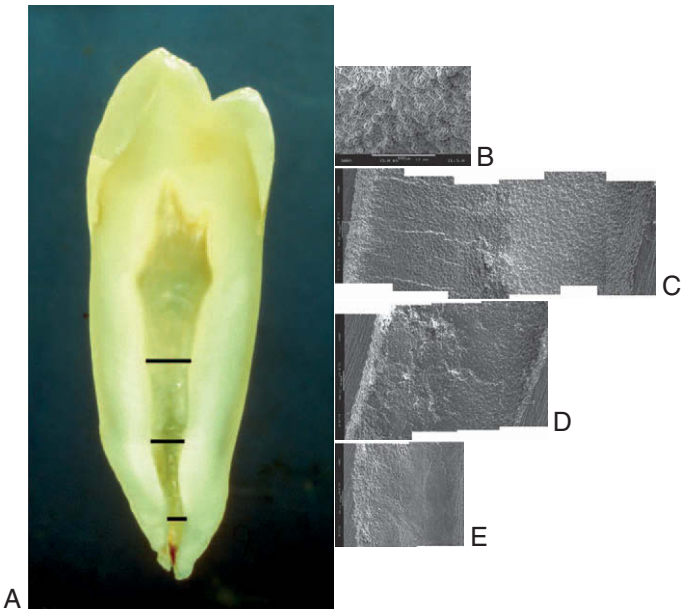

FIG. 9-41 Surface textures of an unprepared root canal at various levels. **A,** Ground section of a mandibular premolar. Areas viewed by scanning electron microscopy (SEM) are indicated by *black lines*. **B,** Canal surface at middle section, showing open dentinal tubules and typical calcospherites (×500). **C-E,** Coronal, middle, and apical areas as compound scanning electron micrographs. Note the numerous open tubules in **C-D,** whereas fewer tubules are visible in **E** (×200).

to diffuse through dentin and display antimicrobial action on the outer root surface. The addition of CHX or iodine potassium iodide to an intracanal dressing of $Ca(OH)_2$ in vitro did not affect the alkalinity (and hence the efficacy) of the $Ca(OH)_2$ suspensions.[385] Chlorhexidine (2%) has been advocated as a final rinse irrigant owing to its substantivity, which allows binding to dentin and sustained antimicrobial activity, especially in endodontic retreatment.[480]

Iodine Potassium Iodide

Iodine potassium iodide (IKI) is a traditional root canal disinfectant and is used in concentrations ranging from 2% to 5%. IKI kills a wide spectrum of microorganisms found in root canals (see Table 9-1) but shows relatively low toxicity in experiments using tissue cultures.[398] Iodine acts as an oxidizing agent by reacting with free sulfhydryl groups of bacterial enzymes, cleaving disulfide bonds. *E. faecalis* often is associated with therapy-resistant periapical infections (see Chapter 15), and combinations of IKI and CHX may be able to kill $Ca(OH)_2$-resistant bacteria more efficiently. One study[385] evaluated the antibacterial activity of a combination of $Ca(OH)_2$ with IKI or CHX in infected bovine dentin blocks. Although $Ca(OH)_2$ alone was unable to destroy *E. faecalis* inside dentinal tubules, $Ca(OH)_2$ mixed with either IKI or CHX effectively disinfected dentin. Others[31] demonstrated that IKI was able to eliminate *E. faecalis* from bovine root dentin when used with a 15-minute contact time. An obvious disadvantage of iodine is a possible allergic reaction in some patients.

MTAD

BioPure (DENTSPLY Tulsa Dental), also known as *MTAD* (*m*ixture of *t*etracycline, *a*cid, and *d*etergent), is an irrigation solution that contains doxycycline, citric acid, and a surface-active detergent (Tween 80).[423] Chemicals and their combinations as root canal irrigants are developed constantly, including solutions based on antibiotics. However, doxycycline and other locally applied antibiotics have been unable to destroy microbiota organized in biofilms. One research group[282] investigated the effect of five antibiotics on a mature biofilm after 8 days of growth on dentin; in their experiment, none of the topically applied substances could eradicate the biofilm. Use of these irrigants is also controversial because of the emergence of increasingly resistant strains of bacteria (e.g., therapy-resistant enterococci), which may be due to overprescription of antibiotics in general. The increased risk of host sensitization by local antibiotics can be circumvented to some degree by using the antibiotic as a dressing. Because exposure to vital tissues is limited, higher microbicidal concentrations may be used.[269] A number of antibiotics, including erythromycin, chloramphenicol, tetracycline, and vancomycin, have been tested successfully against enterococci. In one study, investigators evaluated microbial susceptibility to different antibiotics in vitro and found that enterococcal isolates were resistant to benzylpenicillin, ampicillin, clindamycin, metronidazole, and tetracycline but sensitive to erythromycin and vancomycin.[110] Another investigation[202] used extracted teeth infected with *E. faecalis* and compared the efficacy of NaOCl and EDTA versus NaOCl and MTAD. They concluded that although the NaOCl/EDTA combination consistently disinfected the test specimens, almost half of the teeth rinsed with NaOCl/BioPure MTAD remained contaminated.[202] In a recent study,[371] doxycycline was replaced with CHX in one of the test groups of *E. faecalis*–infected teeth. Whereas no specimens that were cleaned with MTAD or MTAD + CHX showed the presence of residual bacteria, 70% of the samples rinsed with CHX as a substitute for doxycycline demonstrated growth of *E. faecalis*.

The citric acid component in MTAD effectively removed a smear layer.[44,372,421] Under these conditions, BioPure MTAD was more aggressive in eroding dentin than EDTA. In another investigation,[410] however, the addition of NaOCl was necessary to achieve dissolution of organic matter.

Ethylenediamine Tetra-Acetic Acid

EDTA came into use in endodontics in 1957[283]; chelators such as EDTA create a stable calcium complex with dentin mud, smear layers, or calcific deposits along the canal walls. This may help prevent apical blockage (Fig. 9-42) and aid disinfection by improving access of solutions through removal of the smear layer.

Neutral EDTA (17% concentration) showed a higher degree of decalcification of dentin surfaces than RC-Prep (a gel-type preparation of EDTA), although its effect was reduced in apical regions.[441] Similar to MTAD, RC-Prep did not erode the surface dentin layer.[421]

The effect of chelators in negotiating narrow, tortuous, calcified canals to establish patency depends on both canal width and the amount of active substance available, since the demineralization process continues until all chelators have formed complexes with calcium.[191,485] Calcium binding results in the release of protons, and EDTA loses its efficiency in an

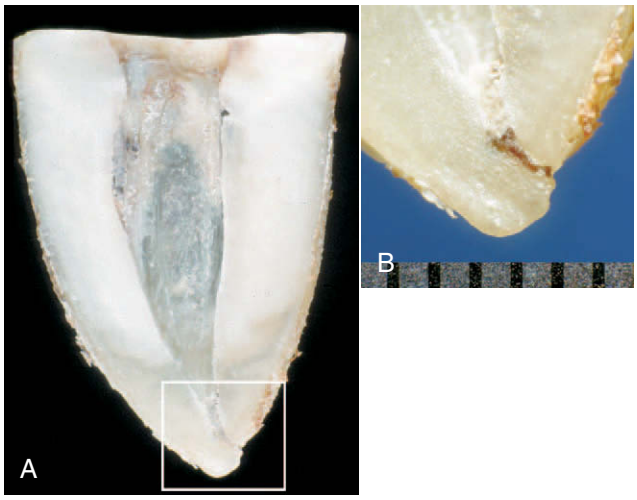

FIG. 9-42 Presence of dentin dust as a possible source of microbial irritation. Tooth #18 underwent root canal therapy. The clinician noted an apical blockage but was unable to bypass it. Unfortunately, intense pain persisted and at the patient's request, the tooth was extracted a week later. **A,** Mesial root of tooth #18; mesial dentin has been removed. **B,** Magnified view (×125) of rectangle in **A** shows an apical block (gradation of ruler is 0.5 mm).

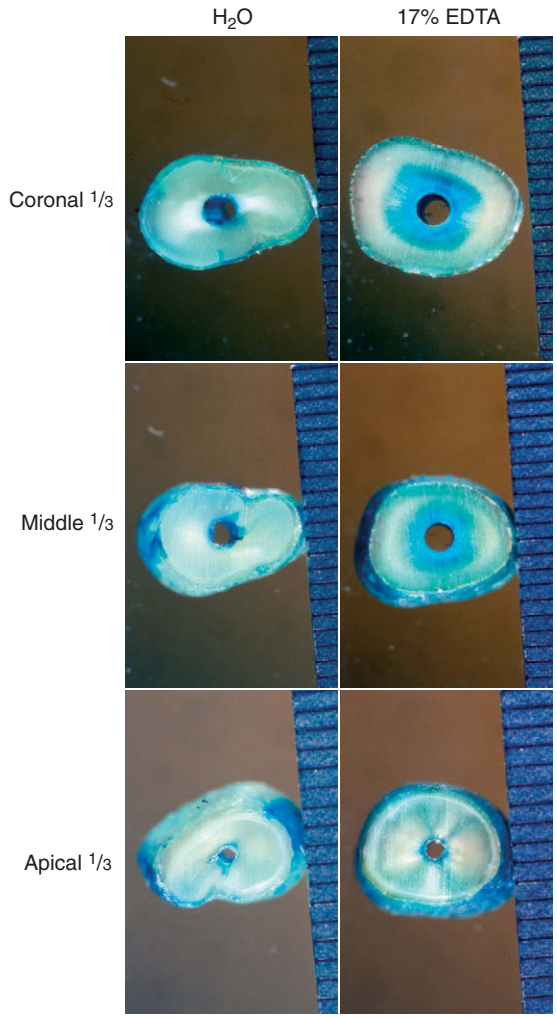

FIG. 9-43 Penetration of irrigants into dentinal tubules after root canal preparation with different dentin pretreatments. *Left column,* Irrigation with tap water and then with blue dye. *Right column,* Smear layer is removed with 17% EDTA, applied in high volume and with a 30-gauge needle, followed by irrigation with blue dye. Note the comparable diffusion of dye in the apical sections, whereas dye penetrated deeper into the dentin in the two coronal sections.

acidic environment. Thus the action of EDTA is thought to be self-limiting.[367] In one study, demineralization up to a depth of 50 µm into dentin was demonstrated for EDTA solutions[191]; however, other reports demonstrated significant erosion after irrigation with EDTA.[421]

A comparison of bacterial growth inhibition showed that the antibacterial effects of EDTA were stronger than citric acid and 0.5% NaOCl but weaker than 2.5% NaOCl and 0.2% CHX.[379] EDTA had a significantly better antimicrobial effect than saline solution. It exerts it strongest effect when used synergistically with NaOCl, although no disinfecting effect on colonized dentin could be demonstrated.[181]

Recent reports have indicated that several disinfecting agents such as $Ca(OH)_2$, IKI, and CHX are inhibited in the presence of dentin.[169,317,318] Moreover, chemical analyses indicated that chlorine, the active agent in NaOCl, is inactivated by EDTA.[161,483] In light of these facts, in addition to the unproven effect of lubricants containing EDTA on rotary-instrument torque, use of these solutions probably should be limited to hand instrumentation early in a procedure. Moreover, an EDTA solution preferably is used at the end of a procedure to remove the smear layer but does not prevent future bacterial penetration between root canal fillings and canal walls.[343,470,483] Clean, smear layer–free canal walls, tubulus openings, and entrances into lateral canals and isthmus areas, taken together with sufficient volume of NaOCl, ensures high disinfecting efficacy by enabling NaOCl to penetrate even into deeper dentin layers (Fig. 9-43).

BOX 9-4

Benefits of Using Irrigants in Root Canal Treatment

- Removal of particulate debris and wetting of the canal walls
- Destruction of microorganisms
- Dissolution of organic debris
- Opening of dentinal tubules by removal of the smear layer
- Disinfection and cleaning of areas inaccessible to endodontic instruments

Calcium Hydroxide

$Ca(OH)_2$ via its alkaline pH is generally very effective at eradicating intraradicular bacteria, with the exception of *E. faecalis*.[133] Increased effectiveness was observed when $Ca(OH)_2$ was mixed with some common irrigating solutions. Although additive effects could not be confirmed, and a reduction in the antimicrobial action of CHX was detected,[176] it appears that $Ca(OH)_2$ mixed with IKI or CHX may be able to kill $Ca(OH)_2$-resistant bacteria[385] (Box 9-4).

Unfortunately, it is not as effective when used short term and is not recommended as an irrigant but rather as an interap-

pointment dressing.[388] To achieve optimal antimicrobial activity, therefore, it requires prolonged exposure[36] or higher temperatures for use as an endodontic irrigant.[131]

Other Irrigants

Electrochemically activated water (also known as *oxidative potential water*) recently was tested as a potential irrigant.[166,250,391] Although this solution is active against bacteria[166] and removes the smear layer,[249] no assessment of its clinical potential is available, and in vitro research indicates that NaOCl is a superior disinfectant.[166]

Hydrogen peroxide traditionally has been used as an irrigant in conjunction with NaOCl; however, no additional benefit beyond NaOCl was registered.[181]

Some authors have advocated the use of 0.2% or 0.5% CHX in addition to NaOCl,[169,181] either as an irrigant or mixed with $Ca(OH)_2$ as an interappointment medicament. These combinations can overcome the inhibiting effect of dentin dust on conventional medicaments[169,318] and can optimize their antimicrobial properties against certain resistant bacteria and yeasts.[449,451]

Recently, one group[233] compared NaOCl with a final 17% EDTA rinse with an equal mixture of 2% NaOCl and 18% etidronic acid during and after instrumentation and a protocol involving 1% NaOCl during preparation and 2.25% peracetic acid after instrumentation. The results indicated that both acids had a similar effect on a smear layer as EDTA but with less demineralization of intratubular dentin. Strong demineralization has been shown to have a negative influence on canal sealability.[115]

Lubricants

In root canal treatment, lubricants are mostly used to emulsify and keep in suspension debris produced by mechanical instrumentation. Although irrigation solutions serve as lubricants, special gel-type substances are also marketed. Two of these are wax-based RC-Prep, which contains EDTA and urea peroxide, and glycol-based Glyde. Another purported function of lubricants is to facilitate the mechanical action of endodontic hand or rotary files. A study evaluating the effects of lubrication on cutting efficiency found that tap water and 2.5% NaOCl solutions increased cutting efficiency compared with dry conditions.[478] The authors of this study cited the ability of a lubricant to remove debris as the factor for the increased efficiency. Similarly, a reduction of torque scores was found when canals in normed dentin disks were prepared with ProFile and ProTaper instruments under irrigation, but the use of a gel-type lubricant resulted in similar torques as in dry, nonlubricated canals.[60,304]

In summary, irrigation is an indispensable step in root canal treatment to ensure disinfection. The tissue-dissolving and disinfecting properties of NaOCl currently make it the irrigant of choice. EDTA should be used at the end of a procedure to remove the smear layer, followed by another flush with NaOCl for maximum cleaning efficiency. This strategy also minimizes inactivation of NaOCl by chemical interactions.[161,481]

CLEANING AND SHAPING: CLINICAL ISSUES

Endodontists widely agree that a major biologic aim of endodontic therapy is to eliminate apical periodontitis by disinfection and sealing of root canal systems. However, considerable disagreement exists over the way this goal should be achieved (see Fig. 9-9). Although "cleaning and shaping" accurately describes the mechanical procedures,[337] it should be emphasized that "shaping and cleaning" more correctly reflects the fact that enlarged canals direct and facilitate the cleaning action of irrigants and the removal of infected dentin.

Microorganisms in the pulp cavity and coronal root canal may be readily killed by irrigants early in a procedure, but bacteria in less accessible canal areas still can elicit apical periodontitis. These bacteria can be eradicated only after root canal preparation.

Biologic Objectives

Some have suggested that canals should be prepared to a uniform and continuous taper[361]; however, this mechanical objective likely addresses obturation rather than antimicrobial efficacy. The preparation shape and antimicrobial efficacy are intimately related through the removal of infected dentin and the delivery of irrigants.[185]

Traditionally, fluids have been delivered to root canals passively by syringe and needle (Fig. 9-44). Active systems such as the NIT are still in an experimental phase.[245] When delivered passively, irrigants have been shown to progress only 1 mm farther than the tip of the needle.[323] Enlarged apical canals are likely to allow increasingly deeper needle placement (see Fig. 9-44), and this improves débridement and disinfection of canals.[7,17,135,434] Nevertheless, thorough cleaning of the most apical part of any preparation remains difficult,[466] especially in narrow and curved canals.[180,295,329]

Mechanical Objectives

An important mechanical objective of root canal instrumentation is full incorporation of the original canals into the prepared shape, meaning that all root canal surfaces are mechanically prepared (*green areas* in Fig. 9-45, *A* and *B*); however, this goal is unlikely to be met with current techniques.[291,310]

Preparation errors such as zips and perforations should be absent. Although these and other procedural problems (Fig. 9-46) per se may not affect the probability of a favorable outcome,[229] they may leave parts of the root canal system inaccessible for disinfection.

Another important mechanical objective is to leave as much radicular dentin as possible so as not to weaken the root structure, thereby preventing vertical fractures. Although no definitive minimal radicular thickness has been established, 0.3 mm is considered critical.[228] Even pretreatment, wall thickness of 1 mm and below has been demonstrated.[147] Straightening of canal paths can lead to minimal remaining wall thicknesses (Fig. 9-47); this underlines the need for adequate access cavity preparation and optimal enlargement of the coronal third of the root canal.

Two primary mechanical elements are the apical width and the endpoint of the prepared shape in relation to the apical anatomy. Traditional treatment has held that canal preparation and subsequent obturation should terminate at the *apical constriction*, the narrowest diameter of the canal. This point is believed to coincide with the cementodentinal junction (CDJ) (see Chapter 7). This definition of working length is based on histologic sections and ground specimens. However, the

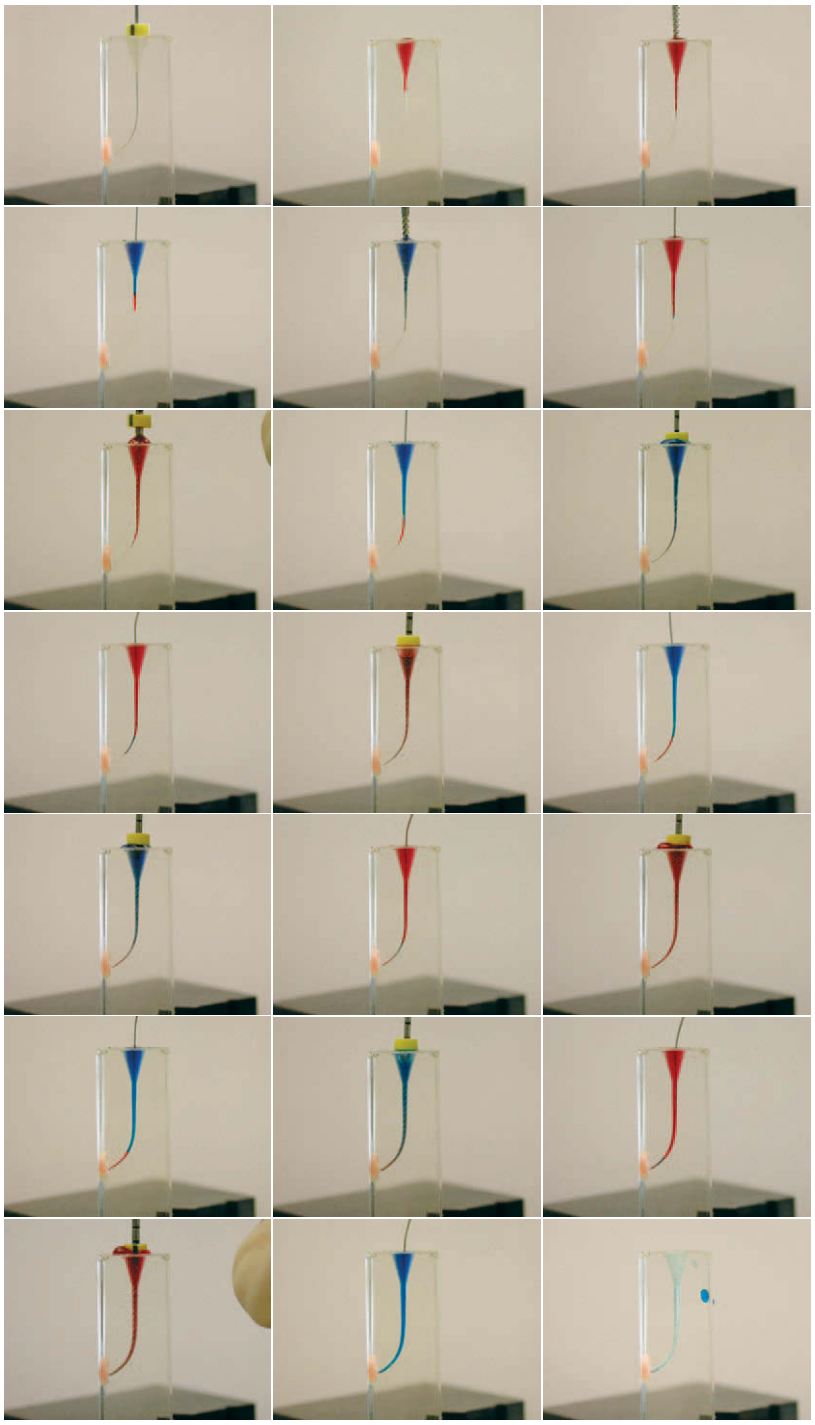

FIG. 9-44 Irrigation and movement of irrigants depends on canal shape. Sequential enlargement of a canal in clear plastic block was performed with a sequence of ProFile instruments in accordance with the manufacturer's recommendations. Alternating irrigation with blue and red fluid was done after each preparation step. Note the apical presence of irrigant after sufficient shape has been provided. Note the distribution of fluid immediately after irrigation with a 30-gauge needle.

position and anatomy of the CDJ varies considerably from tooth to tooth, from root to root, and from wall to wall in each canal. Moreover, the CDJ cannot be located precisely on radiographs. For this reason, some have advocated terminating the preparation 0.5 to 1 mm short of the radiographic apex in necrotic cases and 1 to 2 mm short[177,332,468] in cases involving irreversible pulpitis. In this way, preparation would take place inside the root canal. Although there is no definitive validation for this strategy at present,[352] well-controlled follow-up studies seem to support it.[387,389]

However, working to shorter lengths could lead to the accumulation and retention of debris, which may result in apical blockage (see Fig. 9-42). Such blockage (which consists of collagen fibers, dentin mud, and most importantly, residual bacteria) inside apical canal areas is a major cause of persistent or recurrent apical periodontitis,[172,276,378] currently termed *post-treatment disease*[138,462] (also see Chapter 24). Additionally, because of the creation of apical blockage, working to short lengths may contribute to procedural errors such as apical perforations and fractured instruments.

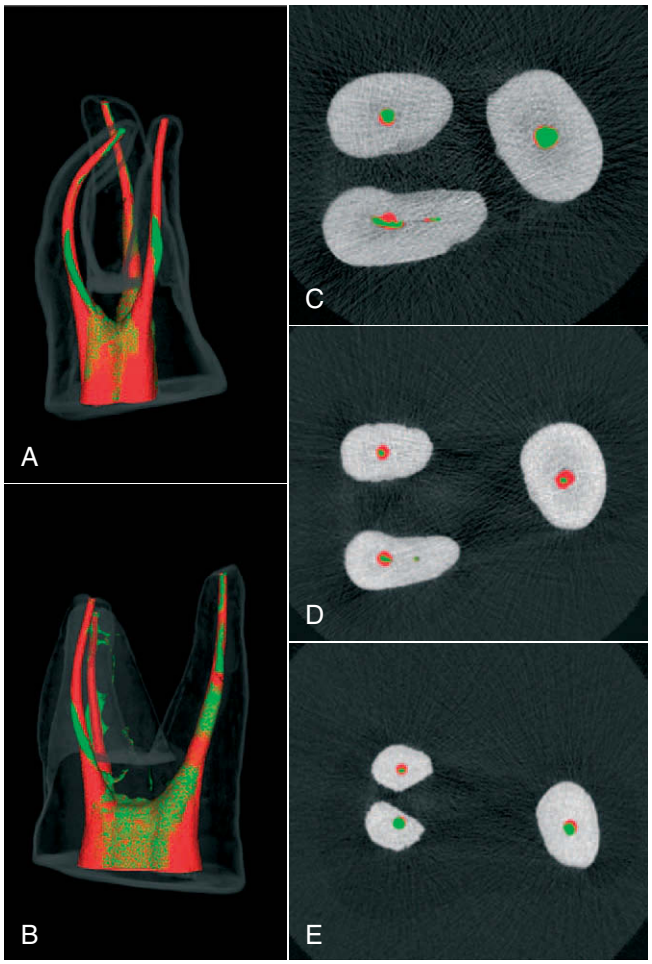

FIG. 9-45 Example of a desired shape, with the original root canal fully incorporated into the prepared outline. **A-B,** Micro–computed tomography reconstructions in clinical and mesiodistal views of a maxillary molar prepared with a NiTi rotary system. The *green area* indicates the pretreatment shape, and the *red area* indicates the posttreatment shape. Areas of *mixed red and green* indicate no change (i.e., no removal of radicular dentin). **C-E,** Cross sections of the coronal, middle, and apical thirds; the pretreatment cross sections *(green)* are encircled by the posttreatment outlines *(red)* in most areas. *(**A-B** from Hübscher W, Barbakow F, Peters OA: Root-canal preparation with FlexMaster: canal shapes analysed by micro-computed tomography.* Int Endod J *36:740–747, 2003.)*

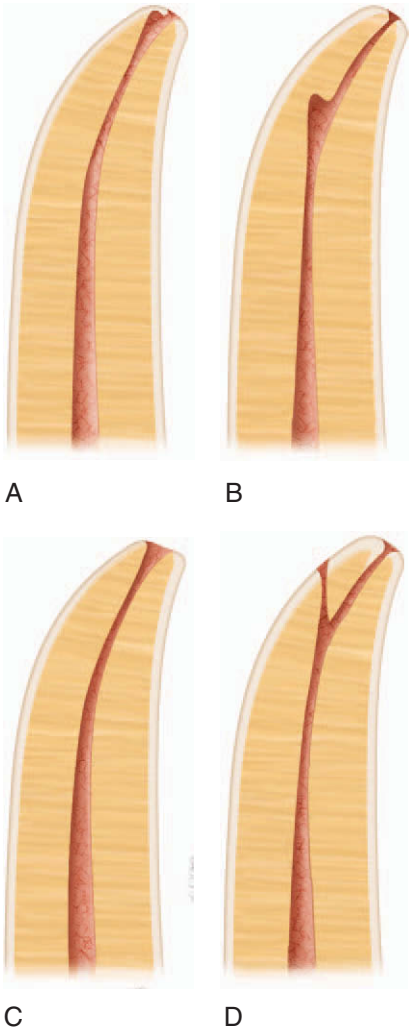

FIG. 9-46 Schematic diagrams showing the most common preparation errors. **A,** Apical zip. **B,** Ledge. **C,** Apical zip with perforation. **D,** Ledge with perforation.

The electronic apex locator has helped clinicians identify the position of apical foramina more accurately; the development of this instrument made it possible to work more precisely and routinely as close as 0.5 mm to the canal terminus (see Chapter 8).

Concepts and Strategies

Two factors are closely related to the preparation length: use of a patency file and the apical width. A *patency file* is a small K-file (usually a size #10 or #15) that is passively extended just through the apical foramen.

Use of a patency file has been suggested for most rotary techniques. This step is believed to remove accumulated debris and help maintain working length. However, the issue is controversial, and many U.S. dental schools did not teach this concept, at least not until recently.[82] Moreover, investigators[152] demonstrated that the use of patency files of varying sizes did not prevent preparation errors.

One concern with the patency file was that instead of having a cleaning effect, the file would push contaminated debris through the foramen. However, an in vitro study suggested that the risk of inoculation was minimal when canals were filled with NaOCl.[198] Maintaining patency throughout an endodontic procedure does not lead to an increase in posttreatment symptoms.[25] No definitive evidence exists either favoring or disproving the use of a patency file, but clinical experience suggests that this technique involves relatively little risk and provides some benefit as long as small files are used carefully.

Like the position of the apical constriction, apical diameters are difficult to assess clinically.[220] Some have recommended gauging canal diameters by passing a series of fine files apically until one fits snugly. However, such an approach is likely to result in underestimation of the diameter.[458] This is a crucial point because the initial canal size is a major determinant for the desired final apical diameter.

TABLE 9-2

Characteristics of Wide and Narrow Apical Preparations

Root Canal Preparation	Benefits	Drawbacks
Narrow Apex	Minimal risk of canal transportation and extrusion of irrigants or filling material Can be combined with tapered preparation to counteract some drawbacks	Little removal of infected dentin Questionable rinsing effect in apical areas during irrigation Possibly compromised disinfection during interappointment medication Not ideal for lateral compaction
Wide Apex	Removal of infected dentin Access of irrigants and medications to apical third of root canal	Risk of preparation errors and extrusion of irrigants and filling material Not ideal for thermoplastic obturation

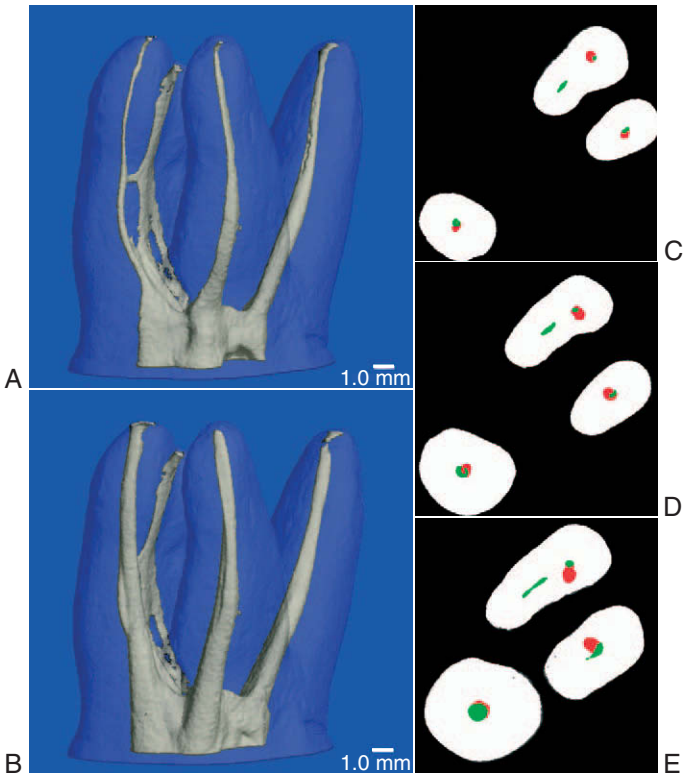

FIG. 9-47 Example of excessive thinning of dental structure during root canal treatment. **A-B,** Micro–computed tomography reconstructions show pretreatment and posttreatment root canal geometry of a maxillary molar. **C-E,** Cross sections of the coronal, middle, and apical thirds with pretreatment canal cross sections. Note the transportation and thinning, in particular, in the main mesiobuccal canal.

An ongoing debate exists between those who prefer smaller apical preparations combined with tapered shapes and those who favor larger apical preparations for better removal of infected dentin and to allow irrigation fluids access to the apical areas. Both sides stress the importance of maintaining the original path of the canal during preparation; otherwise, bacteria infecting the apical third of the root canal may not be reached by a sufficient bactericidal concentration of an antimicrobial agent.[271] Investigators obtained a higher percentage of bacterial elimination in single-root canal systems by using a combination of significant enlargement of the apical third and NaOCl irrigation.[89] Preparation errors (e.g., zips, canal transportation) can occur with wide preparations when either stainless steel or NiTi instruments are used (see Fig. 9-46).

Thorough disinfection of the apical part of a root canal is essential, because this area is likely to contain intraradicular bacteria.[277] Wider apical preparations remove potentially infected dentin, allowing the delivering needle and subsequently the antimicrobial irrigant to penetrate the root canal more deeply.[97,135]

A study investigating rotary NiTi files of three tapers (#.06, #.08, and #.10) with file tips in sizes #20, #30, and #40 showed that size #20 instruments left significantly more debris in the apical third compared with size #40 instruments.[434] On the other hand, a study in which half the samples were prepared to a size #25 file and the other half to a size #40 file found no statistically significant difference in bacterial growth after instrumentation, with no growth observed after 1 week of treatment with a $Ca(OH)_2$ dressing.[473] Another study compared step-down sequences with additional apical enlargement to ISO size #35 or a serial step-back technique with no apical enlargement. NaOCl and EDTA were used as irrigants. In that study, no significant difference was detected in colony-forming units with or without apical enlargement.[102] These researchers concluded that dentin removal in the apical third might be unnecessary if a suitable coronal taper is achieved.

Despite the disagreement over the appropriate width of a preparation (Table 9-2), the distillation of all these studies suggest that root canal preparations should be confined to the canal space, should be sufficiently wide, and should incorporate the original root canal cross sections (see Fig. 9-45). This way, routine root canal treatment results in favorable outcomes at various levels of clinicians' expertise (Fig. 9-48).

CANAL PREPARATION TECHNIQUES

The traditional cleaning and shaping strategy (the step-back technique) focused on the initial preparation of the apical third of the root canal system, followed by various flaring techniques to facilitate obturation.[158,354,420] In an attempt to reach the canal terminus, the clinician first selected a small file, placed an appropriate curve on the instrument, and then tried to work the file to full length. If the terminus could not be reached, the file was removed and, after irrigation, either the same file or a smaller one was inserted. However, not

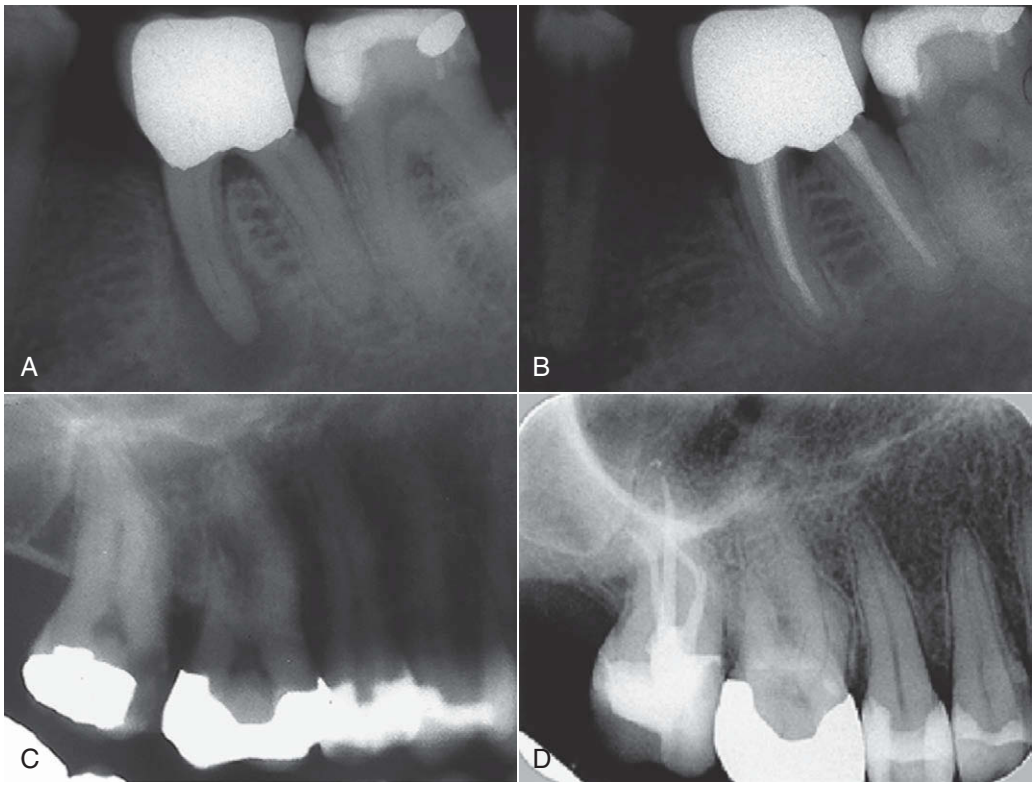

FIG. 9-48 Routine cases treated according to the principles discussed in this chapter. Biologic and mechanical aims were maintained at varying levels of expertise. **A,** Asymptomatic tooth #18 with periradicular lesion; endodontic treatment was indicated. **B,** Recall radiograph after 18 months (treatment was performed by fourth-year student at Zurich Dental School). **C,** Pretreatment radiograph of tooth #2, which was diagnosed with irreversible pulpitis. **D,** Recall radiograph 2 years later shows sound periradicular tissue; the tooth is clinically symptom free (treatment was performed by an endodontist).

infrequently full length may not be reached because of blockage or coronal binding.

Coronal binding is caused by overhangs at the orifice level and also occurs when the canal is less tapered than an instrument, thus binding somewhere coronally. Moreover, a straight root often has a curved canal; buccal and lingual curvatures that cannot be seen on radiographs also need to be detected.[103,312] Passing a precurved negotiating file through a coronally tight canal will straighten the instrument.[395] Nonflared canals do not allow efficient irrigation, which further predisposes to blockage.

Various instrumentation sequences have been developed for hand and rotary instruments; these are discussed later in the chapter. However, the shape of the access cavity is *the* prerequisite that must be optimized before any canal preparation can take place (see Chapter 7).

One approach to the preparation of an adequate access cavity (Fig. 9-49) involves the use of a cylindrical diamond or fissure bur, a safety-ended drill for additional enlargement, and round burs to remove overhangs on outward strokes. The access cavity shape must allow instruments unimpeded access to the middle third of the root canal system. Ultrasonically powered instruments used under an operating microscope greatly facilitate removal of mesial dentin shelves in mandibular molars (Fig. 9-50, *A* and *B*) and other teeth. Preexisting restorations allow for ideal access cavities that serve as reservoirs of irrigants (see Fig. 9-50, *C*).

Basic cleaning and shaping strategies for root canal preparation can be categorized as crown-down, step-back, apical widening, and hybrid techniques. In a crown-down approach, the clinician passively inserts a large instrument into the canal up to a depth that allows easy progress. The next smaller instrument then is used to progress deeper into the canal; the third instrument follows, and this process continues until the terminus is reached. Both hand and rotary instruments may be used in a crown-down manner. However, instrument sets with various tip diameters and tapers allow the use of either decreasing tapers or decreasing diameters for apical progress. Debate continues as to which of those strategies is superior for avoiding taper lock; currently no compelling evidence favors either of them.

In the step-back approach, working lengths decrease in a stepwise manner with increasing instrument size. This prevents less flexible instruments from creating ledges in apical curves while producing a taper for ease of obturation.

As discussed previously, the aim of apical widening is to fully prepare apical canal areas for optimal irrigation efficacy and overall antimicrobial activity. Recently, apical enlargement has been broken down into three phases: preenlargement, apical enlargement, and apical finishing.[448]

Most rotary techniques require a crown-down approach to minimize torsional loads[57] and reduce the risk of instrument fracture. Used sequentially, the crown-down technique can help to enlarge canals further. All basic techniques described

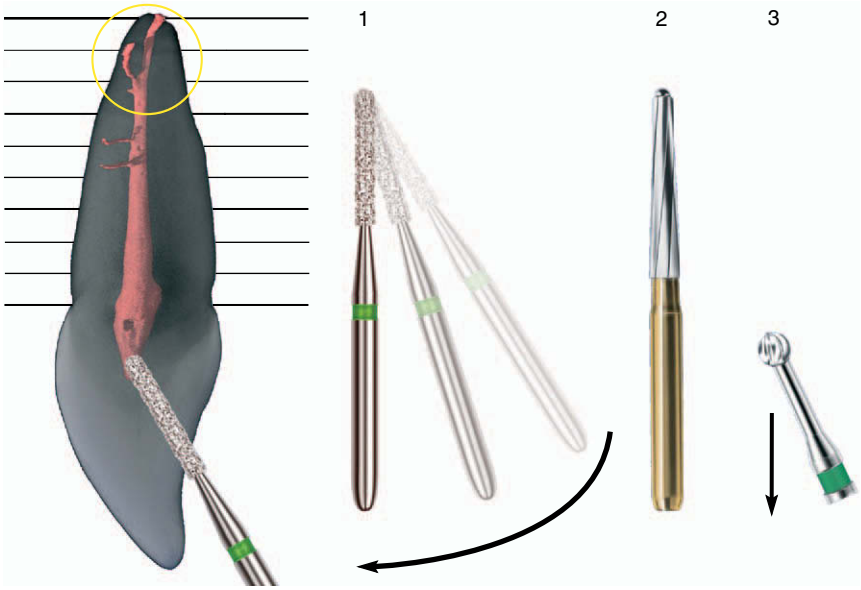

FIG. 9-49 Sequence of instruments used for optimal preparation of an access cavity (e.g., in an incisor). A parallel-sided diamond or steel bur is used to remove overlying enamel in a 90-degree angle toward the enamel surface *(1)*. The bur is then tilted vertically to allow straight-line access to the root canal *(arrow)*. A bur with a noncutting tip (e.g., Endo-Z bur or ball-tipped diamond bur) is then used to refine access *(2)*. Overhangs or pulp horns filled with soft tissue are finally cleared with a round bur used in a brushing or pulling motion *(3)*.

so far may be combined into a hybrid technique to eliminate or reduce the shortcomings of individual instruments.

Root canal preparation can be broken down into a series of steps that parallel the insertion depths of individual instruments. Anatomic studies and clinical experience suggest that most teeth are 19 to 25 mm long. Most clinical crowns are approximately 10 mm long, and most roots range from 9 to 15 mm in length. Roots, therefore, can be divided into thirds that are 3 to 5 mm long.

Provided adequate tools are used and the access cavity design is appropriate, excessive thinning of radicular structures can be avoided (see Fig. 9-47). Vertical root fractures and perforations are possible outcomes of excessive removal of radicular dentin in zones that have been termed *danger zones*.[20] Overenthusiastic filing, for example, may lead to more procedural errors (see Fig. 9-20). On the other hand, ideal preparation forms without any preparation errors and with circular incorporation of the original canal cross sections may be achieved with suitable techniques (see Fig. 9-45).

Preenlargement of the coronal half to two thirds to allow files unimpeded access gives the clinician better tactile control in directing small, adequately precurved negotiating files into the delicate apical third (Fig. 9-51). Gates-Glidden drills can be used sequentially to enlarge the coronal third of the canal in teeth with straight roots (Fig. 9-52). Both step-back and step-down sequences have been recommended.

Besides GG burs, various instruments have been introduced or suggested for coronal preenlargement, such as the ProFile orifice shapers, GT accessory files, the ProTaper Sx, the FlexMaster Intro file, and the size #40, #.10 taper or size #35, #.08 taper RaCe files. These instruments are better suited to and safer for more difficult cases (Fig. 9-53).

Once the coronal portions of a canal have been enlarged, the apical canal areas can be more efficiently prepared. Better clinical results are obtained with optimized access, regardless of the preparation technique used (Fig. 9-54). Only after preenlargement can fine scouting files (also used before rotary files in the coronal areas) provide information about the root canal paths. Preenlarged canals may accommodate hand files, which can be used to gather specific information about the apical third's cross-sectional diameter and anatomy.

Hand Instrumentation

Standardized Technique

The standardized technique adopts the same working length definition for all instruments introduced into a root canal and therefore relies on the inherent shape of the instruments to impart the final shape to the canal. Negotiation of fine canals is initiated with lubricated fine files in a so-called watch-winding movement. These files are advanced to working length and worked either in the same hand movement or with "quarter-turn-and-pull" until a next larger instrument may be used. Conceptually, the final shape should be predicted by the last-used instrument. A single matching gutta-percha point may then be used for root canal filling. In reality, this concept is often violated: curved canals shaped with the standardized technique will be wider than the last used instrument,[19] exacerbated by the pulling portion of the hand movement. Moreover, adequate compaction of gutta percha in such small a taper (~.02) is difficult or impossible[18] (see Chapter 11).

Step-Back Technique

Realizing the importance of a shape larger than that produced with the standardized approach, one investigator[457] suggested the step-back technique, incorporating a stepwise reduction of the working length for larger files, typically in 1-mm or 0.5-mm steps, resulting in flared shapes with 0.05 and 0.10 taper, respectively. Incrementally reducing the working length when using larger and stiffer instruments also reduced the incidence of preparation errors, in particular in curved canals. This concept appeared to be clinically very effective.[273]

Although the step-back technique was primarily designed to avoid preparation errors in curved canals, it applies to the preparation of apparently[103,356] straight canals as well. Several modifications of the step-back technique have been described over the years. Another investigator[420] advocated the insertion of progressively larger hand instruments as deep as they would

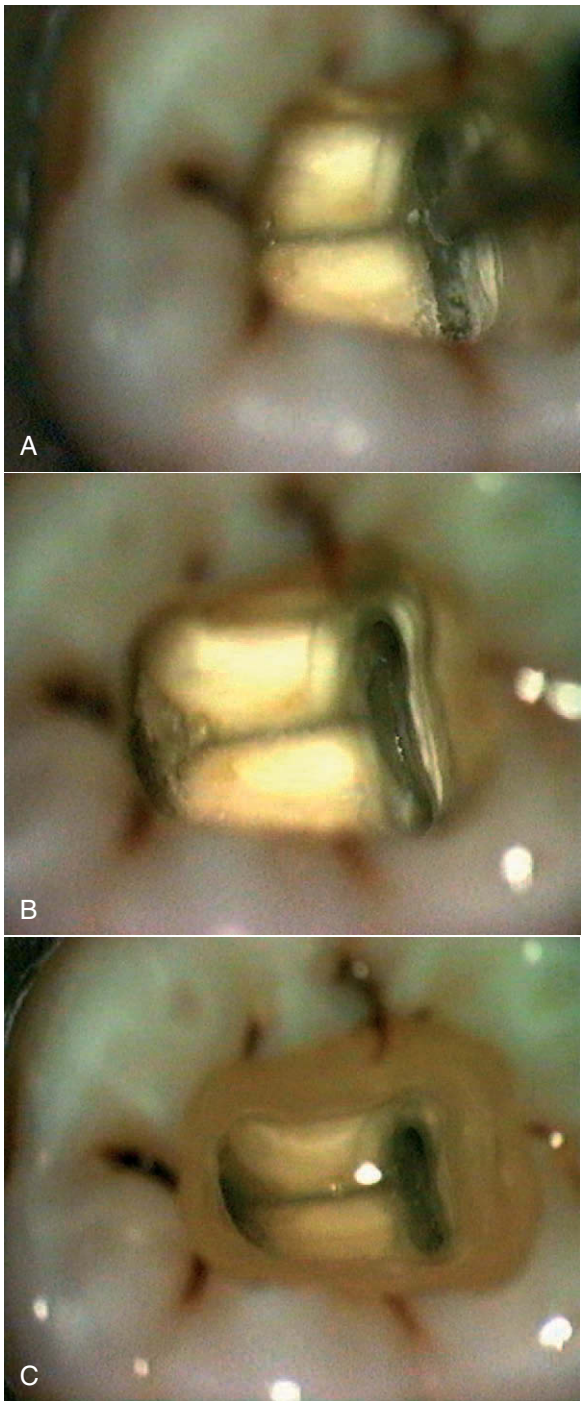

FIG. 9-50 Clinical views of an access cavity in a mandibular molar as seen through an operating microscope (×20). **A,** Modification with an ultrasonically activated tip. **B,** Access cavity after modification. **C,** Cavity is flooded with 1% sodium hypochlorite.

passively go in order to explore and provide some enlargement prior to reaching the working length.

Step-Down Technique

Other investigators[150] described a different approach. They advocated shaping the coronal aspect of a root canal first before apical instrumentation commenced. This technique is intended

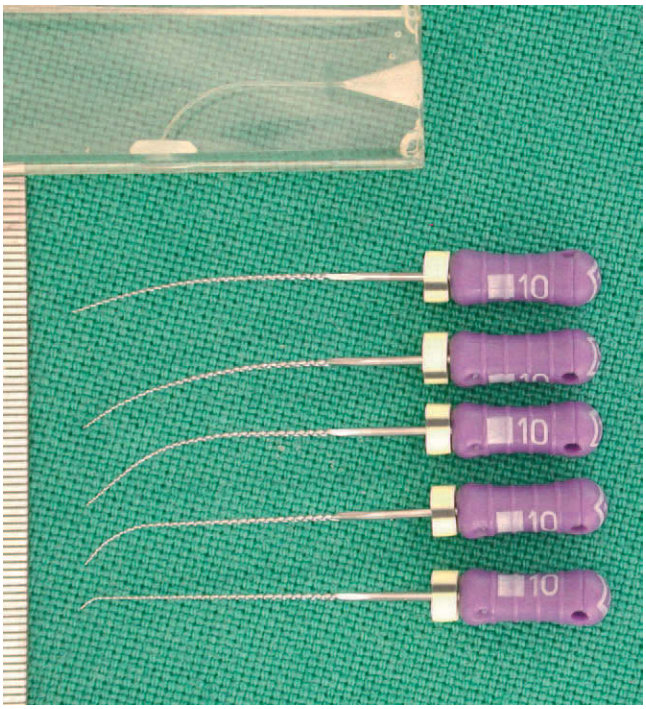

FIG. 9-51 Various precurved, stainless steel hand files for pathfinding and gauging. Compare the curves in the instruments to the ones in a plastic training block (gradation of ruler is 0.5 mm).

to minimize or eliminate the amount of necrotic debris that could be extruded through the apical foramen during instrumentation[134]; moreover, by first flaring the coronal two-thirds of the canal, apical instruments are unimpeded through most of their length. This in turn may facilitate greater control and less chance of zipping near the apical constriction.[225]

Crown-Down Technique

Numerous modifications of the original step-down technique have been introduced, including the description of the crown-down technique.[136,253,348] The more typical step-down technique includes the use of a stainless steel K-file exploring the apical constriction and establishing working length. In contrast, a crown-down technique relies more on coronal flaring and then determination of the working length later in the procedure.

To ensure penetration during step-down, one may have to enlarge the coronal third of the canal with progressively smaller GG drills or with other rotary instruments. Irrigation should follow the use of each instrument and recapitulation after every other instrument. To properly enlarge the apical third and to round out ovoid shape and lateral canal orifices, a reverse order of instruments may be used starting with a size #20 (for example) and enlarging this region to a size #40 or #50 (for example). The tapered shape can be improved by stepping back up the canal with larger instruments, bearing in mind all the time the importance of irrigation and recapitulation.

The more typical crown-down, or double-flare technique[136] consisted of an exploratory action with a small file, a crown-down portion with K-files of descending sizes, and an apical enlargement to size #40 or similar. The original technique included stepping back in 1-mm increments with ascending

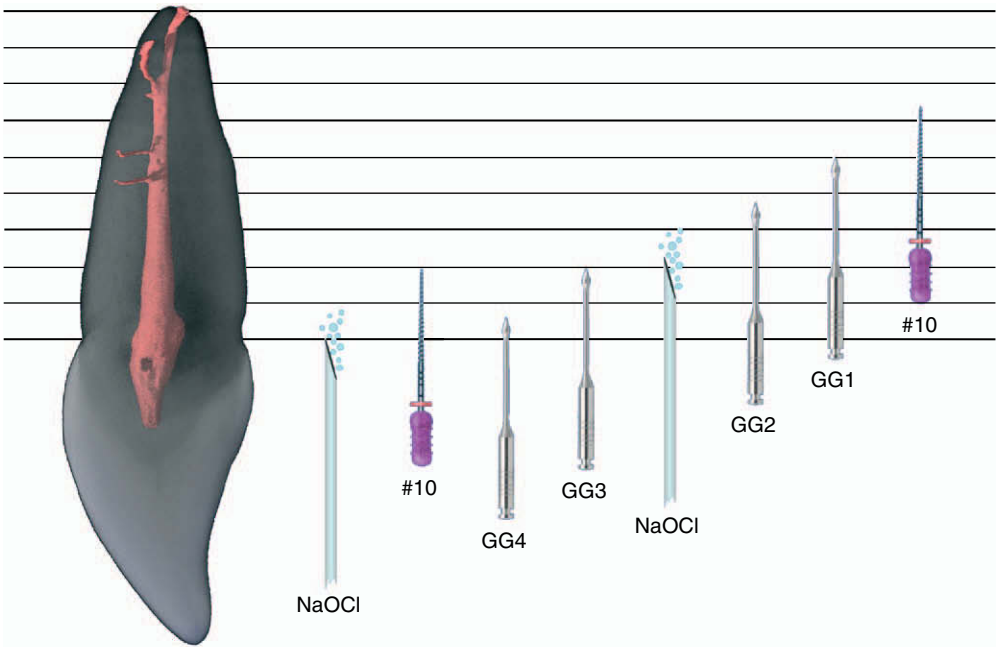

FIG. 9-52 Diagram of coronal enlargement in a maxillary anterior tooth. After preparation of the access cavity (see Figure 9-49) and copious irrigation, Gates-Glidden burs are used in a step-down manner to enlarge the orifice and provide straight-line access into the middle third of the canal. Precurved size #10 K-files are used to explore the canal path and dimension.

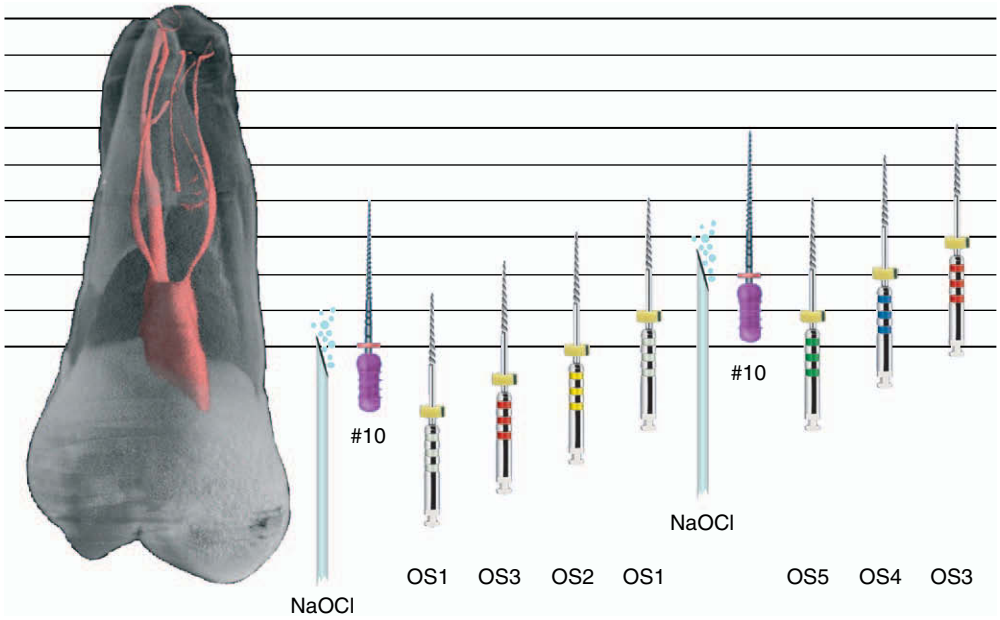

FIG. 9-53 Diagram of coronal enlargement in a more complicated maxillary posterior tooth. This maxillary molar presents several difficulties, including a narrow mesiobuccal canal that exits the pulp cavity at an angle. A possible approach in a case involving difficult entry into the root canal system is to use a small orifice shaper (OS1) after ensuring a coronal glide path with a K-file. Use of a sequence of orifice shapers (OS3 to OS1) then allows penetration into the middle third of the root canal. Wider canals can accept a second sequence of orifice shapers. Copious irrigation and securing a glide path with a size #10 K-file are prerequisites for use of NiTi rotary instruments.

file sizes and frequent recapitulations with a small K-file and copious irrigation. It is further emphasized that significant wall contact should be avoided in the crown-down phase to reduce hydrostatic pressure and the possibility of blockage. Several studies[347,348] demonstrated more centered preparations in teeth with curved root canals shaped with a modified double-flare technique and Flex-R files compared to shapes prepared with K-files and step-back technique. A double-flare technique was also suggested for ProFile rotary instruments.[363]

Balanced Force Technique

Regarding hand movements, a general agreement exists that the so-called balanced force technique creates the least canal aberrations with K-files. Researchers described this technique as a series of rotational movements for Flex-R files, but it can also be used for K-files and other hand instruments such as GT hand files. Many different explanations have been offered for the obvious and undisputed efficacy of the balanced force approach,[91,221,336] but general agreement exists that it provides excellent canal-centering ability, superior to other techniques with hand instruments.[29,69,226]

The balanced force technique involves three or four steps.[334] The first step (after passive insertion of an instrument into the canal) is a passive clockwise rotation of about 90 degrees to engage dentin (Fig. 9-55). In the second step, the instrument is held in the canal with adequate axial force and rotated

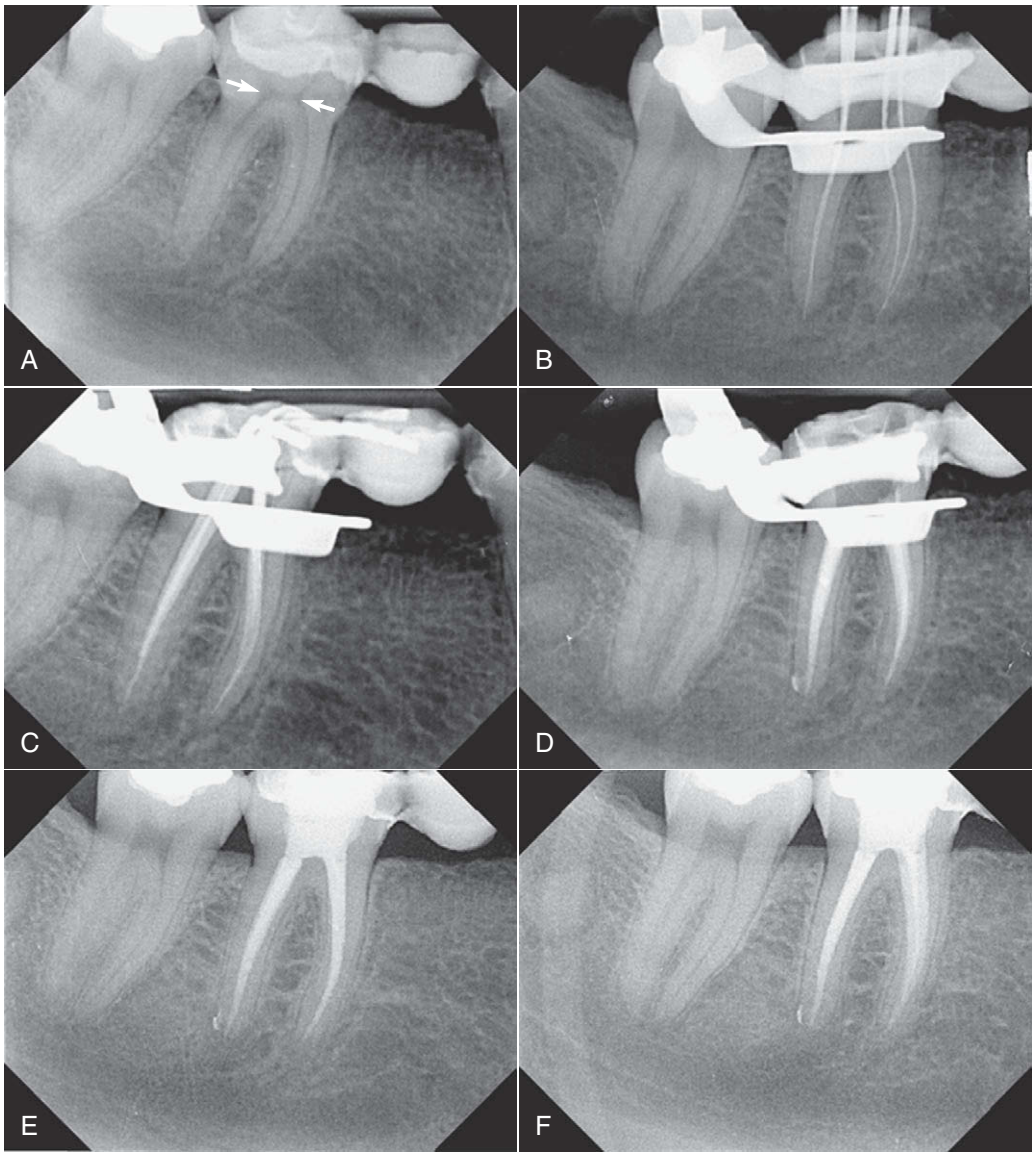

FIG. 9-54 Clinical example of the importance of straight-line access to the middle third of the root canal. **A,** Pretreatment radiograph of tooth #30, diagnosed with irreversible pulpitis. This tooth serves as a retainer for a metal-free, fixed partial denture. Note the prominent dentin shelves (*arrows*). **B,** Working length radiograph with hand instruments inserted into the mesial and distal canals. **C,** Cone-fit radiograph showing tapered preparations after removal of the dentin shelves. **D,** Posttreatment radiograph after thermoplastic compaction of gutta-percha. **E-F,** Follow-up radiographs at 2 and 4 years. The tooth is clinically symptom free, and the periodontal ligament appears to be within normal limits.

counterclockwise to break loose the engaged dentin chips from the canal wall; this produces a characteristic clicking sound. Classically, in the third step, the file is removed with a clockwise rotation to be cleaned; however, because files used with the balanced force technique are not precurved, every linear outward stroke essentially is a filing stroke and may lead to some straightening of the canal path. Therefore, in many cases, the clinician may advance farther apically rather than withdrawing the file, depending on the grade of difficulty.

Rotary Instrumentation

NiTi rotary instruments are an invaluable adjunct in the preparation of root canals, although hand instruments may be able to enlarge some canals just as efficiently when used in appropriate sequences (Fig. 9-56). Hand instruments should be used only after coronal preenlargement (e.g., with GG drills). After preenlargement, the access cavity and canals are flooded with irrigant, and a precurved scouting file is advanced into the canal. A lubricant can help prevent apical blockage in this early stage. Once the working length has been established (aided by an electronic apex locator and radiographically verified), apical enlargement to the desired size begins (Fig. 9-57). As stated previously, various apical preparation designs exist, and the choice is driven mostly by the desired obturation technique, whether an apical stop or an apical taper is prepared. Finally, canal taper is increased by decreasing the working length of larger instruments in 1-mm or 0.5-mm increments, producing 0.05 and 0.10 mm/mm tapers, respectively.

Copious irrigation and frequent recapitulations with a smaller file to working length may be required, and in some

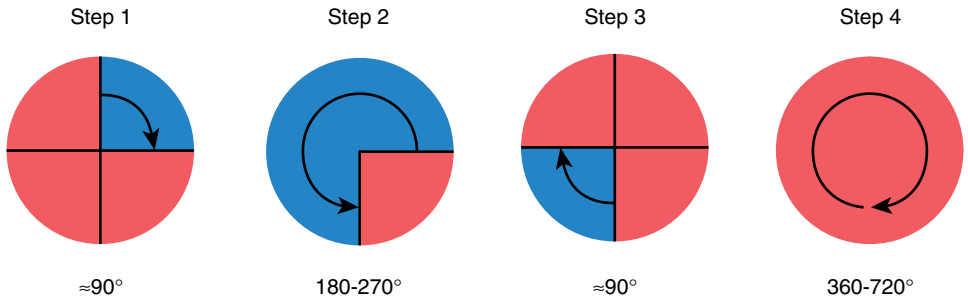

FIG. 9-55 Diagram of handle movements during balanced force hand preparation.
STEP 1: After pressureless insertion of a Flex-R or NiTiFlex K-file, the instrument is rotated clockwise 90 degrees, using only light apical pressure.
STEP 2: The instrument is rotated counterclockwise 180 to 270 degrees; sufficient apical pressure is used to keep the file at the same insertion depth during this step. Dentin shavings are removed with a characteristic clicking sound.
STEP 3: This step is similar to step 1 and advances the instrument more apically.
STEP 4: After two or three cycles, the file is loaded with dentin shavings and is removed from the canal with a prolonged clockwise rotation.

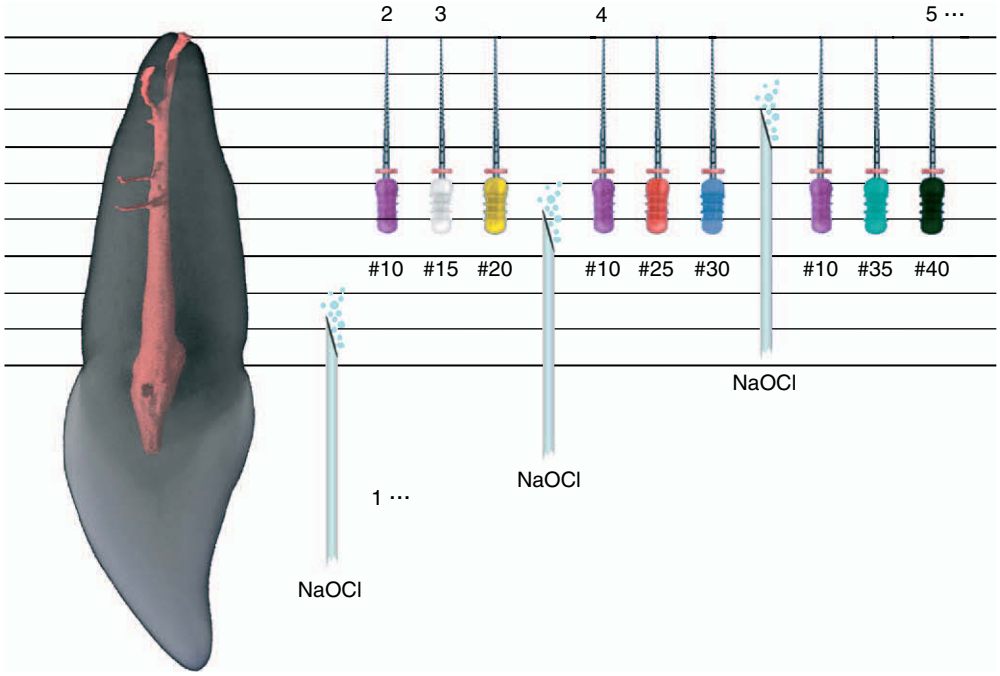

FIG. 9-56 Root canal instrumentation with hand files: Part I. After the orifice has been accessed (see Figs. 9-49 and 9-54) and copious irrigation performed *(1)*, the working length (WL) is determined. A size #10 and/or #15 K-file is advanced to the desired apical preparation endpoint, aided by an electronic apex locator *(2)*. The apical canal areas are then enlarged with K-files *(3)* used in the balanced force technique (see Figure 9-55). Frequent, copious irrigation with sodium hypochlorite is mandatory to support antimicrobial therapy. Frequent recapitulation with fine K-files is recommended to prevent blockage *(4)*. Apical enlargement is complete to the desired master apical file (MAF) size *(5)*, which depends on pretreatment canal sizes and individual strategy. Typically, size #40 or larger may be reached in anterior teeth, as in this example. File sizes larger than #20 may be used with NiTi instruments (e.g., NiTiFlex).

instances, clinicians must devise creative strategies using small crown-down and/or step-back sequences.

In many cases, hand instrumentation produces adequate shapes, but clinicians often choose NiTi rotary instruments either to enlarge curved canals or to produce wider tapers. Fig. 9-58 illustrates the development of these shapes in the mesial root canals of a mandibular molar, clearly showing that substantial areas of the root canal surface are not instrumented, even when apical size #50 or 0.09 taper are reached (see *red areas* in Fig. 9-58, *G* and *I*).

LightSpeed Instruments

Since the introduction of LightSpeed instruments, the manufacturer's guidelines have changed. This section presents a version used for the LightSpeed LS1[32] (Fig. 9-59).

After access and coronal preenlargement with the instrument of choice, working lengths are obtained, and apical enlargement is done with at least a loose-fitting size #15 K-file. LSX instruments are then slowly advanced to working length while registering tactile feedback. The first instrument that experiences resistance 4 mm short of working length is the

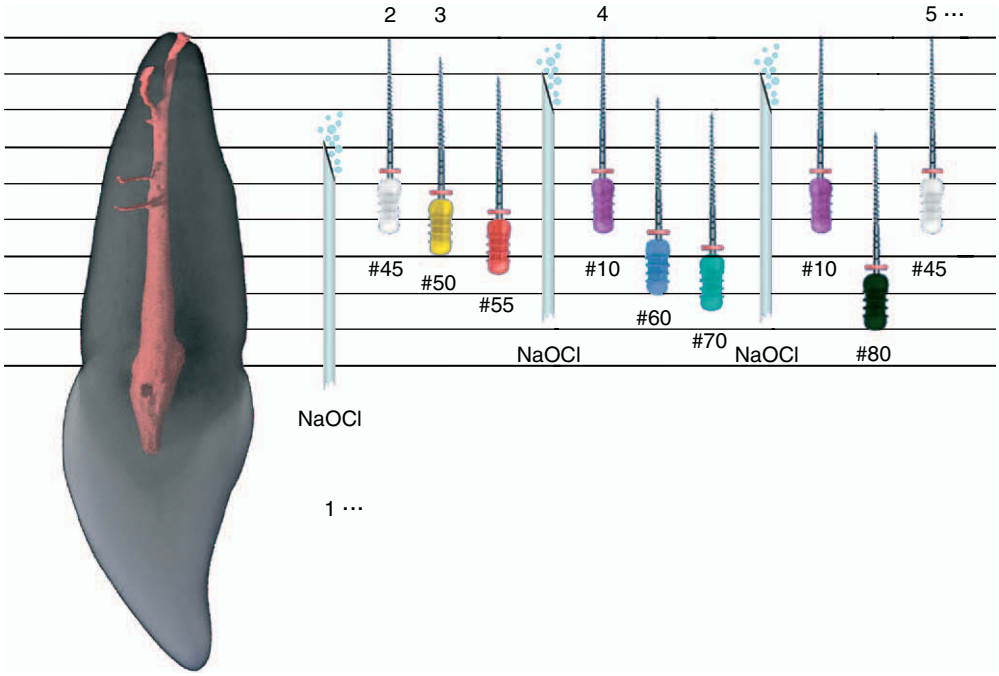

FIG. 9-57 Root canal instrumentation with hand files: Part II. Frequent irrigation with sodium hypochlorite *(1)* is more efficient after the working length (WL) is reached, because irrigation needles may penetrate deeper into the canal. Canal taper is increased to further improve antimicrobial efficiency and to simplify subsequent obturation. Hand instruments are set to decreasing working length in 0.5 mm increments (step-back) from the master apical file (MAF) (*2 to 3*). A fine K-file is used to recapitulate to WL during the procedure *(4),* and the MAF is used as a final recapitulation *(5)* to ensure that remaining dentin chips have been removed.

final apical size; it is then advanced to working length like the smaller instruments before. The next larger instrument is placed to 4 mm short of working length. This prepares the apical 5 mm for a matching SimpliFill obturator (Discus Dental). Midroot shaping is then accomplished with sequentially larger LSX instruments. Finally, the MAR is used to recapitulate to the working length.

All LightSpeed instruments are used in the following way: A slow, continuous apical movement is used until the blade binds; after a momentary pause, the blade is advanced further with intermittent ("pecking") motions.[120]

ProFile

Many different techniques have been advocated for the ProFile,[363] but the general pattern remains a crown-down approach with varying tapers and tip diameters. The ProFile instrument therefore can be used as an example for systems with this basic design (e.g., the HERO 642, K3, and FlexMaster). It must be noted that the manufacturers' instructions for those systems vary somewhat, and the instructions for GT rotary, RaCe, and the Twisted File vary even more. Clinicians should always read the manufacturers' instructions for details on working with those instruments. That said, it also must be noted that the merits of specific instructions have not been scientifically elaborated.

As with other instruments, coronal preenlargement is suggested (see Figs. 9-53 and 9-54). The working length then is determined as described previously, and an open glide path is secured with K-files up to size #15 or #20, depending on the canal anatomy. If canal size permits, canal preparation begins with #.06 taper instruments in descending tip diameters[57] (Fig. 9-60). In more difficult small canals, #.06 tapers are followed by #.04-tapered instruments, also with descending tip diameters (Fig. 9-61). Apical preparation is performed either with multiple shaping waves, as suggested for GT rotary files,[74] or in a step-back manner.[361] Because of their superior resistance to cyclic fatigue, #.02-tapered ProFile instruments are useful for abrupt apical curves. Preparation is complete once a continuous #.06 taper with an adequate apical size is achieved. Recapitulation during the preparation with a small hand file is recommended.

ProTaper

The approach for ProTaper instruments differs from that for most other NiTi rotary files (except the MTwo instrument marketed by VDW in Europe) in that no traditional crown-down procedure is performed (Fig. 9-62).

Size #10 and #15 hand files are precurved to match the canal curvature and then passively inserted into the coronal two thirds of a root canal as pathfinding files, which confirm the presence of a smooth, reproducible glide path. This step is essential for ProTaper shaping instruments, because they are mostly side-cutting and have fine, fragile tips.

Shaping files S1 and S2 are then passively inserted into the scouted canal spaces, which have been filled with irrigant (preferably NaOCl). If necessary, the Sx file can be used at this stage to relocate orifices or remove obstructing dentin. After each shaping file is used, the canals are reirrigated, and a size #10 file is used to recapitulate to break up debris and move it into solution. This process is repeated until the depth of the pathfinding #10 or #15 file is reached.

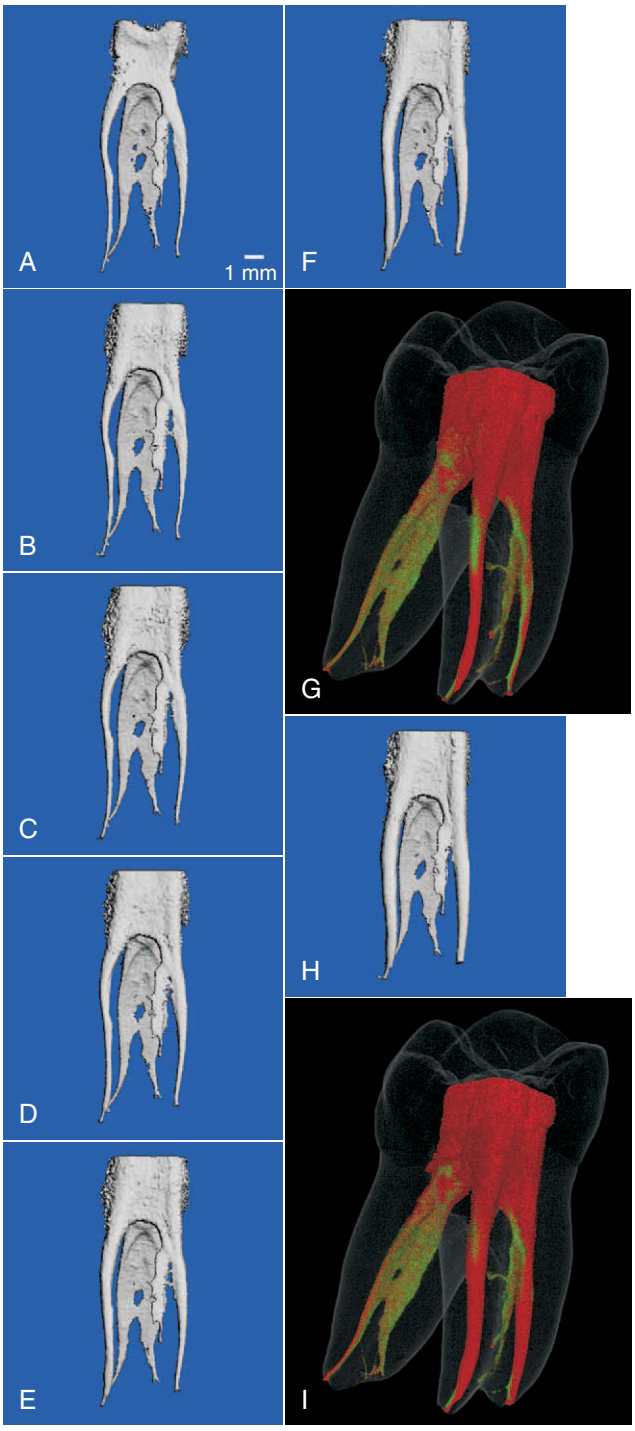

FIG. 9-58 Stepwise enlargement of mesial root canal systems in an extracted mandibular molar demonstrated with micro–computed tomography (μCT) reconstructions. The buccal canal *(left)* was prepared with a LightSpeed (LS) instrument, and the lingual canal *(right)* was shaped with a ProTaper (PT) instrument. **A,** Pretreatment view from the mesial aspect. Note the additional middle canal branching from the lingual canal into the coronal third. **B,** Initial preparation and opening of the orifices, aided by ultrasonically powered instruments. **C,** First step of root canal preparation, up to LightSpeed size #20 and ProTaper shaping file S1. **D,** Further enlargement to LS size #30 and PT shaping file S2. **E,** Apical preparation to LS size #40 and PT finishing file F1. **F,** Additional enlargement to LS size #50 and PT finishing file F2. **G,** Superimposed μCT reconstructions comparing the initial canal geometry *(in green)* with the shape reached after use of the instruments shown in **F. H,** Final shape after step-back with LS instruments and PT finishing file F3. **I,** Superimposed μCT reconstructions comparing initial geometry and final shape. Note the slight ledge in the buccal canal after LS preparation and some straightening in the lingual canal after PT preparation.

After irrigation, the apical third is fully negotiated and enlarged to at least a size #15 K-file, and the working length is confirmed (see Fig. 9-62). Depending on the canal anatomy, the rest of the apical preparation can be done with engine-driven ProTaper shaping and finishing hand files. As an alternative, handles can be placed on these instruments (Fig. 9-63) so that they can be used for the balanced force technique.

ProTapers S1 and S2 are then carried to the full working length, still in a floating, brushing motion. The working length should be confirmed after irrigation and recapitulation with a K-file, aided by an electronic apex locator and/or radiographs. Because of the progressive taper and more actively cutting flutes higher up in the ProTaper design, interferences in the middle and coronal thirds are removed at this stage.

The preparation is finished with one or more of the ProTaper finishing files, used in a nonbrushing manner; because of their decreasing taper, these files will reach the working length passively. Recapitulation and irrigation conclude the procedures (see Fig. 9-62).

Most cases requiring root canal therapy lend themselves to canal preparation with many different systems. Depending on the individual anatomy and the clinician's strategy, various sequences may be used. Fig. 9-64 presents two cases that involved different problems and therefore were approached differently. Mesiobuccal roots of the maxillary molar can show substantial curvature; rotary instrumentation and/or hybrid techniques allow preservation of the curvature (see Fig. 9-64, *A*) and optimal enlargement (see Fig. 9-64, *B*). Often hand instruments other than ISO-normed files (see Fig. 9-63) are used in these cases to ensure a smooth, tapered shape or to eliminate ledges.

Hybrid Techniques

For some time, combining various NiTi preparation systems have been suggested[89,448] to address certain shortcomings of current instruments (Box 9-5). Although many combinations are possible, the most popular and useful ones involve coronal preenlargement followed by different additional apical preparation sequences. However, clinicians must keep in mind that anatomic variations in each canal must be addressed individually with specific instrument sequences. Most important, oval canals extend deep into the apical area,[408,456,464,469] and apical foramina may in fact be oval in most cases.[68] Naturally, a rotating file can produce a round canal at best, so a strategy must be devised for adequately shaping oval canals without overly weakening radicular structure (compare Figs. 9-45 and 9-47). One hybrid approach completely prepared 95% or more of all such canals and resulted in extremely wide apical sizes that may be difficult to achieve with most instrument systems.[210-212]

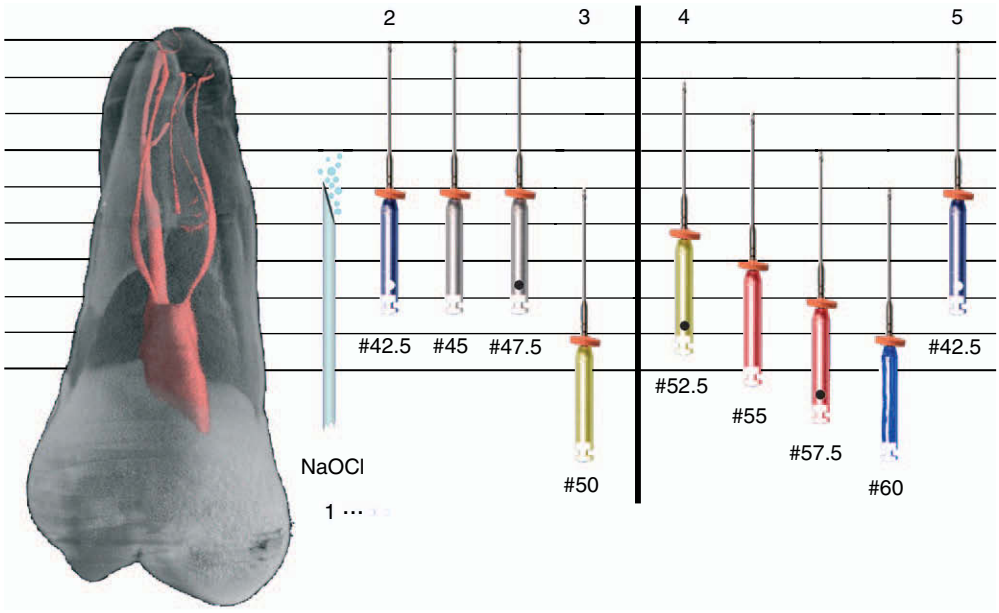

FIG. 9-59 Finishing of LightSpeed preparations to allow obturation. With the canal system flooded *(1)*, apical preparation *(2)* is continued until an LS instrument requires 12 pecks to reach the working length (WL). The next LS instrument *(3)* then is used to a point 4 mm short of the WL to prepare for LightSpeed's SimpliFill obturation system. Alternatively, canals may be flared for other root canal filling techniques by preparing with each subsequent instrument 1 mm shorter *(5)*.

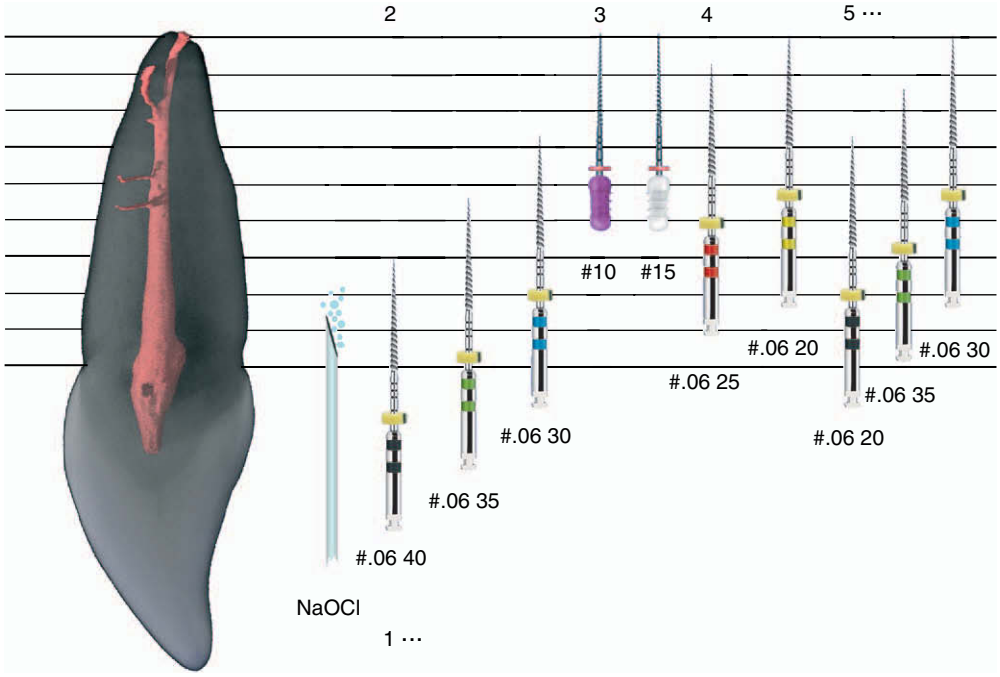

FIG. 9-60 ProFile instrumentation in a wider canal. In irrigated and flooded canals *(1)*, a crown-down preparation is done with a sequence of #.06-tapered ProFile instruments *(2)*. When the apical third is reached, the WL is determined and a glide path is secured *(3)*. Apical preparation is then completed by continuing the crown-down sequence *(4)* up to the desired apical width at the WL. Several shaping waves may be required *(5)*.

Histologic slides (see Fig. 9-41) and µCT reconstructions (see Figs. 9-45, 9-47, and 9-58) show critical areas that were not mechanically prepared despite the use of various individual rotary techniques. The aim of hybridizing NiTi rotary techniques, therefore, is to increase apical size using a fast and safe clinical procedure.

Various clinicians have used this type of hybrid procedure in their practices (see Figs. 9-2, 9-5, 9-15, and 9-63). The technique involves the use of a variety of instruments: GG drills and K-files for establishing straight-line access; ProTaper instruments for body shaping and apical preenlargement; NiTi K-files or LightSpeed instruments

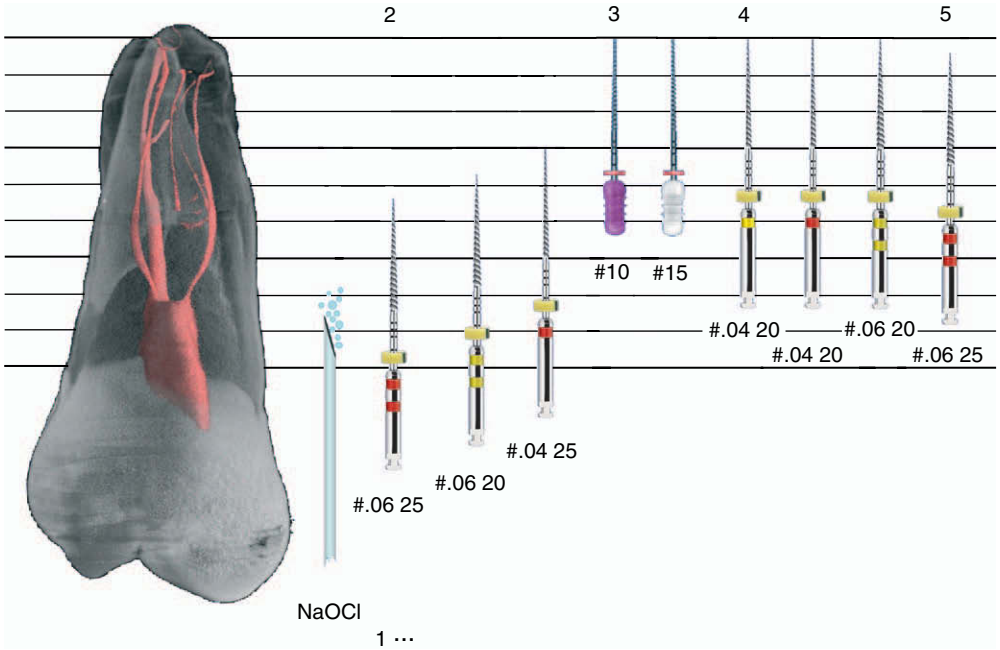

FIG. 9-61 Sequence of ProFile instruments used in constricted canals. After irrigation *(1)* and coronal preenlargement with orifice shapers (see Figure 9-51), ProFile instruments size #25, #.06 taper; size #20, #.06 taper; and size #24, #.04 taper are used as crown-down instruments *(2)*. After the WL has been determined and a glide path secured *(3)*, apical preparation to the desired size begins *(4)*. For additional taper, larger instruments may be used to a point short of the WL.

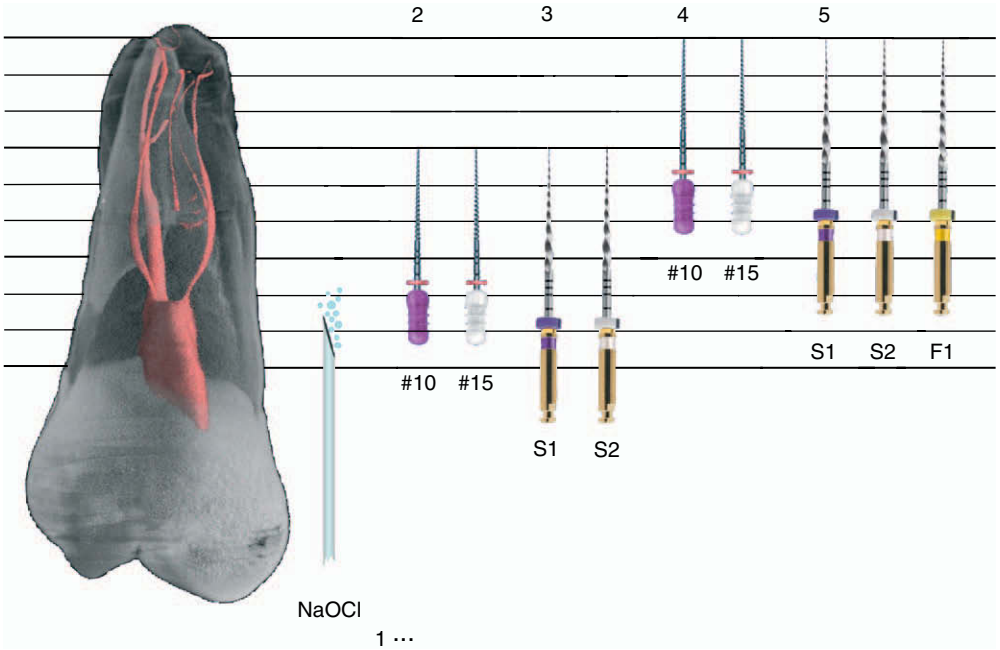

FIG. 9-62 Instrumentation of root canals with ProTaper instruments. After irrigation and scouting (*1* and *2*), the coronal thirds are enlarged with shaping files S1 and S2. Hand files then are used to determine the WL and to secure a glide path. Apical preparation is completed with S1 and S2. Finishing files are used to the desired apical width.

for apical widening; and various instruments for final smoothing.[448]

After a stainless steel file has confirmed a smooth glide path into the coronal two thirds, irrigation and mechanical preparation with a sequence of ProTaper shaping files opens and preenlarges the apical third (Fig. 9-65). Once the working length has been established, the apical third is flooded with NaOCl and further enlarged with ProTaper finishing files F1 and F2. The F3 ProTaper finishing file is relatively inflexible, and because of its side-cutting action, it should be used with caution in curved canals (Fig. 9-66). Further enlargement is possible with the F4 and F5 instruments, but these files may

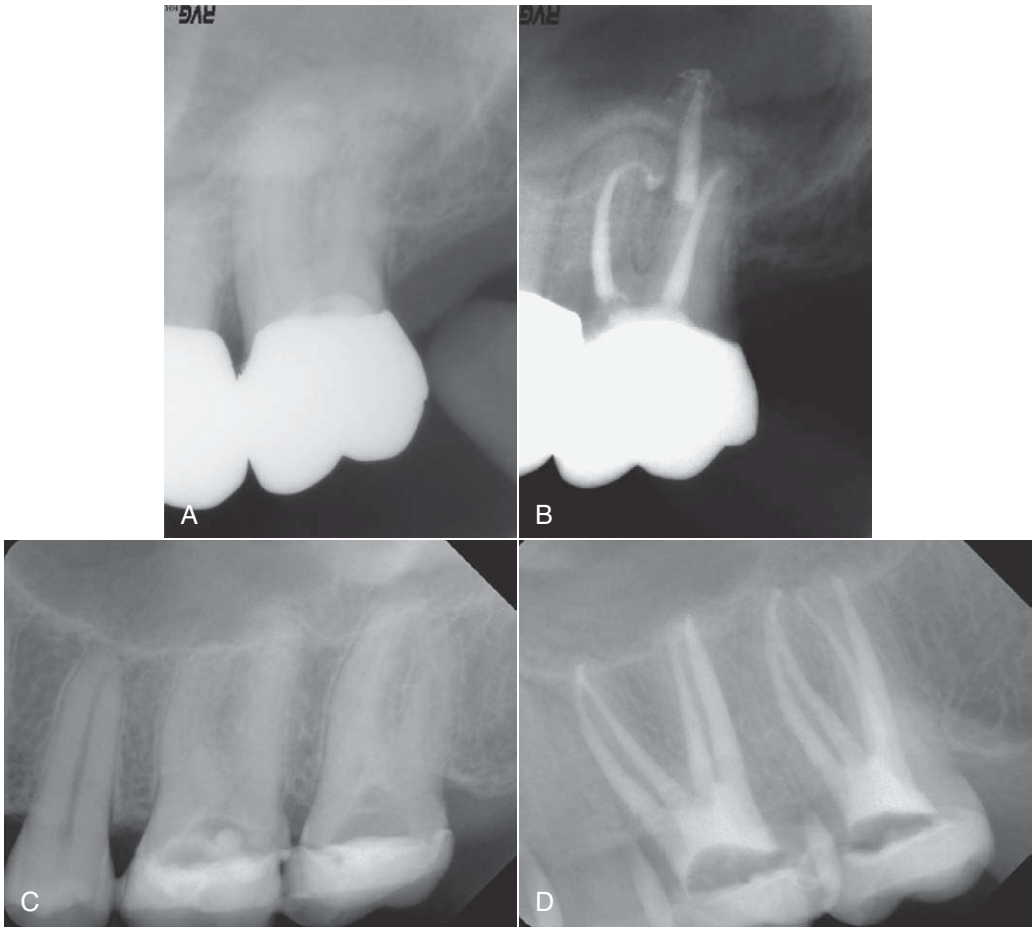

FIG. 9-63 Treatment performed with nickel-titanium rotary and hand instruments to eliminate instrument separation while maintaining biologic aims. **A,** Pretreatment radiograph of tooth #15. **B,** Posttreatment radiograph shows a significant curvature in the mesiobuccal canal and additional anatomy in the lingual root. **C,** Pretreatment radiograph of teeth #14 and #15. BOX 9-5

Benefits of Using a Combination of Instruments for Endodontic Therapy

- Instruments can be used in a manner that promotes their individual strengths and avoids their weaknesses (most important).
- Hand instruments secure a patent glide path.
- Tapered rotary instruments efficiently enlarge coronal canal areas.
- Less tapered instruments allow additional apical enlargement.

not be used in more acutely curved canals. The effectiveness of techniques combining different rotary instruments in enlarging canals recently was documented using superimposed root canal cross sections (Fig. 9-67). This method can help identify insufficiently prepared areas and weakening of the radicular structure.

A different approach—using, for example, NiTi K-files, .02 tapered rotaries (e.g., RaCe), or LightSpeed LSX (Fig. 9-68)—may be also advantageous if larger sizes are desired. Finally, the overall shape may be smoothed with either engine-driven or handheld instruments. Handheld ProTaper or GT instruments may aid removal of acute apical curvatures or ledges and provide access to apical canal areas for irrigants. Some hybrid systems seem to work better than others, but the deciding factors are likely the root canal anatomy and an adequate preparation goal.

Other Systems

Ultrasonically activated files or alternating file movements with special handpieces may be used to work canal areas that rotary instruments cannot reach. However, to date no evidence shows that canal preparation with ultrasonic instruments is clinically superior. Similarly, neither traditional modified handpieces[192,412] nor a recently introduced system (EndoEZE AET; Ultradent, South Jordan, UT) have been shown to allow preparation of adequate canal shapes.[290]

Ultrasonic devices have been linked to a higher incidence of preparation errors and to reduced radicular wall thickness.[234,260,488] Newer analytic systems (e.g., μCT) allow tracking of the amount of dentin removed (Fig. 9-69); however, the

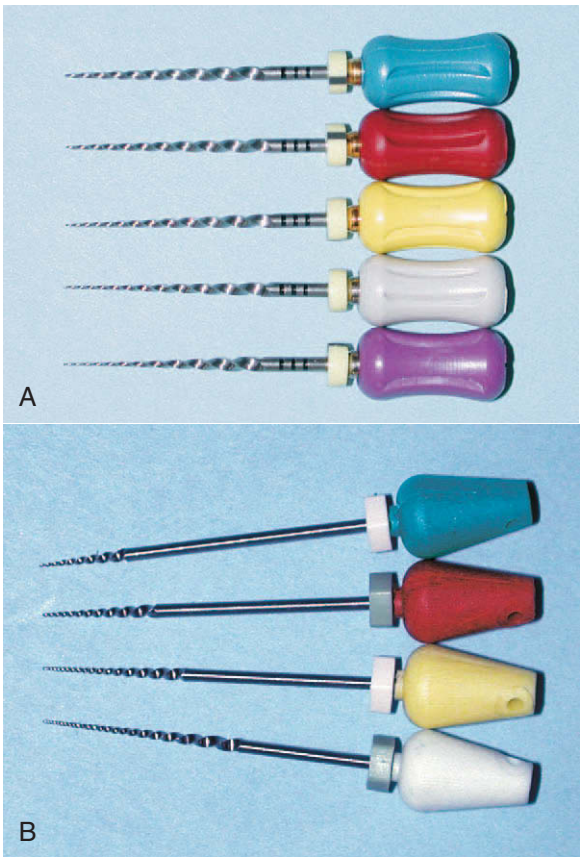

FIG. 9-64 Instruments with increased taper that can be used by hand. **A,** ProTaper instruments with special handles attached to rotary instrument shanks. **B,** GT hand instruments.

amount of potentially infected dentin that should be removed to maximize the chance of a successful outcome is unclear.

CANAL CLEANING TECHNIQUES

As stated earlier in this chapter, irrigants and other intracanal medicaments are necessary adjuncts that enhance the antimicrobial effect of mechanical cleansing and thus augment overall clinical efficacy.[79-81] It is well established that large areas of canal walls, particularly in the apical third but also in ribbon-shaped and oval canals, cannot be cleaned mechanically,[188,308,310,408,456,464] meaning that microbiota present in these untouched areas could survive (see Figs. 9-40, 9-45, and 9-47). Residual bacteria and other microorganisms exist both in these hard-to-reach spaces and in dentinal tubules.[171,300,342] Chemical disinfection is an important cornerstone of a successful outcome because it is directed towards elimination of microorganisms present in dentinal tubules and in the crevices, fins, and ramifications of a root canal system.[287,449] In one study, investigators prepared root canals, irrigated with saline solution, and sampled before, during, and after instrumentation.[112] They then cultivated and counted colony-forming units. These researchers found that with instrumentation alone, progressive filing reduced the number of bacteria regardless of whether rotary or stainless steel hand instrumentation was used. However, no technique resulted in bacteria-free canals. Siqueira et al.[380] confirmed this finding; they found that instrumentation combined with saline irrigation mechanically removed more than 90% of bacteria in the root canal. Many authors have stressed the importance of using antimicrobial irrigants during chemomechanical preparation to ensure complete disinfection.[384]

Substances that have been used to rinse and chemically clean root canals have different purposes, such as dissolution of soft and hard tissues, antimicrobial effect against bacteria or other microorganisms in the root canal, and inactivation of bacterial lipopolysaccharides. These substances also should be as nontoxic as possible to protect the periradicular tissues. Unfortunately, solutions that are toxic for bacterial cells frequently are toxic for human cells as well, so care must be taken to avoid extrusion of irrigants into periapical regions.[70,190]

Several factors are important for efficient root canal irrigation. One critical factor is the volume of irrigant. In a study evaluating the effect of different amounts of fluids, the volume of irrigant was found to affect the cleanliness of the root canal.[435,470] NaOCl and EDTA administered in larger volumes produced significantly cleaner root canal surfaces than smaller volumes.[470]

Irrigation Modes and Devices

There is a common consensus that root canal irrigants are indispensable aids in dissolving and inactivating organic debris and destroying microorganisms. In addition, some agents allow removal of a postpreparation smear layer in order to allow access to dentinal tubules. Several methods of employment of an irrigant inside the canal space are available.

Syringe Delivery

Application of an irrigant into a canal by means of a syringe allows exact placement, replenishing of existing fluid, rinsing out of larger debris particles, as well as allowing direct contact to microorganisms in areas that are reached by the needle tip. The actual exchange of irrigant is restricted to 1 to 1.5 mm apical to the needle tip, with fluid dynamics taking place near the needle outlet.[481] This was the case even if the needle tip diameter was three ISO sizes smaller than the diameter of the apical preparation.[64] Volume and speed of fluid flow are proportional to the cleansing efficiency inside a root canal. Therefore, both the diameter and position of the needle outlet determine successful chemomechanical débridement; placement close to working length is required to guarantee fluid exchange.[64,185,262]

The choice of an appropriate irrigating needle, therefore, is important. Although larger-gauge needles allow the irrigant to be flushed and replenished more quickly, the wider needle diameter does not allow cleaning of the apical and narrower areas of the root canal system (Fig. 9-70). Excess pressure or wedging of needles into canals during irrigation with no possibility of backflow of the irrigant should be avoided under all circumstances[190] to prevent extrusion of the irrigant into periapical spaces. In juvenile teeth with wide apical foramina or when the apical constriction no longer exists, special care must be taken to prevent resorption or overpreparation of the root canal.[107]

Another aspect is closeness of the needle tip or outlet to the apical endpoint of canal preparation to allow direct proximity of fresh irrigant to canal walls.[64,366] In that respect, size

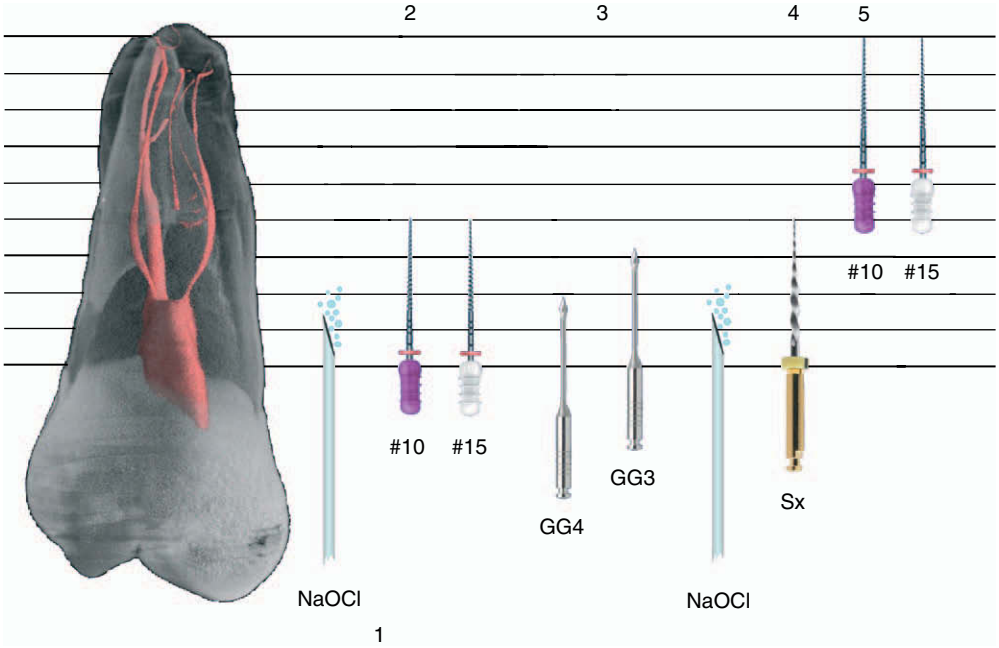

FIG. 9-65 Hybrid technique: Part I. After irrigation *(1)* and scouting *(2)*, GG drills *(3)* and/or ProTaper SX files *(4)* are used for coronal preenlargement and to secure straight-line access to the middle third. Precurved K-files are then used to explore and determine the working length *(5)*.

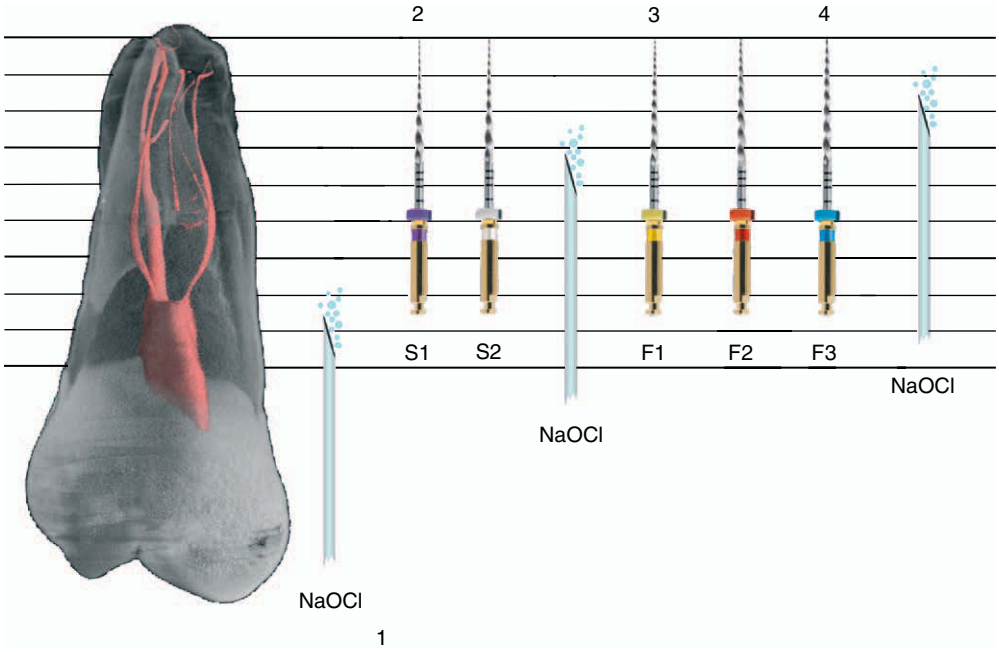

FIG. 9-66 Hybrid technique: Part II. In canal systems flooded with irrigant *(1)*, ProTaper shaping instruments S1 and S2 *(2)* and then finishing instruments F1 and F2 *(3)* are used to preenlarge the apical third, allowing irrigants access to the canals. Finishing instrument F3 may be used if feasible *(4)*.

of the irrigation needle,[97] as well as apical size and taper of root canal preparation,[89,264,280] play a role in allowing contact of irrigants to adjacent canal areas. Most root canals that have not been instrumented are too narrow to be reached effectively by disinfectants, even when very fine irrigation needles are used (see Figs. 9-44 and 9-70). Therefore, effective cleaning of the root canal must include intermittent agitation of the canal content with a small instrument[258,437] to prevent debris from accumulating at the apical portion of the root canal (see Fig. 9-42).

Preparation size[264] and taper[102] ultimately determine how close a needle can be placed to the final apical millimeters of a root canal. Some needles and suction tips may be attached to the air/water syringe to increase both the speed of irrigant

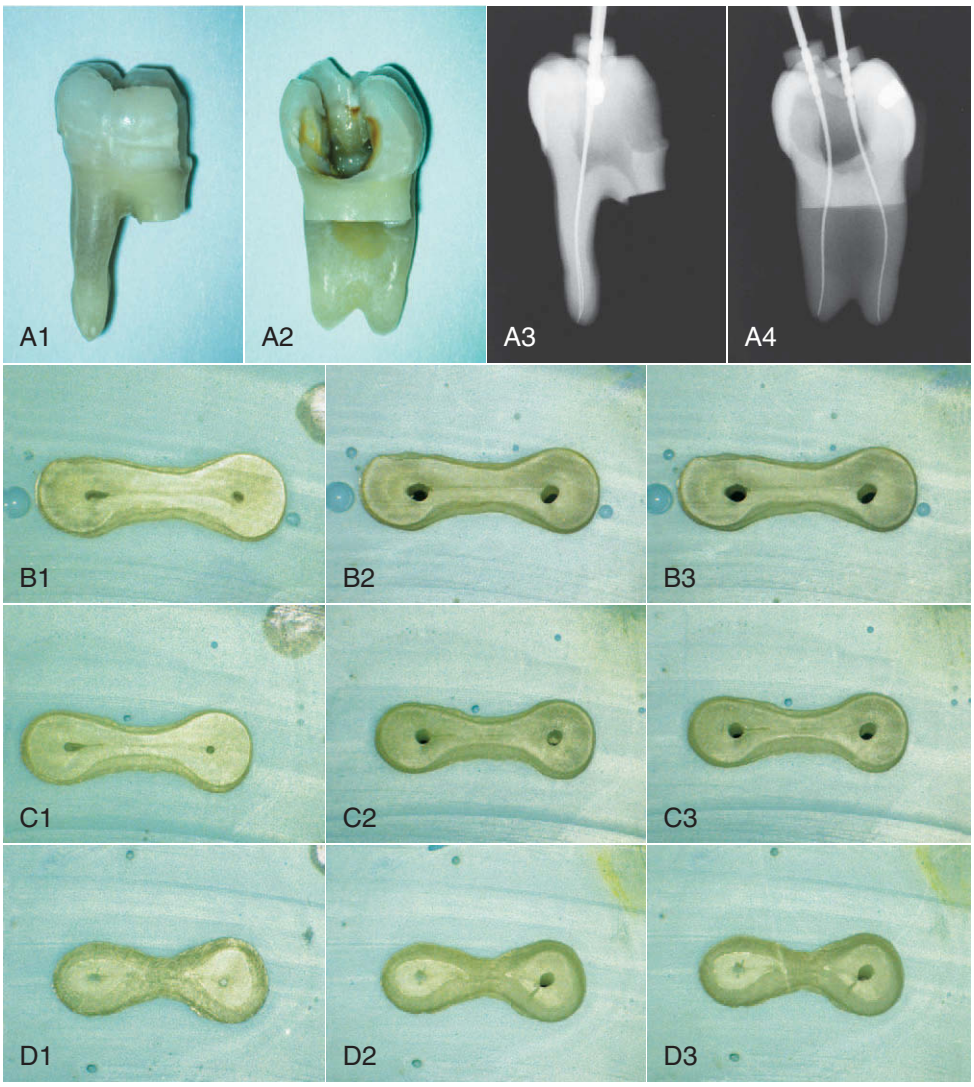

FIG. 9-67 Effect of a hybrid technique on root canal anatomy studied in a Bramante model. **A1-A4,** Both mesial canals of an extracted mandibular molar have been instrumented. flow and the volume of irrigant. Examples include the Stropko Irrigator (Vista Dental Products), which is an adapter that connects to the air/water syringe and accepts standard Luer-lock needle tips for irrigant removal and application as well as air drying.

Manually Activated Irrigation

Irrigant that is placed inside the root canal more effectively reaches crevices and mechanically untouched areas if it is agitated inside the root canal. Coronoapical movements of the irrigation needle,[190] stirring movements with small endodontic instruments,[258,437] and manual push-pull movements using a fitted master gutta-percha cone have been recommended.[186]

Sonically Activated Irrigation

In one study,[341] investigators suggested that both passive sonic or ultrasonic irrigation rendered root canals significantly cleaner than manual preparation. Débridement of root canals supported by sonically and ultrasonically activated irrigation was superior to passive needle application of irrigants.[77,439] However, in comparison to sonic activation, ultrasonic irrigation produced significantly cleaner canals.[200,341] Other investigators discovered no significant difference in débridement between sonic or ultrasonic fluid activation inside a root canal. The difference lies in the oscillating movements: sonic devices range between 1500 Hz and 6000 Hz, and ultrasonic equipment requires vibrations greater than 20,000 Hz.[200,241,401] Sonic or ultrasonic irrigation may be carried out with activated smooth wires or plastic inserts, endodontic instruments, or activated irrigation needles. Examples include EndoSonor (DENTSPLY Maillefer) and EndoSoft ESI (EMS, Nyon, Switzerland) inserts, the EndoActivator System (DENTSPLY Tulsa Dental), and the Vibringe sonic syringe (Vibringe, Amsterdam, Netherlands).

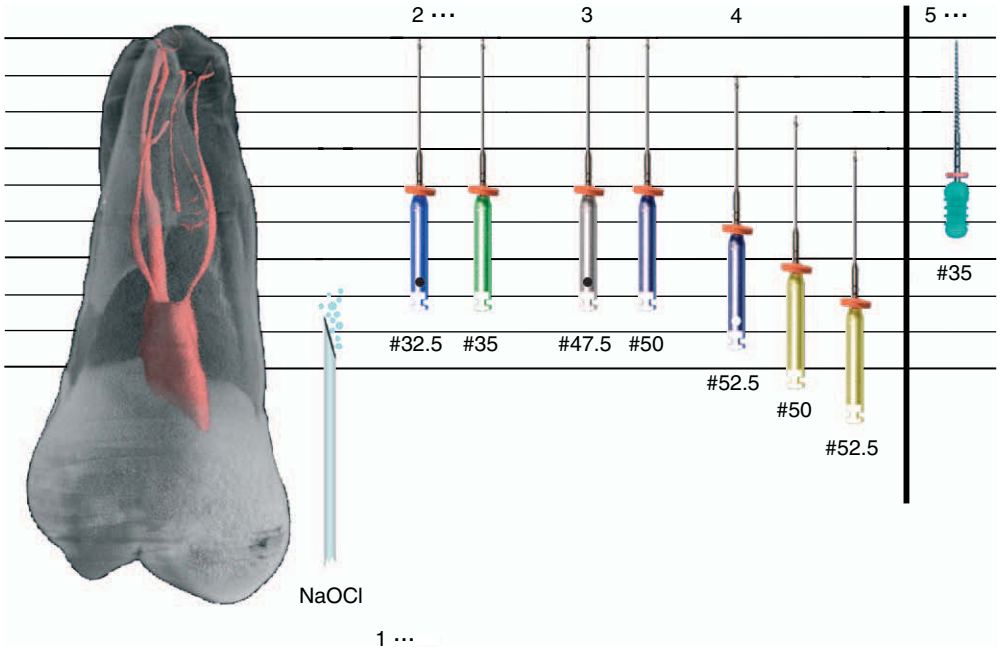

FIG. 9-68 Hybrid technique: Part III. Under irrigation *(1)*, LightSpeed instruments may be used to enlarge substantially (*2* and *3*) and to flare the apical section *(4)*. NiTi hand instruments *(5)* may be used similarly (see text for more detailed explanation).

Ultrasonically Activated Irrigation

Ultrasonically powered instruments have become indispensable now, with well-adapted tips from various manufacturers. During preparation, ultrasonic tips are able to remove minimal amounts of dentin, conserving as much tooth structure as possible. Visibility is better than with burs, and the tips can be diamond coated to increase their efficiency. However, all tips develop significant heat that is transferred through dentin walls and can cause necrosis of surrounding bone if used without coolant. The temperature elevation also takes place during use of ultrasonic power during root canal irrigation[10,195] and improves the antibacterial effect through warming of the irrigating solution.[486]

Ultrasonic action is most effective if the file is able to oscillate freely inside a given root canal.[240] *Passive ultrasonic irrigation* is defined as activation of the rinsing agent without simultaneous preparation of the root canal walls.[436,486] Passive ultrasonic irrigation is believed to promote tissue removal and tissue dissolution and may be done with a smooth wire insert that will avoid damaging canal walls and altering the shape in an undesirable way.[439] This strategy allows cleaning of isthmus areas, fins, or C-shaped canals by acoustic streaming and to a lesser extent cavitation, as well as (to some degree) other hard-to-reach areas such as dentinal tubules or lateral canals. Disinfection is rendered more effective, an important consideration in necrotic cases.[10,90] Kuah et al.[217] demonstrated that to eliminate smear layer and debris in the apical region of a prepared root canal, a 1-minute application of EDTA with ultrasonics followed by a final flush of NaOCl was the most proficient method.

Negative- and Positive-Pressure Irrigation

Another approach to afford better access of irrigation solution is so-called negative-pressure irrigation. Here, irrigant is delivered into the access chamber, and a very fine needle connected to the dental unit's suction device is placed into the root canal. Excess irrigant from the access cavity is then transported apically and ultimately removed via suction. First, a macrocannula, equivalent to an ISO size #55, .02 taper instrument, removes coronal debris. Subsequently, a microcannula, equivalent to a size #32, .02 taper, removes particles lodged close to working length. Such a system is commercially available (EndoVac, Discus Dental) and may prove a valuable adjunct in canal disinfection.[281]

Another device that makes use of pressure-suction technology is the RinsEndo system (Dürr Dental, Bietigheim-Bissingen, Germany). It aspirates the delivered rinsing solution into an irrigation needle that is placed close to working length and at the same time activates the needle with oscillations of 1.6 Hz amplitude. This system has been investigated by several authors and was superior to customary needle irrigation in cleaning and disinfection.[67,262] Researchers[262] used 30-gauge irrigation needles in canals shaped to ISO size #40 and compared irrigation with the RinsEndo system to conventional needle irrigation and so-called manual-dynamic irrigation that involves pumping action of a fitted master gutta-percha cone inside a root canal; in this study, 200 push-pull strokes were delivered. The cleaning effect of the RinsEndo unit was found to be superior to conventional needle irrigation, but the least amount of residual debris was found after hand agitation of a master cone.

Eradication of Microorganisms

Various types of microorganisms—bacteria,[205,215,270,272] yeasts,[449,450] and possibly viruses[339,340]—can infect the pulp and may lead to apical periodontitis (see Chapters 14 and 15 and Fig. 9-7). These microorganisms must be reduced or eliminated to reestablish periradicular health. When bacterial

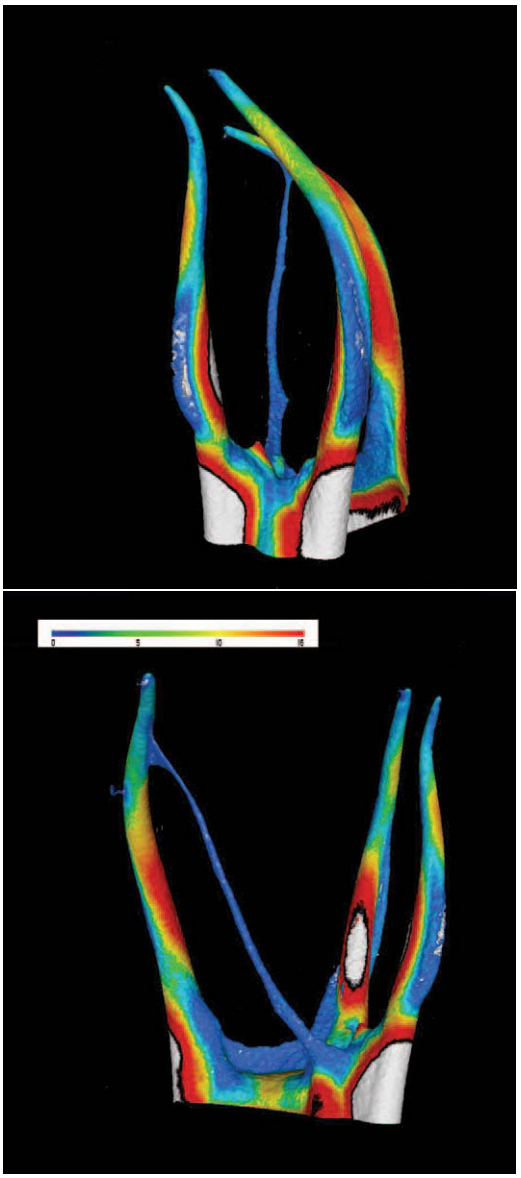

FIG. 9-69 Reconstruction from micro–computed tomography data (36 µm isotropic resolution) showing the amount of removed dentin by color coding. Maxillary molar shaped with ProTaper, apical size #25 (=F2) in mesiobuccal and distobuccal canals; palatal canal shaped to size #30 (=F3). FIG. 9-70 Irrigation needles inserted into prepared root canals. **A-B,** A 27-gauge needle barely reaches the middle third. **C-D,** A 30-gauge, side-venting needle reaches the apical third (see Figure 9-43).

samples test negative after treatment, the prognosis is improved.[381,387] During mechanical root canal preparation, endodontic instruments are used to clean and enlarge root canal systems. Rotating instruments have an additional advantageous "Archimedes screw" effect by which debris is transported in an apicocoronal direction.[112] Even when simple saline was used as an irrigant, a 10-fold to 1000-fold reduction of the bacterial load through mechanical instrumentation was demonstrated.[80,112,288]

However, as noted earlier, instrumentation alone does not produce a bacteria-free root canal. In one study, dentin samples tested positive in most of the teeth after mechanical instrumentation, even though bacteria had been eliminated from the root canals in some cases.[80] In that study, bacteria persisted in seven root canals despite mechanical cleaning and saline irrigation during five consecutive appointments. Moreover, teeth with a high number of bacteria in the initial sample remained infected despite being treated five times.[80] In another study, teeth that caused symptoms tended to have more bacteria than teeth with no clinical symptoms.[288]

Other researchers[287] investigated the effect of endodontic irrigants and dressings in standardized bovine dentin specimens that were infected with test bacteria. They found that bacteria were capable of colonizing the canal lumen and dentinal tubules. In the specimens used, *E. faecalis* rapidly infected the whole length of the tubules, whereas *Escherichia coli* penetrated approximately 600 µm. They also found that IKI appeared to be more effective at destroying bacteria than NaOCl, which was more effective than CHX.

Other investigators have explored the effects of NaOCl (with and without EDTA), CHX, and hydrogen peroxide in varying concentrations when used in sequence or in combination as endodontic irrigants.[181] They found that CHX and NaOCl were similarly effective in eliminating the bacteria

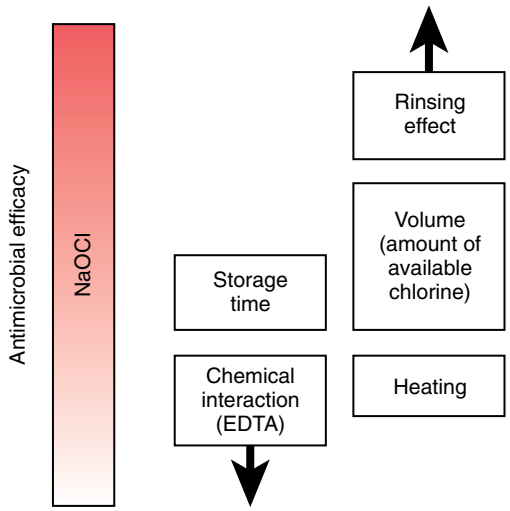

FIG. 9-71 Interaction of sodium hypochlorite with various factors that determine its efficacy.

BOX 9-6

Properties of an Ideal Irrigant for Root Canal Treatment

The irrigant should:
- Be a highly effective disinfectant
- Be nontoxic locally and nonallergenic
- Differentiate between necrotic and vital host tissue
- Retain its effectiveness with dental hard tissue and when mixed with other irrigants

tested. Synergistic effects were observed for some of the irrigants (e.g., CHX and IKI).

Both of the preceding studies used infected dentin specimens. When evaluating literature about antimicrobial efficacy, clinicians must keep in mind that most disinfecting solutions are inhibited or even inactivated by contact with dentin or dentin powder during root canal preparation.[169,317] Moreover, chemical interactions occur between irrigation solutions; for example, NaOCl can become ineffective if it comes in contact with EDTA[161] (Fig. 9-71).

Some of the more difficult to remove endodontic pathogens that can cause treatment failure are enterococci, *Actinomyces,* and *Candida* organisms[47,276,277,378,462] (see Chapter 15). Table 9-1 presents the results of a number of studies evaluating the effectiveness of some commonly used antimicrobial agents.

Currently, the endodontic irrigation solution with the best proteolytic effect is NaOCl,[481] even though it does not meet all the requirements of an ideal irrigant (Box 9-6). It is readily available, inexpensive, and consequently a widely used irrigation solution. As mentioned previously, necrotic tissue and debris are dissolved by the breakdown of proteins into amino acids through free chlorine in NaOCl. However, because unbound chlorine is the important component, the solution

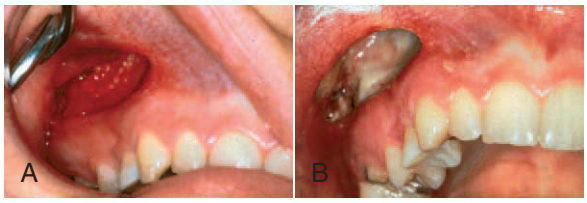

FIG. 9-72 Toxic effect of sodium hypochlorite on periradicular tissues. After root canal treatment of tooth #3, the patient reported pain. **A,** On a return visit, an abscess was diagnosed and incised. **B,** Osteonecrosis was evident after 3 weeks.

must be replenished frequently during preparation to compensate for lower concentrations and to constantly renew the fluid inside the root canal. This is even more important when the root canal is narrow and small and files must carry the NaOCl to the apical third during instrumentation (see Fig. 9-44). A 1% solution is effective at dissolving tissue and providing an antimicrobial effect. The use of 6% commercial household bleach in its undiluted form causes substantial necrosis of wound surface areas and may result in serious clinical side effects (Fig. 9-72). It is diluted in 1:1 or 1:3 ratios with water to produce a 2.5% or 1% solution; both are suitable for clinical endodontic use.[398,477,482]

Importantly, to avoid extrusion and serious damage to periapical tissues, irrigation needles should never be wedged into canals during irrigation.[70] Higher concentrations of NaOCl are more aggressive toward living tissue and can cause severe injuries when forced into the periapical area (see Fig. 9-72).

Such accidents can be prevented by marking the working length on the irrigation needle with a bend or a rubber stop and by passively expressing the solution from the syringe into the canal (see Fig. 9-70). The needle should be continuously moved in an up-and-down motion. It should remain loose in the canal, allowing a backflow of fluid. The goal is to rinse the suspended, concentrated dentinal filings out of the pulp chamber and root canals as new solution is brought down into the most apical areas by the endodontic instrument and the capillary effect.

As stated before, patency files should be used carefully and should not be extended farther than the periodontal ligament, because they are possible sources of irrigant extrusion.

In one study, heating increased the antibacterial action of NaOCl.[104] Heating can be done in several ways; for example, after the solution has been drawn into the irrigating syringe, a syringe warmer can be used (e.g., Syringe Warmer [Vista Dental Products, Racine, WI]) (Fig. 9-73). Heating also enhanced the antibacterial effectiveness of CHX and $Ca(OH)_2$ solutions.[131] A 0.5% NaOCl solution heated to 113° F (45° C) dissolved pulp tissue as efficiently as a 5.25% solution used as the positive control (Fig. 9-74).[386] Heating to 140° F (60° C) resulted in almost complete dissolution of tissue. Studies have shown that 1 minute at 116.6° F (47° C) is the cutoff exposure at which osteoblasts can still survive; however, higher temperatures may in fact be sufficient to kill osteoblasts and other host cells.[128,129] Also, warming of NaOCl to 122° F (50° C)[53] or 140° F (60° C)[5] increases collagen dissolution and disinfecting potential, but it may also have severely detrimental effects on NiTi instruments, causing corrosion of the metal surface after immersion for 1 hour[51] (Fig. 9-75).

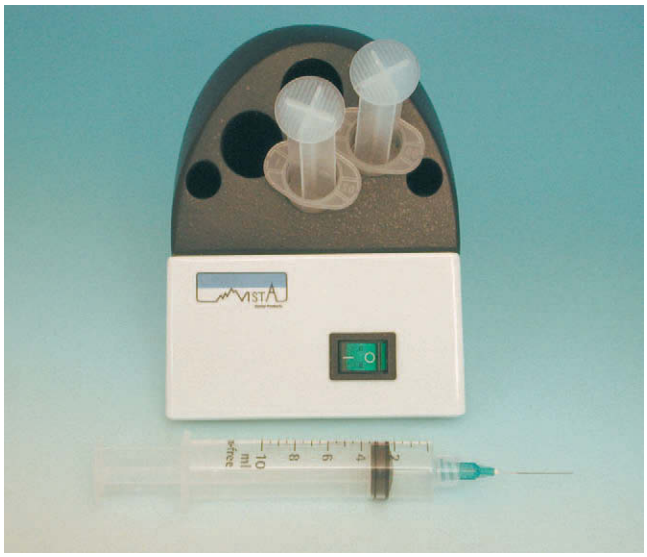

FIG. 9-73 Device for heating syringes filled with irrigation solution (e.g., sodium hypochlorite) before use.

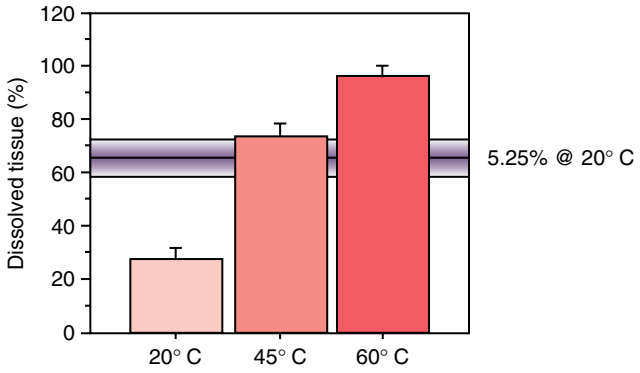

FIG. 9-74 Effect of heating on the ability of 0.5% sodium hypochlorite (NaOCl) to dissolve pulp tissue: NaOCl heated to 113° F (45° C) dissolved pulp tissue as well as the positive control (5.25% NaOCl) did. When the NaOCl was heated to 140° F (60° C), almost complete dissolution of tissue resulted. *(Modified from Sirtes G, Waltimo T, Schaetzle M, Zehnder M: The effects of temperature on sodium hypochlorite short-term stability, pulp dissolution capacity, and antimicrobial efficacy.* J Endod *31:669–671, 2005.)*

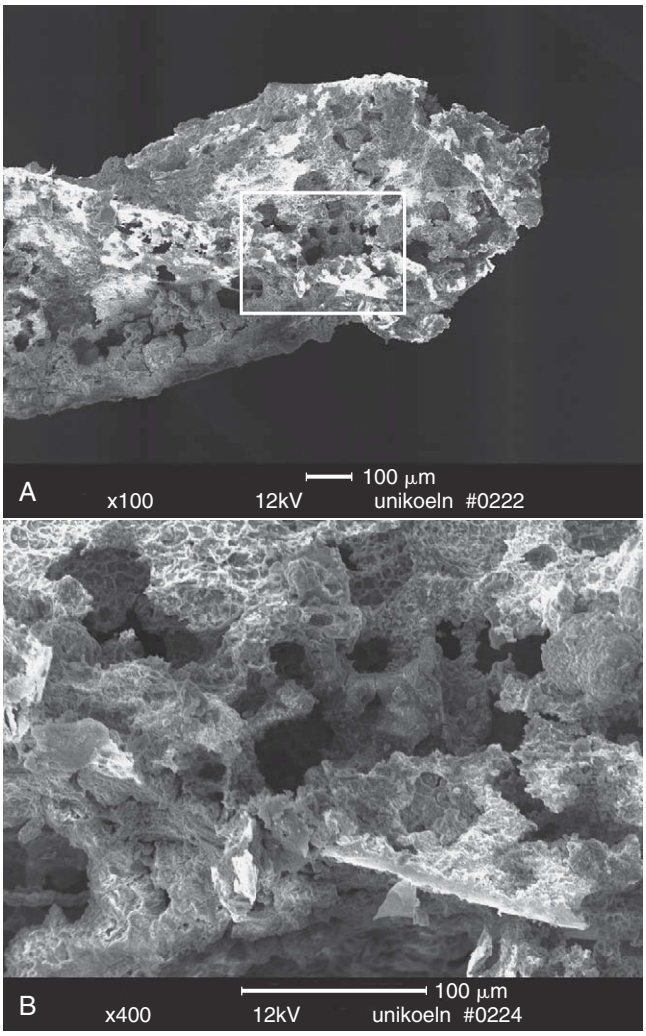

FIG. 9-75 Corrosion of nickel-titanium files in heated sodium hypochlorite (NaOCl). **A,** Rotary instrument immersed for 2 hours in NaOCl heated to 140° F (60° C). **B,** Magnification of rectangular area in **A,** showing severe corrosion.

As stated before, an increase in the temperature of the irrigant may be another reason to include ultrasonic devices in canal irrigation[10,486]; using these devices may also increase the tissue-dissolving capabilities of NaOCl via temperature elevation,[5] but this effect seems to be limited to the main canal.[10] In one study, peak irrigant temperatures during ultrasonic irrigation reached 113° F (45° C) near the file tip but remained at 89.6° F (32° C) on the outer root surface of teeth prepared to a size #45.[86] The effect seems to depend on the insert,[486] possibly due to its oscillation patterns.

Yet another reason for using ultrasonic devices might be enhancement of canal débridement. However, some authors have reported no significant effect with ultrasonics, neither in débriding root canal walls[96,108,258] nor in reducing bacterial counts.[118,382] However, the majority of available studies appear to find both bacterial reduction[194] and improved débridement,[167] as reviewed recently.[438]

Smear Layer Management

EDTA is a decalcifying chelating agent used as a 15% to 17% buffered solution during instrumentation of root canals. The decalcifying efficacy of EDTA-containing pastes is variable.[160,441] EDTA acts as a chelator with calcium ions and removes the dentinal debris produced on the root canal walls during preparation. It thus opens dentinal tubules, promoting better penetration of disinfectants.[154,191,422,485] Whenever the wall of a root canal is instrumented, whether by hand or rotating instruments, the parts of a dentin wall touched by an instrument are covered by a surface layer called the *smear layer*.[261,296] The

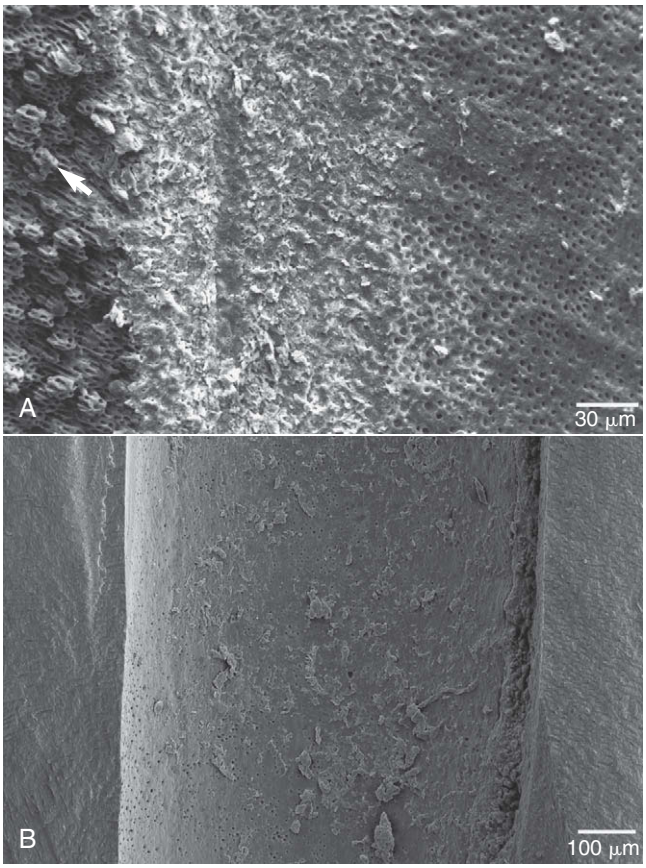

FIG. 9-76 Prepared root canal surfaces after irrigation, showing varying degrees of smear layer. **A,** Scanning electron micrograph (SEM, ×25) showing prepared areas with and without open dentinal tubules. The presence of calcospherites indicates that no mechanical preparation has been done laterally (*arrow*). **B,** SEM, ×400, showing thin, homogenous smear layer and scattered debris in a canal that received a final sequence of a high-volume flush of 17% ethylenediamine tetra-acetic acid (EDTA) followed by 2.5% sodium hypochlorite (NaOCl).

smear layer, which consists of dentin shavings, cell debris, and pulp remnants,[369] can be described as itself having two separate layers: a loose, superficial deposit and an attached stratum that extends into the dentinal tubules, forming occluding plugs.[87]

For some time, clinicians and researchers paid little attention to the smear layer, partly because it was a thin superficial layer (1 to 5 μm) that might be present or not, depending on the type of instrument and the sharpness of its cutting blades.[369] Also, because acids and chelating agents dissolve the smear layer, it was removed and escaped attention in routinely processed specimens (Fig. 9-76).[109] Smear layers are not seen in unprepared canal areas, which may have calcospherites, buttonlike structures that are abundant on intracanal surfaces.

Some authors have reported that an overlying smear layer delays but does not eliminate the effect of medicaments.[287] Others contend that a smear layer may adversely affect disinfection and may also increase microleakage after canal obturation.[369] Although organic substrate in a smear layer may serve as a nutrition source for some species of bacteria,[65,297] some have suggested the converse: that a smear layer can act as a beneficial barrier, preventing microorganisms from entering the dentinal tubules when a root canal is colonized by bacteria between appointments.[121] The potential of intracanal disinfectants has been evaluated in vitro after removal of the smear layer with a combination of 5.25% NaOCl and 17% EDTA.[171] The decalcifying effect of EDTA is self-limiting, so the solution must be replaced at intervals.[191] EDTA can help open very narrow root canals and can decalcify to a depth of approximately 50 μm. Because the smear layer consists of organic and inorganic components, the combined use of NaOCl and EDTA, with time frames of 30 seconds to 60 seconds each, is considered most effective for its removal.[83] In general, it seems beneficial to remove the smear layer in the later phases of endodontic therapy rather than during the early phases. Research continues on ways to improve the effectiveness of irrigation. For example, tensides were added to irrigants more than 20 years ago to reduce their surface tension, thereby improving wetability.[6] The rationale for this increased wetability was to improve the penetration of irrigants into the dentinal tubules,[409] and this concept is still pursued with MTAD today. One irrigation "cocktail" investigated was a mixture of 5% NaOCl and 17% EDTA with the tensioactive chemical Triton X-100; this solution was used with ProFile instruments.[7,144] The study reported that apical smear layer scores were significantly lower compared with those of control groups when the tensioactive agent was used throughout the preparation process. However, a more recent study found no effect of a wetting agent on the action of EDTA, measured as calcium in eluates from root canals in vitro.[484] Rather than surfactant, ultrasonic irrigation appears to promote smear layer removal by EDTA.[238]

Liquid disinfectants were effective against *E. faecalis* in dentinal tubules up to depths of 400 μm. Microbiologic analyses of split root halves showed that early removal of the smear layer resulted in significantly higher bacteria counts.[121] In contrast, other researchers have acknowledged that the smear layer, while acting as a barrier, might block irrigation solutions from entering the dentinal tubules.[42] Moreover, some bacteria (e.g., *Bacteroides gingivalis* and *Treponema denticola*) have the potential to dissolve smear layer proteins,[432] thereby producing gaps which could promote both coronal and apical microleakage and bacterial multiplication.

Fig. 9-77 shows root canal cross sections with very little debris; irrigating solutions can penetrate the dentinal tubules in this example. Some reported that the presence of the smear layer had no significant effect on apical leakage in dye penetration testing.[132,247] Others described an improved seal after removal of the smear layer.[43,411] The latter study, which used a coronal leakage model, found a significantly decreased incidence of bacterial penetration (30% versus 70%) when the canals were irrigated with 17% EDTA and 5.25% NaOCl before obturation. In obturated root canals, a remaining smear layer led to bacterial leakage in 60% of the samples versus no leakage when the smear layer was removed.[101] Other authors had similar results after smear layer removal with EDTA solution alone. Another investigation[421] found that many lateral canals in the apical third of root canal systems cleaned with a barbed broach wrapped with MTAD-soaked cotton showed less erosion than when EDTA was used. Other studies have found

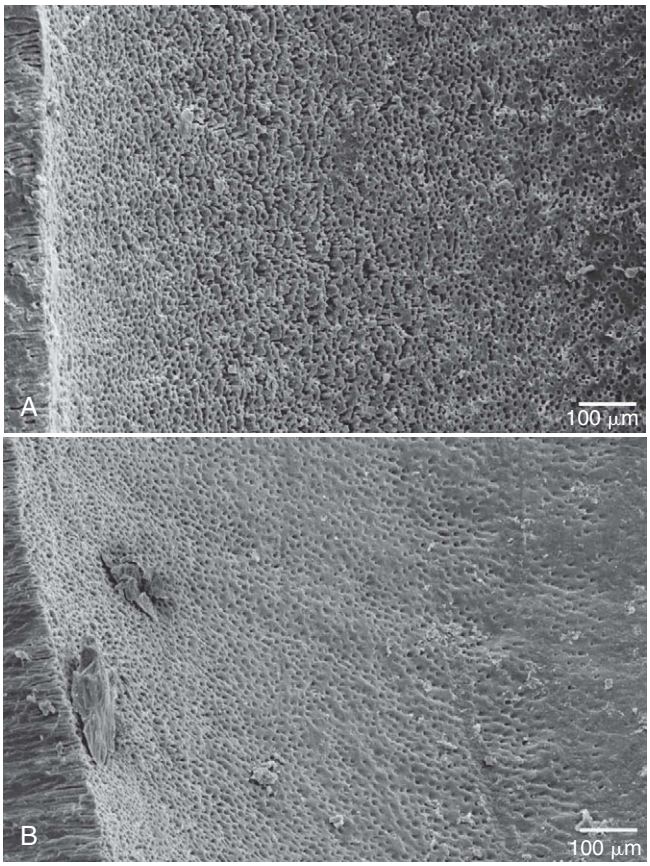

FIG. 9-77 Example of canals with minimal smear layer. **A,** Middle third after irrigation with 17% ethylenediamine tetra-acetic acid (EDTA) and 2.5% sodium hypochlorite (NaOCl). **B,** Apical third with some particulate debris.

that a stronger bond was present when the smear layer was removed,[148] and a statistically significant reduction of microleakage was also measured.[124,349,350] Still another investigation reported increased apical microleakage of the filled root canal after removal of the smear layer.[419]

As shown in Fig. 9-43, dye staining is improved when the dentinal tubules are opened and the smear layer is removed with EDTA, at least in the two more coronal levels. However, this effect is at least partly due to tubular sclerosis and the overall lower number of tubules apically, resulting in fewer diffusion pathways across dentin.[292]

Although the effect of the smear layer on leakage has been widely studied, its removal from root canal walls remains controversial. The apparently conflicting results of studies could stem from differences in the various microleakage test models[467] and from different obturation and irrigation techniques. The problem of coronal leakage has received much attention as a major factor in determining the success or failure in root canal therapy.[47,327,330,331,428]

In two in vitro studies, the noninstrumentation technique, which relies on activated irrigation solutions rather than mechanical preparation, produced excellent canal cleanliness[244,245] (see Fig. 9-10, A). However, preliminary clinical studies identified a need for improvement before this system can be used routinely to clean root canals.[27]

For the time being, root canals must be mechanically enlarged before irrigation. Larger apical preparations enhance the efficacy of irrigation, and the additional use of ultrasonic energy during cleaning and shaping may also increase the efficacy of endodontic irrigants.[87,88,105,224] Ultrasonics used passively in canals with sufficiently large apical preparations may reach and better clean any uninstrumented canal areas.[241,463,465] One investigation studied the débriding ability of 2.5% NaOCl in canal recesses.[105,106] In 10 of 11 cases, these researchers found significantly cleaner histologic sections after ultrasonically activated irrigation. In the ultrasonically treated group, the bacteria count was reduced by 99.8%, but hand filing alone reduced the bacteria count by 99.3%, so the improvement from ultrasonic therapy was limited. With ultrasonics, root canals are débrided by shear stresses produced between the irrigant and the canal wall, with subsequent cell disruption.[9]

Acoustic streaming of the irrigation fluid through ultrasonic treatment has been suggested as a method of improving cleanliness. However, this effect occurs mainly in the most coronal levels; the apical areas were least affected by activated irrigation[96,258] (see Fig. 9-43). Because the amplitude of the oscillation is greatest at the instrument's tip, attenuation and constraint most significantly affect the apical part,[447] where the diameter of the canal is smallest.

One investigator reported that the most effective regimen with ultrasonic energy was to activate every dose of irrigant placed in the canal.[85] With this approach, roughly 18 minutes of irrigation is required per canal. Other investigators used an irrigation time of 1 minute each for EDTA and NaOCl, which seems clinically more practical.[83,258] These authors stated that the use of ultrasonic energy for irrigant activation did not improve débridement compared with control groups. However, bacterial species show varying degrees of susceptibility to ultrasonication.[8,38,255,390]

Because of the conflicting evidence concerning the effectiveness of ultrasonics in root canal therapy, other methods of disinfecting and débriding canals properly must be studied. Such research might include better ways to deliver irrigants and disinfecting solutions.

SUMMARY

Cleaning and shaping are important, interdependent steps in root canal treatment. Cleaning, as demonstrated by an intracanal surface free of smear layer, can be done only after root canals have been sufficiently enlarged to accommodate adequate irrigation needles. Canal preparation is optimized when mechanical aims are fulfilled and enlargement is acceptable; such aims include avoiding both significant preparation errors and weakening of the radicular structure, which can result in fractures.

Taken together and performed to a high standard, the procedures described in this chapter lay the foundation for biologic success in both straightforward (Fig. 9-78) and more complicated (Fig. 9-79) clinical cases. Recall radiographs confirm favorable outcomes or biologic success (i.e., prevention or healing of periradicular periodontitis) over the years. Similarly, adherence to the principles discussed leads to predictable outcomes for root canal treatments.

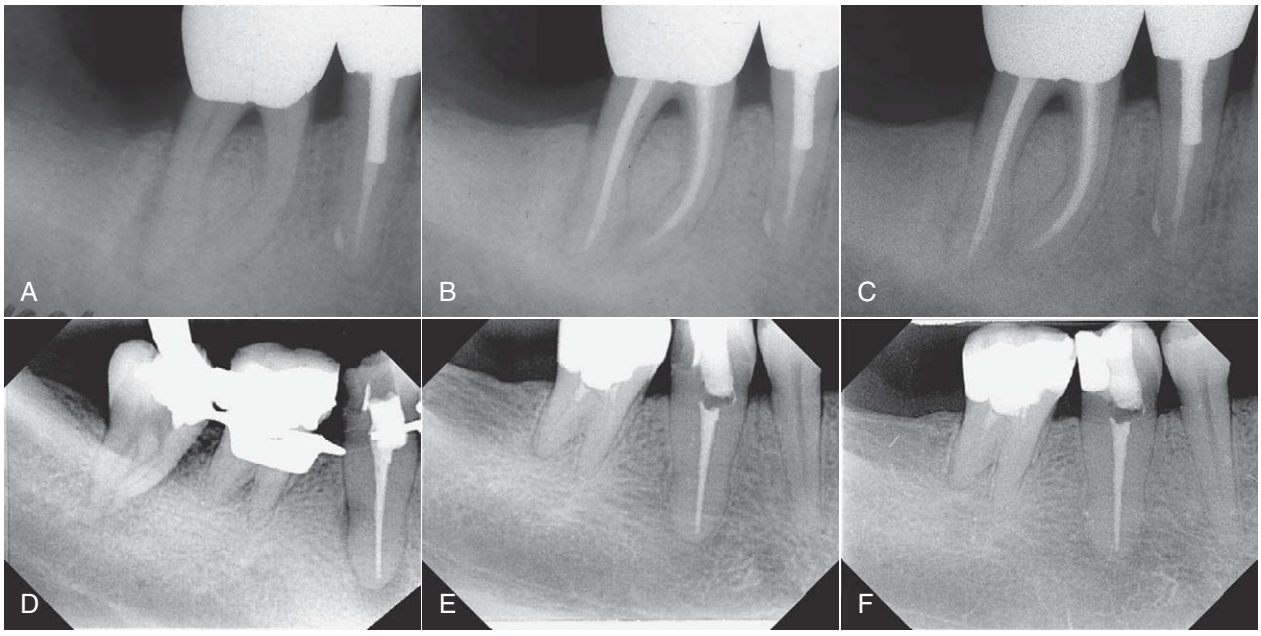

FIG. 9-78 Clinical cases treated according to the principles detailed in this chapter. **A,** Pretreatment radiograph of tooth #30 with a periradicular lesion. **B,** Postobturation radiograph. **C,** Two-year follow-up radiograph shows osseous healing. **D,** Immediate postobturation radiograph of tooth #29 shows both a periapical and a lateral osseous lesion. **E-F,** One-year and three-year follow-up radiographs show progressing osseous healing. Note the imperfect obturation of tooth #30.

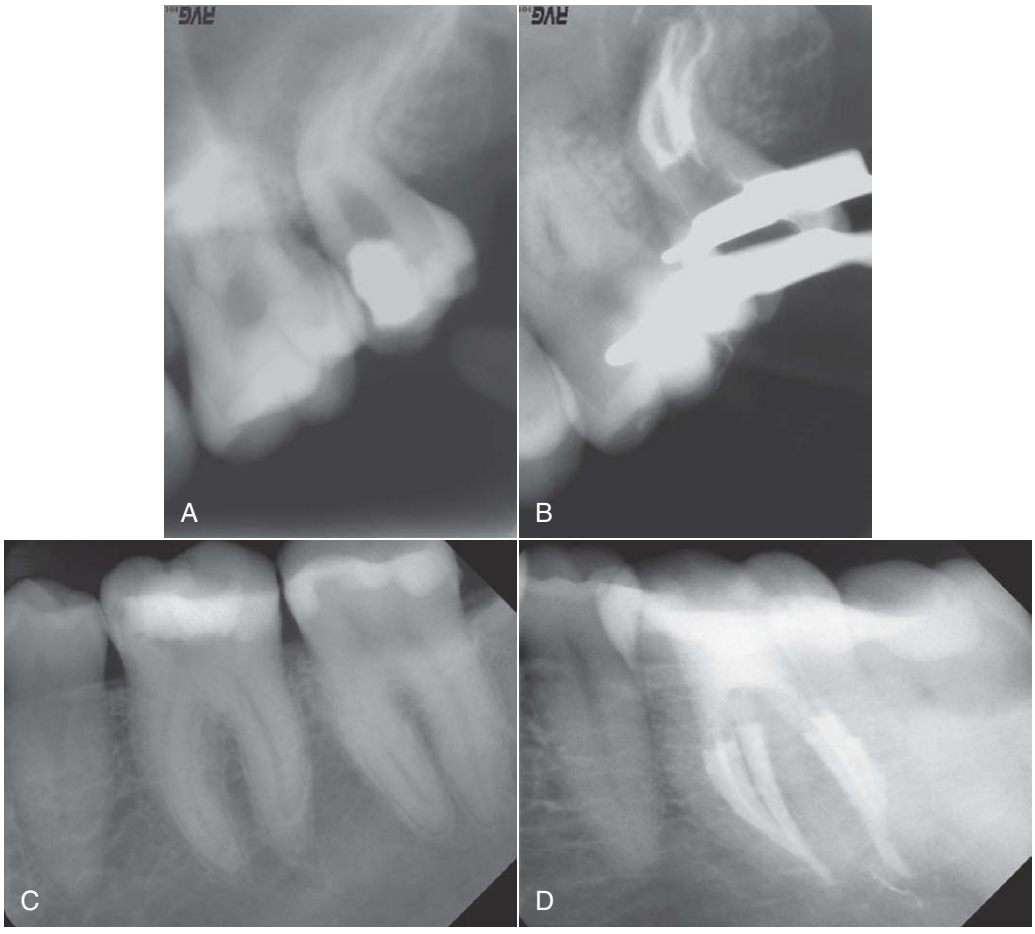

FIG. 9-79 Complicated clinical cases treated with hybrid techniques. **A,** Pretreatment radiograph of tooth #16 indicates laceration and significant curvature of all roots. **B,** Posttreatment radiograph shows multiple planes of curvature. **C,** Pretreatment radiograph of tooth #19, which was diagnosed with irreversible pulpitis. **D,** Angulated posttreatment radiograph shows three canals in the mesiobuccal root canal system, all of which were prepared to apical size #50. CHAPTER 10

Obturation of the Cleaned and Shaped Root Canal System

WILLIAM T. JOHNSON and JAMES C. KULILD

CHAPTER OUTLINE

IMPORTANCE OF EFFECTIVELY SEALING THE ROOT CANAL SYSTEM
HISTORICAL PERSPECTIVES
TIMING OF OBTURATION
- Vital Pulp Tissue
- Necrotic Pulp Tissue

LENGTH OF OBTURATION
PREPARATION FOR OBTURATION
THE IDEAL ROOT CANAL FILLING
TYPES OF SEALERS
- Zinc Oxide and Eugenol
- Calcium Hydroxide Sealers
- Noneugenol Sealers
- Glass Ionomer Sealers
- Resin
- Silicone Sealers
- Bioceramic
- Medicated Sealers

SEALER PLACEMENT
CORE MATERIALS
- Silver Cones
- Gutta-Percha
- Activ GP
- Resilon
- Custom Cones

METHODS OF OBTURATION
- Lateral Compaction
- Warm Vertical Compaction
- Continuous Wave Compaction Technique
- Warm Lateral Compaction
- Thermoplastic Injection Techniques
- Carrier-Based Gutta-Percha
- Thermomechanical Compaction
- Solvent Techniques
- Pastes
- Immediate Obturation

CORONAL ORIFICE SEAL

IMPORTANCE OF EFFECTIVELY SEALING THE ROOT CANAL SYSTEM

Success in endodontic treatment was originally based on the triad of débridement, thorough disinfection, and obturation with all aspects equally important. At present, successful root canal treatment is based on broader principles. These include diagnosis and treatment planning; knowledge of anatomy and morphology; the traditional concepts of débridement, thorough disinfection, and obturation; and the coronal restoration. A meta-analysis of factors influencing the efficacy of primary root canal treatment found that the following four factors influenced success: the absence of a pretreatment periapical lesion, root canal fillings with no voids, obturation to within 2.0 mm of the apex, and an adequate coronal restoration.[214]

In an early radiographic study of success and failure, Ingle and colleagues[145] indicated that 58% of treatment failures were due to incomplete obturation. Unfortunately, teeth that are poorly obturated are often poorly prepared. Procedural errors such as loss of length, canal transportation, perforations, loss of coronal seal, and vertical root fracture may have occurred and have been shown to adversely affect the apical seal.[341]

Since the classic study by Ingle and colleagues, great emphasis has been placed on developing materials and techniques for obturating the radicular space. Various experimental methods have been used to assess microleakage after obturation, including radioisotopes,[83] dyes,[151] bacteria,[56] proteins,[202] endotoxins,[56] glucose penetration,[225] and computerized fluid filtration.[309] These methodologies have employed a variety of in vitro conditions and experimental periods that often produce conflicting results. Fortunately, clinical success rates after endodontic treatment are high despite the varied conditions, materials, and techniques employed.[62,179,256] Circumstantial evidence indicates that the cleaning and shaping procedures provide an aseptic environment, and with this

elimination of the etiology for pathosis the method of obturation becomes less critical.

A primate study of infected teeth with apical periodontitis demonstrated nonhealing in 28% of the teeth with no bacteria after cleaning and shaping whereas the presence of bacteria after cleaning and shaping resulted in 79% being classified as not healed.[98] When no bacteria were present, healing occurred regardless of the quality of the obturation. When bacteria were present at the time of obturation, there was a correlation between the quality of obturation and nonhealing. Results emphasized the role of bacteria in apical pathosis and the importance of cleaning and shaping procedures.

In a controlled animal study,[253] periapical lesions were created by removing the pulp and leaving the teeth open to the oral cavity. In the control group the canals were cleaned and shaped before obturation with gutta-percha and a resin sealer. The teeth of the experimental group were cleaned and shaped as in the control group but left unobturated. At 190 days the animals were killed and histological evaluations were performed. There was no difference in the healing between the instrumented and obturated teeth and the instrumented and unobturated teeth, emphasizing the importance of cleaning and shaping in eliminating bacteria. Although obturation may not influence the short-term success rates, results may be different in long-term studies if coronal leakage were to occur.

At present there is no effective method for determining whether cleaning and shaping procedures have been effective. The criteria of clean dentinal filings and/or enlargement beyond the first file to bind at working length proved to be unreliable.[326] Although the length of preparation has been emphasized, the irregular canal diameter (the forgotten dimension) may be a more significant factor in success and failure.[146] Evidence indicates canals are often underprepared in the apical one third.[55] Historically, culturing has been employed and obturation delayed until a "negative" culture was obtained. In contemporary endodontic treatment culturing has been abandoned during routine care.[209] With vital pulp tissue, bacteria are not a major concern. In necrotic cases the organisms involved in the disease process are primarily facultative or obligate anaerobes that may not grow in culture. Molecular microbiologic techniques (polymerase chain reaction) have demonstrated that a variety of organisms are present that do not grow in culture.[288,289] The role these organisms play in the disease process is not well understood. The reader is referred to Chapter 15 for a fuller discussion of this vexing issue.

The process of cleaning and shaping determines both the degree of disinfection and the ability to obturate the radicular space. Obturation is therefore a reflection of the cleaning and shaping and is evaluated on the basis of length, taper, density, level of gutta-percha removal, and the coronal seal (adequate provisional restoration) (Fig. 10-1). It is not possible to assess the quality of the seal established during obturation with a radiograph, and it is important to remember that no material or technique prevents leakage.[2,122] Indeed, obtaining an impervious seal may not be feasible because of the porous tubular structure of dentin[2] and canal irregularities.

The primary etiology of pulpal and periradicular pathosis is, as discussed in Chapter 15, bacterial.[155,205] Pulpal remnants, necrotic tissue, bacteria, and bacterial by-products remaining in the inaccessible areas of a cleaned and shaped canal system could initiate and/or perpetuate a lesion because the host defense mechanisms are unable to remove them. Studies indicate that root canal systems cannot be completely cleaned and disinfected.[132,287,326,344] Obturation of the radicular space is necessary to eliminate leakage. Obturation reduces coronal leakage and bacterial contamination, seals the apex from the periapical tissue fluids, and entombs the remaining irritants in the canal.[81]

Coronal leakage has also been demonstrated to contribute to treatment failure.[244,315] Maintaining an effective coronal seal and placing an appropriate restoration, as discussed in Chapter 22 should be considered an essential component of successful endodontic treatment.[134] Investigators suggest that it is more prudent to use a final restorative material versus a temporary material to prevent leakage.[319] One study[244] reported that good postendodontic restorations resulted in significantly more successful cases when compared with good endodontics (80% vs. 75.7%) and poor restorations resulted in significantly more periradicular inflammation cases when compared with poor endodontics (30.2% vs. 48.6%). The success rate for a good restoration and good endodontics was 91% compared with a success rate of 18% with the poor endodontic treatment and a poor restoration. In combination with technically good restorations the success rate was 81%. With poor restorations the success rate was 71%. Technically poor endodontics combined with either good restorations or poor restorations had significantly lower success rates of 56% and 57%, respectively. The radiographic quality of the endodontic treatment was significantly more important than the technical quality of the coronal restoration when the periapical status of endodontically treated teeth was evaluated. Investigators[12] noted that the prognosis for endodontically treated posterior teeth restored with crowns was enhanced sixfold. Thus, the ability to deliver combined high-quality endodontic and restorative treatment is a major factor in good clinical outcomes.

Using histologic and microbiologic techniques, investigators evaluated 39 teeth that were without proper restorations for at least 3 months and exposed to caries and the oral environment.[246] Thirty-four specimens were without radiographically discernible periradicular pathosis. Lesions were detected on five roots. Stainable bacteria were found in abundance at the orifice and in dentinal tubules but were absent midroot and apically in 37 roots. Inflammatory cell infiltrates were absent or sparse in 32 teeth whereas 7 teeth exhibited distinct inflammation. Despite pathosis involving five roots the results indicated that well-obturated root canals are resistant to bacterial penetration when exposed to the oral environment. Findings in this study were consistent with an observational study finding that coronal leakage was not a significant factor in root canal failure, using matched pairs of teeth for analysis.[247]

Three-dimensional obturation of the radicular space is essential to long-term success. The canal system should be sealed apically, coronally, and laterally. Various methods have been advocated for obturation. Unfortunately, all materials and techniques result in some degree of leakage.[346] Although a poorly obturated canal and leakage are correlated, radiographic evaluation of obturation does not correlate well with leakage.[124,164] An adequate radiographic appearance of the obturation may not correlate with an adequate seal (Fig. 10-2).[90] Variation in radiographic interpretation by the clinician, the overlying osseous structures, and the lack of uniformity in the obturation materials are significant variables.[29,86,87,164]

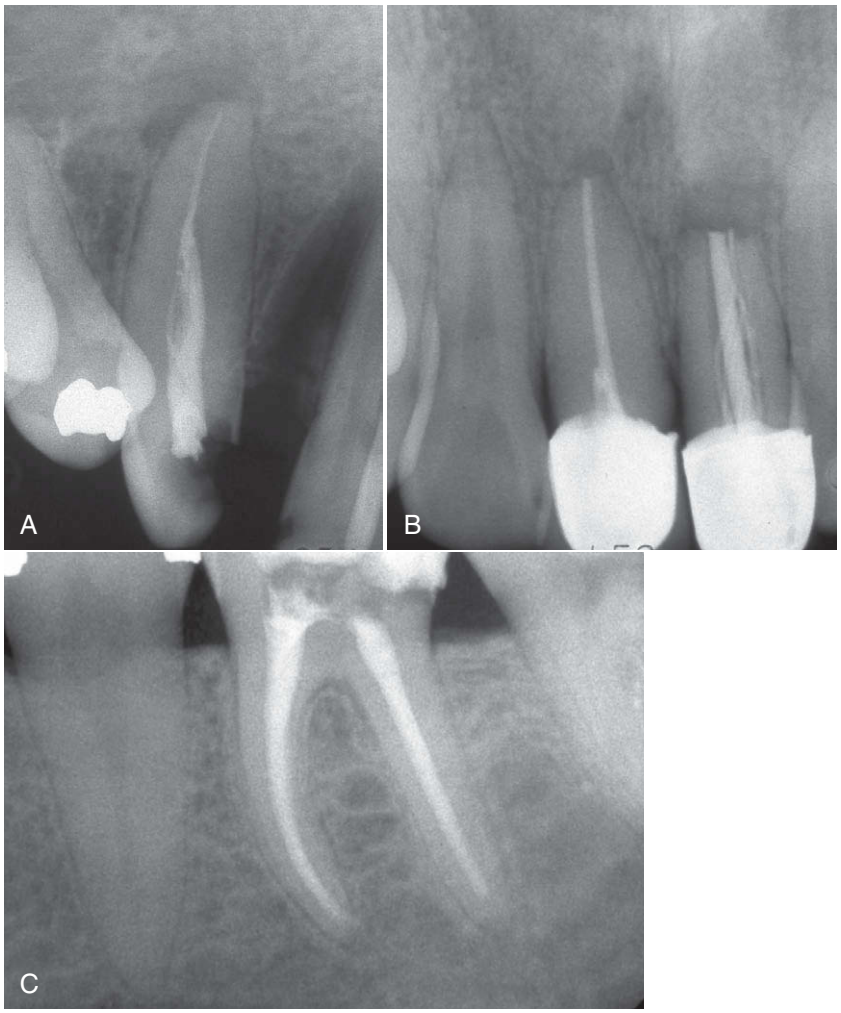

FIG. 10-1 Examples of inadequate obturation. **A,** Maxillary right canine with adequate length but lacking density and no coronal seal. Central incisor is filled to adequate length but obturation exhibits voids. **B,** Maxillary central incisors. Maxillary right central incisor exhibits a lack of density and taper. Maxillary left central incisor has voids and unfilled canal space. **C,** Mandibular left first molar with adequate obturation; provisional restoration shows poor adaptation on the distal because of the failure to remove caries.

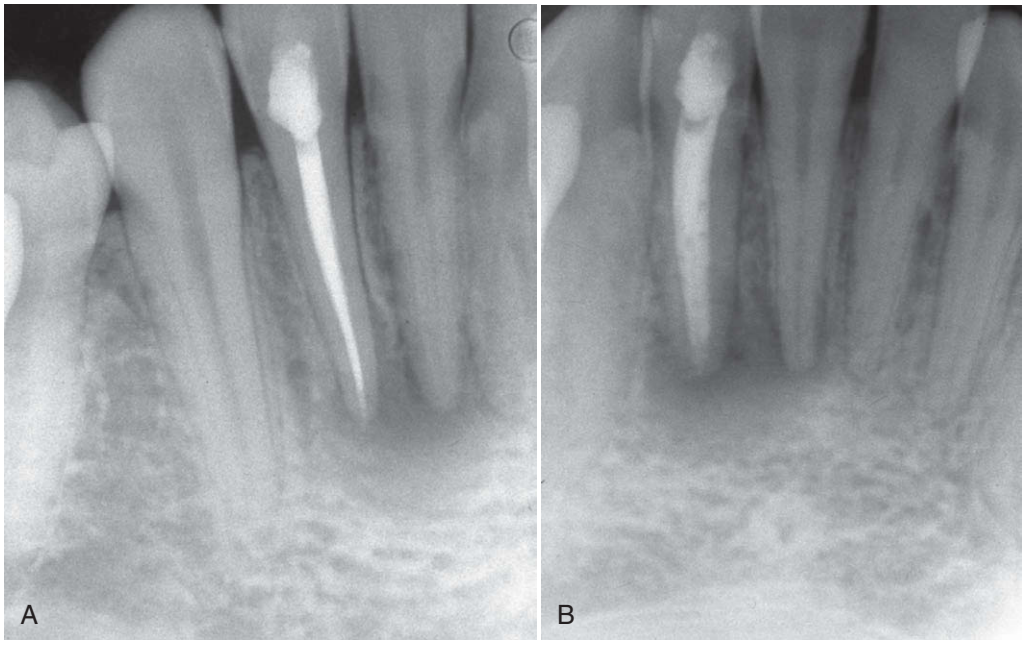

FIG. 10-2 A, Posttreatment radiograph of a mandibular left lateral incisor with ostensibly adequate obturation. **B,** Angled view reveals voids.

In a prospective study the Toronto group[100] evaluated success and failure of endodontic treatment at 4 to 6 years after completion of treatment. Teeth were treated by using flared preparation and vertical compaction of warm gutta-percha or step-back preparation and lateral compaction. Differences were noted with the adequacy of the fill and the treatment technique. Adequate length had a higher success rate (87%) when compared with inadequate length (77%). The flared preparation and vertical compaction had a higher success rate (90%) when compared with step-back preparation and lateral compaction (80%). This study also agreed with previous studies[291,302] indicating preexisting apical pathosis as a factor reducing a favorable prognosis and highlighted the obturation technique as a factor influencing success and failure.[291]

HISTORICAL PERSPECTIVES

The achievement of a "hermetic seal" is often cited as a major goal of root canal treatment. According to accepted dictionary definitions, the word *hermetic* means sealed against the escape or entry of *air*—or made airtight by fusion or sealing. However, root canal seals are commonly evaluated for *fluid* leakage—a parameter used to praise or condemn obturation materials and techniques. This occurs both apically and coronally. Somehow the term *hermetic* has crept into endodontic nomenclature in a manner probably quite similar to the invention of an airtight seal. A god of wisdom, learning, and magic in ancient Egypt, Thoth, better known as Hermes Trismegistus (Hermes thrice greatest), is credited with this invention.[270] His significant contribution to civilization allowed the preservation of oils, spices, aromatics, grains, and other necessities in previously porous, earthenware vessels. A simple wax seal of the vessel walls helped to create the "hermetic seal." Endodontically speaking, the term *hermetic* is inappropriate; instead, terms such as *fluid-tight, fluid-impervious,* or *bacteria-tight* seals are more contemporary.

In 1924 Hatton[129] indicated, "Perhaps there is no technical operation in dentistry or surgery where so much depends on the conscientious adherence to high ideals as that of pulp canal filling." The essence of this statement had been significantly influenced by years of trial and error in both the techniques and materials used to obturate the prepared root canal system. Much of the frustration and challenge that emanated from this concern, however, was due to the lack of development in root canal preparation techniques coupled with indictments of the "focal infection" craze of that era.[144]

Before 1800, root canal filling, when done, was limited to gold. Subsequent obturations with various metals, oxychloride of zinc, paraffin, and amalgam resulted in various degrees of success and satisfaction.[166] In 1847 Hill developed the first gutta-percha root canal filling material known as "Hill's stopping."[166] The preparation, which consisted principally of bleached gutta-percha and carbonate of lime and quartz, was patented in 1848 and introduced to the dental profession. In 1867 Bowman made claim (before the St. Louis Dental Society) of the first use of gutta-percha for canal filling in an extracted first molar.[10]

References to the use of gutta-percha for root canal obturation before the turn of the twentieth century were few and vague. In 1883 Perry claimed that he had been using a pointed gold wire wrapped with some soft gutta-percha (the origin of the present-day core carrier technique?).[234] He also began using gutta-percha rolled into points and packed into the canal. The points were prepared by cutting base plate gutta-percha into slender strips, warming them with a lamp, laying them on his operating case, and rolling them with another flat surface (a contemporary technique still used by a few to custom roll a large cone?). Perry then used shellac warmed over a lamp and rolled the cones into a point of desired size, based on canal shape and length. Before placing the final gutta-percha point, he saturated the tooth cavity with alcohol; capillary attraction let the alcohol run into the canal, softening the shellac so that the gutta-percha could be packed (the forerunner of a chemical-softening technique?).

In 1887 the S.S. White Company began to manufacture gutta-percha points.[159] In 1893 Rollins introduced a new type of gutta-percha to which he added vermilion.[328] Because vermilion is pure oxide of mercury and therefore dangerous in quantity, many people justifiably criticized this technique.

With the introduction of radiographs for the assessment of root canal obturations, it became painfully obvious that the canal was not cylindrical, as earlier imagined, and that additional filling material was necessary to fill the observed voids. At first, hard-setting dental cements were used, but these proved unsatisfactory. It was also thought that the cement used should possess strong antiseptic action, hence the development of many phenolic or formalin-type paste cements. The softening and dissolution of the gutta-percha to serve as the cementing agent, through the use of rosins, was introduced by Callahan in 1914.[52] Subsequently a multitude of various pastes, sealers, and cements were created in an attempt to discover the best possible sealing agent for use with gutta-percha.

Over the past 70 to 80 years the dental community has seen attempts to improve on the nature of root canal obturation with these cements and with variations in the delivery of gutta-percha to the prepared canal system. During this era the impetus for these developments was based heavily on the continued belief in the concept of focal infection, elective localization, the hollow-tube theory, and the concept that the primary cause for failure of root canal treatment was the apical percolation of fluids, and microorganisms, into a poorly obturated root canal system.[83,252] From this chronological perspective of technical and scientific thought this chapter clarifies and codifies contemporary concepts in the obturation of the cleaned and shaped root canal system.

TIMING OF OBTURATION

Factors influencing the appropriate time to obturate a tooth include the patient's signs and symptoms, status of the pulp and periradicular tissue, the degree of difficulty, and patient management.

Vital Pulp Tissue

At present the consensus is that one-step treatment procedures are acceptable when the patient exhibits a completely or partially vital pulp.[318] Removal of the normal or inflamed pulp tissue and performance of the procedure under aseptic conditions should result in a successful outcome because of the relative absence of bacterial contamination. Obturation at the initial visit also precludes contamination as a result of leakage during the period between patient visits.

Elective root canal treatment for restorative reasons can be completed in one visit provided the pulp is vital, to some degree, and time permits. Obturation of patients whose condition is urgent depends on the pretreatment diagnosis. When pain occurs as the result of irreversible pulpitis, obturation can occur at the initial visit because removal of the vital tissue will generally resolve the patient's pain.

Necrotic Pulp Tissue

Patients who present with pulp necrosis with or without asymptomatic periapical pathosis (chronic apical periodontitis, chronic apical abscess, condensing osteitis) may be treated in one visit, based on the best available information. When patients present with acute symptoms caused by pulp necrosis and acute periradicular abscess, obturation is generally delayed until the patient is asymptomatic. However, more than 20 years ago, investigators demonstrated that cases with soft-tissue swelling could be completed in one visit with appropriate endodontic treatment, incision for drainage, and a regimen of antibiotics.[296] Management of these patients, however, may be more difficult should problems persist or become worse after the completion of treatment.

During the 1970s there was concern about the timing of obturation. Performing endodontic treatment in one visit was controversial. Conventional wisdom suggested that patients would have a higher incidence of posttreatment pain; however, studies demonstrated that the incidence of pain was not increased in patients who were treated in one appointment versus those treated in multiple appointments.[107,210,217,220,249,294]

In contrast to teeth with vital pulp tissue, teeth exhibiting pulp necrosis frequently exhibit bacterial contamination and may require a different approach to treatment.[318] Sjögren and colleagues[290] raised questions regarding the long-term prognosis of teeth exhibiting necrotic pulp tissue and apical periodontitis treated in a single visit. In their clinical study the authors thoroughly instrumented 55 infected teeth with apical pathosis, using only 0.5% sodium hypochlorite (NaOCl) [*Editor's note:* Today, stronger concentrations of NaOCl are more commonly used. The reader is referred to Chapters 9 and 15 for a fuller discussion of this issue.] Before obturation, cultures were obtained, using advanced anaerobic bacteriologic techniques. After cleaning and shaping, bacteria could be detected in 22 teeth. Complete healing occurred in 94% of cases that yielded a negative culture, whereas the rate of successful treatment of teeth with positive cultures before obturation was 68%, a statistically significant difference.

However, other investigators were unable to confirm Sjögren's results, in a study of 39 patients with periapical lesions exhibiting both positive and negative canal cultures at the time of obturation. Twenty-one teeth were treated in one visit and 18 in two visits with an interappointment dressing of calcium hydroxide. Periapical healing was observed over a period of up to 4.5 years. Complete radiographic healing occurred in 81% of the cases in the one-visit group and in 71% of the cases in the two-visit group.[236] A randomized control trial comparing the difference in success between one- and two-visit procedures, using a standardized protocol, demonstrated no significant differences in success at 12 months in 63 patients.[230] A 2-year clinical and radiographic study demonstrated no statistical difference in healing between one- and two-visit treatments; however, negative cultures at obturation produced 80% success compared with 44% when cultures were positive. In addition, 52% of teeth with positive cultures were classified as uncertain with regard to healing compared with 7% of the negative culture group.[206]

In a prospective clinical study, investigators evaluated the effect of calcium hydroxide as an interappointment dressing on the periapical healing of lesions associated with necrotic pulps in 73 patients. Thirty-six teeth were endodontically treated in one visit. Thirty-one teeth were treated in two visits with calcium hydroxide as an intracanal medicament. Periapical healing increased with the length of the observation period. In both treatment groups the success rate exceeded 90%, and no statistically significant difference existed between the two groups.[327]

Controlled laboratory studies support the use of calcium hydroxide as an antimicrobial agent before obturation of teeth with pulp necrosis. Two studies[156,157] evaluated periapical healing of infected root canals in dogs. After inducing periapical pathosis the teeth were treated by immediate obturation or with calcium hydroxide for 1 week before obturation. Results of the radiographic[156] examination at 6 months indicated complete healing was similar for the one-visit (35.3%) and calcium hydroxide (36.8%) groups. The calcium hydroxide group, however, had fewer failed cases (15.8% vs. 41.2%) and more improved cases (47.4% vs. 23.5%) when compared with the one-visit group.[157] In histologic evaluations the calcium hydroxide group had significantly less inflammation than the one-visit group. One study also evaluated periapical healing of infected teeth in dogs after immediate obturation or with prior calcium hydroxide treatment for 7 or 14 days. Results indicated both calcium hydroxide groups were superior to the one-visit group, with the 14-day calcium hydroxide group being superior to the 7-day group.[139]

Other investigators overinstrumented and overextended teeth 45 minutes after extraction. After the procedures, teeth exhibiting vital pulps and no periradicular disease were without bacteria. Teeth exhibiting periradicular pathosis before extraction demonstrated a high percentage of bacteria at the root apices. The organisms were found to remain firmly attached to resorptive lacunae, indicating the instrumentation/obturation procedures were unable to eliminate the organisms.[121]

In general, obturation can be performed after cleaning and shaping procedures when the canal can be dried and the patient is not experiencing swelling. An exception is the presence or persistence of exudation from the canal. Obturation of a canal that cannot be dried is contraindicated.

A few studies suggest that complete cleaning and shaping should be accomplished and calcium hydroxide placed as an antimicrobial and temporary obturant in necrotic cases that cannot be treated in one visit[290] because investigators noted that bacteria in instrumented, unfilled canals can multiply and reach their pretreatment numbers in 2 to 4 days.[50]

Procedural concerns also dictate the time of obturation. Difficult cases may require more time for preparation and can be managed more uneventfully in multiple appointments. Patients may require multiple short appointments because of medical conditions, their psychologic state of mind, and fatigue.

LENGTH OF OBTURATION

One of the controversies in endodontics that remains unresolved is the apical limit of root canal treatment and obturation. Early studies identified the dentinocemental junction as the apical limit for obturation.[70,117,118,221,292] However, this histologic landmark cannot be determined clinically, and it has been found to be irregular within the canal. The dentinocemental junction may be several millimeters higher on the mesial canal wall when compared with the distal wall. In addition, the dentinocemental junction does not coincide with the narrowest portion of the canal or apical constriction. The reader is referred to Chapter 7 for more information about this anatomy.

Traditionally, the apical point of termination has been approximately 1 mm from the radiographic apices as determined by radiographs. Kuttler[174] noted that the apical anatomy consists of the major diameter of the foramen and the minor diameter of the constriction (Fig. 10-3), with the apical constriction identified as the narrowest portion of the canal. The average distance from the foramen to the constriction was found to be 0.5 mm, with the foramen varying in distance from the apex up to 2.5 mm. Kuttler also noted that the foramen-to-constriction distance increases with age because of cementum deposition. Supporting this finding, other investigators found that the location of the foramen was not at the apex. Deviations occurred in 92% of the roots and averaged 0.6 mm.[48] Still another investigator noted in 92% of examined teeth that the apical constriction was between 0.5 and 1 mm from the apex.[61] One study noted the average apex-to-constriction distance was 0.9 mm and that 95% of the constrictions were between 0.5 and 1 mm in diameter[88]; this study also noted that the classic apical anatomy described by Kuttler was present in only 46% of the teeth. Other variations identified were the tapering constriction, the multiconstriction, and the parallel constriction. Other investigators examined 230 roots of permanent teeth stereomicroscopically and with radiographs.[30] Results of this study indicated a deviation of the foramen from the apex in 76% of the roots with microscopy and 57% with radiography; the mean distance was 1 mm.

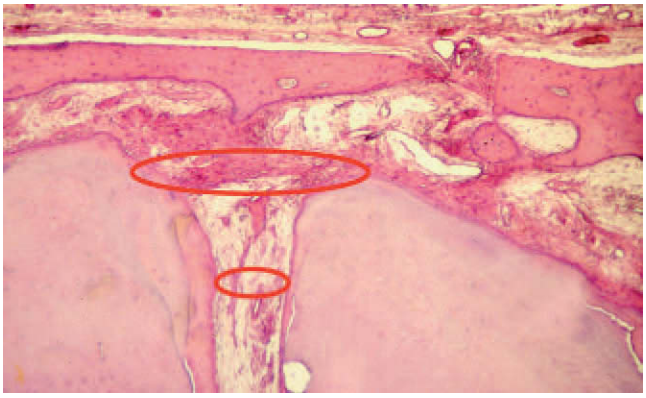

FIG. 10-3 Histologic section of a root apex, demonstrating anatomy of the classic foramen and constriction.

A later study found that no foramina coincided with the long axis of the root, with the distance ranging from 0.2 to 3.8 mm (Fig. 10-4).[121] Root resorption is an additional factor in length determination. Resorption is more common with necrosis and apical bone resorption, and this can result in loss of the constriction (Fig. 10-5).[154,195] On the basis of these findings it appears that canals filled to the radiographic apex reflect an overextension of the obturating material.

A study by the Toronto group[99] on the prognosis of retreatment identified perforation, pretreatment periradicular disease, and adequate length of the root canal filling as factors significantly influencing success and failure. The authors speculated that canals filled more than 2 mm short harbored necrotic tissue, bacteria, and irritants that when retreated could be cleaned and sealed. The success rate for negotiating the apical unfilled canal was 74%.

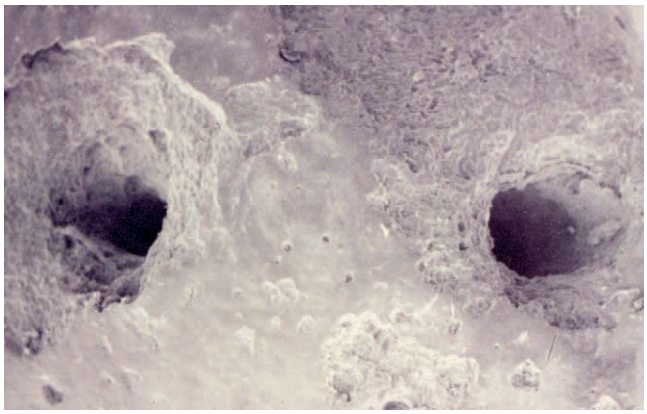

FIG. 10-5 Scanning electron microscopy of a tooth exhibiting a necrotic pulp and apical pathosis and resorption.

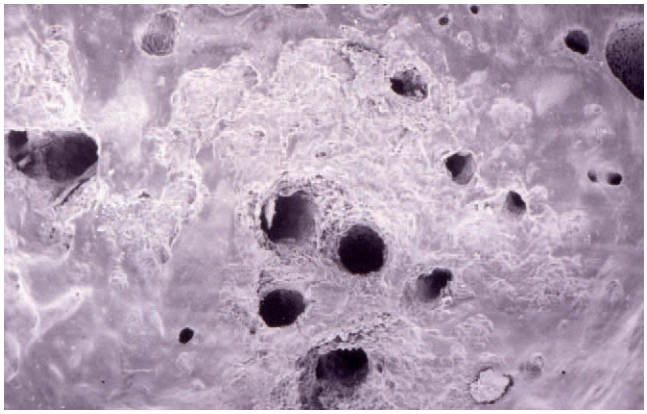

FIG. 10-6 Scanning electron microscopy of the apex of an extracted tooth that was removed because of pulp necrosis. Note the multiple accessory foramina and resorption.

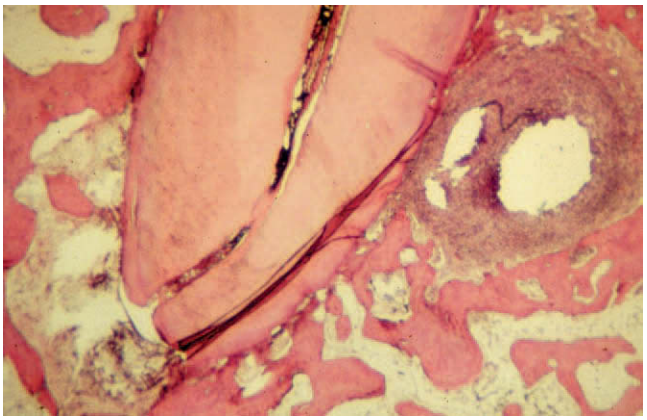

FIG. 10-7 Histologic section of a mesial root of a mandibular molar with a lateral canal present and associated lesion. Will the lesion resolve after the removal of the main canal contents, or will the lesion persist because of necrotic pulpal remnants in the lateral canal? The question remains unanswered.

FIG. 10-8 Posttreatment radiograph of a mandibular right first molar with a lateral canal associated with the distal root.

Controversy also exists regarding the role accessory canals play in success and failure (Fig. 10-6). For example, one scanning electron microscopy (SEM) study of the apical anatomy of each tooth group except the third molars noted no pattern for foraminal openings[120]; the number of accessory canals ranged from 1 to 16. Although lateral canals can be associated with pathosis, one study indicates that accessory canals are common but play little role in periradicular pathosis (Fig. 10-7).[17]

Further, other studies demonstrated that it is not possible to completely débride the canal space regardless of the technique or irrigant.[177,326] Investigators[329] noted that these anatomic structures are only demonstrated. Often, smaller apical accessory canals remain unfilled or partially filled.[322] Accessory/lateral canals are often obturated by chance and only serendipitously identified on the posttreatment radiograph (Fig. 10-8).

Investigators compared obturation of lateral canals, using six obturation techniques in resin blocks.[85] All techniques were able to obturate lateral canals with sealer. Warm vertical compaction, carrier-based thermoplastic gutta-percha, continuous wave compaction, and vertically compacted high-temperature gutta-percha filled lateral canals with gutta-percha significantly better than lateral compaction or warm lateral compaction. The use of sealer enhanced the ability of the gutta-percha to obturate the lateral canals.[85]

The importance of length control in obturation relates to extrusion of materials. Studies indicate that extrusion decreases the prognosis for complete regeneration.[27,105,271,272,291,293,301] One study evaluated the quality of root canal treatment in an American population.[47] Periapical disease was evident in 4.1% of all teeth and 31.3% of root-filled teeth, and the study noted that a periapical pathosis was found with 43% of the teeth with overfills. In another study of 1000 cases, investigators found that overfilling resulted in a failure rate of 37%. This was four times greater than for cases filled short.[301] A third study found that, in necrotic cases, better success was achieved when the procedures terminated at or within 2 mm of the radiographic apex.[348] Obturation shorter than 2 mm from the apex or past the apex resulted in a 20% lower success rate. For vital cases, termination between 2 and 3 mm was acceptable. Other investigators found that teeth obturated less than 2 mm from the apex had a higher success rate when compared with cases obturated more than 2 mm from the apex.[229]

On the basis of biologic and clinical principles, instrumentation and obturation should not extend beyond the apical foramen. This was demonstrated in one study that histologically evaluated 41 human root-filled teeth from 36 patients.[248] In six cases exhibiting overfills, histologic examination revealed severe inflammation.

Whereas the guideline of 1 mm from the radiographic apex remains rational when using radiographs, the point of apical termination of the preparation and obturation remains empiric. The use of an apex locator in conjunction with radiographs and sound clinical judgment makes this decision more logical. The need to compact the gutta-percha and sealer against the apical dentin matrix (constriction of the canal) is necessary to prevent extrusion of materials into the periapical tissues. Deciding where the apical constriction of the canal lies is based on the clinician's basic knowledge of apical anatomy, tactile sensation, radiographic interpretation, apex locators, apical bleeding, and (if not anesthetized) the patient's response.

PREPARATION FOR OBTURATION

During the cleaning and shaping process, organic pulpal materials and inorganic dentinal debris accumulate on the canal wall, producing an amorphous irregular smear layer (Fig. 10-9),[22,198,227] as shown in a study noting that the smear layer is superficial, with a thickness of 1 to 5 μm,[198] and this superficial debris can be packed into the dentinal tubules to various distances.[1]

In cases of necrosis this layer may also be contaminated with bacteria and their by-products. For example, one study found that bacteria can extend 10 to 150 μm into the dentinal tubules of necrotic teeth.[273] Another study noted that capillary action and fluid dynamics play a role in packing debris into the tubules[3] and yet another investigation noted a mean penetration of 479 μm after a 28-day incubation period.[232]

The smear layer is not a complete barrier to bacteria but may act as a physical barrier, decreasing bacterial penetration into tubules. This was illustrated by a study demonstrating that removal of the smear layer permitted colonization of the dentinal tubules at a significantly higher rate when compared with leaving the smear layer in place.[84]

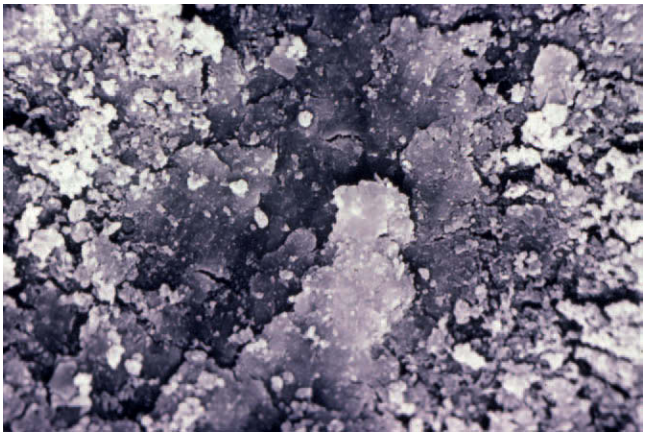

FIG. 10-9 Scanning electron microscopy of a prepared canal wall. The tubules are covered with a smear layer of organic and inorganic material.

The smear layer may also interfere with adhesion and penetration of sealers into dentinal tubules.[335] Evidence indicates that sealer penetration into dentinal tubules does not occur when the smear layer is present.[106,226] For example, one study found that removal of the smear layer permitted Roth 811 (Roth International, Ltd., Chicago, IL), Calciobiotic root canal sealer (CRCS; Coltène/Whaledent, Cuyahoga Falls, OH), and Sealapex (SybronEndo, Orange, CA) to penetrate to between 35 and 80 μm, whereas the presence of the smear layer obstructed tubular penetration of all sealers.[171] Further, other studies found that smear layer removal increased bond strength and reduced microleakage in teeth obturated with AH-26 (DENTSPLY Maillefer, Ballaigues, Switzerland).[91,108] Another investigation found that a combination of smear layer removal, AH-26 as the sealer, and vertical compaction of gutta-percha had a cumulative effect in reducing leakage.[310]

There does not appear to be a consensus on removing the smear layer before obturation.[59,274,282] The advantages and disadvantages of the smear layer remain controversial; however, *growing evidence supports removal of the smear layer before obturation*.[143,282] The organic debris present in the smear layer might constitute a substrate for bacterial growth,[227] and it has been suggested that the smear layer prohibits sealer contact with the canal wall and permits leakage.[25] Bacterial penetration in the presence of a smear layer in canals obturated with thermoplasticized gutta-percha and sealer has been shown to be significantly higher than with smear layer removal before obturation.[227] An additional consideration is the presence of viable bacteria that remain in the dentinal tubules and use the smear layer for sustained growth and activity.[40] Removal of the smear layer introduces the possibility of reinfecting the dentinal tubules if leakage occurs.[274] However, one study demonstrated that bacteria present before obturation are not viable after obturation.[81]

The smear layer may also interfere with the action of irrigants used as disinfectants.[222] When the smear layer is not removed, it may slowly disintegrate and dissolve around leaking obturation materials, or it may be removed by bacterial by-products such as acids and enzymes.[274]

The smear layer may interfere with the adhesion and penetration of root canal sealers. It also may prevent gutta-percha penetration during thermoplastic techniques.[123] Significant tubular penetration of gutta-percha and sealers has been shown with thermoplasticized obturations[123] and with dentin-bonded composite resins.[181] Removal of the smear layer also enhances the adhesion of sealers to dentin and tubular penetration.[181,219,274,333] Root canal filling materials adapt better to the canal walls after smear layer removal.[82,219,333-335]

One investigation examined the penetration depth of three different root canal sealers into the dentinal tubules with and without the smear layer. Scanning electron microscopy of extracted single-rooted human teeth obturated by lateral compaction of gutta-percha, using AH Plus (DENTSPLY Maillefer), Apexit (Ivoclar Vivadent, Schaan, Liechtenstein), and Roth 811, demonstrated that the smear layer prohibited the sealers from penetrating dentinal tubules. Smear layer removal allowed the penetration of all sealers to occur to various depths.[168] Another study found that removal of the smear layer reduced both coronal and apical leakage regardless of the sealer tested.[66]

Another study examined the smear layer and the passage of bacteria through and around obturating materials,[64] using

human maxillary incisors obturated with gutta-percha and AH-26. The teeth were exposed to standardized bacterial suspensions containing *Fusobacterium nucleatum, Campylobacter rectus,* and *Peptostreptococcus micros* for a period of 60 days, using a leakage model employing upper and lower chambers. Results indicated that 60% of the samples in which the smear layer was not removed demonstrated bacterial leakage. There was no leakage in specimens from which the smear layer was removed.

One study reported no difference in the apical and middle thirds of canals irrigated with 17% ethylenediaminetetraacetic acid (EDTA), using either the traditional syringe or a newer irrigation device, the Quantec-E irrigation system (SybronEndo).[276]

An additional method for removing the smear layer involves sonic and ultrasonic instruments. In early studies of ultrasonic instrumentation, investigators noted the technique was effective in removing the smear layer.[72] Another investigator also demonstrated smear layer removal with ultrasonication and NaOCl.[54] One study compared the cleaning efficacy of short-term sonic and ultrasonic passive irrigation with 5.25% NaOCl after hand instrumentation in the apical 3 to 6 mm of maxillary molar root canals.[254] Passive sonic or ultrasonic irrigation for 30 seconds resulted in significantly cleaner canals than hand filing alone, and ultrasonic irrigation produced significantly cleaner canals than irrigation. However, other studies found ultrasonication and NaOCl to be ineffective in removing the smear layer.[21,325]

A new method for removing the smear layer employs the use of a mixture of a tetracycline isomer, an acid, and a detergent (MTAD) (BioPure; DENTSPLY Tulsa Dental Specialties, Tulsa, OK) as a final rinse to remove the smear layer.[312] MTAD removed most of the smear layer; however, some organic components of the smear layer remained on the surface of the root canal walls. The effectiveness of MTAD in completely removing the smear layer was enhanced when low concentrations of NaOCl were used as an intracanal irrigant before the use of MTAD as the final rinse. Further studies demonstrated that MTAD was superior to NaOCl in antimicrobial action.[277,278] Another study showed that MTAD was effective in killing *Enterococcus faecalis* at 200-fold dilution, which was more potent than NaOCl because it ceased being active when diluted 32-fold; EDTA had no antimicrobial activity.[313] One investigator found MTAD to be less toxic than eugenol, 3% H_2O_2, $Ca(OH)_2$ paste, 5.25% NaOCl, chlorhexidine gluconate (Peridex), and EDTA.[354] Other investigators found no significant difference in flexural strength and modulus of elasticity in dentin bars exposed to MTAD, indicating no alteration in the physical properties of the dentin, and noted that teeth treated with the MTAD protocol for clinical use (20 min of 1.3% NaOCl/5 min of MTAD) may not need any additional dentin conditioning before the application of bonding agents.[193]

After the completion of cleaning and shaping procedures, removal of the smear layer is generally accomplished by irrigating the canal with 17% disodium EDTA and 5.25% NaOCl (Fig. 10-10).[22] Chelators remove the inorganic components, leaving the organic tissue elements intact. NaOCl is necessary for removal of the remaining organic components. Fifty percent citric acid has also been shown to be an effective method for removing the smear layer,[20,131] as has tetracycline.[16,131]

FIG. 10-10 Scanning electron microscopy of the canal wall after removal of the smear layer with 17% EDTA and 5.25% sodium hypochlorite.

Chelating agents were introduced to endodontic treatment by Nygaard-Ostby in 1957 for treatment of calcified narrow root canals.[216] EDTA is the chelating solution customarily used in endodontic treatment. It is available in both liquid and paste forms with common concentrations between 15% and 17%.[143] A detergent is frequently added to the liquid to decrease surface tension, to increase the cleaning ability, and to enhance the bactericidal action of the solution.[323] The effectiveness of EDTA is related to time of application, the pH, and the concentration.[208,216]

Demineralization results in increased dentin permeability[119] because of the removal of the smear layer and plugs and enlargement of the tubules. It appears that the tubular enlargement is due to selective removal of the peritubular dentin.[141] The action of chelators and acids appears to be more effective in the coronal and middle thirds of the root and is reduced apically.[143,188] This reduced activity may be a reflection of canal size.[172] This is a clinical concern because of the more irregular structure of dentin in the apical third. Another investigation demonstrated marked variations in the apical portion of the root,[204] including accessory root canals, areas of resorption and repaired resorptions, pulp stones, irregular or absent primary tubules, irregular secondary dentin, and cementum-like tissue lining the apical root canal wall. The variable structure of the apical region of human teeth presents challenges to the use of endodontic obturation techniques requiring adhesives, because this may influence the dentin bonding ability in the apical region.[204]

EDTA appears to be biocompatible when used clinically[216]; however, irreversible decalcification of periapical bone and neuroimmunologic disturbances have been noted.[269] Extrusion of both NaOCl and EDTA in clinical treatment should be avoided.[130,228,306]

The recommended time for removal of the smear layer is 1 to 5 minutes.[53,143,264] The small particles of the smear layer are primarily inorganic with a high surface-to-mass ratio that facilitates removal by acids and chelators. Investigators have found

that a 1-minute exposure to 10 ml of EDTA was adequate to remove the smear layer and that a 10-minute exposure caused excessive removal of both peritubular and intratubular dentin.[53]

The use of EDTA in combination with NaOCl is recommended[300,307] and may enhance the cleaning[188,349] and antimicrobial effects of these solutions when compared with using them alone.[49]

THE IDEAL ROOT CANAL FILLING

Various endodontic materials have been advocated for obturation of the radicular space. Most techniques employ a core material and sealer. Regardless of the core material a sealer is essential to every technique and helps achieve a fluid-tight seal.

The American Association of Endodontists' *Guide to Clinical Endodontics*[96] outlines contemporary endodontic treatment. Nonsurgical root canal treatment of permanent teeth "involves the use of biologically acceptable chemical and mechanical treatment of the root canal system to promote healing and repair of the periradicular tissues." The process is accomplished under aseptic conditions with rubber dam isolation. Regarding obturation, the guide states, "Root canal sealers are used in conjunction with a biologically acceptable semi-solid or solid obturating material to establish an adequate seal of the root canal system." In this area the guidelines indicate that "Paraformaldehyde-containing paste or obturating materials have been shown to be unsafe. Root canal obturation with paraformaldehyde-containing materials is below the standard of care for endodontic treatment" (Fig. 10-11). Chapter 11 gives further information about this issue.

Assessment of nonsurgical treatment is based primarily on the posttreatment radiographic examination. The radiographic criteria for evaluating obturation include the following categories: length, taper, density, gutta-percha and sealer removal to the facial cementoenamel junction in anterior teeth and to the canal orifice in posterior teeth, and an adequate provisional restoration or definitive (Fig. 10-12).

Quality assurance is accomplished through a careful evaluation of treatment procedures. Only by this approach can deficiencies be identified and corrected. Although the anatomy and morphology of the radicular space vary tremendously, the obturated root canal should reflect the original canal shape. Procedural errors in preparation, such as loss of length, ledging, apical transportation, apical perforation, stripping perforation, and separated instruments, may not be correctable. Errors in obturation, such as length, voids, inadequate removal of obturation materials, and temporization, may be correctable.

Radiographic interpretation may vary among clinicians because of differences in radiopacity in root canal sealer/cements, constituents in specific brands of gutta-percha, interpretation of voids in vivo versus in vitro,[353] the overlying bony anatomy, radiographic angulation, and the limited two-dimensional view of the obturated root canal or canals.

An often overlooked aspect in the assessment of root canal obturation is the density of the apical portion of the fill.[122] The apical third of the canal may be filled with a sea of root canal cement and a single master cone or poorly compacted mass of

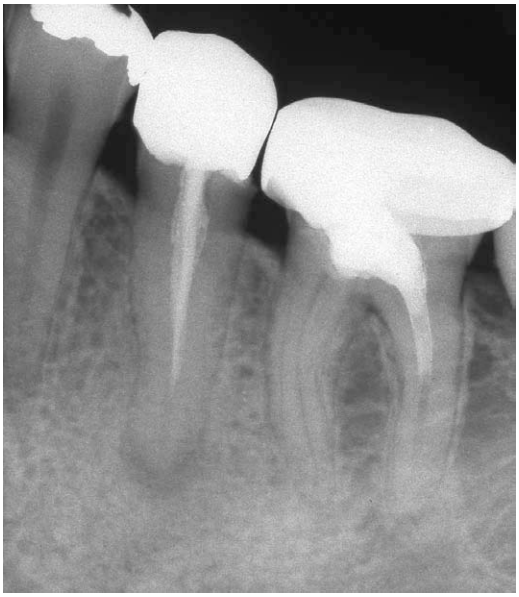

FIG. 10-11 A periapical radiograph of a mandibular left second premolar and first molar, demonstrating Sargenti paste root canal treatment. In addition to the toxic material, the technique often accompanies inadequate cleaning and shaping procedures.

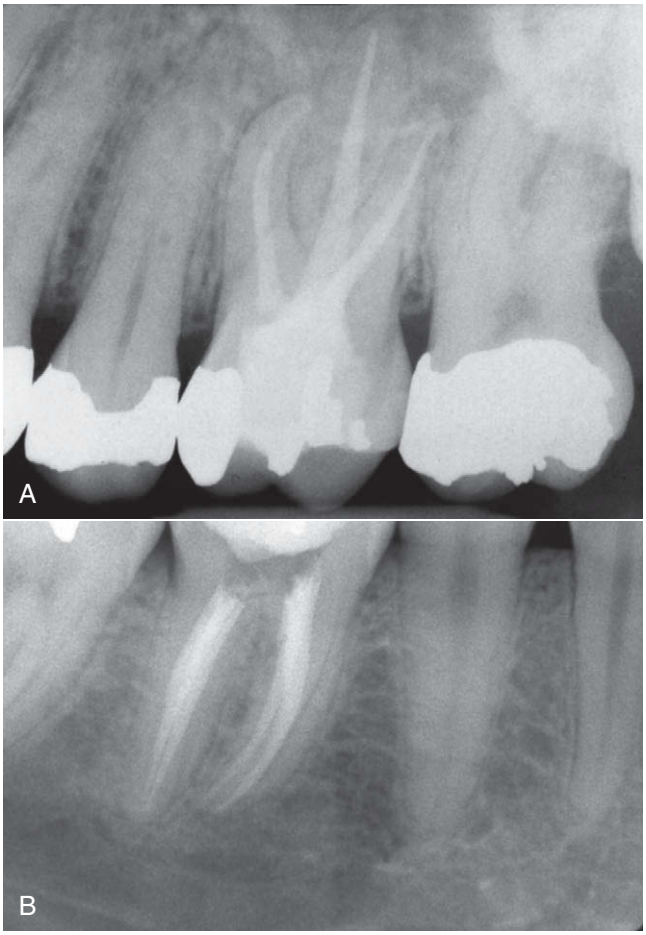

FIG. 10-12 A, Posttreatment radiograph of a maxillary right first molar, demonstrating adequate length, density, and taper. **B,** Posttreatment radiograph of a mandibular right first molar with an adequate obturation.

previously softened gutta-percha. Radiographically, the apical third of the canal appears less radiodense. An ill-defined outline to the canal wall is evident, along with obvious gaps or voids in the filling material or its adaptation to the confines of the canal. Because of the use of highly radiopaque root canal sealers/cements, the apical portion may be filled only with sealer, giving the clinician the false impression of a dense, three-dimensional obturation with gutta-percha.

Root canal sealers vary in radiopacity.[243,305] Some contain silver particles or significant amounts of barium sulfate to enhance their radiopacity. Although these components may enhance visualization of anatomic structures such as lateral canals, it is important to realize they do not increase the sealing ability of the sealer and the quality of the obturation. They may also give the impression that a canal is well obturated when voids are masked by the density of the sealer. It is erroneous to claim that obturations with highly radiopaque sealers are better than those made with less radiopaque materials. This type of comparison and claim to superiority are both unfounded and unwarranted. The radiographic appearance or aesthetic appearance of the obturated canal system should be secondary to meticulous cleaning and shaping. Although assessment of the root canal obturation is based on radiographic findings, root canal sealers do not have to be highly radiopaque to be effective.

TYPES OF SEALERS

Root canal sealers are necessary to seal the space between the dentinal wall and the obturating core interface. Sealers also fill voids and irregularities in the root canal, lateral and accessory canals, and spaces between gutta-percha points used in lateral condensation. Sealers also serve as lubricants during the obturation process. Grossman[115] outlined the properties of an ideal sealer (Box 10-1). At present no sealer satisfies all the criteria.

Sealers should be biocompatible and well tolerated by the periradicular tissues.[297] All sealers exhibit toxicity when freshly mixed; however, their toxicity is greatly reduced on setting.[176] Sealers are resorbable when exposed to tissues and tissue fluids.[13] Tissue healing and repair generally appear unaffected by most sealers, provided there are no adverse breakdown products of the sealer over time.[35,41-43,45] Breakdown products from the sealers may have an adverse effect on the proliferative capability of periradicular cell populations.[113] As a result, sealers should not be placed routinely in the periradicular tissues as part of an obturation technique.[176] Although an osteogenic response has been observed,[138,295,303,316] the ability of these sealers to sustain a high pH over time has been questioned.[170]

The most popular sealers are zinc oxide–eugenol formulations, calcium hydroxide sealers, glass ionomers, and resins. Regardless of the sealer selected, all exhibit toxicity until they have set. For this reason, extrusion of sealers into the periradicular tissues should be avoided (Fig. 10-13).

BOX 10-1

Properties of an Ideal Sealer

- Exhibits tackiness when mixed to provide good adhesion between it and the canal wall when set
- Establishes a hermetic seal
- Radiopaque, so that it can be seen on a radiograph
- Very fine powder, so that it can mix easily with liquid
- No shrinkage on setting
- No staining of tooth structure
- Bacteriostatic, or at least does not encourage bacterial growth
- Exhibits a slow set
- Insoluble in tissue fluids
- Tissue tolerant; that is, nonirritating to periradicular tissue
- Soluble in a common solvent if it is necessary to remove the root canal filling

Zinc Oxide and Eugenol

Zinc oxide–eugenol sealers have a history of successful use over an extended period of time. Zinc oxide–eugenol sealers will absorb if extruded into the periradicular tissues.[13] They exhibit a slow setting time,[6] shrinkage on setting, solubility,[158,235] and they can stain tooth structure.[75,320] An advantage to this sealer group is antimicrobial activity.[4,15,133,203]

An early zinc oxide–eugenol sealer was introduced by Rickert and Dixon.[245] This powder/liquid sealer contained silver particles for radiopacity. Although it was possible to demonstrate the presence of lateral and accessory canals the sealer had the distinct disadvantage of staining tooth structure if not completely removed. Marketed as Pulp Canal Sealer (SybronEndo) and Pulp Canal Sealer EWT (extended working time), this sealer is popular with clinicians using thermoplastic techniques. Procosol (Procosol, Inc., Philadelphia, PA) is a modification of Rickert's formula in which the silver particles have been removed (zinc oxide, hydrogenated resin, bismuth subcarbonate and barium sulfate; liquid eugenol).

Grossman[116] modified the formulation and introduced a nonstaining formula in 1958 (Box 10-2). This is the formulation in Roth's Sealer (Roth International). Tubli-Seal (SybronEndo) is a catalyst/base zinc oxide–eugenol sealer that is convenient to mix but has a faster setting time when compared with the liquid/powder sealers. Tubli-Seal EWT provides an extended working time. Wach's sealer (Balas Dental, Chicago, IL) contains Canada balsam, which gives the material a sticky or tacky property that softens the gutta-percha into a more homogeneous mass when used with lateral compaction.

Calcium Hydroxide Sealers

Calcium hydroxide sealers were developed for therapeutic activity. It was thought that these sealers would exhibit antimicrobial activity and have osteogenic–cementogenic potential. Unfortunately, these actions have not been demonstrated. Solubility is required for release of calcium hydroxide and sustained activity. This is inconsistent with the purpose of a sealer. Calciobiotic root canal sealer (CRCS) is a zinc oxide–eugenol sealer with calcium hydroxide as one ingredient. Sealapex (SybronEndo) is a catalyst/base system. The base contains zinc oxide, calcium hydroxide, butyl benzene, sulfonamide, and zinc stearate. The catalyst contains barium sulfate and titanium dioxide as radiopacifiers in addition to resin, isobutyl salicylate, and aerosol R 972. Apexit and Apexit Plus (Ivoclar Vivadent, Schaan, Liechtenstein) consist of an activator (disalicylate, bismuth

Correction by nonsurgical techniques is not possible. **C,** Maxillary right first molar with extrusion of the sealer and gutta-percha.

BOX 10-2

Formula for Zinc Oxide–Eugenol Root Canal Sealer

Powder	Liquid
Zinc oxide	42 parts
Staybelite resin	27 parts
Bismuth subcarbonate	15 parts
Barium sulfate	15 parts
Sodium borate, anhydrous	1 part

hydroxide/bismuth carbonate, and fillers) and a base (calcium hydroxide, hydrated colophonium, and fillers).

Noneugenol Sealers

Developed from a periodontal dressing, Nogenol (GC America, Alsip, IL) is a root canal sealer without the irritating effects of eugenol. The base contains zinc oxide, barium sulfate, and bismuth oxychloride.

Glass Ionomer Sealers

The glass ionomers have been advocated for use in obturation because of their dentin-bonding properties. Ketac-Endo (3M ESPE, Minneapolis, MN) enables adhesion between the material and the canal wall.[105] It is also difficult to properly treat the dentinal walls in the apical and middle thirds with preparatory bonding agents to receive the glass ionomer sealer. A disadvantage of glass ionomers is that they must be removed if retreatment is required.[189] This sealer has minimal antimicrobial activity.[133]

Activ GP (Brasseler USA, Savannah, GA) consists of a glass ionomer–impregnated gutta-percha cone with a glass ionomer external coating and a glass ionomer sealer (Fig. 10-14). Available in .04 and .06 tapered cones, the sizes are laser verified to ensure a more precise fit. This single cone technique is designed to provide a bond between the dentinal canal wall and the master cone (monoblock). A bacterial leakage study comparing Activ GP/glass ionomer sealer, Resilon/Epiphany, and gutta-percha (GP)/AH Plus demonstrated no statistically significant differences at 65 days.[103]

FIG. 10-14 Activ GP (Brasseler USA, Savannah, GA) glass ionomer–coated gutta-percha points and sealer.

FIG. 10-15 AH Plus sealer is a resin formulation. *(Courtesy DENTSPLY, Konstanz, Germany. All rights owned by and used with permission from DENTSPLY International, Inc.)*

Resin

Resin sealers have a long history of use, provide adhesion, and do not contain eugenol. AH-26 is a slow-setting epoxy resin that was found to release formaldehyde when setting.[167,298] AH Plus is a modified formulation of AH-26 in which formaldehyde is not released (Fig. 10-15).[182] The sealing abilities of AH-26 and AH Plus appear comparable.[79] AH Plus is an epoxy-bis-phenol resin that comes in two tubes. It exhibits a working time of approximately 4 hours.

EndoREZ (Ultradent Products, South Jordon, UT) is a methacrylate resin with hydrophilic properties. When used with EndoREZ resin-coated gutta-percha cones the dual cure EndoREZ sealer bonds to both the canal walls and the core material.

Diaket, a polyvinyl resin (3M ESPE), consists of a powder composed of bismuth phosphate and zinc oxide and a liquid consisting of dichlorophen, triethanolamine, propionylacetophenone, and copolymers of vinyl acetate, vinyl chloride, and vinylisobutyl ether. The material appears to be biocompatible.[212]

FIG. 10-16 GuttaFlow trituration capsule and injection syringe (Coltène/Whaledent, Cuyahoga Falls, OH).

Other resin-based sealers, Epiphany (Pentron Clinical Technologies, Wallingford, CT) and RealSeal (SybronEndo), have been introduced for use with a new core material, Resilon (Pentron Clinical Technologies). Advocates of these sealers propose that they bond to the canal wall and to the core material to create a "monoblock." One study indicated that the bond strength to dentin can be influenced by the irrigant used. Water and chlorhexidine decreased the bond strength compared with NaOCl, NaOCl/EDTA, and NaOCl/MTAD. The use of EDTA and MTAD did not improve the bond strength compared with NaOCl alone.[324]

Silicone Sealers

RoekoSeal (Coltène/Whaledent, Germany) is a polyvinylsiloxane that has been reported to expand slightly on setting.

GuttaFlow (Coltène/Whaledent) is a cold flowable matrix that is triturated. It consists of gutta-percha added to RoekoSeal (Fig. 10-16). The material is provided in capsules for trituration. The technique involves injection of the material into the canal, followed by placement of a single master cone. The material provides a working time of 15 minutes and it cures in 25 to 30 minutes. Evidence suggests that the material fills canal irregularities with consistency[355] and is biocompatible,[36,95] but the setting time is inconsistent and may be delayed by final irrigation with sodium hypochlorite.[36] Sealing ability appears comparable to other techniques in some studies and inferior in others.[38,169,207,225]

Bioceramic

Bioceramic (BC) sealer is composed of zirconium oxide, calcium silicates, calcium phosphate monobasic, calcium hydroxide, and various filling and thickening agents. The material is available in a premixed syringe with calibrated intracanal tips. As a hydrophilic sealer it utilizes moisture within the canal to complete the setting reaction and it does not shrink on setting. It is biocompatible and exhibits antimicrobial properties during the setting reaction. The manufacturer advocates expressing the sealer into the coronal one third to one half of the canal and then seating the master gutta-percha cone.

Medicated Sealers

Sealers containing paraformaldehyde are strongly contraindicated in endodontic treatment (Fig. 10-17). Although the lead and mercury components may have been removed from these zinc oxide–eugenol formulations over time, the severely toxic paraformaldehyde content has remained a constant. These sealers are not approved by the U.S. Food and Drug Administration[10] and are unacceptable under any circumstances in clinical treatment because of the severe and permanent toxic effects on periradicular tissues.[275] A paste containing 6.5% paraformaldehyde as well as lead and mercury was advocated for use by Sargenti[258-260] and originally marketed as N-2. Lead has been reported in distant organ systems when N-2 is placed within the radicular space.[223] In another study the investigators reported the same results regarding systemic distribution of the paraformaldehyde component of N-2.[31] Removal of the heavy metals resulted in a new formulation: RC2B. Other paraformaldehyde sealers include Endomethasone, SPAD, and Reibler's paste. The toxic in vivo effects of these materials on the pulp and periapical tissues have been demonstrated over time.[67,213]

In addition to the toxic nature of the material, clinicians employing the material place it with a lentulo spiral. Overextension has resulted in osteomyelitis and paresthesia.[97,165] One clinician reported irreversible neurotoxicity, manifested as dysesthesia, in cases where paraformaldehyde pastes were forced through the apical foramen into the periapical tissues.[165] The reader is referred to Chapter 11 for further discussion about this harmful material and technique.

SEALER PLACEMENT

Various methods of sealer placement have been advocated, including the master cone, lentulo spirals, files and reamers, and ultrasonics. Investigators compared sealer placement using a file rotated counterclockwise, the lentulo spiral (Fig. 10-18), an ultrasonic file, and coating the master gutta-percha cone.[336] Placement did not differ with the various techniques; however, the investigators noted the most variation in sealer coating was in the apical area.[336] Another study compared sealer placement with a K-type file, the lentulo spiral, and using the master cone in curved canals. Results demonstrated no significant differences in the techniques after obturation; no technique covered more than 62.5% of the canal wall surface.[125] Other investigators found that ultrasonics produced the best sealer distribution when used circumferentially.[299] These findings were supported by another study that found ultrasonic placement to be superior to manual techniques.[1]

The method of obturation does not seem to affect the sealer distribution on the canal wall in the apical portion of the canal; however, lateral compaction results in better distribution in the mid-coronal areas when compared with warm vertical compaction.[343] Another well-controlled study reported that none of five obturation techniques evaluated resulted in uniform sealer distribution along the entire length of the core obturation material.[142] Evidence indicates that the method of obturation affects the sealer penetration into tubules. This was exemplified by a study finding that thermoplastic techniques produced deeper sealer penetration into tubules.[78] Removal of the smear layer enhances sealer penetration into the dentinal tubules.[77]

BOX 10-3

Properties of an Ideal Obturation Material

- Easily manipulated and provides ample working time
- Dimensionally stable with no shrinkage once inserted
- Seals the canal laterally and apically, conforming to its complex internal anatomy
- Nonirritating to the periapical tissues
- Impervious to moisture and nonporous
- Unaffected by tissue fluids—no corrosion or oxidization
- Inhibits bacterial growth
- Radiopaque and easily discernible on radiographs
- Does not discolor tooth structure
- Sterile
- Easily removed from the canal if necessary

CORE MATERIALS

Although a variety of core materials have been used in conjunction with a sealer/cement, the most common method of obturation involves gutta-percha as a core material. Regardless of the obturating technique, emphasis should be placed on the process of cleaning and shaping the canal. The materials and techniques described do not routinely provide for an impervious seal of the canal system; all materials leak to some extent.[2] The choice of obturation techniques depends on the unique circumstances each case provides.

The properties of an ideal obturation material were outlined by Grossman[115] (Box 10-3). Historically, a variety of materials have been employed to obturate the root canal space. Solids, semisolid materials, and pastes have been employed. A common solid material was the silver cone.

Silver Cones

Jasper[148] introduced cones made of silver, which he claimed produced the same success rate as gutta-percha and were easier to use. The rigidity provided by the silver cones made them easy to place and permitted more predictable length control; however, their inability to fill the irregularly shaped root canal system permitted leakage (Fig. 10-19). When silver points contact tissue fluids or saliva, they corrode.[39] The corrosion products have been found to be cytotoxic and produced pathosis or impeded periapical healing.[271]

With the introduction of rigid silver cones it became possible to easily place them to length. This resulted in clinicians often failing to properly clean and shape the canal before obturation. Treatment failures were the result of leakage and failure to remove the irritants from the root canal system. The use of silver cones today is considered to be below the standard of care in contemporary endodontic practice. For further information about this issue, the reader is referred to Chapter 11.

Gutta-Percha

Gutta-percha is the most popular core material used for obturation. Major advantages to gutta-percha are its plasticity, ease of manipulation, minimal toxicity, radiopacity, and ease of removal with heat or solvents. Disadvantages include its lack of adhesion to dentin and, when heated, shrinkage on cooling. Gutta-percha is the *trans* isomer of polyisoprene (rubber) and exists in two crystalline forms (α and β).[112] In the unheated β phase the material is a solid mass that is compactable. When heated the material changes to the α phase and becomes pliable and tacky and can be made to flow when pressure is applied. A disadvantage to the α phase is that the material shrinks on setting.[267]

Gutta-percha cones consist of approximately 20% gutta-percha, 65% zinc oxide, 10% radiopacifiers, and 5% plasticizers.[104] Attempts have been made to make gutta-percha more antimicrobial by the addition of materials such as iodoform,[63] calcium hydroxide,[190] chlorhexidene,[192] and tetracycline.[201] The clinical effectiveness of adding these materials has not been demonstrated.

Unlike rubber, room temperature gutta-percha cannot be compressed or made to flow. Compaction results in transmission of forces to the material and the canal wall equally and may result in root fracture. Gutta-percha can be made to flow if it is modified by either heat or solvents such as chloroform. This permits adaptation to the irregularities of the canal walls.

The α form of gutta-percha melts when heated above 65° C. When cooled extremely slowly, the α form will recrystallize. Routine cooling results in the recrystallization of the β form. Although the mechanical properties for the two forms are the same, when α-phase gutta-percha is heated and cooled it undergoes less shrinkage, making it more dimensionally stable for thermoplasticized techniques. The use of α-phase gutta-percha for obturation has increased as thermoplastic techniques have become more common.

Gutta-percha cones are available in standardized and nonstandardized (conventional) sizes. The nonstandard nomenclature refers to the dimensions of the tip and body (Fig. 10-20). A fine-medium cone has a fine tip with a medium body. Standardized cones are designed to match the taper of stainless steel and nickel–titanium instruments (Figs. 10-21 and 10-22). A size 40/04 has a tip of 0.4 mm and a taper of 0.04 mm per millimeter. Unfortunately uniformity in manufacturing is not present, and the actual cone size varies.[111,197]

Although the points cannot be heat sterilized, a study found that gutta-percha points can be sterilized before use by placing the cones in 5.25% NaOCl for 1 minute. This study also found that 2% glutaraldehyde, 2% chlorhexidine, and 70% ethyl alcohol were not effective in killing *Bacillus subtilis* spores.[287]

FIG. 10-19 Silver cones are advocated for ease of placement and length control. **A,** Radiograph of a facial maxillary right central incisor obturated with a silver cone. **B,** Tissue discoloration indicating corrosion and leakage. **C,** Lingual view indicates coronal leakage. **D,** Corroded silver cone removed from the tooth. **E,** Posttreatment radiograph of the tooth.

Activ GP

Activ GP (Brasseler USA) consists of gutta-percha cones impregnated on the external surface with glass ionomer (see Fig. 10-14). Single cones are used with a glass ionomer sealer. Available in .04 and .06 tapered cones, the sizes are laser verified to ensure a more precise fit. The single cone technique is designed to provide a bond between the dentinal canal wall and the master cone. A bacterial leakage study comparing Activ GP/glass ionomer sealer, Resilon/Epiphany, and gutta-percha/AH Plus demonstrated no statistically significant differences in leakage at 65 days.[103]

Resilon

The resin-based obturation systems Epiphany (Pentron Clinical Technologies), RealSeal (SybronEndo), and Resinate (Obtura Spartan, Earth City, MO) have been introduced as alternatives to gutta-percha (Figs. 10-23 and 10-24). Resilon is a high-performance industrial polyurethane that has been adapted for dental use.

The resin sealer bonds to a Resilon core, and attaches to the etched root surface. The manufacturer claims that this forms a "monoblock" (Fig. 10-25). With traditional techniques there is a gutta-percha–sealer interface and a tooth–sealer

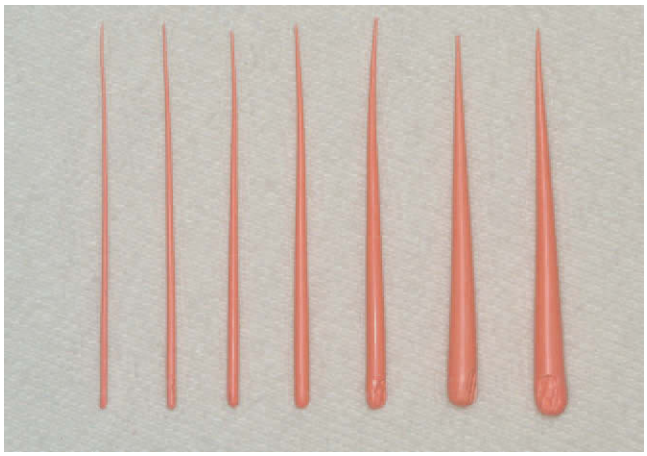

FIG. 10-20 Nonstandard gutta-percha cones: extra fine, fine fine, fine, medium fine, fine medium, medium, large, and extra large.

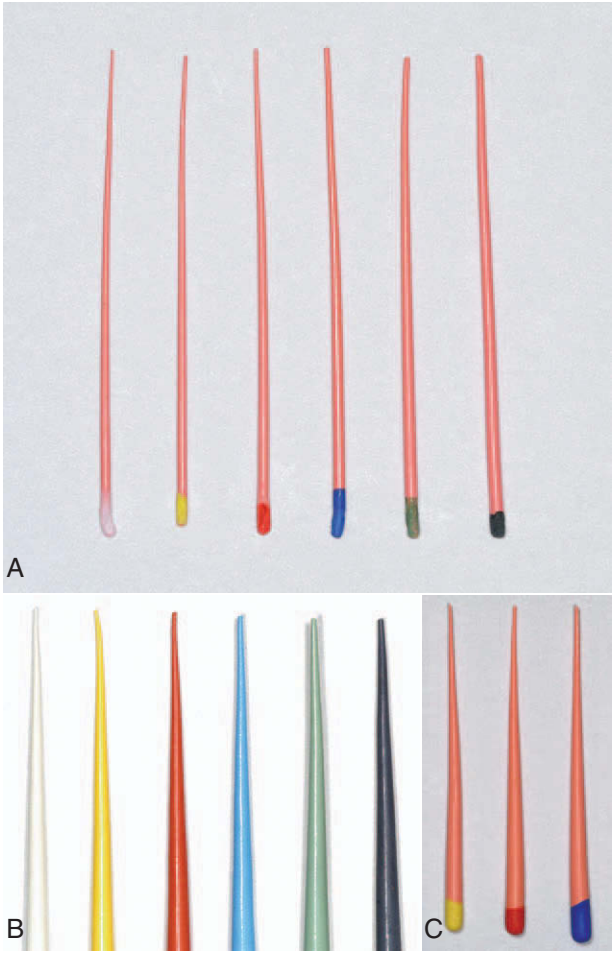

FIG. 10-21 A, Standard gutta-percha cone sizes #15 to #40. **B,** Standard cones #.06, taper sizes #15 to #40. **C,** Standard cones Protaper F1, F2, F3.

interface. With Resilon the resin sealer bonds to both the canal wall and the cone. Whether a monoblock is achievable remains controversial.[242,308] An in-depth review article on the subject of monoblocks indicates that with current materials and techniques, the monoblock has yet to be achieved.[308]

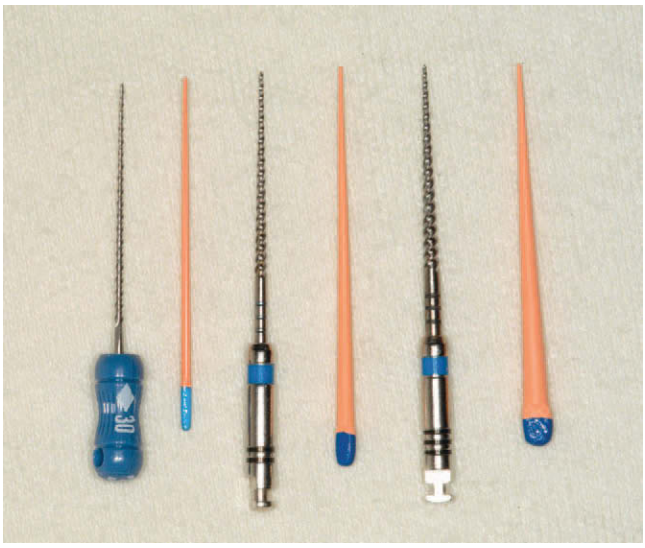

FIG. 10-22 Size #30 standard gutta-percha points exhibiting #.02, #.04, and #.06 tapers.

FIG. 10-23 Epiphany system (Pentron Clinical Technologies, Wallingford, CT) with the primer, thinning resin, sealant, and standard Resilon points. *(Courtesy SybronEndo, Orange, CA.)*

The system resembles gutta-percha and can be placed by lateral compaction, warm lateral or vertical compaction, or thermoplastic injection. It consists of a resin core material (Resilon) composed of polyester, difunctional methacrylate resin, bioactive glass, radiopaque fillers, and a resin sealer. Resilon is nontoxic, nonmutagenic, and biocompatible. The core material is available in nonstandard and standard cones and pellets for use in thermoplastic techniques (see Fig. 10-24).

After cleaning and shaping procedures an appropriate master cone is placed into the prepared canal and a radiograph/image is exposed to verify the apical position. Because NaOCl may affect the bond strength of the primer, EDTA should be

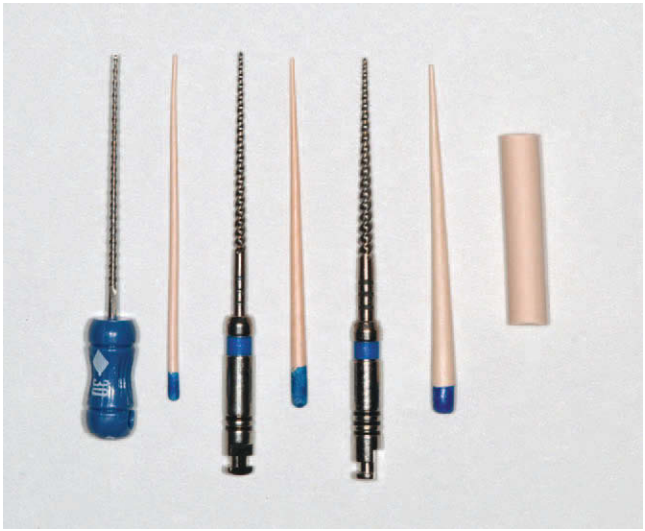

FIG. 10-24 Resilon #.02, #.04, and #.06 tapered points and a thermoplastic plug for use in the Obtura II system (Obtura Spartan, Earth City, MO).

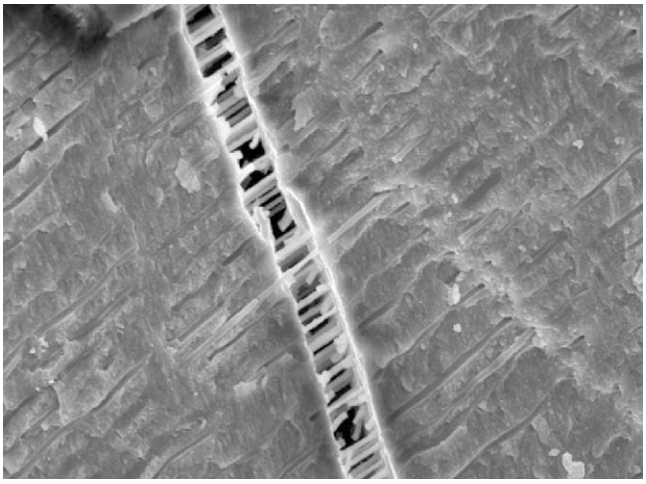

FIG. 10-25 Scanning electron microscopy view of Resilon tags extending into the dentinal tubules.

the last irrigant used before rinsing the canal with sterile water, saline, or chlorhexidine.

After drying the canal a self-etch primer (sulfonic acid–terminated functional monomer, 2-hydroxyethyl methacrylate [HEMA], water, and polymerization initiator) is used to condition the canal walls and prepare them for bonding to the resin sealant (resin matrix of bisphenol A-glycidyl methacrylate [Bis-GMA], ethoxylated Bis-GMA, urethane dimethacrylate [UDMA], and hydrophilic difunctional methacrylates and fillers [70%] of calcium hydroxide, barium sulfate, barium glass, bismuth oxychloride, and silica). Two or three drops are placed in the canal with a pipette, a syringe, or a paper point that wicks the material to the working length. The excess primer is removed, the resin sealer is dispensed onto a mixing slab, and the viscosity is adjusted with the thinning resin. The sealer is applied with a paper point, Resilon point, or lentulo spiral. The canal is then obturated by lateral compaction, warm vertical compaction, or thermoplastic injection. The sealer takes approximately 25 minutes to set, so it is recommended that the coronal surface of the material be light cured for 40 seconds.

When using the System B (SybronEndo) for warm vertical compaction, the temperature setting should be 150° C at a power of 10. With the Obtura II thermoplasticized injection system (Obtura Spartan) the temperature settings vary depending on the needle tip employed. For the 25-gauge needle a 160° C setting is selected, for the 23-gauge needle a 140° C setting is used, and for the 20-gauge needle the setting that is recommended is 120° C to 130° C.

Resilon appears to be comparable to gutta-percha in its ability to seal the radicular space.[19] Investigators evaluated coronal leakage of Resilon, using *Streptococcus mutans* and *E. faecalis* in roots that were filled by lateral and vertical compaction techniques with gutta-percha and AH-26 or Resilon and Epiphany sealer.[283] Resilon showed significantly less coronal leakage when compared with gutta-percha. In another study, investigators used a dog model to assess the ability of Resilon or gutta-percha and AH-26 to prevent apical periodontitis in teeth inoculated with microorganisms. Results indicated periapical inflammation in 18 of 22 roots (82%) obturated with gutta-percha and AH-26 whereas the Resilon group exhibited periapical inflammation in 4 of 21 roots (19%).[284] Still another study demonstrated that teeth filled with Resilon were more resistant to fracture than roots filled with gutta-percha and AH-26 sealer.[311] More recent evidence suggests that Resilon does not strengthen roots.[114,338]

Resilon appears to be biocompatible. Implantation in the subcutaneous tissues of rats demonstrated fibrous encapsulation and negligible inflammation at 60 days.[34]

One retrospective study compared the success and failure rates between obturation with gutta-percha and Kerr Pulp Canal Sealer and obturation with Resilon or Epiphany, with recall examination between 12 and 25 months. Statistical analysis indicated that the results were indistinguishable.[71] Another study demonstrated that 82 randomly selected clinical cases treated with Resilon produced success rates at 1 year that were comparable to cases treated with gutta-percha.[69]

Custom Cones

When the apical foramen is open or a canal is large a custom cone may need to be fabricated (Fig. 10-26). This permits the adaptation of the cone to the canal walls, reduces the potential for extrusion of the core material, and may improve the seal.[24,160] The technique involves selection of a master cone and fitting that cone 2 to 4 mm short of the prepared length with frictional resistance. The cone is grasped with locking cotton pliers or a hemostat so that it can be placed into the canal in the same spatial relationship each time. The cone is removed and the tip is softened in chloroform, eucalyptol, or halothane for 1 or 2 seconds. Only the outer superficial portion of the cone is softened. The central core of the cone should remain semirigid. The cone is then placed into the canal and gently tamped to length. The process can be repeated until an adequate impression of the canal is obtained at the prepared length. A radiograph is exposed to verify proper fit and position. An alternative to solvents is softening with heat.[161]

Large canals may necessitate fabricating a large master cone before canal adaptation. This can be accomplished by heating

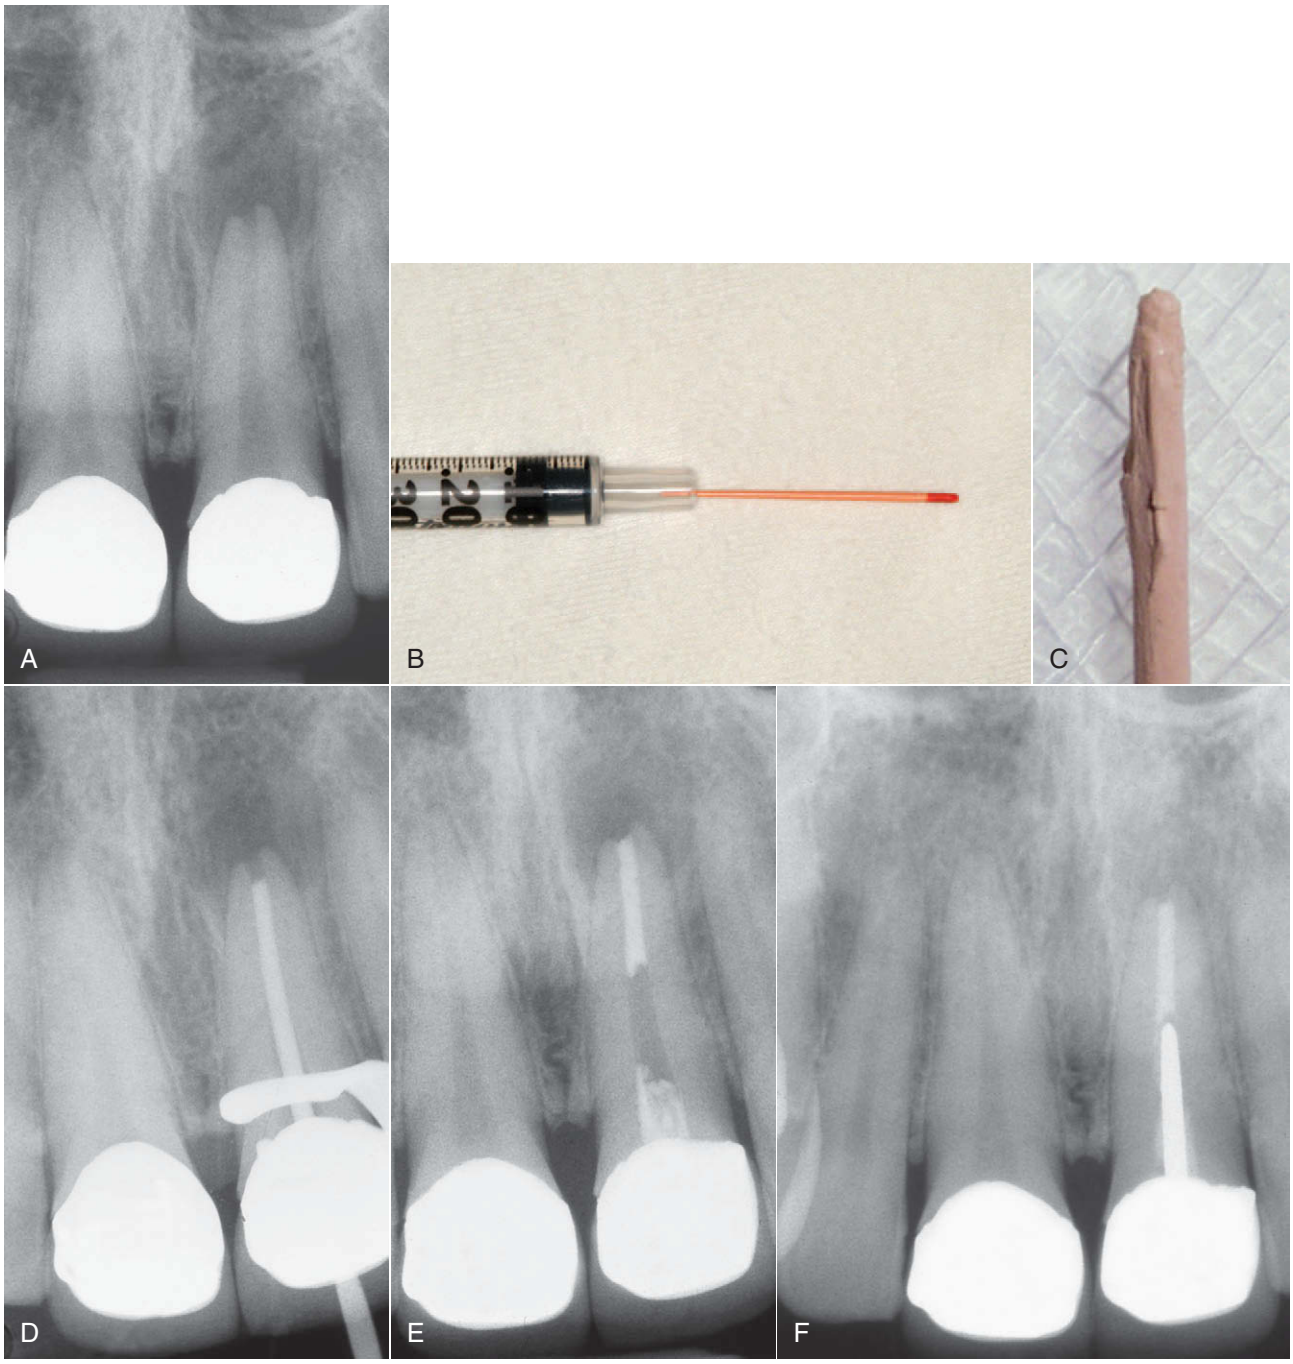

FIG. 10-26 Apical root resorption often results in an open apex requiring fabrication of a custom cone. **A,** Pretreatment radiograph of the maxillary left central incisor with pulp necrosis and chronic apical periodontitis. Apical root resorption is present. **B,** In fabricating a custom master cone a gutta-percha point is fit several millimeters short before softening in solvent and tamping into place. **C,** Softening the apical 2 to 3 mm in chloroform that has been placed in a tuberculin syringe. **D,** The completed custom cone represents an impression of the apical portion of the canal. **E,** The posttreatment radiograph with post space prepared. **F,** A 1-year follow-up radiograph demonstrating osseous regeneration.

several large gutta-percha cones and rolling the mass between two glass slabs until an appropriate size is obtained (Fig. 10-27). A spatula may also be used to shape the cone.

METHODS OF OBTURATION

To date little evidence exists to support one method of obturation as being superior to another and the influence of treatment technique on success/failure has yet to be determined.[11,215] The prospective Toronto studies have suggested that warm vertical compaction may be superior to lateral compaction; however, definitive evidence is lacking.[76,231]

Lateral Compaction

Lateral compaction is a common method for obturation (Fig. 10-28).[51] The technique can be used in most clinical situations

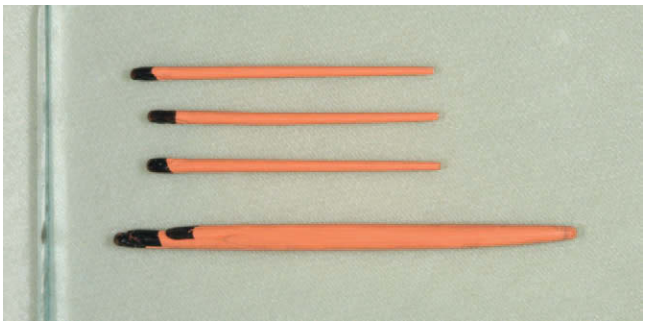

FIG. 10-27 For large canals, several gutta-percha points can be heated and rolled together, using a spatula or two glass slabs.

and provides for length control during compaction.[109] A disadvantage is that the technique may not fill canal irregularities[347] as well as warm vertical compaction or thermoplastic techniques.[345] The procedure can be accomplished with any of the acceptable sealers.

After canal preparation a standard cone is selected that has a diameter consistent with the prepared canal diameter at the working length. Standard cones generally have less taper when compared with conventional cones and will permit deeper spreader penetration.[233] An alternative is to adapt an appropriately tapered nonstandard cone by cutting small increments from the tip. This "master cone" is measured and grasped with forceps so that the distance from the cone tip to the forceps is equal to the prepared length. A reference point on the cone can be made by pinching the cone. The cone is placed in the canal, and if an appropriate size is selected, there will be resistance to displacement or "tug back." If the cone is loose it can be adapted by removing small increments from the tip. If the master cone fails to go to the prepared length a smaller cone can be selected. Devices are available to cut cones accurately at a predetermined length (Tip Snip; SybronEndo). When the cone extends beyond the prepared length a larger cone must be adapted or the existing cone shortened until there is resistance to displacement at the corrected working length.

The master cone placement is confirmed with a radiograph. The canal is irrigated and dried with paper points. Sealer is applied to the canal walls, and a spreader is prefitted so as to allow it to be inserted to within 1.0 to 2.0 mm from working length. Appropriate accessory points are also selected to closely match the size of the spreader. The correlation between spreader size and nonstandard cones is variable,[44,357] and in small curved canals there does not appear to be a difference in the quality of obturation with nonstandard cones when compared with standard cones.[135,321]

Finger spreaders provide better tactile sensation and are less likely to induce fractures in the root when compared with the more traditional D-11T hand spreader.[74,183,184] In addition to the type of spreader, forces applied, and amount of dentin removed, spreader size may be a factor in root fracture, with large sizes inducing more stress.[238] Spreaders made from nickel–titanium are available and provide increased flexibility,[28] reduce stress,[89] and provide deeper penetration when compared with stainless steel instruments.[152,268,339] The spreader should fit to within 1 to 2 mm of the prepared length, and when introduced into the canal with the master cone in place, it should be within 2 mm of the working length.[7] There appears to be a correlation between establishing a seal and spreader penetration.[7,281]

After placement the spreader is removed by rotating it back and forth as it is withdrawn. An accessory cone is placed in the space vacated by the instrument. The process is repeated until the spreader no longer goes beyond the coronal one third of the canal. The excess gutta-percha is removed with heat and the coronal mass is compacted with an appropriate plugger. Only light pressure is required during lateral compaction because the gutta-percha is not compressible, and because as little as 1.5 kg of pressure is capable of fracturing the root (Fig. 10-29). In addition to the force applied, investigators have noted that removal of dentin during preparation is a significant factor in root fracture.[337]

A disadvantage to lateral compaction is that the process does not produce a homogeneous mass. The accessory and master cones are laminated and remain separate. It is hoped that the space between each of the cones is filled with sealer.

The excess gutta-percha in the chamber is then seared off and vertically compacted with a heated plugger at the orifice or approximately 1 mm below the orifice in posterior teeth. Warm vertical compaction of the coronal gutta-percha enhances the seal.[351] In anterior teeth the desired level is the cementoenamel junction on the facial surface.

An alternative to lateral compaction with finger spreaders is ultrasonics.[18] For example, one study found that the technique produced adequate obturation and a 93% clinical success rate.[356]

Another study used ultrasonic-energized files in a warm lateral compaction technique and found that the amount of gutta-percha by weight increased by 33% with two applications of ultrasonics when compared with lateral compaction.[80] Unfortunately, investigators found that the mean internal temperature rise was 29° C at the 6-mm level with external heat generation exceeding the safe limit of 10° C.[302]

Warm Vertical Compaction

Schilder[266] introduced warm vertical compaction as a method of filling the radicular space in three dimensions. Preparation requirements for the technique include preparing a canal with a continuously tapering funnel and keeping the apical foramen as small as possible.

The armamentarium includes a variety of pluggers and a heat source. Schilder pluggers come in a variety of sizes (#8 = 0.4 mm, #8½ = 0.5 mm, etc., for sizes #9, #9½, #10, #10½, #11, #11½, #12) with increasing diameter. The instruments are marked vertically at 5-mm intervals. Various ISO standardized instruments are also available (Fig. 10-30).

The technique involves fitting a master cone short of the corrected working length (0.5 to 2 mm) with resistance to displacement (Fig. 10-31). This ensures that the cone diameter is larger than the prepared canal. Nonstandard cones that closely replicate the canal taper are best because they permit the development of hydraulic pressure during compaction. After the adaptation of the master cone it is removed and sealer is applied. The cone is placed in the canal and the coronal portion is removed with heat. A heated spreader or plugger is used to remove portions of the coronal gutta-percha and soften the remaining material in the canal. The Touch 'n

The cones are then removed at the orifice with heat, and the coronal mass is vertically compacted with a plugger. **K,** Interim radiograph may be exposed to assess the quality of obturation. **L,** Posttreatment radiograph demonstrating adequate length, density, and taper. The gutta-percha is removed to the level of the orifice, and a coronal seal has been established with an adequate provisional restoration.

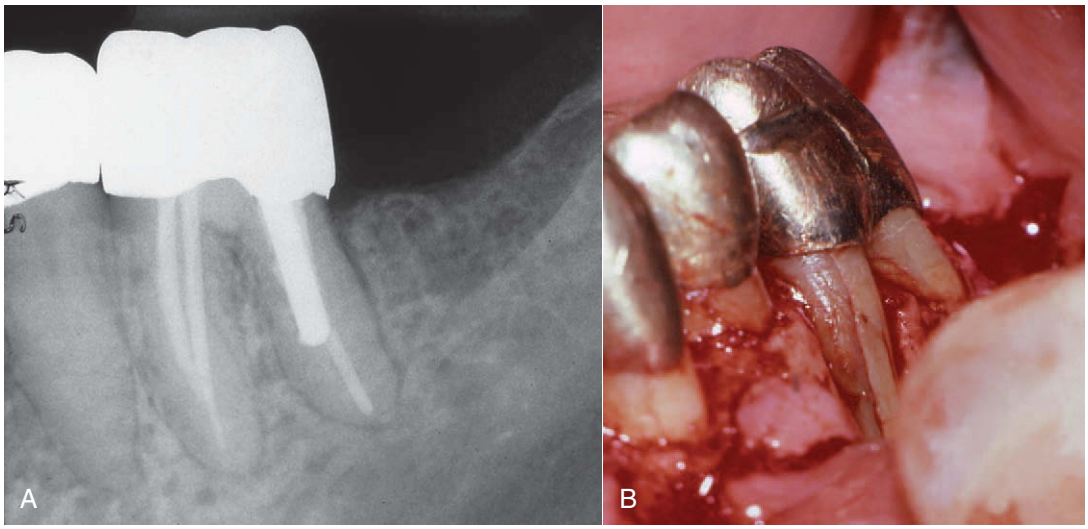

FIG. 10-29 Vertical root fractures can occur with excessive compaction forces. **A,** Follow-up radiograph of a mandibular left first molar. A deep isolated periodontal probing defect was associated with the buccal aspect of the mesiobuccal root. **B,** Flap reflection revealed a vertical root fracture.

Heat (SybronEndo) (Fig. 10-32), EI DownPak (EI/Hu-Friedy, Chicago, IL), and System B (SybronEndo) (Fig. 10-33) are alternatives to applying heat with a flame-heated instrument because they permit temperature control. A plugger is inserted into the canal and the gutta-percha is compacted, forcing the plasticized material apically. The process is repeated until the apical portion has been filled. The coronal canal space is backfilled, using small pieces of gutta-percha. The sectional method consists of placing 3- to 4-mm sections of gutta-percha approximating the size of the canal into the root, applying heat, and compacting the mass with a plugger.

One study[33] measured temperature changes in the canal with warm vertical compaction. The maximal temperatures occurred coronally and decreased apically. The authors reported that the maximal temperature in the canal was 118° C 8 mm from the apex. At 0 to 2 mm from the apex the maximal temperature decreased to 44° C. Another study compared root surface temperatures for warm vertical obturation using the System B heat source, the Touch 'n Heat device, and a flame-heated carrier in maxillary and mandibular incisors and premolars 2 mm below the cementoenamel junction. System B and the Touch 'n Heat produced a surface temperature rise that was less than 10° C for all maxillary incisors and premolar teeth. The Touch 'n Heat produced a greater than 10° C rise in mandibular incisors. The flame-heated carrier produced temperature changes greater than 10° C in all experimental teeth. Because the critical level of root surface heat required to produce irreversible bone damage is believed to be greater than 10° C the findings suggest that warm vertical compaction with the System B should not damage supporting periodontal structures; however, caution should be exercised with the Touch 'n Heat and flame-heated carriers.[180]

The potential for vertical root fracture is also present with warm vertical compaction.[32] The forces developed appear to be equal to lateral compaction. Investigators compared warm vertical compaction and lateral compaction as a function of time. Results indicated that the forces developed with the two techniques were not significantly different. In a follow-up study, the mean value for wedging with warm vertical compaction was 0.65 ± 0.07 kg, whereas for lateral compaction it was 0.8 ± 0.1 kg.

Warm thermoplastic techniques have the advantage of producing movement of the plasticized gutta-percha, filling irregularities and accessory canals better than lateral compaction.[85,342] This was illustrated in a study that reported a correlation between the quality of adaptation and the depth of heat application and canal size. Heat application close to the apical extent of the preparation produced the best results, and adaptation was better in small canals when compared with wide canals.[341] However, thermoplasticized techniques result in more extrusion of obturation materials.[175] There appeared to be no consistent differences between the techniques in sealing the canal space.[342]

Advantages of warm vertical compaction include filling of canal irregularities and accessory canals. Disadvantages include a slight risk of vertical root fracture because of compaction forces, less length control than with lateral compaction, and the potential for extrusion of material into the periradicular tissues. Warm vertical compaction is difficult in curved canals, where the rigid pluggers are unable to penetrate to the necessary depth. To allow the rigid carriers to penetrate within 4 to 5 mm of the apex, the canals must be enlarged and tapered more, in comparison with the lateral compaction technique; however, excessive removal of tooth structure weakens the root.

Continuous Wave Compaction Technique

A variation of warm vertical compaction is the continuous wave compaction technique.[46] The increasing use of nickel–titanium rotary preparation techniques and the fabrication of standard cones for files of greater taper have resulted in more clinicians using thermoplasticizing techniques. The manufacturing of cones to mimic the tapered preparation permits the application of greater hydraulic force during compaction when appropriately tapered pluggers are used. The continuous wave compaction technique employs an electric heat carrier, the

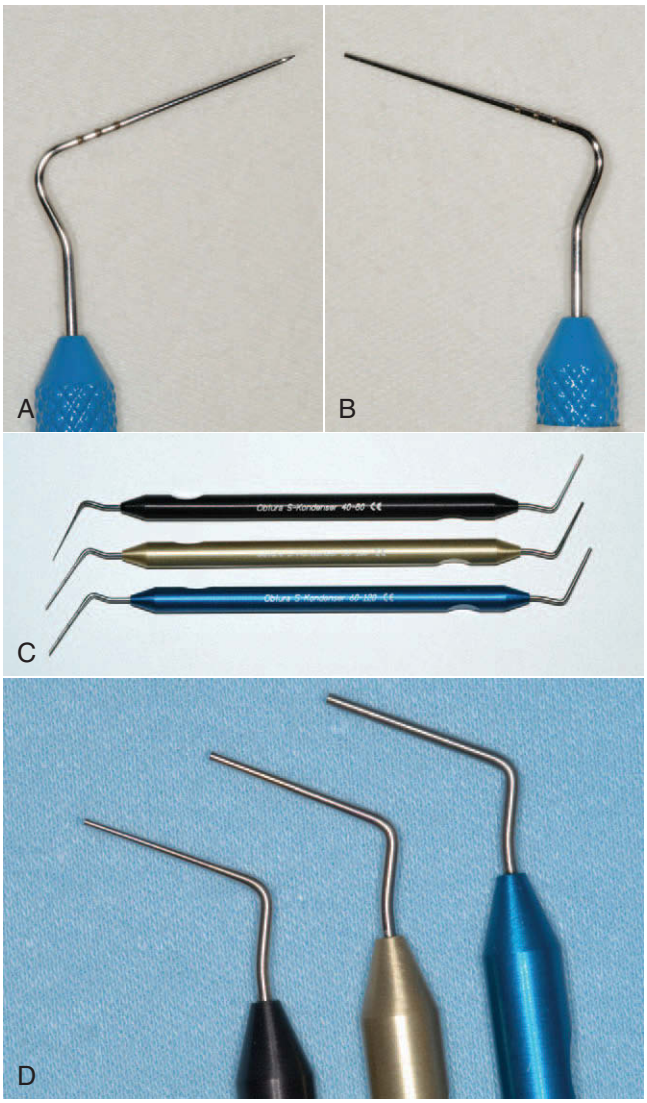

FIG. 10-30 Various pluggers are manufactured for compacting warm gutta-percha. **A,** ISO standard spreader. **B,** ISO standard plugger. **C,** Obtura S Kondensers (**C,** courtesy Obtura Spartan, Earth City, MO). **D,** Closeup of Obtura S-Kondensers.

System B unit, and #.04, #.06, #.08, #.10, and #.12 tapered stainless steel pluggers, each with a tip diameter of 0.5 mm (see Fig. 10-33). The #.06 tapered plugger approximates the fine nonstandard gutta-percha cone, the #.08 plugger the fine-medium cone, the #.10 plugger the medium cone, and the #.12 plugger the medium-large cone. Pluggers are consistent with the ProFile GT instruments (DENTSPLY Tulsa Dental Specialties), and Autofit gutta-percha cones (SybronEndo) are also available.

The electric heat source permits a variable temperature setting. The recommended temperature setting for the System B unit is 200° C. One study evaluated internal and external temperature changes with the System B unit with varied tips and temperature settings of 200° C, 250° C, and 300° C. At 6 mm from the apex, the System B unit set at 300° C with the fine-medium plugger produced the highest mean internal temperature (74° C). The authors noted that the external temperature setting never exceeded the critical 10° C rise with any temperature setting or tip configuration.[302] This was confirmed in another study that measured temperature changes 2 mm apical to the cementoenamel junction and 1.5 mm from the apex. Results indicated that temperature changes apically were negligible. The mean change near the cementoenamel junction was 4.1° C.[322]

Another study reported that obturation temperature elevations produced during obturation with System B were significantly less ($P < 0.001$) than with warm vertical compaction. An elevation of external root surface temperature by more than 10° C was noted with vertical compaction.[285] Investigators measured the root surface temperatures while using the System B heat source at various temperature settings from 250° C to 600° C. Results indicated that the highest temperature occurred 5 mm from the apex, and this was the only site that exceeded the 10° C rise. On the basis of this study a temperature setting of 250° C or greater may be potentially hazardous.[101] For example, investigators using a thermocouple and simultaneous infrared analysis of temperatures found that the root surface temperature averaged 13.9° C whereas the infrared technology indicated a 28.4° C rise at the same sites.[200]

After selecting an appropriate master cone, a plugger is prefitted to fit within 5 to 7 mm of the canal length (Fig. 10-34). Placing the plugger deeper into the canal may enhance the flow of gutta-percha.[5] The point of plugger binding should be noted because once the instrument reaches this point the hydraulic forces on the gutta-percha will decrease and forces on the root will increase. There appears to be a correlation between the depth of the heated plugger relative to the working length and the quality of obturation and filling of canal irregularities.[37,153,345] Increasing the temperature settings does not seem to increase the effectiveness of obturation.[153]

The System B unit is set to 200° C in the touch mode. The plugger is inserted into the canal orifice and activated to remove excess coronal material. Compaction is initiated by placing the cold plugger against the gutta-percha in the canal orifice. Firm pressure is applied and heat is activated with the device. The plugger is moved rapidly (1 to 2 s) to within 3 mm of the binding point (Fig. 10-35). The heat is inactivated while firm pressure is maintained on the plugger for 5 to 10 seconds. After the gutta-percha mass has cooled a 1-second application of heat separates the plugger from the gutta-percha, and it is removed. The pluggers are designed to heat from the tip to their shank, which decreases the potential for dislodging the compacted mass and prevents a second application of heat to the material. Confirmation that the apical mass is still present in the canal can be established with hand pluggers. Two hand instruments are manufactured with tip diameters of 0.4 and 0.9 mm and 0.7 and 1.4 mm. It should be noted that with the continuous wave technique the heat source is placed only to within 5 to 7 mm from the tip of the gutta-percha; the apical portion of the gutta-percha remains essentially a single cone technique as the heat transfer does not take place in the apical 2 to 5 mm of the gutta-percha.[265]

In ovoid canals, where the canal configuration may prevent the generation of hydraulic forces, an accessory cone can be placed alongside the master cone before compaction. With type II canals the master cones are placed in both canals before compaction. A hand plugger is used to stabilize the cone in one canal while the other is being obturated.

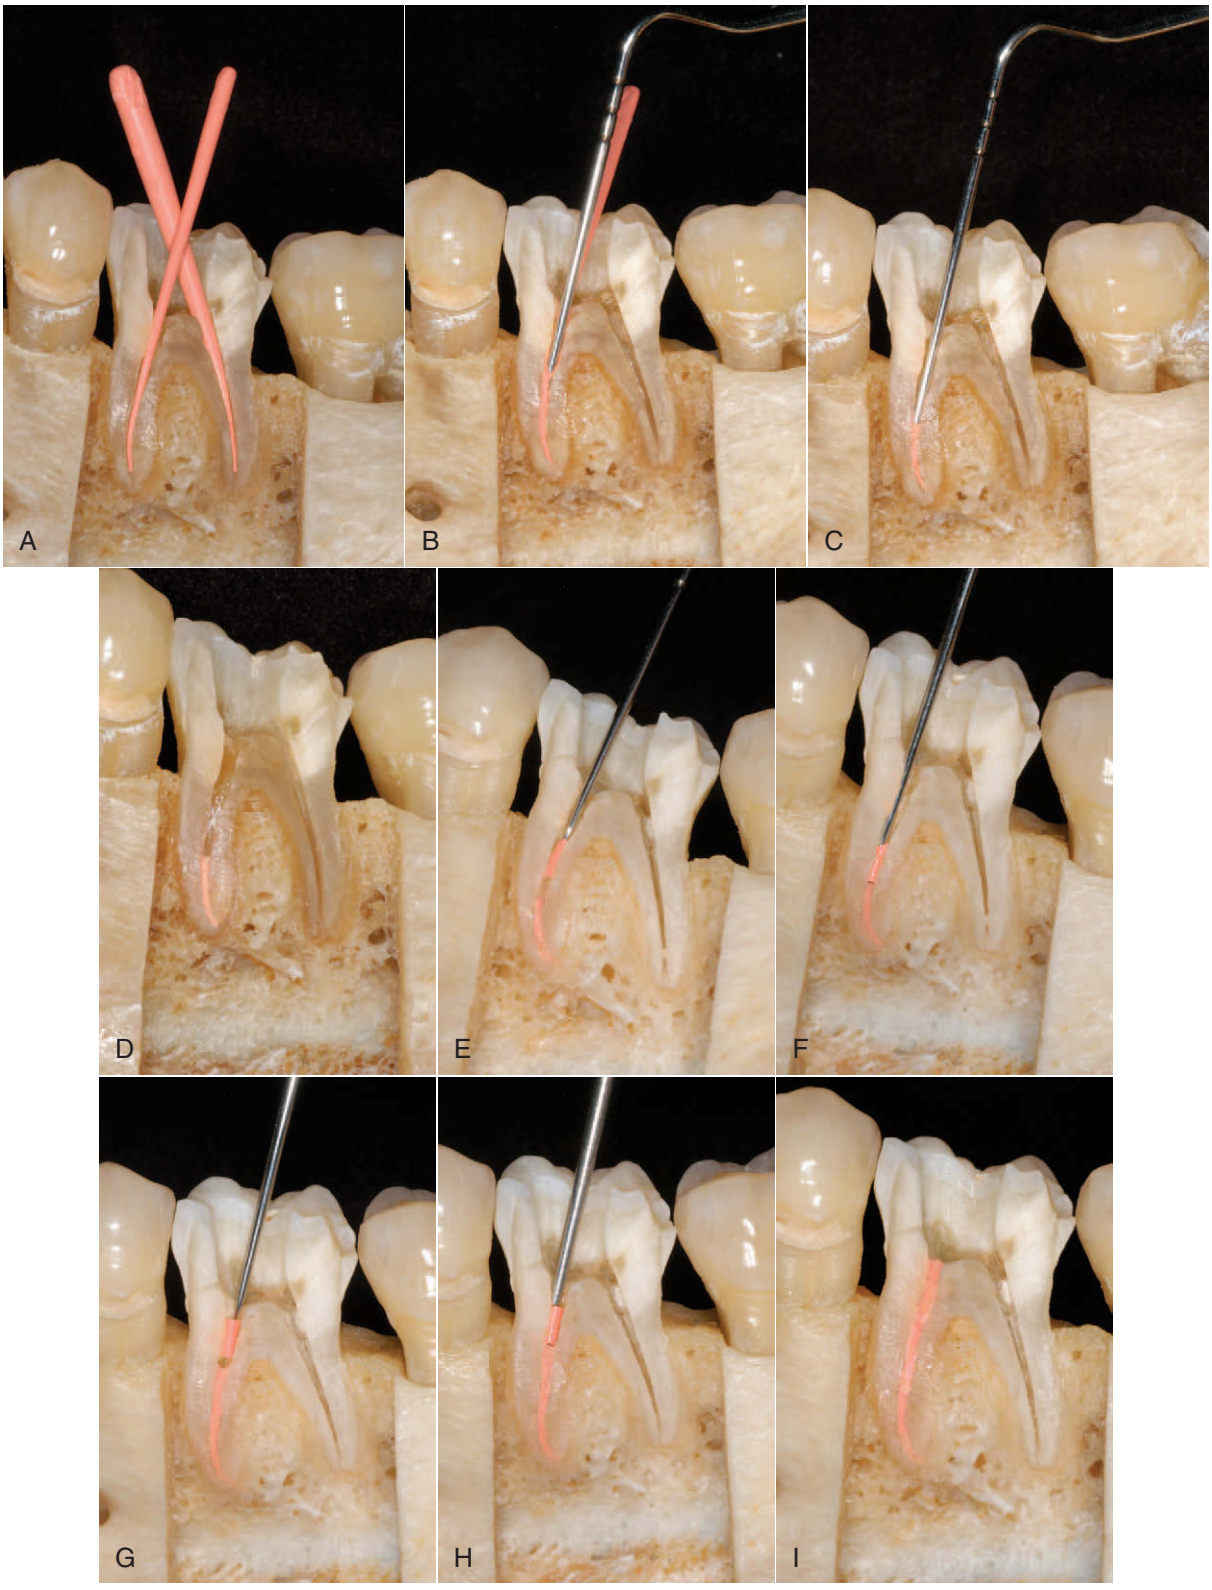

FIG. 10-31 Warm vertical compaction of gutta-percha employs heat and various condensers. **A,** Nonstandard cones are selected and fit short of the prepared length because they more closely replicate the prepared canal. **B,** Heated pluggers or spreaders are used to apply heat to the master cone and remove the excess coronal material. **C,** A room temperature plugger is used to compact the heated gutta-percha. **D,** Apical compaction is complete. **E,** A gutta-percha segment is placed in the canal, and heat is applied. **F,** The heated segment is compacted. **G,** The process is repeated for the coronal portion of the canal by placing and heating a segment of gutta-percha. **H,** A plugger is again used to compact the heated material. **I,** Completed obturation.

FIG. 10-32 The Touch 'n Heat unit. *(Courtesy SybronEndo, Orange, CA.)*

Filling the space left by the plugger can be accomplished by a thermoplastic injection technique (Obtura II or Ultrafil 3D [Coltène/Whaledent], Calamus [DENTSPLY Tulsa Dental Specialties], Elements [SybronEndo, Orange, CA], or HotShot [Discus Dental, Culver City, CA]) (Fig. 10-36)[150] or by fitting an accessory cone into the space with sealer, heating it, and compacting by short applications of heat and vertical pressure.

Warm Lateral Compaction

Lateral compaction of gutta-percha provides for length control, which is an advantage over thermoplastic techniques. The Endotec II device (Medidenta) provides the clinician with the ability to employ length control while incorporating a warm gutta-percha technique (Fig. 10-37). Investigators demonstrated that the Endotec II produced a fusion of the gutta-percha into a solid homogeneous mass.[147] One study evaluated three thermoplasticized filling techniques and lateral compaction, using a bacterial metabolite model, and found the Endotec to be superior to lateral compaction alone, lateral thermocompaction, and the Ultrafil 3D.[162] The use of warm lateral compaction with the Endotec demonstrated an increased weight of

gutta-percha mass, by 14.63%, when compared with traditional lateral compaction.[187] Another study found a 24% increase in weight with warm lateral compaction when using the System B device.[211] Using the Endotec II, one investigation reported a statistically significantly better ability of warm vertical and warm lateral compaction techniques versus cold lateral compaction to reproduce artificially produced canal irregularities in a split-tooth model.[68] Another group of investigators used the EndoTwinn (Hu-Friedy), an instrument for warm lateral compaction, in a similar experiment. The EndoTwinn instrument also possesses the ability to vibrate the electronically heated tip. They reported that warm lateral compaction, using both heat and vibration, and warm vertical compaction of gutta-percha provided statistically better replication of defects than cold lateral compaction.[173] EI, a subsidiary of Hu-Friedy, has now introduced the EI DownPak (Fig. 10-38), a variation of the original EndoTwinn that can be used with either warm lateral or warm vertical compaction techniques. Other investigators compared the stress generated with lateral compaction and warm lateral compaction, using the Endotec, and found that the warm lateral compaction technique created less stress during obturation.[196] An additional concern is the

heat generated by the technique. Evaluation of the effects of warm lateral and warm vertical compaction on periodontal tissues demonstrated that neither technique produced heat-related damage.[57]

The warm lateral compaction technique involves adapting a master cone in the same manner as with traditional lateral compaction. An appropriate-size Endotec II tip is selected. Endotec II tips are available in various taper and tip diameters. The sizes consist of #.02/20 and #.02/40. The device is activated and the tip is inserted beside the master cone to within 2 to 4 mm of the apex, using light pressure. The tip is rotated for 5 to 8 seconds and removed. An unheated spreader can be placed in the channel created to ensure adaptation and then an accessory cone is placed. The process is continued until the canal is filled.

Thermoplastic Injection Techniques

Heating of gutta-percha outside the tooth and injecting the material into the canal is an additional variation of the thermoplastic technique (Fig. 10-39). The Obtura III (Fig. 10-40), Calamus (Fig. 10-41), Elements (Fig. 10-42), HotShot (Fig. 10-43), and Ultrafil 3D (Fig. 10-44) are available devices. The Obtura II system heats the gutta-percha to 160° C, whereas the Ultrafil 3D system employs a low-temperature gutta-percha that is heated to 90° C.

Obtura III

The Obtura III system (Obtura Spartan, Earth City, MO) consists of a hand-held "gun" that contains a chamber surrounded by a heating element into which pellets of gutta-percha are loaded (see Fig. 10-40). Silver needles (varying gauges of 20, 23, and 25) are attached to deliver the thermoplasticized material to the canal. The control unit allows the operator to adjust the temperature and thus the viscosity of the gutta-percha. At 6 mm from the apex a study found that the highest internal temperature with the Obtura II was 27° C.[302]

Canal preparation is similar for other obturation techniques. The apical terminus should be as small as possible to prevent extrusion of gutta-percha. The technique requires the use of sealer, and once the canal is dried, the canal walls are coated with sealer, using the last file used to length or a paper point. Gutta-percha is preheated in the gun, and the needle is positioned in the canal so that it reaches within 3 to 5 mm of the apical preparation. Gutta-percha is then gradually, passively injected by squeezing the trigger of the "gun." The needle backs out of the canal as the apical portion is filled. Pluggers dipped in alcohol are used to compact the gutta-percha. A segmental technique may also be used, in which 3- to 4-mm segments of gutta-percha are sequentially injected and compacted. In either case, compaction should continue until the gutta-percha cools and solidifies to compensate for the contraction that takes place on cooling.

The difficulties with this system include lack of length control. Both overextension and underextension are common results. To overcome this drawback, a hybrid technique may be used, in which the clinician begins filling the canal by the lateral compaction technique. When the master cone and several accessory cones have been placed so that the mass is firmly lodged in the apical portion of the canal, a hot plugger is introduced, searing the points off approximately 4 to 5 mm from the apex. Light vertical compaction is applied to restore the integrity of the apical plug of gutta-percha. The remainder of the canal is then filled with thermoplasticized gutta-percha injected as previously described.

Investigators studied, at 3, 6, and 12 months posttreatment, the success rate of 236 teeth obturated with the Obtura system. Results indicated that 96% of the cases were successful, with the highest success rate being in teeth filled flush with the apex (97%) when compared with overextensions (93%) and filling short (93%).[304] Another study compared lateral compaction with Thermafil (DENTSPLY Tulsa Dental Specialties) and Obtura II in root canal models and found that the Obtura II produced the best adaptation to the canal walls.[332] Other investigators found that continuous wave obturation with the Obtura II backfill initially produced a better bacterial seal when compared with lateral compaction, using bilaterally matched teeth and an anaerobic bacterial leakage model.[147]

Ultrafil 3D

Ultrafil 3D (Coltène/Whaledent) is a thermoplastic gutta-percha injection technique involving gutta-percha cannulas, a heating unit, and an injection syringe (see Fig. 10-44). The system employs three types of gutta-percha cannulas. The Regular Set is a low-viscosity material that requires 30 minutes to set. The Firm Set is also a low-viscosity material but differs in that it sets in 4 minutes. The manufacturer recommends compaction after the initial set with both materials. Endoset has a higher viscosity and does not flow as well. It is recommended for techniques employing compaction and sets in 2 minutes. The heater is preset at 90° C and does not require adjustment.

Each cannula has a 22-gauge stainless steel needle that measures 21 mm in length. The needles can be precurved. Cannulas can be disinfected but are not designed for heat sterilization procedures. Heating time varies, but for a cold unit it takes 10 to 15 minutes. In a warm heater the recommended time is 3 minutes. After removing the cannula from the heater the needle should be placed on the hot part of the heater for several seconds. The gutta-percha remains able to flow for 45 to 60 seconds depending on the viscosity.

Calamus

The Calamus flow obturation delivery system (DENTSPLY Tulsa Dental Specialties) is a thermoplastic device equipped with a cartridge system with 20- and 23-gauge needles (see Fig. 10-41). The unit permits control of temperature and also the flow rate. Pluggers are also available for use with the system. The 360 degree activation switch allows great tactile sensation during use.

Elements

The Elements obturation unit (SybronEndo) consists of a System B heat source and plugger as well as a handpiece extruder for delivering thermoplastic gutta-percha or RealSeal from a disposable cartridge (see Fig. 10-42). The cartridges come with 20-, 23-, and 25-gauge needles for gutta-percha and 20- and 23-gauges for RealSeal.

HotShot

The HotShot delivery system (Discus Dental) is a cordless thermoplastic device that has a heating range from 150° C to 230° C (see Fig. 10-43). The unit is cordless and can be used with either gutta-percha or Resilon. Needles are available in 20, 23, and 25 gauges.

GuttaFlow

GuttaFlow (Coltène/Whaledent) consists of a cold, flowable matrix that consists of polydimethylsiloxane matrix filled with very finely ground gutta-percha (see Fig. 10-16). The material is provided in capsules for trituration in an amalgamator. The technique involves injection of the material into the canal and placing a single master cone to length. The material provides a working time of 15 minutes and it cures in 25-30 minutes. Evidence suggests that the material fills canal irregularities with consistency[355] and is biocompatible,[36,95] but the setting time is inconsistent and may be delayed by final irrigation with sodium hypochlorite.[36] Sealing ability appears comparable to other techniques in some studies and inferior in others.[38,169,207,225]

Carrier-Based Gutta-Percha

Thermafil, Profile GT Obturators, GT Series X Obturators, and ProTaper Universal Obturators

Thermafil (DENTSPLY Tulsa Dental Specialties) was introduced as a gutta-percha obturation material with a solid core (Fig. 10-45). Originally manufactured with a metal core and a coating of gutta-percha, the carrier was heated over an open flame. The technique was popular because the central core provided a rigid mechanism to facilitate the placement of the gutta-percha. Advantages included ease of placement and the pliable properties of the gutta-percha. Disadvantages were that the metallic core made placement of a post challenging and retreatment procedures were difficult. In addition, the gutta-percha was often stripped from the carrier, leaving the carrier as the obturating material in the apical area of the canal.

Changes in the carrier systems include the development of a plastic core coated with α-phase gutta-percha (Fig. 10-46) and a heating device that controls the temperature (Fig. 10-47). Obturators are designed to correspond to the ISO standard file sizes, variable tapered nickel–titanium rotary files, and the ProFile GT and GT Series X nickel–titanium rotary files (DENTSPLY Tulsa Dental Specialties) (see Fig. 10-46). Size verifiers are available to aid in selection of the appropriate carrier and should fit passively at the corrected working length (see Fig. 10-45).

As with all techniques, a sealer is required. Grossman formulation sealers and resin sealers consistent with AH-26 and AH Plus are acceptable; however, Tubli-Seal and Wach's paste are not recommended.

Removal of the smear layer is strongly recommended (see Chapter 9) and has been shown to enhance the seal with Thermafil.[25] After drying the canal a light coat of sealer is applied

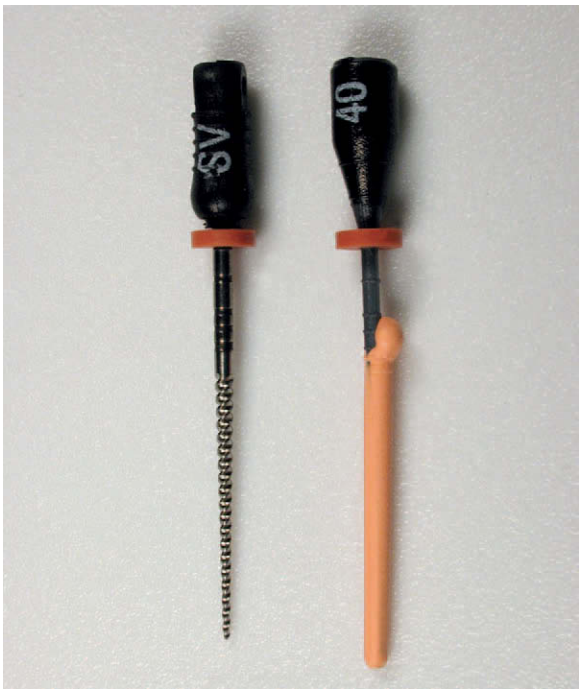

FIG. 10-45 Thermafil carrier and size verifier (DENTSPLY Tulsa Dental Specialties, Tulsa, OK).

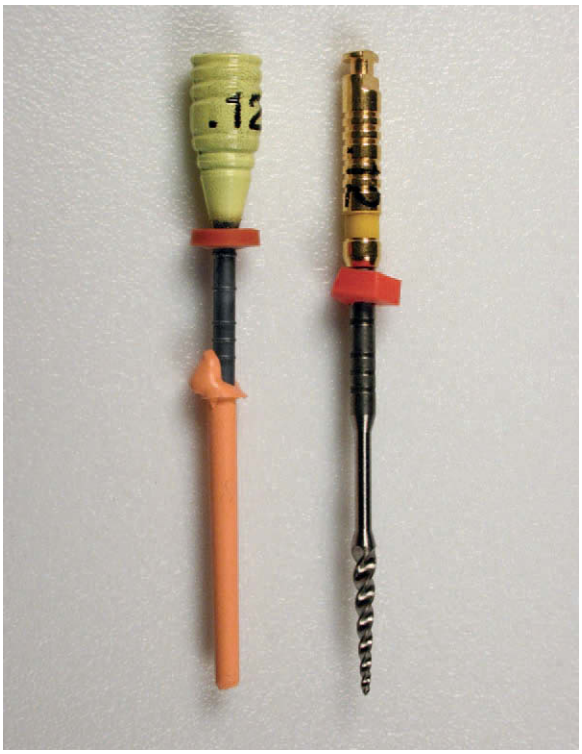

FIG. 10-46 GT obturator and instrument (DENTSPLY Tulsa Dental Specialties, Tulsa, OK).

FIG. 10-48 Thermafil carrier placed in the distal canal.

and a carrier is marked, set to the predetermined length. This is accomplished by using the millimeter calibration markings on the carrier shaft. Markings are made at 18, 19, 20, 22, 24, 27, and 29 mm. Gutta-percha on the shaft that may be obscuring the calibration rings can be removed with a surgical blade or knife. The carrier is disinfected with 5.25% NaOCl for 1 minute and rinsed in 70% alcohol.

The carrier is then placed in the heating device. When the carrier is heated to the appropriate temperature the clinician has approximately 10 seconds to retrieve it and insert it into the canal (Fig. 10-48). This is accomplished without rotation or twisting. Evidence suggests that the insertion rate affects the

obturation. The fill length and obturation of irregularities increase with increasing insertion rates.[186] A rapid insertion rate enhances obturation.[186]

The position of the carrier is verified radiographically. The gutta-percha is allowed 2 to 4 minutes to cool before resecting the coronal portion of the carrier, which can be several millimeters above the canal orifice. This is accomplished by applying stabilizing pressure to the carrier and cutting the device with an inverted cone, round bur, or a specially designed Prepi bur (DENTSPLY Tulsa Dental Specialties). Heated instruments are not recommended for this process because this may result in displacement.

Vertical compaction of the coronal gutta-percha can be accomplished. When necessary, gutta-percha can be added, heat softened, and compacted. An advantage to this technique is the potential for movement of gutta-percha into lateral and accessory canals (Fig. 10-49)[340]; however, extrusion of material beyond the apical extent of the preparation is a disadvantage.[65,73,175]

Pro-Post drills (DENTSPLY Tulsa Dental Specialties) are recommended if post space is required for restoration of the tooth. The unique eccentric cutting tip keeps the instrument centered in the canal while friction softens and removes the gutta-percha and plastic carrier.

When retreatment is necessary the plastic carrier has a groove along its length to provide an access point for placement of a file. Chloroform and hand files can be used to remove the gutta-percha surrounding the carrier. Rotary #.04 and #.06 nickel–titanium files may also be used to remove the obturation materials. Retreatment rotary nickel–titanium files are available in three different sizes to facilitate removal of gutta-percha and the carrier.

FIG. 10-49 Apical obturation of accessory canals by the Thermafil technique. *(Courtesy DENTSPLY Tulsa Dental Specialties, Tulsa, OK. All rights owned by and used with permission from DENTSPLY International, Inc.)*

The plastic carriers are composed of two nontoxic materials. Sizes #20 to #40 are manufactured from a liquid crystal plastic. Sizes #40 to #90 are composed of polysulfone polymer. Both have similar physical characteristics, with the polysulfone carriers being susceptible to dissolution in chloroform.

Successfil

Successfil (Coltène/Whaledent) is a carrier-based system associated with Ultrafil 3D (Fig. 10-50); however, the gutta-percha used in this technique comes in a syringe. Carriers (titanium or radiopaque plastic) are inserted into the syringe to the measured length of the canal. The gutta-percha is expressed on the carrier, with the amount and shape determined by the rate of withdrawal from the syringe. Sealer is lightly coated on the canal walls, and the carrier with gutta-percha is placed in the canal to the prepared length. The gutta-percha can be compacted around the carrier with various pluggers depending on the canal morphology. This is followed by severing of the carrier slightly above the orifice with a bur.

SimpliFill

SimpliFill (LightSpeed Technology, San Antonio, TX/Discus Dental) is gutta-percha or Resilon manufactured for use after canal preparation with LightSpeed instruments (Fig. 10-51). The carrier has an apical plug with 5 mm of gutta-percha. The technique involves fitting a carrier that is consistent with the master apical rotary file (LightSpeed Technology/Discus Dental) to within 1 to 3 mm of the prepared length (Fig. 10-52). The apical gutta-percha plug can be modified by clipping the end in 1-mm increments to obtain an appropriate fit if the plug is too small. Once the cone is fitted it is withdrawn and sealer is applied to the canal walls. AH Plus is recommended. The SimpliFill carrier is slowly advanced to the prepared length. This may require firm pressure. With the plug at the corrected working length the handle is quickly rotated a minimum of four complete terms in a counterclockwise direction to separate the shaft from the apical gutta-percha. The coronal space can then be filled with gutta-percha, using lateral compaction or the warm thermoplastic technique. When using lateral compaction it is recommended that the first cone be the

FIG. 10-50 Successfil is an additional carrier system (Coltène/Whaledent, Cuyahoga Falls, OH).

FIG. 10-52 SimpliFill fitted to 1 to 3 mm from the prepared length.

same size as the SimpliFill carrier. This sectional technique is efficient, and leakage potential is similar to that of other common techniques.[257]

Thermomechanical Compaction

McSpadden introduced an instrument, the McSpadden Compactor, with flutes similar to a Hedström file but in reverse. When activated in a slow-speed handpiece the instrument would generate friction, soften the gutta-percha, and move it apically. Rotary compactors similar in design have been developed and advocated. To increase flexibility the instrument is available in nickel–titanium.

The technique requires fitting a master cone short of the prepared length and applying sealer. A compactor is selected on the basis of the size of the canal and inserted alongside the gutta-percha cone 3 to 4 mm from the prepared length. The handpiece is activated and the gutta-percha is heated by the friction of the rotating bur. The pliable mass is compacted apically and laterally as the device is withdrawn from the canal.

Advantages include simplicity of the armamentarium, the ability to fill canal irregularities,[128,163,191,261,262] and time. Disadvantages include possible extrusion of material, instrument fracture,[218] gouging of the canal walls, the inability to use the technique in curved canals, and heat generation.[23,102,126,199,262,263] Microseal condensers (SybronEndo) are a variation of this product.

Solvent Techniques

Gutta-percha can be plasticized with solvents such as chloroform, eucalyptol, and xylol. Disadvantages include shrinkage caused by evaporation, voids, the inability to control the obturating material, and irritation of periradicular tissues. The Callahan and Johnston technique involved dissolving gutta-percha in chloroform and placing the mixture into the canal with a syringe.[52] A gutta-percha cone was then softened and placed into the canal; the mass hardened as the solvent evaporated. Unfortunately, shrinkage occurred with the evaporation process.[241] The techniques using solvents have been abandoned and replaced with materials and methods that do not exhibit shrinkage.

Pastes

Pastes fulfill some of the criteria outlined by Grossman[115] and can adapt to the complex internal canal anatomy; however, the flow characteristic can result in extrusion or incomplete obturation. The inability to control the material is a distinct disadvantage, and when extrusion occurs it can be corrected only by surgical intervention. In addition, pastes are sometimes used as a substitute for complete cleaning and shaping procedures, and the addition of paraformaldehyde results in severe toxicity.

Immediate Obturation

Apical barriers may be necessary in cases with immature apical development, cases with external apical root resorption, and cases where instrumentation extends beyond the confines of the root. Dentin chips, calcium hydroxide, demineralized dentin, lyophilized bone, tricalcium phosphate, hydroxyapatite, and collagen have been advocated for placement as a barrier in canals exhibiting an open apex. The barriers are designed to permit obturation without extrusion of materials into the periradicular tissues but are often incomplete and do not seal the canal.[255]

Dentin chips appear to confine materials to the canal space during instrumentation/obturation and may encourage development of a biologic seal.[94,255] Enhanced healing, minimal inflammation, and apical cementum deposition have been noted histologically.[224] A concern with this technique is contamination of the dentin with bacteria, because investigators found that infected dentin adversely affected healing.[139]

Calcium hydroxide has also been extensively used as a common apical barrier. Calcium hydroxide has been shown to induce an apical barrier in apexification procedures.

Calcifications similar to dentin plugs have been noted at the apical foramen.[239] Calcium hydroxide has the advantage of being free of bacterial contamination and may provide a better, although imperfect, apical seal.[330]

Immature teeth exhibiting pulp necrosis or teeth with apical resorption traditionally were treated with calcium hydroxide to establish an apical barrier (apexification) before obturation. Studies have demonstrated that teeth treated with calcium hydroxide for prolonged periods are more susceptible to fracture.[9,251] Immediate obturation is an alternative to apexification. An apical barrier material should confine obturation materials to the canal space[94] and enhance healing by inducing cementum and bone formation.[137,224,239] Mineral trioxide aggregate (MTA) (ProRoot MTA; DENTSPLY Tulsa Dental Specialties) has been successfully employed as an apical barrier material before obturation (Fig. 10-53).[279]

After the cleaning and shaping procedures the canal is dried and MTA is placed. The material is compacted into the apical portion of the root to form a barrier. After the material sets, gutta-percha can then be compacted without extrusion (Fig. 10-54). Other investigators found that hand compaction of MTA provided better adaptation to the canal walls with fewer voids when compared with ultrasonic placement.[8] Another investigation reported that ultrasonic placement of a 4-mm apical plug of MTA improved the seal[352] and that placement of a composite resin as the obturation material enhanced the seal and strengthened the root.[178]

MTA is sterile, biocompatible, and capable of inducing hard tissue formation.[92,140] The technique has been shown to be clinically successful and can be accomplished quickly, eliminating the need for numerous visits and possible coronal recontamination during the months required for apexification.[110,185]

Clinical evidence supports this technique. In a study comparing calcium hydroxide with mineral trioxide aggregate in 15 children, each having paired immature teeth with necrotic pulps, two teeth treated with $Ca(OH)_2$ exhibited pathosis on recall examination whereas all the teeth treated with MTA were clinically and radiographically successful.[93] A prospective clinical study found the success rate of MTA barriers and immediate obturation in 43 cases to be 81%.[286] In another study, 85% of 20 teeth with immature apical development were considered healed and 5% were considered healing after immediate barrier placement.[136] The time required for healing is comparable to traditional apexification with $Ca(OH)_2$ and treatment time is reduced.[240]

Another option for treating immature teeth with pulp necrosis involves regenerative techniques including revascularization (see also Chapter 16).[127,317] Advantages include continued increasing thickness of the canal walls, apical root development, and apical closure.[280] The technique involves copious irrigation, minimal canal preparation, and the use of an antibiotic paste as an interim medication. At a subsequent visit bleeding is induced in the canal to induce a clot that is covered with MTA. When the MTA is set a definitive restoration can be placed to ensure a coronal seal.[14]

FIG. 10-53 Mineral trioxide aggregate is available as ProRoot MTA. This material is advocated for use in apexification, repair of root perforations, repair of root resorption, root-end fillings, and pulp capping. *(Courtesy DENTSPLY Tulsa Dental Specialties, Tulsa, OK. CORONAL ORIFICE SEAL

No matter which technique is used to obturate the canals, coronal microleakage can occur within a short time through seemingly well-obturated canals,[56,314] potentially causing infection of the periapical area. Early research efforts focused on the quality of the seal in the apical part of the root canal system to prevent percolation of apical fluids. However, contemporary research efforts have identified the importance of maintaining a coronal seal to prevent bacterial leakage.[149] Leakage studies indicate that the coronal seal can be enhanced by the application of supplemental restorative materials over the canal orifice[237,250,331] and by placing a definitive coronal restoration as soon as is feasible.[244]

Cavit (Premier Dental Products, Plymouth Meeting, 3M Espe Dental Products) has traditionally been advocated as an acceptable material. One study demonstrated that placement of 3.5 mm of Cavit or SuperEBA cement (Bosworth, Skokie, IL) decreased bacterial leakage by 85% and 65%, respectively, when compared with unsealed controls, which all leaked at 45 days.[237] In an animal study in which the access openings were left open for 8 months, placing a dentin-bonded composite resin or IRM in the orifice decreased periapical inflammation from 89% for teeth without orifice plugs to 39% with plugs.[350] Another study demonstrated in a dog model that MTA placed in the orifice decreased inflammation in teeth inoculated with bacteria.[194]

Another method to retard leakage through the obturated canal, should failure of the coronal restoration occur, is to cover the floor of the pulp chamber with a lining of bonded material after removal of excess gutta-percha and sealer to the canal orifice.[26,58,181] This results in the formation of a hybrid layer with microtags of resin in the tubules. A resin-modified glass ionomer cement is placed approximately 1 mm thick over the floor of the pulp chamber and polymerized with a curing light. Investigators found that this procedure resulted in none of the experimental canals showing bacterial leakage at 60 days.[60]

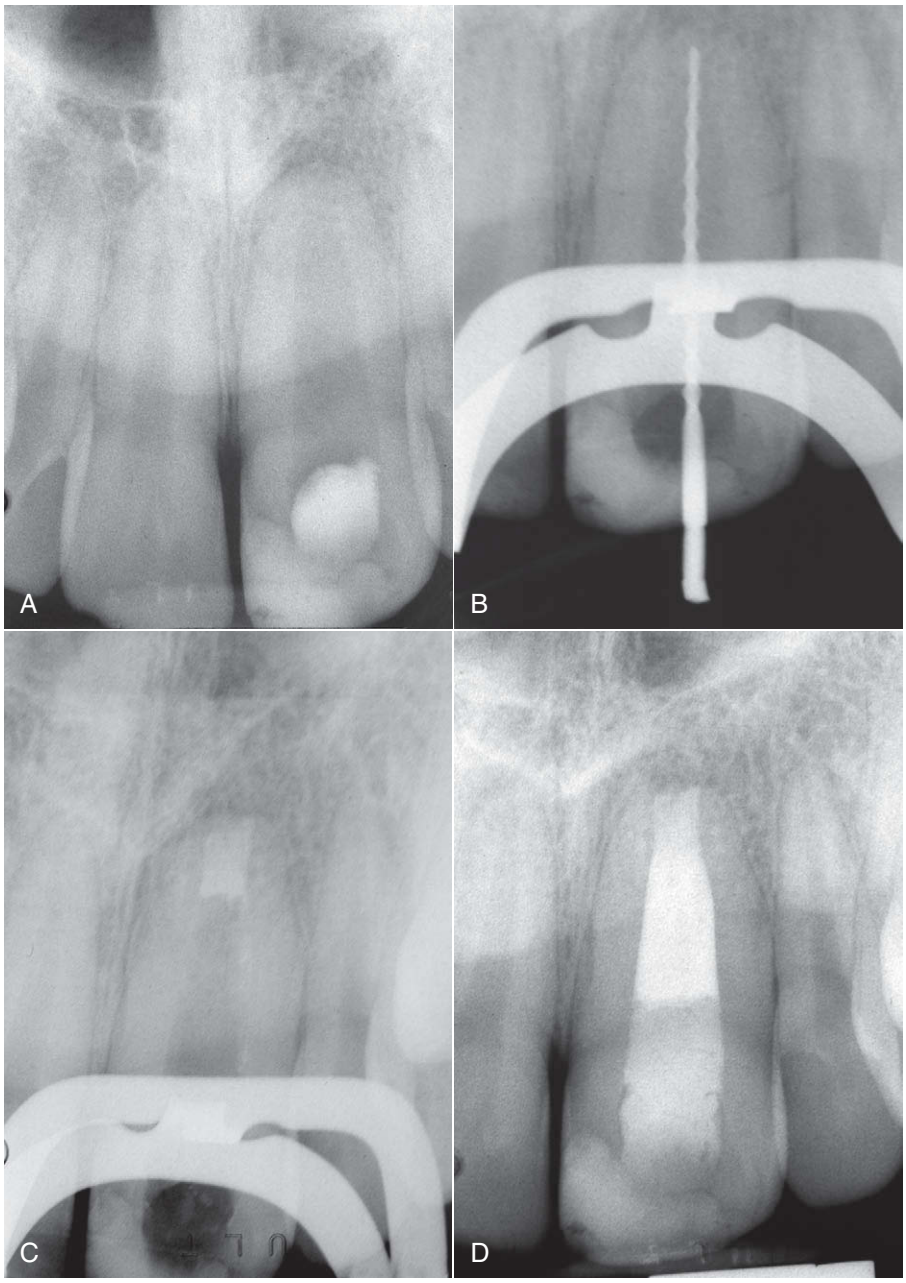

FIG. 10-54 Immediate obturation employs a barrier technique to prevent extrusion when the apex is open. This case involves a maxillary left central incisor with pulp necrosis caused by trauma. **A,** Pretreatment radiograph demonstrates a large canal with an open apex. **B,** Working length is established and the canal is prepared. **C,** Mineral trioxide plug is placed. **D,** The canal is obturated with gutta-percha.

Infective Endocarditis

ENDODONTIC RECORD EXCELLENCE

Importance

Endodontic therapy records serve as an important map to document and guide the clinician's journey down the correct diagnostic and treatment path. Documentation is essential to attaining endodontic excellence.

The dental record must contain sufficient information to identify the patient, support the diagnosis, justify the treatment, and document the course and result of treatment. Records also are fundamental means of communication among health care professionals, designed to protect the patient's welfare.

Content

Endodontic treatment records should include the following information:

1. Name of patient
2. Date of visit
3. Medical (periodically updated) and dental history
4. Allergies and adverse drug reactions
5. Chief complaints
6. Radiographs of diagnostic quality
7. Pulpal and periodontal tests performed
8. Clinical examination findings
9. Differential and final diagnoses
10. Treatment plan
11. Prognosis
12. Referrals, including patient refusals (if any)
13. Communications with other health care providers
14. Progress notes (including complications)
15. Completion notes
16. Canceled or missed appointments and stated reasons
17. Emergency treatment
18. Patient concerns and dissatisfactions
19. Planned follow-ups
20. Drug and laboratory prescriptions
21. Patient noncompliance
22. Consent forms
23. Accounting
24. Recall notifications
25. Author name or initials for each treatment entry
26. E-mail address
27. Emergency contact persons and addresses
28. Phone number including home, work, and cell

Function

Dental records should document the following information:

1. Course of therapy by recorded diagnosis, informed consent, treatment, and prognosis
2. Communications among the treating clinician, other health care providers, consultants, subsequent treating practitioners, and third-party carriers
3. Necessity and reasonableness of diagnosis and treatment capable of peer review and dental insurance carrier evaluation
4. Standard of care compliance
5. Adverse reactions or events with explanation
6. Follow-up comments to medical history–positive responses

Patient Information Form

A patient information form provides essential data for patient identification and office communication. The patient's name; home, business, e-mail addresses; and telephone and fax numbers are needed to contact the patient for scheduling purposes and inquire about postoperative sequelae.[144] Location information about the patient's spouse, relative, or a close friend who can be notified in an emergency is also suggested. In the event the patient is a minor, the responsible parent or guardian should provide the information. Questions about dental insurance and financial responsibility are included on the form to avoid any later misunderstandings and help fulfill federal requirements of the Truth in Lending Law, applicable if four or more installment payments are arranged (whether or not there are interest or late-payment charges).[79] Patient information should be updated periodically (Fig. 11-1).

Medical Health History

Past and present health status should be thoroughly reviewed by the clinician before proceeding with treatment so that dental treatment can be safely initiated. Health questionnaires open avenues for discussion about problems of major organ systems and important biochemical mechanisms, such as blood coagulation, allergy, immunocompromised status, need for antibiotic prophylaxis, and disease susceptibility. The clinician may request that the patient be examined by a physician or undergo laboratory testing under medical supervision to determine whether a suspected medical problem may require attention before endodontic therapy proceeds or if drug sensitivity or allergy mandates treatment modifications.[29,135,152] Current medications, medical therapy, and the name and location of the treating physician are essential.

Medical histories must be updated periodically (or at least annually or sooner as the need arises). The patient should be asked to review the previous and current medical history (Fig. 11-2). If no changes are necessary, the patient should date and sign the history form. If any changes occurred, the patient should identify each updated medical change, the date, and sign the form where indicated for medical update information. Periodically the patient should provide an entirely new updated form rather than changing data on the old form. Earlier medical histories should be retained in the chart for future reference. If physician communication for treatment occurs, the clinician should record such contacts. In addition, the clinician should verify physician approvals for treatment by fax, with

TELL US ABOUT YOUR MEDICAL HISTORY

First Name: _____ Last Name: _____

How would you describe your health? Please circle one. Excellent Good Fair Poor

When did you have your last physical examination? _____

Are you currently being treated for any illness or medical condition? Yes ____ No ____

If yes, please describe: _____

_____

Who is treating you for this condition? _____

Have you ever had any kind of surgery? Yes ____ No ____

When did you have this surgery? _____

What type of surgery did you have? _____

Have you ever had any trouble with prolonged bleeding after surgery? Yes ____ No ____
Do you wear a pacemaker or any other kind of prosthetic device? Yes ____ No ____
Are you taking any medication or drugs at this time? Yes ____ No ____
Have you ever taken Fen-phen and/or Redux (diet drugs)? Yes ____ No ____
What medications, drugs, or herbs are you taking?

_____

Why are you taking these medications? _____

_____

Have you ever had a reaction or complication to a local anesthetic or drug (like penicillin)? Yes ____ No ____

If yes, please explain: _____

Please circle any present or past illness you now have or had in the past:

Alcoholism	Blood pressure	Epilepsy	Hepatitis	Kidney or liver	Rheumatic fever
Allergies	Cancer	Glaucoma	Herpes	Mental	Sinusitis
Anemia	Diabetes	Head/neck injuries	Immunodeficiency (HIV)	Migraine	Ulcers
Asthma	Drug dependency	Heart/valve disease	Infectious diseases	Respiratory	Venereal disease

Are you allergic to Latex or any other substances or materials? Yes ____ No ____

If so, please explain. _____

If female, are you pregnant? Yes ____ No ____

Is there any other information that should be known about your health? _____

_____

Signature of Patient (or Parent) _____ Date _____

FIG. 11-2 Medical history form.

verification of receipt or letter or preferably both, and retain copies in the chart.

Updating the medical history requires the practitioner to be apprised of changes in the patient's medical condition and any new medications the patient is taking, including over-the-counter or herbal medications and/or supplements. A patient untrained in medical science may not appreciate the fact that new medications may suggest new diseases or changes in existing disease status. For instance, certain regurgitating valvular heart diseases may require antibiotic prophylaxis.[269] New medications may also cause a synergistic effect with other medications the patient is using or another treating clinician is prescribing.

Clinicians who pass the buck by claiming, "Oh it was my secretary or my new assistant—I could do nothing about it," are nonetheless legally liable for their staff's actions or inactions.[270] A clinician exclusively relying on staff members to obtain medical histories in a waiting room full of patients is making a mistake, because the accuracy of the histories must first be checked and then followed up by the clinician. Training and monitoring staff are duties clinicians cannot afford to ignore. President Harry Truman's sage advice, "The buck stops here," applies to treating clinicians who overdelegate to nonclinician staff members who lack the requisite dental education for adequate medical history follow-up.

Dental History

The dental history should include past dental difficulties, name and address of current or most recent treating clinician, chief complaint (including duration, frequency, type and intensity of any pain), relevant prior dental treatment, and attitude regarding teeth retention. Positive responses suggest further patient consultation and consideration for obtaining records (by written release) for elucidation from the patient's previous and/or present treating clinician.[188] After receiving positive responses, the clinician may also wish to obtain prior and concurrent treaters' radiographs for current comparison and notes of any progressive changes (Fig. 11-3).

Diagnostic and Progress Records

Diagnostic and progress records often combine fill-in and check-off types of forms. Fill-in or essay-type forms allow greater latitude of response to a question, resulting in a more detailed description. However, one drawback to these forms is that they are open to oversights unless a clinician is very conscientious in following up with further clinical information.

Using only an essay-type health history is insufficient. Often a patient may not appreciate the significance of important symptoms. A check-off format is efficient and more practical. Forms with questions that reveal pertinent data alert the clinician to medical or dental conditions that warrant further consideration or consultation.[29] Moreover, such records can document any missing medical information the patient failed to provide orally. At the end of the check-off portion of the medical history, an essay question allows the patient to provide any omitted pertinent medical information or elaborate on check-marked items.[221,231]

Electronic Records

Electronic records represent current methodology for recording patient information (see Chapter 28 for details).[246] Several safeguards are essential for their use. First, patient confidentiality and security must be protected. Consider using AES encryption with at least 2048 bit key. Be certain that only the clinician and authorized staff view patient data in conformance with the Health Insurance Portability and Accountability Act (HIPAA) security standards, effective April 2005.[120] Second, data backup of patient records, including digital radiographs and account ledgers, should be stored off-site. The entire hard drive should be periodically backed up for additional protection.[70] Multiple copies of the backup data should be stored in more than one geographic location, and fault protection such as RAID Level 1 or 5 should be installed to prevent data loss.

Radiographs

Radiographs are essential for diagnosis and also serve as additional documentation of the patient's pretreatment condition. A panographic radiograph is not diagnostically accurate for endodontics and therefore should be used only as a screening device (see Chapter 5).[114,219,279] Diagnostic quality periapical plain-film or digital radiographs are essential aids for diagnosis, for working films (e.g., measuring the length of root canals, fitting gutta-percha cones), to verify the final fill, and for follow-up comparisons at recall examinations. Therefore the clinician should retake any radiographs that lack diagnostic quality and retain all radiographs.

Digital radiography is recommended because it increases endodontic efficiency. No developing time is needed, so procedural radiographs can be viewed instantly and approved or retaken with little time in between (no downtime is required to wait for a film to exit the film processor). Newer digital x-rays with improved sensor technology use high-resolution CCD (charged coupling device) chips rather than CMOS (complementary metal-oxide semiconductor) technology, and provide close-up zooming with improved image quality as described in Chapter 29.

Evaluation and Differential Diagnosis

Diagnosis includes evaluating pertinent history of the current problem, clinical examination, pulpal testing, periodontal probe charting, and recorded radiographic results. If therapy is indicated, the reasons should be discussed with the patient in an organized way. When other factors affect the prognosis (e.g., strategic importance or restorability of the tooth), the clinician should consider further consultation with the referring clinician or specialists, including a prosthodontist, periodontist, or both, before initiating endodontic treatment.

Diagnosis is essential in treatment decisions. Recommending extractions for undiagnosed pain etiology is generally contraindicated. Chronic idiopathic orofacial pain warrants referrals and consultation with other health care professionals, lest wholesale extractions worsen the patient's dental state and not relieve pain (see Chapter 3).[5] For instance, in a long-term follow-up study of patients with chronic facial pain and without recognizable odontologic pathosis, some patients were subsequently diagnosed with maladies ranging from cracked-tooth syndrome to medication-mediated illnesses.[5] Accordingly, referral to other specialists is essential, lest a patient be misdiagnosed with idiopathic or atypical facial pain when instead, pain etiology was misdiagnosed. Cone-beam computerized tomography (CBCT) has greatly aided diagnosing pain sources caused by root fractures and incompletely filled, overfilled, or

TELL US ABOUT YOUR DENTAL SYMPTOMS

First Name: _____ Middle Initial:_____ Last Name: _____

1. Are you feeling any pain at this time? If not, please go to Question 5. Yes ____ No ____
2. If yes, where is the pain located?_____ Any pus? Yes ____ No ____
3. When did you first notice any symptoms?_____
4. Did symptoms occur suddenly or gradually? _____
5. Please check the intensity, frequency, and quality of the discomfort, which most closely describes your pain:

INTENSITY	FREQUENCY	QUALITY
(On a scale of 1 to 10) 1 = Mild, 10 = Severe		
1 __ 2 __ 3 __ 4 __ 5 __ 6 __ 7 __ 8 __ 9 __ 10 __	__ Constant __ Intermittent __ Momentary __ Occasional	__ Sharp __ Dull __ Throbbing

6. Is there anything you can do to relieve the pain? Yes ____ No ____

   If yes, what? _____
7. Is there anything that provokes pain or that you do to cause the pain to increase? Yes ____ No ____

   If yes, what? _____
8. When eating or drinking, is your tooth sensitive to: Heat ____ Cold ____ Sweets ____
9. Does your tooth hurt when you bite down or chew? Yes ____ No ____
10. Does it hurt if you press the gum tissue around this tooth? Yes ____ No ____
11. Does a change in posture (lying down or bending over) cause your tooth to hurt? Yes ____ No ____
12. Do you grind or clench your teeth? Yes ____ No ____

    If so, do you wear a splint or night guard? Yes ____ No ____
13. Has a restoration (filling or crown) been placed on this tooth recently? Yes ____ No ____
14. Prior to this appointment, has root canal therapy been started on this tooth? Yes ____ No ____
15. Any recent or past trauma or injury to this tooth? Yes ____ No ____

    If the answer to the preceding question is yes, describe recent or past trauma and occurrence date.

    _____
16. Is there anything else we should know about your teeth, gums, or sinuses that would assist us in our diagnosis or treatment? _____

missed extra canals that two-dimensional (2D) periapical imaging may obscure.*

Fig. 11-4, *A-B* demonstrates the advantage of CBCT three-dimensional (3D) imaging compared to 2D imaging. In *A*, the nail appears inside the cranium, contrasted with *B*, which shows the nail taped outside the skull.

Diagnostic Tests

Sound endodontics begins with a proper diagnosis. Otherwise, unnecessary or risky treatment with compromised prognosis follows. Generally, as described in greater detail in Chapter 1, the following endodontic tests should be performed to arrive at a correct and accurate endodontic diagnosis:

1. Percussion
2. Thermal testing
3. Electrical testing (optional)
4. Palpation
5. Mobility
6. Periodontal assessment (pockets, mobility, furcations)

Both positive and negative pulpal testing results should be recorded. Juries, peer-review committees, and insurance consultants often disbelieve unrecorded test results. Uncharted test findings may be regarded as never having been done. Consequently, reasonable clinicians should record all testing results, both positive and negative.

Treatment Plan

Treatment records should contain a written plan that includes all aspects of the patient's oral health. Treatment plans should be coordinated, preferably in writing, with other concurrent or jointly treating clinicians. If an aspect of the patient's care is not under direct supervision, the clinician is proceeding improperly. Also, the clinician should initiate contact with the other treating clinician. The patient should also be advised of the problem. For instance, endodontic treatment will probably fail if underlying periodontal pathosis is ignored or untreated, so the clinician should assess the patient's entire dentition, not just a single root canal system. The clinician should also recommend a periodontal consultation to both the patient and referring clinician if periodontal therapy is required. Follow the maxim: If you fail to plan, plan to fail.

Examination

After gathering the dental and medical history, findings obtained from the various phases of the clinical and radiographic examinations are recorded as shown in Fig. 11-5. Lists in each category afford the clinician a systematic format for recording details pertinent to an accurate diagnosis. Appropriate descriptions are circled, followed by the necessary notations in the accompanying spaces. Tabular arrangement allows easier recording and comparison of diagnostic test data acquired from one tooth on different dates or from different teeth on the same visit. A pain intensity index (i.e., 0 to 10) or pain classification (i.e., mild +, moderate ++, severe +++) should be used to differentiate diagnostic test results.

Diagnosis

Careful analysis of accumulated examination data should result in the determination of an accurate pulpal and periapical diagnosis. Clinical conditions and the probable etiologic factors for the presenting problem are circled. Alternative modalities of therapy are considered and analyzed. The recommended treatment plan is circled, followed by a prognostic assessment of the intended therapeutic course.

Patient Consultation

Patients should be advised of each diagnosis and should consent to the treatment plan before therapy is instituted. Consultation should include an explanation of reasonable alternative treatment approaches and rationales and treatment consequences of each alternative therapy, including risks from nontreatment or delayed treatment that may affect the outcome of intended therapy. Such discussion is documented by completing the checklist items.

FIG. 11-5 Diagnosis and treatment form.

Treatment

All treatment provided on a given date is documented by placing a check mark (✓) within the designated procedural category. Only the most frequent retreatment procedures are included for tabulation. Descriptions of occasional procedures or explanatory treatment remarks should be entered in writing. A separate dated entry should be made for each patient visit, phone call, e-mail message, and fax communication (e.g., consultations with the patient or other clinicians) or correspondence (e.g., biopsy report, treatment completion letters).

Individual root canal lengths are recorded by (1) circling the corresponding anatomic designation and the method of length determination (e.g., radiograph or electronic measuring device), (2) writing the measurement (in millimeters), and (3) indicating the reference point. For any medication prescribed, refilled, or dispensed, the treatment record should show the date and type of drug (including dose, quantity, and instructions for use) in the treatment table under the heading "Rx." Fig. 11-6 also gives a sample medication log. Periodic recall intervals, dates, and findings are entered in the spaces provided.

If the scope of the examination or treatment is intentionally limited, such as a screening examination or emergency endodontic therapy, the limited scope of the visit should be recorded. Otherwise, the chart appears as if the examination was superficial and treatment incomplete. If a suspicious apical lesion requires subsequent reevaluation, the clinician should record the future reevaluation date and differential diagnosis (e.g., "Small apical lesion on #28. Reevaluate for changes in 2 months. Also, check for any root fractures."). If this is not done, it appears (on the chart) as if the clinician ignored a potentially pathologic condition, such as suspected root fracture. A soft-tissue examination (including cancer check) is a standard part of any complete dental examination. E-mail prescriptions and correspondence should be documented with hard copies in the chart unless virtually all treatment records are stored in electronic format.[154,246]

Informed Consent Form

After endodontic diagnosis, the benefits, risks, treatment plan, and alternatives to endodontic treatment—including any patient refusal of recommended treatment and consequences of refused treatment—should be presented to the patient or the patient's guardian. This will document acceptance or rejection of treatment recommendations. The patient or guardian, along with a witness (who can be a staff member), should sign and date the consent form. Any informed-consent video should similarly be noted. Subsequent changes in the proposed treatment plan should also be discussed and initialed by the patient to indicate continued acceptance and acknowledge the patient's understanding of any newly disclosed risks, alternatives, or referrals.

Despite a patient's confirmed signature on an informed consent form, a jury is free to believe that the patient never read the informed consent form's content before signing. For instance, the patient may claim it was impossible to have read the consent form, because he or she did not have reading glasses when signing, and no clinician ever explained the form contents. Another frequent factual scenario is when the patient claims the staff stated it was a standard consent form that was a mere procedural formality requiring patient signature, rather than a detailed informed consent form. Consequently, numerous legal cases have been lost at trial on the issue of inadequate informed consent despite a signed patient consent form.

To obviate a patient's claim that no explanation ever occurred, a patient questionnaire can additionally be used. Patients can be instructed that unless they score 100%, proposed procedures will not be done (because patient understanding is imperative and essential for cooperation, including postoperative care). To be effective, the patient questionnaire should be relatively short and simple (Fig. 11-7). Also, the patient should be given an opportunity to correct any incorrect answers after the clinician reviews with the patient the reasons why the patient answered incorrectly. Note that the majority of answers are false. This precludes a patient from guessing the correct answer by assuming that all test questions are necessarily true.

Treatment Record: Endodontic Chart

Chart

A suggested chart is presented in Fig. 11-8 to facilitate recording of information pertinent to the diagnosis, recommendations, and treatment of the endodontic patient. Systematic acquisition and arrangement of data from the patient questionnaire, along with clinical and radiographic examinations and careful recording of treatment performed, expedites accurate diagnosis and maximizes clinician efficiency. Suggested chart format and use are described in the sections that follow.

General Patient Data

Patient name, address, phone numbers, referring clinician, and chief complaint are printed or typed in the corresponding space at the patient's initial office visit. The patient's appointment and financial record are divided into two parts as follows:

1. The treating clinician or staff completes the first portion after the diagnosis and treatment plan have been formulated and presented to the patient. Tooth number and quoted fee are posted. Treatment plan is recorded by circling the appropriate description. Under "Special Instructions," specific treatment requests by the referring clinician are circled. Details of planned adjunctive procedures (e.g., hemisection, root resection) may be written in the adjacent space, along with information from the patient data section. The clinician can then use this for general reference during future treatment. The secretary or treatment coordinator can also use this information when scheduling appointments and establishing financial arrangements.
2. Business personnel complete the second portion. Financial agreements, third-party coverage, account status, and appointment data, including the day, date, and scheduled procedure, are recorded.

Either the clinician or the assistant may complete portions of the diagnosis and treatment sections, but *the clinician should review and approve all entries.*

Dental History

Chief complaint should include whether the patient is symptomatic at the time of examination and/or recent past. Narrative facts regarding the presenting problem are then recorded. Additional details of the chief complaint obtained during

successive questioning are recorded by circling the applicable word within each symptom parameter. The pain intensity index (i.e., 0 to 10) or pain classification (i.e., mild +, moderate ++, severe +++) should be registered alongside the appropriate description. For accurate assessment of the effects of prior dental treatment pertaining to the examination site, a summarized account of such procedures should be documented. In addition, all pretreatment signs and symptoms should be described. It is essential that the patient comprehend all communications with the clinician and staff. If there is any language comprehension difficulty, the clinician should ask the patient whether he or she understands completely the language the clinician is speaking. To verify patient comprehension, the clinician should ask the patient to repeat important information that has been conveyed. A clinician- or patient-provided interpreter may be necessary if language problems exist.[57]

Medical History

More medical history information is obtained from a patient-administered questionnaire than from the clinician obtaining an oral history solely from the patient.[29,231] Maximum

ENDODONTIC INFORMED CONSENT QUESTIONNAIRE

In order to help your understanding of endodontic benefits, risks, and alternatives, please answer the following questions by checking the true box if the statement is correct and the false box if the statement is incorrect. In the event that your answers suggest the need for further explanation, Dr. Cohen will review root canal treatment (and options) with you and answer any questions.

Please feel free to ask questions so that you may feel comfortable with your understanding of the surgical endodontic procedure on tooth number 19 and your consent to endodontic surgery.

	True	False
1. Endodontic surgical success is guaranteed.	☐	☐
2. Since endodontic surgery is carefully done, there is no chance of any infection occurring after surgery.	☐	☐
3. As with any surgical procedure involving the human body, there are associated risks. One of these risks is numbness of the lower lip or chin on the side that the surgery is done. Any numbness is usually temporary but, on rare occasions, it can be permanent.	☐	☐
4. Daily oral hygiene care after endodontic surgery is unnecessary.	☐	☐
5. Dr. Cohen is unavailable for emergency calls after business hours.	☐	☐

I understand that I may ask Dr. Cohen any question I may have regarding endodontics at any time. Dr. Cohen has answered all of my questions, if any, to my satisfaction.

FIG. 11-8, cont'd B, Diagnosis and treatment form with notes.

information is obtained if the clinician reviews with the patient the written health history form the patient has completed.

Information (e.g., personal physician's name, address, and phone number; patient's age; date of last medical examination) is recorded for reference. The clinician can obtain a detailed medical history by completing a survey of common diseases and disorders along with a comprehensive review of corresponding organ systems and assorted pathologic conditions. Specific entities that have affected the patient are circled. Essential remarks regarding these entries (e.g., details of consultations with the patient's physician) should be documented on an attached blank sheet with dated treatment notes attached to the back of the chart (see Fig. 11-2). A review of the patient's medical status (including recent or current conditions, treatments, and medications) completes the medical history. Updated medical histories which the patient signs or initials should be done at least annually and at reevaluation visits.

Drug History

A current drug history, both written and oral, is necessary to alert the clinician to any potential for interaction between any newly prescribed drugs and any other medication, supplements or over-the-counter medication the patient is already taking.

In patients aged 57 through 85, 40% potentially are at risk of a major drug reaction—half involving various prescription medications and the other half anticoagulant drug reactions. About half of prescription users also concurrently take over-the-counter medications plus dietary supplements.[153,196]

Risks of drug interactions or side-effects incidence may not be discovered and/or appreciated in premarket research-controlled drug trials for newly marketed drugs, despite FDA approval. For example, rofecoxib (Vioxx) was withdrawn from the market in September 2004 after increased incidences of myocardial infarcts and strokes manifested in a postmarket research study of 2600 patients. Merck's voluntary recall followed an FDA researcher's claim that the FDA tried to ostracize and intimidate him after he raised safety concerns over Vioxx.[21] Currently, pharmaceutical manufacturers budget more for marketing than research and development.[96] Some drug manufacturers have suppressed publication of adverse research.[38,170,272] U.S. Senators Chuck Grassley (R, IA) and Herb Kohl (D, WI) are probing the financial relationships among the drug industries, health care prescribers, and researchers (Senate Bill 2029 [http://thomas.loc.gov]). If their Physician Payments Sunshine Act passes, it would require companies to disclose payments to medical/dental professionals who tout their drugs in seminars or publications.

For newly marketed drugs, the small number of premarket patients studied may lack sufficient statistical power to expose serious side effects that occur infrequently but are nonetheless life threatening.[272] For instance, mibefradil (Posicor) was withdrawn from the market after 1 year because it increased plasma concentrations of 25 other coadministered drugs, including erythromycin.[196,197] In another example, the popular prescription nighttime heartburn drug, Propulsid (cisapride), was linked to 70 deaths and more than 270 significant negative reactions.[263] Other examples include the risk of esophageal cancer with bisphosphonate[272] and bisphosphonate-associated osteonecrosis.[69,232] In 2008, the FDA added a black box warning label for Levaquin-associated risks of tendonitis (www.levaquin.com/levaquin/medication).

FDA Drug Approval

Until 1962, drug companies were allowed to promote their products for any use so long as they were shown to be "safe" for one use. Manufacturers were marketing drugs with serious side effects for minor conditions and to vulnerable populations, resulting in many injuries and deaths. Ineffective drugs were the rule rather than the exception. When a retrospective review of all drugs was conducted after 1962, the National Academy of Sciences found that fully 80% of the uses for which drugs were being promoted could not be shown to be effective. Since 1962, the FDA has required prescription drug manufacturers to demonstrate safety and efficacy with animal and randomly controlled research trials conducted with FDA-approved protocols. FDA "approval" to market new drugs for specific uses is termed *premarket approval* (PMA).

In a New Drug Application (NDA) to the FDA, findings from many clinical studies are done to assess a new drug's efficacy and safety and to gain the FDA's PMA to market the drug. An NDA judges whether the proposed new drug (1) causes more good than harm (benefit outweighs the risk), (2) is comparatively more effective than already existing marketed drugs, or (3) has unreasonably frequent and/or severe side effects (risk outweighs the benefit).[23,257]

In 2008, $58 billion in privately funded drug research was approximately twice the basic federal medical research budget and encompassed an estimated 50,000 clinical trials among 2.3 million patients. Medicare drug spending is forecast to grow from 2 billion in 2000 to 153 billion in 2016, a 7550% increase.[199] In 2007, one in seven U.S. residents younger than age 65 skipped prescribed medications because of rising prescription cost.[81,123]

The Pharmaceutical Research and Manufacturers Association of America has created an online database that summarizes clinical study results involving hundreds of prescription medicines. Notwithstanding, the sheer volume of clinical testing has overwhelmed the FDA's ability to independently assess commercial trials and make all test results public. Deceptive marketing, unreported side effects, and hidden payments to medical/dental researchers highlight the gap between the number of clinical trials conducted and the number published.*

Comprehensive clinical data filed with the FDA for gaining market approval of a new drug (PMA) forms the basis for safety information that accompanies every prescription label.[86,88]

For the first time, under a new federal law[89] effective in 2009, researchers in PMA trials will have to post their basic research results publicly on a federal online registry maintained by the National Library of Medicine. However, new registry regulation will only cover new tests, not tests with poor results done prior to the effective date of the new law. Moreover, findings are not independently FDA verified. Instead, the FDA relies on the manufacturer's submitted trial data research.

Until September 2007, researchers only had to report the start of a clinical trial and was under no federal legal obligation

*References 14, 147, 159, 178, 207, 216, 222, 229, 239, 254, and 272.

to report the outcome in the FDA's registry or in a peer-reviewed journal. Consequently, clinical data on health risks could be downplayed or benefits extolled selectively in any one of 5200 peer-reviewed biomedical journals.[254,273]

By January 31, 2009, as a voluntary patient guide, the federal registry (www.clinicaltrials.gov) logged 67,000 studies. The results of all drug trials that were ongoing on or after September 27, 2007, must be reported at ClinicalTrials.gov if the products under study have FDA approval. The results for drugs not yet receiving FDA approval do not have to be posted. A deficiency of the current law is that the results of older trials of drugs that were FDA approved before September 27, 2007, and that were no longer the subject of ongoing trials on or after September 27, 2007, do not need to be posted. Such drugs constitute the vast majority of current prescription drugs. The FDA considers much of the data on clinical trials it receives from sponsors—and its own analyses of these data—to be "confidential commercial information." FDA drug-trial information released to the public is frequently heavily redacted. Redacted disclosure occurs in response to one or multiple requests made under the Freedom of Information Act, but usually only after a prolonged delay. The FDA Amendments Act of 2003 Section 916 institutionalizes this limitation by mandating that the FDA publish on its website key information related to approval of an application for a drug that contains a previously approved active ingredient only after it has received three Freedom of Information Act requests.

In a 2008 University of California, San Francisco (UCSF) study of 164 clinical trials testing 33 different drugs submitted for FDA approval, approximately one in four had yet to be published.[216] Virtually all of the unpublished findings were negative. The UCSF study also reported that in 900 FDA filings involving 90 new drugs, more than half the clinical trials were still unpublished 5 years after the drug had FDA approval. UCSF researchers who reviewed the FDA's regulatory paperwork for dozens of recently FDA-approved (PMA) drugs found that in some clinical trials previously reported to the FDA, when subsequently submitted for publication, conclusions were changed, statistics revised, and outcomes altered to make treatments appear more effective. Among 43 outcomes reported in the FDA filings that did not favor a drug, 20 were never published. In four out of five instances in which the statistical significance of findings were changed from the FDA filing, the published version was more favorable. Positive effects of a new drug were more likely to be submitted for publication than those reporting negative findings. Basic principles of evidence-based practice requires the analysis of all data. Publishing only some results but not others undermines the ability to adequately assess a product's safety and efficacy, which is FDA's standard for FDA approval of drugs or devices.

Journals want to sell journals. Companies wish to increase profits. Researchers promote career advancements and seek research funding. Consequently, conflict potentials are pervasive. To offset these temptations, failure to timely report basic data about clinical test results in the federal public registry can subject researchers to fines of $10,000 a day and/or loss of their federal research funding (Public Health Service Act Section 302[J]).[86,273]

In 2009, the Government Accounting Office (GAO) concluded in GAO's 2009 High-Risk Series, *FDA Oversight of Medical Products*[259]:

> *New Laws, the complexity of items submitted to FDA for approval, and the globalization of the medical products industry are challenging FDA's ability to guarantee the safety and effectiveness of drugs, biologic, and medical devices. As a result, the American consumer may not be adequately protected from unsafe and ineffective medical products. FDA needs to improve the data it uses to manage the foreign drug inspection program, do more inspections of foreign establishments that manufacture drugs or medical devices, more systemically review the claims made in drug advertising and promotional material, and ensure that drug sponsors accurately report clinical trial results.*

Globalization of clinical research is a relatively recent phenomenon. The number of countries serving as trial sites outside the United States more than doubled in 10 years. Conversely, the proportion of trials conducted in the United States and Western Europe decreased.[100] Clinical testing in developing countries help overcome stringent FDA regulatory barriers for FDA drug approval.[16]

Wide disparities in education, economic and social standing, and health care systems may jeopardize the rights of research participants in foreign countries. Foreign participants may lack understanding of the investigational nature of therapeutic products and/or the use of placebo research participant groups. In some places, financial compensation for research participation may exceed participants' annual wages. Standards of health care in developing countries may also allow ethically problematic study designs or clinical research trials that would not be allowed in wealthier countries. In one study, only 56% of the 670 researchers surveyed in developing countries reported that their research had been reviewed by a local institutional review board or health ministry.[128] In another study, 90% of published clinical trials conducted in China in 2004 did not report ethical review of the protocol, and only 18% adequately discussed informed consent.[280]

Developing countries will also not realize the benefits of clinical research trials if the drugs being evaluated do not become readily available for host-country research participants after FDA approval is obtained.[16] The Declaration of Helsinki includes an expectation that every patient enrolled in a clinical trial should, at the end of the trial, be assured access to the best proven therapy identified in the research study.

Geographically distinct populations can have different genetic profiles; such differences have been shown to be related to the safety and effectiveness of drugs and medical devices. For example, a study of 42 genetic variants associated with pharmacologic response in drug studies showed that more than two thirds had significant differences in frequency between persons of African ancestry and those of European ancestry.[105] Genetic diversity is often not considered in study design and interpretation and in the reporting of trial results.

From fiscal 2002 through 2007, the FDA issued 15 warning letters to foreign companies with serious deficiencies, but the agency only reinspected four of the companies, and then only 2 to 5 years later. Decades ago, most pills consumed in the United States were made here. But like other manufacturing operations, drug plants have been moving to Asia because labor, construction, regulatory, and environmental costs are lower there. The world's growing dependency on Chinese drug manufacturers become apparent in the heparin scare. In 2007,

Baxter Intentional and APP Pharmaceuticals split the domestic market for heparin, an anticlotting drug needed for surgery and dialysis. When federal drug regulators discovered that Baxter's product had been contaminated by Chinese suppliers, the FDA banned Baxter's product and turned almost exclusively to the one from APP. However, APP also obtained its heparin product from China. Of the 1154 pharmaceutical plants with generic drug application to the FDA in 2007, only 13% were in the United States; 43% were in China, and 39% were in India.[259] Drug labels often claim that the pills are manufactured in the United States, but the listed U.S. plants are often the sites where foreign-made drug powders are pounded into pills and packaged.

Under the Prescription Drug User Fee Act, known as PDUFA, pharmaceutical companies pay the FDA to facilitate their PMA applications. Congress provided PDUFA with added power to impose restrictions on the sale of drugs and enforce regulations requiring that postmarketing surveillance studies be timely completed rather than delayed or evaded. Notwithstanding PUDFA, in 2008 the FDA was still missing target dates to act on NDAs because the FDA lacks sufficiently adequate staffing to handle PMA applications.[210]

Dietary Supplements

The Dietary Supplements Health and Education (DSHE) Act allows dietary supplements to be sold directly to consumers without any oversight or FDA regulation. In response to intense lobbying by the multibillion-dollar dietary supplement industry, Congress in 1994 exempted these products from FDA regulation.[153,167,277] Products may contain amounts claimed, but they need not, and nothing can prevent their sale if they do not. For example, an analysis of ginseng[167] products showed no ginseng at all in some products. The DSHE Act places the burden of proof for dietary supplements' safety on the FDA and not the manufacturer. As a result, consumers of herbal supplements must depend on self-regulation within the industry for assurance of product quality, consistency, potency, and purity.[134,277] An understaffed and overworked FDA can hardly be expected to be a vigorous enforcer.

An herbal product label can state the way the product is intended to affect "the structure or function" of the body but cannot claim its use for a specific disease. Manufacturers thus use creative language that complies technically with the statute but generally is confusing and/or deceptive.[167]

A current medication history form should include over-the-counter, herbal, and illicit drugs, many of which have the potential for synergistic or antagonistic interaction with clinician-prescribed drugs.[277] Ma-huang, or ephedra, a major component of many weight loss supplements, has been associated with more than 800 adverse health effects, including the death of major league baseball player Steve Bechler. It is an amphetamine-like compound with the potential for overstimulating the central nervous system and heart. Ephedra/ma-huang has been associated with 54 deaths, primarily involving cranial hemorrhage or stroke.[28,117] Echinacea increases potential for liver damage when used with steroids. Gingko biloba and feverfew interfere with anticoagulants such as warfarin (Coumadin).[53] Dong quai root, willow bark, goldenseal, guarana, horse chestnut, and bilberry tablets/supplements also have antiplatelet properties.[242] Ginseng may cause rapid heartbeat and/or high blood pressure in some individuals, as well as coagulation disruption. Vitamin E has antiplatelet properties and inhibits vital clot formation. Gingko and selenium are powerful anticoagulants, three times stronger than vitamin E. In 1998, California investigators found about one third of 260 imported Asian drugs were either spiked with unlisted drugs or contained mercury, lead, or arsenic. In 2009, the FDA warned of 70 weight loss pills containing potentially harmful drugs unlisted on their labels.

A Los Angeles police officer who experienced a crippling stroke after taking an ephedra-based energy supplement, Dymetradine Xtreme, was awarded $4.1 million.[20] The retail store owner had read but disregarded 30 journal articles warning of strokes, heart attacks, seizures, and other ailments. The stroke occurred before the FDA banned ephedra from sale in April 2004. Nonetheless, Internet sales proliferated.[242]

The formulations for herbal supplements—or *botanicals,* as they are correctly called—such as St. John's wort and echinacea are often complex, highly variable, and impure. Many are toxic, carcinogenic, or otherwise dangerous. Side effects include blood-clotting abnormalities, high blood pressure, life-threatening allergic reactions, abnormal heart rhythms, exacerbation of autoimmune diseases, and interference with life-saving prescription drugs.

The American Society of Anesthesiologists has warned patients to stop taking herbal supplements at least 2 weeks before surgery to avoid dangerous interactions with anesthesia.

Congress exempted supplements from oversight under a 1994 law that prevents federal regulators from requiring manufacturer's proof that botanicals are safe or effective, or even that dosage information on the label is correct. In 1999, the FDA allowed manufacturers to make dubious health claims, such as for products to treat conditions such as premenstrual syndrome and acne, although only a few botanicals are proven efficacious for anything.

MedWatch

Newly marketed drugs may not list all potential adverse drug reactions or events because of the limited number of patients in research trials before marketing. Therefore the FDA's MedWatch program encourages clinicians to report known or suspected drug reactions. MedWatch encourages reporting of serious unexpected adverse drug reactions whose nature and severity are inconsistent with or absent from the drug's labeled warnings.[87-90,196] Clinician reporting to the FDA is confidential and voluntary. The patient's identity need not be disclosed. Clinicians should contact the FDA by telephone at (800) FDA-1088 or fax at (800) FDA-0178 to obtain the FDA Medical Products Reporting Program (MedWatch) form (FDA form #3500). The back portion of the *Physicians' Desk Reference* (PDR) contains a MedWatch form. Clinicians can also download the MedWatch reporting form at http://www.fda.gov/medwatch/getforms.htm and report suspected drug interactions, reaction, or adverse product events at http://www.fda.gov/medwatch/report.htm. Other electronic drug databases are available to report and access important drug interaction information.[275] For FDA-approved safety-related drug labeling online, see www.fda.gov/MedWatch.

Adverse drug reactions are injuries occurring when drugs are administered at usual doses. These reactions represent the primary focus of regulatory agencies and postmarketing

surveillance. An adverse drug event suggests medication prescribing or dispensing errors that compromise patient safety. Unfortunately, clinicians report only between 1% and 5% of adverse drug incidents to the FDA, since clinician reporting is voluntary.[150] On the other hand, drug manufacturers must report known adverse drug incidents to the FDA.[88]

Clinicians should document adverse drug reactions not only in the progress notes but also in the allergy section of the chart in order to assess whether future use of the same drug is contraindicated and to prevent a harmful recurrence. Predictable adverse drug reactions that manifest should also be recorded as consideration for future disuse of the involved particular drug.

ENDODONTICS AND HEART DISEASE

Associations between chronic infections such as periodontal diseases and coronary heart disease (CHD) have been suggested.[226] Conversely, supporting evidence linking root canal–filled teeth or teeth with periapical disease to CHD is lacking.[94]

Abbreviations

Abbreviated records can be frustrating if the clinician is unable to decipher one's own or other clinicians' handwritten entries, so the clinician should use standard or easily understood abbreviations. Pencil entries are legally valid, but ink entries are less vulnerable to a plaintiff's claim of erasure or alteration. A short pencil is better than a long memory; records remember, but patients and clinicians may forget.

A sample of a completed endodontic chart (see Fig. 11-9) illustrates its proper use. Box 11-1 lists a key to the abbreviations.

Computerized Treatment Records

Clinicians are increasingly using computerized record storage as described in Chapter 29. To avoid a claim of record falsification, whatever computer system is used should be able to demonstrate that records indicating earlier treatment were not recently falsified. Software technology, such as the "write only read memory" (WORM) system, used to identify computer data tampering, is not foolproof because it cannot detect tampering where an entire disk of recent origin has been substituted for an earlier version. Periodically, a hard copy of computer data should be printed out, hand-initialed, dated in ink, and stored in the chart to provide written verification of the computer records if the office is not a virtual paperless office.[246]

Health Insurance Portability and Accountability Act

The Department of Health and Human Services' Security and Electronic Signature Standards rule is part of the Health Insurance Portability and Accountability Act (HIPAA) of 1996. This act emphasizes the safeguarding of clinicians' health care information and permits a patient to obtain a copy of the requesting patient's records. Most states have authorized digital electronic signatures as binding for most contracts and orders. Digital signatures with electronic transactions are authorized by the Third Millennium Electronic Commerce Act (also called the *Electronic Signature in Global and National Commerce Act*).[255]

BOX 11-1

Standard Abbreviation Key

Ab	=	Antibiotic
ABS	=	Abscess
access	=	Access cavity
AG or AmAL	=	Amalgam
AE	=	Air embolus
analg.	=	Analgesic
apico	=	Apicoectomy
B-U	=	Buildup of tooth
Bisp	=	Bisphosphate
BW	=	Bite wing
canal	=	Identify canal that has been cleaned and shaped
CBCT	=	Cone-beam computed tomography
comp	=	Composite
cotton	=	Placed in pulp chamber between treatments
CRN	=	Crown
Dx	=	Diagnosis
ENDO	=	Endodontics
EPT	=	Electric pulp test
epin	=	Epinepherine
final	=	Final file
Fx	=	Fracture
G.G.B.	=	Gates-Glidden bur
G.P.	=	Gutta-percha
I & D	=	Incision and drainage
I.P.	=	Irreversible puplitis
L.A. or local	=	Local anesthetic
mm	=	Millimeters
O+D	=	Open and drain
P.A.	=	Periapical
perio	=	Periodontal
post	=	Preformed, custom, or transilluminated post
pt	=	Patient
pulpec	=	Pulpectomy
R.D.	=	Rubber dam
Rel occ	=	Relieved occlusion
resorp.	=	Resorption
retro	=	Retrograde procedure
S/R	=	Suture removal
s.file	=	Serial filing
S/D	=	Single insurance or dual coverage
sealer	=	Sealer type used
sepr	=	Separated
sutr	=	Suture
SX	=	Symptom
tech.	=	Technique for canal obturation
temp	=	Temporary restoration
test	=	Test file
Tx	=	Treatment
WNL	=	Within normal limits

Pertinent HIPAA requirements stipulate that:

1. Original records and radiographs should not be released but only copies provided to the patient. A reasonable copying charge may be requested before or after release of the copies.
2. A patient may amend health information in the chart that the patient believes to be incorrect or incomplete.

The clinician may respond to the patient's proposed chart amendments.

3. Notice of office privacy practices should be provided to the patient, and the patient should acknowledge receipt in writing.
4. If privacy rights are violated, the patient can file a grievance with the secretary of the Department of Health and Human Services. Patients cannot be penalized for complaining.
5. Confidential dental and medical information may be shared with other clinicians, based on a need to know.
6. All e-mail communications between clinician and patient must use a secure network and be stored on a secure server.

Record Size

Although there is little harm in recording too much information, there is great danger in recording too little. Standard 8½ × 11 inch or larger clinical records possess the advantage of providing the treating clinician adequate space for clinical notes.

Identity of Entry Author

Either a clinician or an auxiliary can chart clinical entries unless state law indicates otherwise. Some states require clinicians and assistants to sign or initial each treatment entry.[39] What is important is that the correct clinical information is recorded. Each person who makes a clinical chart entry should record the date and initial the entry. Otherwise, the author's identity may be forgotten if the individual who recorded the entry is needed in a legal proceeding. For instance, initialing the entry makes it easier to identify the particular clinician or auxiliary who, after the original recording, is now employed elsewhere. A separate log of clinician and staff initials should be created and stored for later comparison to identify the entrant's initials (Fig. 11-9).

Clinician and Staff Initials Log

Clinician	Staff	Initials	Date
Edwin J. Zinman		EZ	6-01-09
	Alyssa Malfatti	AM	6-01-09
Stephen Cohen		SC	6/1/09
	Kelly Fishman	KF	7/1/09

FIG. 11-9 Clinician and staff initials log.

Patient Record Request

Patient requests for record transfers or copies must be honored. It is unethical to refuse to transfer patient records, on patient request, to another treating clinician.[10]

Moreover, refusing to provide patient records is illegal in some states, subjecting the clinician to discipline and fines should the records not be provided to the patient on written request, even if an outstanding balance is owed.[42]

Patient Education Pamphlets

Patient education pamphlets may be used in litigation as evidence that a patient was properly informed and given endodontic alternatives but instead chose extraction. Such pamphlets include the American Dental Association's (ADA's) *Your Teeth Can Be Saved by Endodontic Root Canal Treatment* or the American Association of Endodontists' (AAE's) *Your Guide to Endodontic Treatment, Your Guide to Endodontic Retreatment,* and *Your Guide to Endodontic Surgery*. The clinician should indicate in the patient's chart which particular pamphlets the patient was provided or which video was shown, since this may prove useful should the patient later deny being informed of endodontic alternatives.

Postoperative Instructions

It is unlikely a patient will remember oral postoperative instructions unless accompanied with written instructions. After endodontic procedures, the patient may be sedated or affected by analgesic drugs. Accordingly, written postoperative instructions are beneficial. Emergency phone numbers to contact the treating clinician should be included on the form. Written instructions reduce postoperative morbidity and pain and improve patient compliance.[4] Document that both written and oral postoperative instructions were provided. If treating in close proximity to the inferior alveolar nerve canal (IANC), place a precaution, such as seen in Fig. 11-10, in the postoperative instruction sheet.

Recording Referrals

Every clinician, including the endodontic specialist, has a duty to refer under appropriate circumstances. If consultations with additional experts or specialists become necessary, referrals should be recorded lest they be forgotten or refused. Carbonless, two-part referral cards allow the clinician to provide an original referral slip to the patient while retaining a copy for

If numbness persists the next morning or suddenly within three days following root canal treatment, immediately telephone our office so we may treat or refer to another specialist to surgically remove any root canal filling material overfill impinging upon the sensory jaw nerve, causing altered sensation to the lip and/or chin.

FIG. 11-10 Postoperative information sheet.

the patient's chart. The clinician or staff member should document the fact that the original referral card was given to the patient and record the name of the person who provided the referral card and the date on which it was provided. Document if mailed to the patient. A copy of the referral card should also be sent to the referred doctor. If the patient fails to keep the referral appointment, this copy will provide proof that a referral was made. The clinician should request that the patient and the referred clinician report back if the referral appointment is canceled. Staff should calendar to verify that the referral consultation occurred.

Record Correction

Records must be complete, accurate, legible, and dated. All diagnosis, treatments, and referrals should be recorded. Chart additions may expand, correct, define, modify, or clarify (as long as they are currently dated to indicate a belated entry).

To correct an entry, the clinician should make a line through (but not erase or obscure) the erroneous entry. The correction should then be written on the next available line and dated. Handwriting and ink experts use ink chemical tags, age dating, and infrared technology to prove falsified additions, deletions, or substitutions. If records are proved to be falsified, the clinician may be subject to punitive damages in civil litigation. In addition, the clinician may be subject to license revocation for intentional misconduct.[39] Professional liability insurance policies may defend but will usually not indemnify punitive damages if the clinician is found to have committed fraud or deceit.[43,45] In addition, insurance carriers may deny renewal of professional liability coverage to a clinician who fraudulently alters dental records.

If an erroneous entry occurs, the clinician should add another entry dated as a late entry to demonstrate later corrected information. Fig. 11-11 gives an example of the proper method of belated record correction.

When patient records have been requested or subpoenaed, it is wise to refrain from examining in detail prior to copying to avoid the temptation to clarify or belatedly add an entry. Alteration of clinical records is a cause of large settlements.

Spoliation

Spoliation is the destruction or significant alteration of evidence, or the failure to preserve property for another's use as evidence, in pending or reasonably foreseeable litigation under Fed. R. Civ. P. 37(b)(2)(C).[78]

Spoliation occurs when the wrongdoer alters, changes, or substitutes dental records in an attempt to defeat a civil lawsuit.[47,258] It is far easier to defend a dental negligence lawsuit with poor records compared to attempting to justifiably defend altered (falsified) records. A jury and/or a judge will likely conclude the clinician acted with consciousness of guilt for falsifying records compared with excusing staff clerical oversight if records are poorly maintained. Dental records, like all business records, deserve accuracy and completeness.

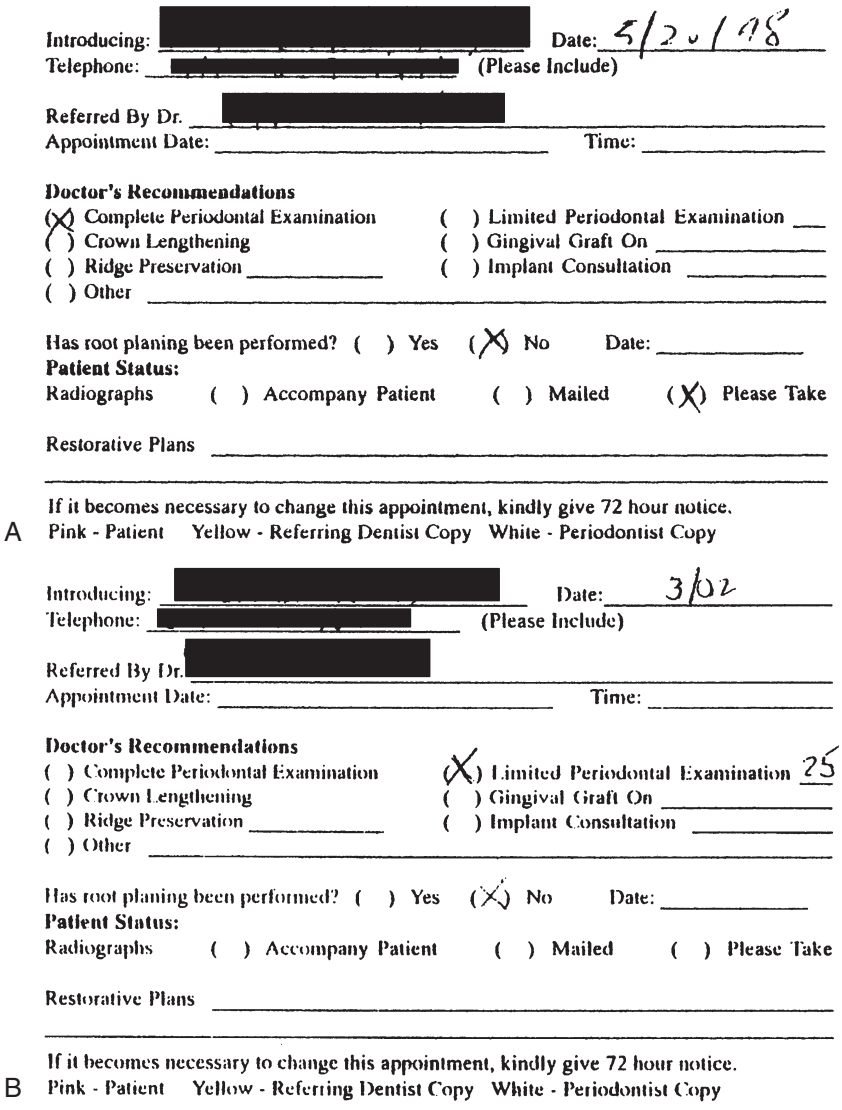
Questioned document experts utilize ink age dating, examine watermarks, or apply infrared techniques to ascertain substituted pages and additions or deletions in records, including prior erasures, entries underneath whiteouts, and indentations made when one page is overwritten on another page. Infrared technique analyzes these patterns of indentations underneath the altered pages that detect belated second entries. In one case, the defendant clinician claimed a written referral was made to a specialist in 1998, but the patient refused the referral. During litigation, the patient denied the referral and subpoenaed records of the print shop where the specialist's referral forms were printed. These subpoenaed records proved the carbon copy of the form used for the purported 1998 referral was instead first printed in 2000, which was 2 years after the alleged referral was made (Fig. 11-12, *A-B*).

In another example, altered records were detected in nine different entries in one medical negligence case involving an undiagnosed malignancy. The physician's carrier subsequently settled for $1 million. Also, the defendant personally paid a separate fine to the court. As part of the settlement, the defendant authored an article for the Washington Medical Association detailing why records falsification is wrong.[17]

Records are subjected to (1) audits by insurance carriers for documentation that treatment was performed, (2) review by peer review committees, and (3) subpoena by state licensing boards or agencies for disciplinary proceedings. Accordingly, falsified records expose the clinician not only to civil liability for professional negligence but also to criminal penalties for criminal offenses, such as insurance fraud.[47,251,255,258,260]

Deliberate record alteration with intent to deceive may also subject the clinician to licensing[39] and ethical discipline as well as punitive damages for deceitful misconduct. Insurance carriers may defend but not indemnify a verdict for intentional material alteration of dental records done with intent to deceive.

Digital radiography may have dental advantages, but because the digital images originally may be computer manipulated, they may be legally suspect as altered.[137,251] Therefore, hard copies of the digital images may also be printed and dated in ink to show the informational baseline upon which the clinician based diagnostic or therapeutic decisions. This also protects against computer glitches, such as disk drive crashes, electrical power surges, computer viruses, and operator delete errors.



False Claims

Performing or billing for unnecessary endodontic therapy, such as prophylactic endodontic therapy with every crown preparation, subjects the clinician to fraud. In non–pulpal exposure crown preparation, the likely incidence of subsequent endodontic therapy is approximately 3%. Therefore performing prophylactic endodontics on the other 97% of patients represents unnecessary and therefore fraudulent treatment. Excessive treatment also ethically violates the Hippocratic Oath of "primum non nocere" (i.e., "first, do no harm").

The Federal False Claims Act carries both civil and general penalties of treble damages, fines, and attorneys' fees for fraudulently billing government programs, such as CHAMPUS (Civilian Health and Medical Program of the Uniformed Ser-

- 10-13-09-Corrected entry for 10-12-09. (Entry should have recorded): Hot, cold, and percussion tests plus one. Recommend re-evaluation in 24 hours and repeat pulpal tests. Next visit scheduled 10/13/09 at 9 a.m.

vices) or Medicare. Fines between $5000 and $10,000 per claim form apply if the U.S. mail was used for a false-claim submission. If any portion of the claimed treatment was fraudulently misrepresented, even if a small minority, a violation results.[258] Fraudulent intent need not be conclusively proved. Reckless disregard for the accuracy of submitted data is all that is necessary to obtain a federal criminal conviction or prove civil wrongdoing.[252]

LEGAL RESPONSIBILITIES

Malpractice Prophylaxis: Importance of Records

Good clinicians keep good records. Records represent the single most critical evidence a clinician can present in court as confirmation that an accurate diagnosis, proper planned treatment, and informed consent were provided.

Prevention is the goal of modern dental care. Competent endodontic treatment performed within the requisite standard of care not only saves endodontically treated teeth but also helps prevent a lawsuit for professional negligence. Thus sound and carefully applied endodontic principles protect both patient and clinician. Prudent practices reduce avoidable and unreasonable risks associated with imprudent endodontic diagnosis or therapy.

Standard of Care

Good endodontic practice, as defined by the courts, is the standard of reasonable care legally required to be performed by a reasonably careful clinician. The standard of care does not require perfection; instead, the legal standard is the reasonable degree of skill, knowledge, and care ordinarily possessed and exercised by reasonably careful clinicians under similar circumstances.[140]

Although the standard of care is flexible to accommodate individual variations in treatment, it is objectively tested based on what a reasonable clinician should do. Reasonable conduct represents a minimum standard required for legal due care. Reasonable care is care based upon reasoning supported by sound science such as evidence-based peer-reviewed literature. Additional precautionary steps that rise above this minimal floor of reasonableness and reach towards the ceiling of ideal care are laudable, but they are not legally mandated. Again, the standard of care does not require perfection; nor does it require ideal endodontics. Nevertheless, prudent clinicians should always strive to achieve a higher level of care than barely or minimally adequate care. Excellent clinicians always strive to do their best and practice endodontics at the highest level. Some have criticized this concept by contending that average care is below average, since 49% of clinicians practice as a minority compared to the majority of clinicians. Careful clinicians should strive to avoid the mediocrity of minimally acceptable care and instead zealously pursue a goal of endodontic excellence.

The written policies and procedures of a clinician, institution, or organization may be used as evidence of standard of care. An expert may consider these the appropriate standard of care in testifying about alleged breaches of standard of care on that issue. For instance, an expert may rely upon AAE's 1998 position paper on paraformaldehyde-containing root canal filling materials as substandard practice, as well as the fact that all U.S. dental schools teach that toxic paraformaldehyde substances should not be used for adult patients as a root canal obturant.

Health Maintenance Organization Care versus Standard of Care

Reasonably careful or prudent practitioners (not insurance carriers) set the standard of care. Third-party payers may limit reimbursement but should not limit access to quality care. Clinicians have an affirmative duty on behalf of patients to appeal insurance carrier care denial decisions and, in some states, are protected against retaliation.[267] The clinician who complies (without protest) with restrictive limitations or denials imposed by a third-party payer when sound judgment dictates otherwise cannot avoid ultimate responsibility for the patient's care.[267]

Although dental insurance companies do not set the standard of care, insurance carriers may contractually limit dental benefits. Therefore a clinician is obligated to inform patients of their dental needs, regardless of carrier reimbursement. Patients may then elect to pay out of pocket or decline uninsured services. Informed choice is uninformed if the clinician fails to provide patients with all reasonable options and alternatives.[171]

If an insurance carrier denies endodontic therapy or limits endodontics to only certain clinical conditions, a prudent clinician must provide informed consent to the patient both legally and ethically that a tooth may be endodontically treated and retained rather than extracted.[51,181,233,245,281] The California Dental Association's Dental Patient Bill of Rights advises patients that "You have the right to ask your clinician to explain all treatment options regardless of coverage or cost."[41]

Clinicians may agree to a discounted fee with a health maintenance organization (HMO) carrier but must never discount the quality of care provided. Peer review and the courts recognize only one standard of care. A lower, double, or different standard of care for reduced-fee HMO plans is not legally recognized. Expediency should not be exercised at the expense of quality patient care. Section Three of the ADA Code of Ethics affirms, "Managed care contract obligations do not excuse clinicians from their ethical duty to put the patient's welfare first."

An Illinois appellate court held that a clinician may be sued for injuries a patient experiences as a result of the clinician's failure to disclose a contractual arrangement with the patient's HMO that creates financial incentives to minimize diagnostic tests and referrals to specialists. The court recognized a distinct cause of action for breach of fiduciary duty for failure to disclose these types of financial incentives.[192] In reaching its conclusion, the court cited an American Medical Association (AMA) ethics opinion that stated that a clinician must ensure that a patient is aware of financial incentives through which health insurers limit diagnostic tests and treatment options.

Managed care organizations use a variety of strategies to influence the practice styles of providers. One of the most controversial of these methods is the use of financial incentives designed to limit referrals to specialists. Such financial incentives usually take the form of bonus payments drawn from surpluses in risk pools funded by "withholds." These funds are deducted from the primary care provider's base payments or otherwise reserved under contracts in which the care provider bears financial risk. Such bonuses are based on referral limitations.[111]

Plans that delay treatment approval, resulting in endodontic complications or tooth nontreatability, may be subject to liability.[193,245] HMO carriers have not always succeeded in arguing that the 1974 Employee Retirement Income Security Act (ERISA) preempts state law for dental negligence claims against entities who administrate health care benefits to an ERISA plan and shift blame to the clinician.[200]

Capitation systems have a built-in incentive to undertreat, delay, or discourage treatment and access to care. For the HMO-paid clinician, the patient may be perceived as a threat to profits. Thus capitation creates incentives that can transform clinicians from the patient's advocate to the patient's adversary.

Although clinicians seem like double agents serving two masters (i.e., managed care carriers and patients), the law is clear that the clinician must always act in the patient's best interest, since the clinician owes a fiduciary obligation to the patient. Should the carrier deny requested care, the clinician is legally obligated to appeal the decision to protect the patient's dental health.[267] A patient's best interest is always paramount, both legally and ethically, to a clinician's financial interest.[97,268]

Although profitable to insurance carriers, the success of denying or limiting benefits has created an era of rightfully indignant patients and frustrated clinicians. Consequently, the clinician must guard against patient disappointment with limited insurance benefits by explaining that although insurance carriers determine coverage under their patients' insurance policy, carriers do not set the standard of care. Regardless of how much or how little is covered by the patient's insurance carrier, prudent and reasonably careful clinicians set the standard of care. Providing less than necessary care because of

insurance carriers' dictates may explain resulting deficient endodontics but does not excuse such conduct. Moreover, the legal doctrine of informed consent mandates the patient be informed of alternative therapy choices which the patient may pay privately even though the HMO denies approval for alternative therapies. Follow the maxim: Do not x-ray a patient's pocketbook. Reasonable informed consent is primarily based upon patient choice and not cost alone.

Dental Negligence Defined

Dental negligence is defined as a violation of the standard of care (i.e., an act or omission that a reasonably careful or prudent clinician under similar circumstances would not have done).[140] *Negligence* is equated with carelessness or inattentiveness.[145] *Malpractice* is a lay term for such professional negligence. Dental negligence occurs for two reasons:

1. A clinician does not possess a reasonable degree of education and training to act prudently, or
2. Despite reasonable schooling, additional training, and continuing education, the clinician acts with unreasonable carelessness or imprudently fails to act as a reasonably careful clinician should act.

One simple test to determine if an adverse outcome results from negligence is to ask the following question: Was the treatment result reasonably avoidable? If the answer is "yes," it is probably malpractice. If the answer is "no," it is instead an unfortunate maloccurrence that resulted despite reasonable care attempts.

Not all examples of negligent endodontic treatment are included in this chapter, because the myriad of malpractice incidents far exceeds its scope and length. Rather, only select examples are elucidated for educational purposes.

Locality Rule

The locality rule, which provides for a different standard of care in different communities, is rapidly becoming outdated. Originating in the 19th century, the rule was designed to acknowledge differences in facilities, training, and equipment between rural and urban communities.[161,282]

The trend across the United States is to move from a locally based standard to a statewide standard, at least for generalists. For endodontists, a national standard of care is applied, since the AAE Board is national in scope.[235] Because of nationally published endodontic literature, advances in Internet communication, continuing education courses, and reasonably available transportation for patients, no disparity generally exists between rural and urban endodontic standards. A current exception may be the limited geographic availability of specific cone-beam CT technology such as the Accuitomo or Kodak 9000. Their higher resolution provides superior radiographic endodontic diagnosis compared with 2D imaging and even other CBCT devices.* As CBCT machine pricing is lowered and availability increases, the locality rule may be broadened beyond a local community for CBCT technology. On the other hand, time is critical if an endodontic overfill enters the IANC.[206] In such instances, a referral to a distant CBCT facility may be required to assess the need for immediate microsurgical removal or instead obtain at the very least a medical CT in the local geographic area.

*References 54, 73, 127, 138, 163, and 166.

A clinician should provide reasonably careful endodontic care to a patient regardless of treatment locality. Rather than focusing on different standards for different communities, more important considerations include knowledge of endodontic advances in the field gained with continuing education to utilize improved diagnostics, instrumentation, and therapeutic interventions.

The locality rule has two major drawbacks. In areas with small populations, clinicians may be reluctant to testify as expert witnesses against other local clinicians. Also, the locality rule allows a small group of clinicians in an area to establish a local standard of care inferior to what the law requires of larger urban areas. Peer-reviewed publications are available to all clinicians in print and online. Clinicians can easily travel great distances to attend continuing education courses or attend webcasts in their own office; to blame technologic ignorance on a clinician's rural location is inexcusable with modern media, computer technology, and travel ease.

Standards of Care: Generalist versus Endodontist

A general practitioner performing treatment ordinarily performed exclusively by specialists, such as apical endodontic surgery, periodontal surgical grafting, or full bony impaction surgery, will be held to the specialist's standard of care.[103,104] To avoid performing treatment that is below the specialist's standard, a generalist should refer to a specialist rather than perform procedures that are beyond the general practitioner's training or competency. The three levels of clinical skill are (1) competency or beginning level, (2) proficiency, and (3) mastery. To err is human. Even specialists may not always know what they believe they know.[74,145] Approximately 80% of general practitioners in the United States provide some endodontic therapy. Endodontic expansion into the realm of the generalist can be linked to (1) refinements in root canal preparation and improved obturation (i.e., packing) techniques currently taught in dental schools; (2) continuing education courses; and (3) significant improvements in the armamentarium of instruments, equipment, and materials available to all clinicians.

Ethical Guidelines

The ADA's Code of Ethics guides conduct that distinguishes the dental profession from a trade by placing patient service paramount and profit secondary.[97] Section 5 of the ADA Code of Ethics regarding veracity ("truthfulness") states that "Professionals have a duty to be honest and trustworthy in their dealings with people." Accordingly, both ethically and legally,[129] clinicians are obligated to communicate truthfully and without deception to patients. Announcements to the public must be truthful so that the average person is not materially misled. Truth in dentistry is the rule and not the exception.[97]

Section 5.I of the ADA Code of Ethics provides: General Practitioner Announcement … general clinicians who wish to announce the services available in their practices are permitted to announce the availability of those services so long as they avoid any communications that express or imply specialization. Thus clinicians should not misrepresent or overstate the facts of their training and competence in any way that would be false or misleading in any material or significant manner to

the public or their peers. General clinicians should avoid false and misleading self-representation regarding endodontic "superiority." Implying credentials which the generalist lacks misrepresents a general clinician's endodontic skill and knowledge as equivalent to a board-eligible or board-certified endodontist. A generalist's 30-year experience may be little more than 1 year's experience repeated 30 times. Every state has specific laws governing advertising. Consult your state's law, because each state deals differently with specialty announcements.

Telephone directory listings are organized into categories based on types of procedure, such as endodontics. Generalists must also state in such ads that endodontic services are being provided by general clinicians. The public is entitled to be informed of the distinction between an endodontist specialist versus a generalist, although each provide endodontics. Only a board-eligible or board-certified clinician is entitled to represent that the clinician is an endodontist. With this distinction in mind, the ADA-recognized endodontic specialty organization is entitled the American Association of Endodontists, not the American Association of Endodontics.

Standard of Care for Endodontics

Endodontists set the standard for routine endodontics. Therefore if the endodontist's standard of care cannot be met, such as the need for microscopy, the generalist should refer the patient to an endodontist.[55,103,104,149]

Endodontists should not forget their general clinician training. Even though a patient may be referred for a specific procedure or undertaking, the endodontist should not overlook sound biologic principles inherent in the overall treatment. A specialist may also be held liable for relying solely on the information referral card or radiographs of the referring clinician if the diagnosis or therapeutic recommendations prove incorrect, unnecessary, or the referral card lists the wrong tooth for treatment. Fig. 11-13 demonstrates a general clinician's radiograph showing apparent complete endodontic fill within the canal space, whereas Fig. 11-14 demonstrates an endodontist's radiograph showing a transported canal. This difference is explained by radiographic quality and angulation. Taking radiographs at different angles improves radiographic accuracy.[163,166]

Endodontists should not provide rubber-stamp treatment to whatever the clinician refers or recommends. Without performing an independent examination, the endodontist risks misdiagnosis and resulting incorrect treatment. Prevention of misdiagnosis or incorrect treatment requires an accurate medical and dental history preceding a clinical examination (not only of the specific tooth or teeth involved but also of the general oral condition). Obvious problems such as oral lesions, periodontitis, or gross decay should be noted in the chart and the patient advised regarding a referral for further examination, testing, or another specialist's consultation.

Radiographs from the referring clinician should be reviewed for completeness, clarity, and diagnostic accuracy. An endodontist should expose a new radiograph to verify current status before treatment and only use the referring clinician's radiograph for historical comparison. Unfortunately, the referring clinician may surreptitiously forward a pretreatment film with the referred patient, rather than the referring clinician's own posttreatment film depicting a perforation or broken file that necessitated the referral. This may occur whenever an errant clinician attempts to fraudulently conceal negligently performed endodontic treatment in an attempt to shift blame for bungled treatment to the endodontist. In such cases, a valuable lesson is learned when the endodontist exposes independent pretreatment radiographs, rather than relying exclusively on the referring clinician's radiographs to determine current status of endodontic treatment.

Poor oral hygiene may contribute to periodontal disease. In such cases, endodontic treatment may be compromised unless the associated periodontal condition, along with the tooth being tested endodontically, is brought under periodontal disease control, including any crown-lengthening needs (see Chapter 18 for more information). Referral to a periodontist may be necessary before or contemporaneous with completion of endodontic treatment.

FIG. 11-13 A general clinician's radiograph that ostensibly shows a complete endodontic fill within the root canal space.

FIG. 11-14 Endodontist's radiograph demonstrating a transported canal.

In summary, it is necessary for the endodontist to:

1. Be alert to any contributory medical or dental condition within the operative area of endodontic treatment that can affect treatment.
2. Undertake an independent diagnostic and radiographic examination of the treatment area and treatment plan rather than relying solely on the referring clinician.
3. Perform a general dental examination (at least a screening) to diagnose any hard- and soft-tissue pathosis.
4. Evaluate status and prognosis of adjacent and opposing teeth.
5. Advise the referring clinician and patient of pertinent findings.

Ordinary Care Equals Prudent Care

Ordinary is commonly understood (outside its legal context) to mean "lacking in excellence" or "being of poor or mediocre quality."[179] As expressed in the context of actions for negligence, however, ordinary care has assumed a technical legal definition somewhat different from its common meaning. The eighth edition of *Black's Law Dictionary* describes ordinary care as "that degree which persons of ordinary care and prudence are accustomed to use or employ … that is, reasonable care."[31]

In adopting this distinction, the courts have defined *ordinary care* as "that degree of care which people ordinarily prudent could be reasonably expected to exercise under circumstances of a given case."[83] It has been equated with the reasonable care and prudence exercised by ordinarily prudent clinicians under similar circumstances.[107,213] It is not extraordinary or ideal care. Thus ordinary care is not average care but instead equates with prudently careful care. Stated otherwise, average care may be below the average of what all reasonable clinicians should practice.

Although the standard required of a professional cannot be only that of the most highly skilled practitioner, neither can it be limited to the arithmetic-average member of the profession, because those who possess somewhat less than median skill may still be competent and qualified to treat.[213] By such an illogical definition of average care, half of all clinicians would automatically fall short of the mark and be negligent as a matter of law. As one court explained, "We are not permitted to aggregate into a common class the quacks, the young men who have not practiced, the old ones who have dropped out of practice, the good, and the very best, and then strike an average between them."[227] Thus the standard of care equates with *reasonable* and not average care.

Customary Practice versus Negligence

Customary practice may constitute evidence of the standard of care, but it is not the only determinant. Moreover, if the customary practice constitutes negligence, it is not considered reasonable (although or even if customarily practiced by a majority of clinicians).[26] Rather, the reasonably careful clinician is the standard of care and not an average or mediocre practitioner. For instance, a majority of clinicians did not perform biologic testing of the dental unit water lines despite ADA recommendations to do so.[181,183] However, careful clinicians did follow the ADA's recommendation (Box 11-2 and Fig. 11-15).

Merely because a majority of clinicians in a community practice a particular method does not establish it as the standard of care if such practice is unreasonable or imprudent.[26] Ultimately, the courts determine what constitutes reasonable practice by considering available dental knowledge and evaluating the relative risks versus benefits of a particular procedure.

Again, the law does not require dental perfection.[249] Instead, the legal yardstick by which prudent conduct is measured is what a reasonably prudent clinician should do under the same or similar circumstances, regardless of how many or how few clinicians conform to such standard.

In one case, it was not customary practice in the state of Washington for ophthalmologists to test patients under 40

BOX 11-2

Typical Examples of Negligent Customs

- Failing to probe and record periodontal pockets
- Failing to take diagnostic-quality radiographs
- Failing to refer patients for complicated procedures
- Failing to use aseptic practices such as gloves and face masks
- Failing to use rubber dams for endodontics
- Failing to install or periodically check valves in dental units to prevent water retraction, suck-back, and cross-contamination
- Failing to do thermal pulp testing as an aid to diagnosing pulpal disease (see Chapter 1)
- Failing to discontinue quaternary ammonium chloride–based products for precleaning and/or disinfection of environmental surfaces
- Failing to use a microscope for fractured file retrieval
- Failure to include CAMBRA in a comprehensive new patient exam
- Failure to use CBCT technology to guide implant placement when placement is in close proximity to the IANC (see Fig. 11-16 for implant "harpooning" of IANC).

FIG. 11-15 Implant "harpooned" inferior alveolar nerve canal.

years old for glaucoma, because the incidence was only 1 in 25,000 patients. Nevertheless, the Supreme Court of Washington state held that the defendant ophthalmologist was negligent as a matter of law, irrespective of customary medical practice, since a negligent custom is no defense.[121,175]

Little excuse exists for failing to routinely probe and chart periodontal pockets before rendering endodontic therapy, no matter how many other clinicians in the community may fail to do so. The benefit of probing for periodontal disease substantially outweighs the virtually nonexistent risk of conducting this valuable diagnostic procedure. A legal defense likely to invoke a jury's wrath is to claim that a necessary diagnostic or prophylactic procedure is "too time consuming," when dental and medical patient health are placed at risk if not done. If the benefit outweighs the risk a reasonable clinician complying with the standard of care should opt for the beneficial diagnostic test or treatment. For instance, the Accuitomo and Kodak 9000 CBCT may prove an invaluable benefit for diagnosing the etiology of tooth or endodontic pain when compared to the relatively low radiation risk. Thus the CBCT diagnostic benefit outweighs the radiation risk if a differential diagnosis can not accurately rule in or rule out a final diagnosis.[165]

Continuing Education

Continuing education should not add new skills at the expense of compromising or eliminating core clinical values. A prudent practitioner should be cautious adding a new methodology that is counterintuitive to basic biomechanical principles.[185] As a general maxim, "Don't be the first nor the last to adopt new technology."

Scientific Research Evaluation

In evaluating scientific research, the clinician should remember that epidemiologic data of risk factors are not always equivalent to etiology. Thus *epidemiology* is not a synonym for *etiology*. The scientific community has never exclusively relied on epidemiology as the accepted method of evaluating cause-and-effect relationships in an effort to make clinical decisions. Accordingly, clinicians should not consider only one class of data to supply ultimate proof when conducting an evaluation. Instead, clinicians should consider the strength of any study to be related to the presence and contributing cause of other cofactors.[108,197,198,205] The unusual characteristics of a particular patient can place the patient at higher risk than the average patient.[124]

New products and procedures are often introduced faster than epidemiologic and toxicologic studies are implemented to evaluate their potential risks. Academic medical/dental centers are facing severe pressure on their reimbursement for health care services and postgraduate education. This creates the need to examine additional sources of revenue to fund their tripartite mission of education, research, and patient-care delivery. Reduced government spending for research has resulted in proprietary interests (with proprietary goals) funding more research.[118] Since 1984, the *New England Journal of Medicine's* policy has been to refuse publication of research done by those with financial ties to drug makers. But in 1999, the journal admitted conflicts in nearly half of the drug studies published since 1997.[15] The next year, the retiring editor of the *New England Journal of Medicine* concluded that despite tax-supported privileges and extraordinary pharmaceutical industry profits, the best interests of society were not always served. A public trust more accountable to science was needed.[14]

Evidenced-Based Endodontics

Although much emphasis is currently placed on evidence-based medicine and dentistry, most clinical practices are not based on data derived from randomized clinical trials.[198] It is virtually impossible to conduct a trial to test the validity of every possible patient-management option. Many therapeutic choices are so compelling that a test would be unethical; others are so trivial that a test might not be worth the time or effort. Clinicians do not always practice in conformity to evidence-based research, even when evidence is available from randomized clinical trials. This is because knowing the right answer is only the first step in the process of adopting a new treatment methodology. Many clinicians will not use a new drug simply because supporting research data indicate that it works. Instead, identification of the probable mechanism of action is often a prerequisite before adopting a new treatment. Moreover, the test of time may eventually reveal an adverse effect of a particular drug or device (e.g., defects that were not identified before marketing). Even if the new product's research proves beneficial, comparative effectiveness studies with other time-proven and tested products are needed to determine a new product's relative worthiness.[108,159,205,239]

Nevertheless, clinicians should not avoid using certain drugs if the data supporting their use are overwhelming. When the results of a clinical trial conflict with a widely held mechanistic model, many clinicians doubt research-based evidence.[187] However, when the results from well-researched clinical trials become so convincing that the evidence can no longer be ignored, a prudent clinician embraces the new paradigm and discards previously held concepts. Endodontic science advances as disproved older concepts retreat. For example, delaying extractions until after several days of antibiotic use to reduce infection is no longer the accepted practice. Rather, immediate extraction, along with any necessary antibiotics, is the preferred current therapy.[4] Another example is one-visit

endodontics, which has proven as effective as two-visit endodontics.[84,186,202]

New Products

New devices that lack definitive research studies should be used cautiously. For instance, high-intensity, wireless, fast-curing lights may generate heat at the wand tip and cause pulpal pathosis. First-generation halogen bulbs require longer composite curing time to achieve polymerization but generate only 400 to 800 mW/cm. Plasma arc bulbs reduce curing time but generate 2000 mW/cm.

Hydron was marketed without long-term clinical testing. Its purported biocompatibility and reduced inflammation portended an improved endodontic drug for obturation. Postmarketing failures resulted from inadequate premarket testing that lacked long-term research. Thus Hydron's inability to obturate canals with a durable filling material resulted in both clinicians and patients being harmed as postmarket guinea pigs. Hydron's in vitro research did not match in vivo patients' experiences.

Other examples include Endocal 10 (formerly Biocalex 6/9), which proved ineffective. Arsenic to promote devitalization of the pulp resulted in local osteonecrosis. Thermafil metal carriers proved difficult to remove and were replaced with plastic carriers. Advance cement was touted as an improved luting cement for retaining permanent restorations. The high incidence of marginal leakage with Advance resulted in its withdrawal from the market in 2000. A multimillion-dollar class action settlement resulted against the manufacturer on behalf of California clinicians with unsealed margins of crowns cemented with Advance luting agent.[101]

Older devices, over time and with sufficient patient experience, may manifest adverse events. Overheating with ultrasonic tips for post removal has resulted in teeth and tissue loss (Fig. 11-16). Accordingly, despite insufficient label warnings on some ultrasonic devices, ample water coolant, rest periods, and avoidance of prolonged ultrasonic device use are needed for safe post removal.[68,71,102]

FDA Approval

Despite FDA approval, some drugs are marketed with fraudulent concealment of the number and nature of adverse event incidents.[8]

FDA Clearance

The applicant must receive FDA approval of its PMA application prior to marketing the device as FDA approved. PMA approval is based on an FDA determination that the PMA contains sufficient valid scientific evidence to assure that the device is safe and effective for its intended uses.

The FDA lists certain products which are exempt from premarket notification requirements under The Food and Drug Administration Modernization Act of 1997 (The Modernization Act),[86] which include the following endodontic products:

- Root canal posts
- Gutta-percha

Negligence Per Se

Compliance with a health safety statute does not conclusively establish due care, because regulations require only minimal care and not (necessarily) prudent care or what the law regards as due care.[58,248]

Ability to Foresee Unreasonable Risk

Each endodontic procedure has a variable degree of inherent risk. The standard of care requires that the clinician avoid unreasonable risks that may harm the patient. Treatment is deemed negligent when a reasonably careful clinician would have foreseen some unreasonable risk of harm to the patient.

FIG. 11-16 Results of overheating a post with an ultrasonic device during post removal.

Failure to follow the dictates of sound endodontic practice increases the risk of negligently induced deleterious results. Accordingly, prophylactic endodontic practice is designed to prevent foreseeable or reasonably avoidable injury risks. Foreseeability connotes predictability.

It is not necessary that the exact injuries that occur be foreseeable. Nor is it necessary to foresee the precise manner or circumstances under which injuries are inflicted. It is enough that a reasonably prudent clinician would foresee that injuries of the same general type would likely result in the absence of adequate safeguards.[213]

Informed Consent Principles

In General

The legal doctrine of informed consent requires that the patient be advised of reasonably foreseeable material risks of endodontic therapy, the nature of the treatment, reasonable alternatives, and the consequences of nontreatment.[51,141,182] This doctrine is based on the legal principle that individual patients have the right to do with their own bodies as they see fit, including the right to prematurely lose teeth regardless of recommended dental treatment. Once the clinician has informed the patient of the diagnosis, treatment risks, prognosis, and nontreatment risks, as well as recommendations for corrective treatment or alternative therapy, the patient has the right to decide how or if to proceed. An adult of sound mind is entitled to elect to do nothing about existing endodontic disease. Rather than elect corrective treatment, the patient may elect to suffer nontreatment consequences, including present or future tooth loss and/or apical abscess.

To be legally effective, a patient's consent to treatment involving potentially serious injury complications must include informed consent. Accordingly, a clinician has a fiduciary duty to disclose all material or essential information necessary for the patient to make a decision.[51,141,182] The scope of a clinician's duty to disclose information is measured by the amount of knowledge a reasonable patient requires to make an informed choice. Material information is that disclosure a clinician knows (or should know) that would be regarded as significant by a reasonable person in the patient's position who must decide whether to accept or reject a recommended endodontic procedure.

If a clinician fails to reasonably disclose information that would make a reasonable person in the patient's position decline the procedure, the clinician may be liable should an undisclosed risk manifest. Beyond the foregoing minimal disclosure, a clinician must also reveal such additional information as a skilled practitioner of good standing would provide under similar circumstances.

The personal bond between clinician and patient has long been considered an essential element of the therapeutic environment. Information is empowering. Laws requiring informed consent place patients on a closer footing with their clinicians. In addition to the transfer of information in both directions, bonding takes place when the clinician and patient engage in a conversation of length and substance. Canned disclosure displaces this human interaction. One of the surest safeguards clinicians can have against malpractice litigation is the bond of personal relationship forged with their patients.[221]

Informed Consent

Adequate informed consent requires that a patient be informed of the ABC's—the alternatives, benefits, and complications—of a proposed treatment, along with the pros and cons of the alternative therapies or options.[51,141,182] A patient has a right to be informed of these ABC's from the treating clinician and not solely from an informed consent form or by a front office staff person who lacks a dental license.

Informed consent must be presented in layperson's language, so that the patient can appreciate and understand what the treatment risks are.

A patient is not expected to consent to negligent care. Accordingly, informed consent applies only to treatment which complies within the standard of care. If the clinician is reasonably careful during treatment, but an untoward results occurs, the clinician is not liable if the patient was forewarned of the potential risk prior to the treatment.

A reasonably unavoidable risk which manifests during treatment represents a maloccurrence and not malpractice. For example, a small percentage of endodontic failures are due to non-negligent reasons. The clinician should be sensitive to the patient's feelings of disappointment. When endodontics fails, regardless of cause, it is a 100% failure rate for the patient.

Patient treatment refusals should be documented. Some states require informed refusal disclosures advising the patient about the consequences of refusing treatment or diagnostic modalities.

Consent

Simple consent occurs when the clinician makes the treatment decision unilaterally and obtains the patient's consent without offering the patient a choice. Conversely, informed consent is a joint decisional process whether to proceed with treatment or not.

Patients are legally empowered to decide for themselves when substantial competing risks are involved with each separate treatment choice. A patient's therapeutic choice is particularly apt when there is no professional consensus for the best treatment. For instance, different implant systems exist with arguably different risks for each. A decision to proceed with an immediate implant versus waiting for osseointegration before initiating restorations requires that a risk-versus-benefit analysis be provided to the patient. Such decisions should include comparative peer-reviewed longevity research results compared with newer short-term immediate implant research. The benefits of immediate implant placement are attractive to both patient and clinician. To fairly compare researched implant survivability studies, the variables should similarly be controlled for each study, such as whether the implants are placed in native bone, socket size, and shape.

Emergency endodontic treatment often requires that the patient be provided pain relief. Acute pain clouds the patient's decisional process; palliative treatment provides immediate pain relief so that on a return visit, the patient can rationally decide among treatment choices. With ample time, the patient can rationally decide and compare choices such as completion of endodontics and a crown versus extraction followed by an implant with crown. Also, an extraction which may result in alveolar ridge bone loss and the need for bone grafting are considerations the clinician should explain to the patient.

Patient choices may be influenced by cost, convenience, time off work, travel needs, esthetics, or a myriad of other reasons. The clinician plants the seeds of the decisional tree, but the patient decides which branch of the tree should be followed.

Informed Consent Application

Informed consent is a flexible standard that considers reasonably foreseeable consequences, depending on the clinical situation present both before and during treatment. For instance, a fractured or separated endodontic instrument left in the root canal creates the possibility of root canal failure or impaired success (depending on whether the fracture occurred in the coronal, middle [least favorable], or apical third of the root canal). The clinician must advise the patient of the relative risk of future failure and suggest treatment alternatives to correct the problem. An adequately informed patient can better make an intelligent choice among apicoectomy, referral to an endodontist utilizing microscopy for attempted retrieval, or close radiographic observation at recall visits.[55,149,160] In Fig. 11-17, the clinician overinstrumented and perforated the inferior alveolar nerve (IAN), causing both a permanent dysesthesia and paresthesia. The clinician should have immediately referred the patient to an endodontist for attempted gutta-percha retrieval before the endodontic sealant containing eugenol set and caused more deleterious chemical injury to the IAN. If retrieval was unsuccessful, the patient should have been referred to a microsurgeon within 48 hours from occurrence for optimal opportunity to prevent chemical cytotoxic injury to the IAN.[206]

Adequate disclosure includes clinical judgment and experience, which assesses current research and applies it to the clinical needs of each patient. Today's advance may be tomorrow's retreat if materials, devices, or instruments lacking adequate long-term study of safety and efficacy predictably fail. For instance, the one-component bonding agent is more technique sensitive than its two-component predecessor. This is because the one-component agent contains acetone that desiccates the tooth surface and requires a moist surface to avoid postoperative sensitivity. Long-term testing before marketing would have revealed that the two-step system is more reliable and forgiving.[250] Reasonable clinicians do not sacrifice patient safety for speed and profit and then compensate with desensitizing agents. Clinicians should be more sensitive to limited research on new products or devices lest the patient be the injured guinea pig.

Material disclosure concerns whether the patient was provided sufficient information for a reasonable patient to achieve a general understanding of the proposed treatment or procedure. This disclosure includes information concerning any dentally acceptable alternatives, any predictable risks of serious injury, and any likely consequences should the patient refuse the proposed therapy. The standard to be applied is whether a reasonable person in the patient's position would have consented to the procedure or treatment in question if adequately informed of all significant perils.[48] Informed consent applies only to inherent risks of non-negligent treatment, because a patient's consent to negligent treatment is voidable as being contrary to public policy.[253] Accordingly, a patient who refuses necessary diagnostic radiographs should be refused treatment.

This is probably due to file overinstrumentation. *(Courtesy Anthony Pogrel, DDS, MD.)*

If warnings are limited to some risks but not others, some courts have held that the patient can recover for all surgical injuries including warned risks.[130]

Restorative Informed Consent

Patient choices for restorations may discount longevity and elect instead esthetics. In one study, amalgams lasted 15 years, composites 6 years, and conventional glass isomers 7 years.[91] Shorter-term restorations' longevity increases the frequency of restoration replacement and increased potential for endodontic therapy with each replacement. Nevertheless, it is the patient's treatment choice after the clinician first explains relative risks, benefits, and alternatives.

DIFFERENT SCHOOLS OF THOUGHT

After the clinician advises treatment, if other reasonable clinicians would disagree or if there are other respectable schools of thought on the correct treatment, this material information should be disclosed to the patient.[261,281] For example, there may be two schools of thought concerning the optimal treatment for retrofilling and apicoectomy. One school posits that a retrograde with intermediate restorative material (IRM) mineral trioxide aggregate (MTA) is the appropriate procedure, whereas the minority review asserts that retrograde with Super EBA is the preferred treatment.[278] One can assume further that an explanation of these two different methods of treatment constitutes material information for the purposes of informed consent. The mere fact that there is a disagreement within the relevant endodontic community does not establish that the selection of one procedure as opposed to the other constitutes negligent endodontic therapy. Because competent endodontists regularly use both procedures, a patient would have a difficult time proving dental negligence (i.e., that the endodontist failed "to have the knowledge and skill ordinarily possessed, and to use the care and skill ordinarily used, by reputable specialists practicing in the same field and in the same or a similar locality and under similar circumstances"). Moreover, neither school of thought possesses long-term clinical research results to prognosticate apical sealant insolubility rates in an 18-year-old patient with an additional 60-year life expectancy.[237] Long-term durability depends on an insoluble seal to reduce the risk of bacterial leakage.[48,189] Fig. 11-18 represents a preoperative and postoperative radiograph of a successful apicoectomy and retrograde in a 14-year-old.

On the other hand, the specialist would have a duty under the above hypothetical circumstances to disclose the two recognized schools of treatment so that the patient could be sufficiently informed to make the final personal decision. An

endodontist, being the expert, appreciates the risks inherent in the procedure prescribed, the risks of a decision not to undergo the treatment, and the probability of a successful outcome of the treatment. Once this information has been disclosed, this aspect of the endodontist's expert function has been performed. The weighing of these risks against the individual subjective fears and hopes of the patient is not an expert skill. Such evaluation and decision constitute a nondental judgment reserved for the patient alone.[51,141] In this hypothetical situation, failure to disclose such material information would deprive the patient of the opportunity to weigh the risks. Consequently, the clinician would have failed in the duty of disclosure, which the doctrine of informed consent requires.

When improved technology offers clearly superior results, it no longer becomes a patient choice issue but rather a requisite requirement to fulfill the standard of care. Apical microsurgery with ultrasonic tips for retrofilling exemplifies improved technology and the current standard of practice. Likewise, apical retrogrades should be done with MTA and not with amalgam.[48] Finally, microscopic endodontics represents the current standard of care for apical surgery or fractured instrument retrieval.[55,136,149,160]

AVOIDING PATIENT CLAIMS

If a clinician fails to obtain adequate informed consent, a plaintiff can recover damages (even in the absence of any negligent treatment) should the patient testify that performed treatment would have been refused if the clinician had provided information concerning possible risks. Therefore discussions of treatment risks with the patient must be documented. Informed consent forms are very helpful, although not legally mandated, because a jury may believe that the patient was informed orally. Equally if not more important than consent forms is a chart notation indicating that the clinician discussed informed-consent risks and alternatives (and that the patient understood and accepted this information). Patients may mentally block out frightening information. Trauma and a potent anesthetic agent can create retrograde amnesia. Therefore clinicians must document (in the patient's chart) any risks, benefits, alternatives, and consequences of nontreatment provided to the alert patient before sedation.

Clinicians should follow only the patient-authorized and consented treatment plan. If an emergency precludes advising treatment risks to the minor patient, lack of informed consent may be defensible as implied consent (because no reasonable parent would refuse necessary, emergency treatment).

The following example demonstrates how a clinician should record any recommended treatment the patient has refused and the reason for refusal:

> *"Patient refused endodontic referral for consultation with endodontist (Dr. Goodguy) because husband was laid off work last month and cannot afford treatment. After Dr. G. provided explanation, patient states she understands detrimental delay risks."*

Patients may initial any referral refusal on the chart. Although patient signature is not mandatory, it will enhance the clinician's credibility should the patient later dispute a referral was made.

Reasonable familiarity with a new product or technique is required before it is used. In addition, a patient is entitled to know the clinician's personal experience with a particular modality because the patient has a right to choose between reasonable alternatives or to seek care from a clinician who has more extensive experience with a particular modality or new product. A clinician who fails to obtain informed consent may be liable for injury caused by a product or instrument. The fact that the clinician followed the manufacturer's instructions is no defense if the clinician did not provide adequate information concerning a product or instrument risk (to permit the patient to intelligently weigh the disclosed information and choose among treatment options).

Endodontic Informed Consent

If the practitioner's own statistical experience varies significantly from national statistics, using statistics presented in national literature regarding success rates for endodontic procedures is considered insufficient disclosure and does not fulfill the legal requirements of informed consent (Fig. 11-19).[116,236]

Among specialists, the reported incidence of treatment complications in endodontics is relatively low. Based on a Southwest Endodontic Society retrospective study, a reasonable endodontist or a practitioner with similar abilities should disclose the following facts to patients[233]:

1. Endodontic therapy cannot be guaranteed.
2. Although endodontic therapy is usually successful, a small percentage of teeth are lost due to complications or treatment failure, despite competent endodontic care.
3. Slight overextending or underfilling of root canals occurs in 2% to 4% of cases, which may contribute to treatment failure.
4. Slight to moderate transient postoperative pain may occur. Severe postoperative pain rarely occurs.
5. Irreparable damage to the existing crown or restoration secondary to endodontic treatment is uncommon after the access opening is restored.

VIDEO-INFORMED CONSENT

Animated video-informed consent shown to the patient is a dynamic method of providing informed consent. Because the video-informed consent is considered part of the clinician's records, in the event the patient disputes having ever been advised of (1) the nature of endodontic disease, (2) the availability of endodontic specialists, or (3) the relative indications for nonsurgical versus surgical endodontic care, the videotape can be played back to the jury as proof that the patient was informed. It is doubtful a jury would believe a forgetful patient who admits having previously viewed the videotape, because the videotape refreshes the stream of memories that may have otherwise faded into the unconscious.

A patient viewing the videotape is more likely to understand the informed consent disclosure of a technical procedure. After viewing the videotape and discussing its contents with the clinician, the patient should sign a video consent form to verify that the video was viewed, and all the patient's questions were answered.

Alternative Technique Choices

Filling the root canal with the lateral compaction method or instead using vertical warm gutta-percha carrier delivery

INFORMED CONSENT

We are concerned not only about your dental health and endodontic treatment needs, but also about your right as a patient to make the treatment decision that you feel is best for you. Our commitment to you is to provide you with detailed and complete information about your dental needs as we diagnose them. We will share our diagnostic processes with you, and we invite and welcome all of your questions regarding our treatment.

Towards this aim of a mutual sharing of information, we feel it is important to advise you of the reasonably foreseeable risks of endodontic therapy. The following is important information you should consider to aid your treatment decision.

- Root canal therapy is a procedure designed to retain a tooth that may otherwise require extraction. Root canal therapy has a very high degree of success. However, it is a biological procedure, and results cannot therefore be guaranteed.
- Approximately 5% to 10% of teeth that have undergone nonsurgical root canal therapy may require retreatment or root-end surgery.
- Despite our best efforts, approximately 5% of endodontically treated teeth may fail and require extraction.
- Final restoration (crown) of the tooth that has undergone root canal therapy is essential to root canal success and retention of the tooth. A final restoration should be completed within 30 days of root canal therapy. This restoration should be done by your restorative dentist.

Signature of Patient (or Parent) _____ Date _____

Witness _____ Date _____

systems, including heat-transfer units for warm gutta-percha, are both currently taught methodologies.[160] Each technique has zealous advocates. Both methods are reasonable and acceptable choices, and each method conforms to the standard of care. The choice of techniques changes as new products are introduced and scientific research is conducted. The vertical warm gutta-percha technique promises to deliver improved flow to fill lateral canals and is likely to predominate in the 21st century as the preferred methodology. Nonetheless, lateral compaction has a long-term proven track record, particularly with less-experienced practitioners, and is less technique sensitive.

Referrals to Other Specialists

Every clinician, including specialists, will at some time need to refer a patient to another specialist for treatment to comply with the standard of care required of a reasonably careful clinician.[98]

Generally, if the referral takes place within the same dental practice, the legal doctrine of respondeat superior ("let the master answer") may be applicable. Under this doctrine, a clinician is liable for the dental negligence of a person acting as his or her agent, employee, or partner.[214] Liability is determined by whether the principal clinician controls the agent clinician's activities or methodology, regardless of whether such control is actually exercised.

If the referral is made (even within the same physical environment) to an "independent contractor" endodontist who does not diagnose or treat under the direction or supervision of the referring clinician, and that referring clinician has no right of control as to the mode of performing the treatment, the principle of agency and responsibility for the acts of another does not apply.[184] The legal test for agency is the principal's right to control, regardless if the control is exercised over the agent. However, if the independent contractor or referring clinician in the same practice does not provide adequate notice of this independent relationship to the patient, the independent contractor will still be liable under the legal doctrine of ostensible agency. Thus, despite an independent contractor agreement, a patient can legally infer the so-called independent clinician is instead an employee, since neither clinician in the group practice disclosed an independent contractor relationship to the patient.

To ensure that the referred clinician is not considered the agent of the referring clinician within the same facility, fees for the referred clinician should not be set by the referring clinician nor should the fees be divided equally or shared based on some other arrangement. Also, the referred clinician should bill separately and exercise independent diagnostic and therapeutic judgment. The patient should be advised that the referred clinician is independent of the referring clinician. Otherwise, the referred clinician or specialist may be regarded or inferred to be the ostensible agent of the referring clinician in the same office although not intended. The legal test for agency is how the facts or circumstances appear to a reasonable patient, regardless of the clinician's understanding or written contract intent that the other treating clinician is to be considered an independent contractor. Thus, agency may be actual in fact or, alternatively, ostensible (i.e., implied by circumstantial conduct).[142]

Surgical versus Nonsurgical Endodontics

Litigation to determine whether nonsurgical or surgical endodontics was the proper treatment choice will not be decided by any one clinician, the ADA, the AAE, or the ablest of judges. Rather, after considering all the evidence and the opinions of experts, a jury of the patient's peers will decide the disputed matter. Depending on the individual case, the jury may decide that either a combination of nonsurgical and surgical endodontic therapy, rather than one method exclusively, should have been attempted. The jury may also decide that the patient should have been advised of the availability of such alternative therapy. Similarly, the jury may determine that apical surgery should have been done microscopically rather than macroscopically, depending on expert testimony regarding the relative advantages of each method or upon presenting clinical circumstances (e.g., suspected calcification, viewing a separated instrument).

Microscopic Endodontics

Microscopic endodontics improves posture and reduces neck and back fatigue.[13] Identification of microfractures in teeth[55,149,160,191] and removal of diseased dental tissue are easier and more accurate when done microscopically.

> *"The operating microscope is an indispensable tool for state-of-the-art endodontic treatment. The specialty practice should not be without a microscope; this instrument is useful in all phases of endodontic treatment from diagnosis to placement of the final restoration."*[136]

Successful root canal treatment requires the prevention of microorganisms and toxins from the oral flora penetrating through the root canal system into the periapical tissues. Inadequate obturation of the root canal system is the most frequent cause of failure. Either coronal or apical leakage adversely affects success.[63,64,241]

Failing endodontics that necessitate endodontic disassembly should first be considered for a nonsurgical option because it is less invasive and therefore represents risk reduction. The clinician should first evaluate for coronal leakage, fractures, missed canals, silver point corrosion, and incomplete obturation. Root canal systems can then be recleaned or correctly transported and then thoroughly disinfected, reshaped, and packed in three dimensions to avoid apical surgery by providing instead adequate coronal, lateral, and apical seal nonsurgically.

New Products

Today's clinician exploring ways to improve the quality and success of endodontic therapy is constantly presented with new dental products and techniques. For prescribing and using drugs or other agents, the ADA's Principles of Ethics, Section 5D, provide this guideline[10]:

> *"Except for formal investigative studies, dentists shall be obliged to prescribe, dispense, or promote only those devices, drugs and other agents whose complete formulae are available to the dental profession. Dentists shall have the further obligation of not holding out as exclusive any device, agent, method or technique if that representation would be false or misleading in any material respect."*

Ethical clinicians should not indiscriminately adopt every new product. Instead, the supporting research should be reviewed, rather than risk the patient's welfare with inadequately tested or researched products only tested in vitro. Again, "Don't be the first nor the last to adopt new technology."

Separated Instruments

Risk reduction of broken files can be accomplished if all hand and rotary nickel and titanium (NiTi) cleaning and shaping files are not resterilized and reused but are discarded after single-tooth use. Efficiency is also increased, because approximately 50% of cutting efficiency is lost after initial use. Episodes of broken instruments will be dramatically reduced and nearly eliminated when files are used correctly and discarded after single-tooth use. Breakage increases sharply when hand or rotary shaping files are reused. Therefore the clinician should discard rotary instruments after a single-use visit. Chair and staff time efficiency, along with improved safety, dictates single-visit use of files.[189]

The clinician should save broken or defective instruments (e.g., a file that was broken inside a canal) (Fig. 11-20). The instrument manufacturer may be liable because the product was defective, rather than the clinician being liable for dental negligence.[215] Electron microscopy spectrographic analysis can determine if manufacturing defects with contaminants caused the break, rather than the clinician excessively stressing the instrument.

Equipment and Supplies

Equipment should be kept in good repair by checking and following the manufacturer's recommended maintenance schedule. The clinician should carefully read the manufacturer's instruction warnings on instruments and inform staff of any important points. Infection control in operating dental equipment is mandatory, such as updating and maintaining dental units with check valves to prevent water retraction or suckback. The clinician should inspect check valves monthly and change clogged valves immediately.[152] Water retraction testers, at no charge to the clinician, are available from some manufacturers (A-dec [Newberg, OR], for instance). The clinician or a staff member should also disassemble the unit's handpiece, run water through the line for a few seconds, and then stop. If a bubble of water is visible at the end of the water hose holes, the check valve is operating properly. If a bubble of water is not visible, water may be sucked back because of an absent or clogged check valve. An absent or clogged check valve is a source of cross-contamination, so it is important for the clinician or staff to perform weekly spore testing of the autoclave and monthly bacteriologic testing of water lines.[11] The clinician or staff should consider using filters and should flush dental-unit water lines daily with FDA-approved chemical disinfectants to reduce water tubing biofilm. Some chemical disinfectants claim improved cost effectiveness by increasing handpiece and bur longevity concomitant with water-line purging or with continual use during treatment. Fig. 11-21 shows a student who was burned by an inadequately maintained handpiece that overheated. This case settled for $280,000.

Prescription Drugs

Clinicians should exercise extreme caution when administering or prescribing dangerous drugs. For sedative or narcotic drugs, cautionary directions should be written on prescriptions, and the pharmacist should place these directions on the prescription container as a patient reminder. For example, for the appropriate drugs, the clinician should prepare a

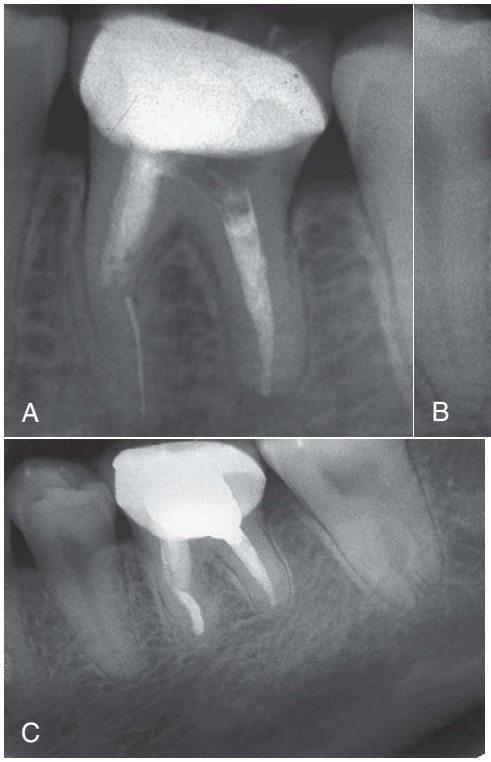

FIG. 11-20 A, Nickel-titanium file broken inside the mesiobuccal canal of the mandibular first molar. **B,** Due to patient discomfort, the segment was surgically removed and MTA was used as root-filling material. **C,** Periapical radiograph 2½ years post-treatment shows complete healing. FIG. 11-21 A, Before injury. **B-D,** A music student was burned by an inadequately maintained handpiece that overheated. This lawsuit was settled for $280,000.

prescription rubber stamp or obtain preprinted prescriptions that state the following:

> *"Do not drive or operate dangerous machinery after taking medication because drowsiness is likely to occur. Alcohol, sedative, or tranquilizing drugs will cause drowsiness if taken in combination with this prescribed drug."*

The ADA and American Medical Association (AMA) provide prescription drug warning pads. Clinicians should document each drug information form provided with the prescription in the patient's chart.

Overuse of antibiotics risks resistant-strain development and side effects. Studies demonstrate generally no increased therapeutic efficiency of endodontic therapy with antibiotics when performed in the absence of facial swelling.[262] Unless persistent infections occur or compelling systemic reasons exist (e.g., uncontrolled diabetes, antibiotic prophylaxis necessary because of mitral valve regurgitation), antibiotics should not be prescribed prophylactically.[188] Neither pain nor localized swelling alone justifies antibiotics. However, extraoral swelling, cellulitis, or lymphadenopathy may require surgical drainage, antibiotics, or both. The U.S. Centers for Disease Control and Prevention (CDC) estimates about one third of all antibiotic outpatient prescriptions are unnecessary.[9]

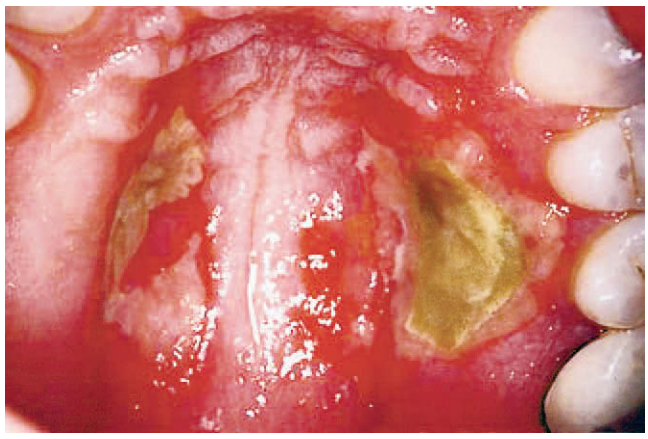

FIG. 11-22 Excessive local anesthetic resulting in palatal tissue sloughing with AMSA (wand) injection.

Product liability may include whether the manufacturer provides adequate hazard warnings for safe use of its product (Fig. 11-22).

Clinician's Liability for Staff's Acts or Omissions

A clinician is liable for the acts or omissions of the clinician's staff under the doctrine of respondeat superior ("let the master answer"). This is termed *vicarious liability,* which means that the clinician is responsible not because of personal wrongdoing, but because the clinician assumes legal responsibility for the conduct of employees and agents who act in the course and scope of their employment.

The clinician should instruct the staff in advising patients regarding posttreatment complaints. For example, if the staff ignores signs of infection, such as difficulty in swallowing or breathing or elevated temperature, and dismisses the patient's complaints as normal postoperative swelling, the clinician may be held liable for injury to the patient, such as delayed cellulitis, diagnosis or treatment of Ludwig's angina, brain abscess, or other serious complications.

A clinician must be cautious when delegating responsibilities and give clear instructions to ensure that staff members properly represent the clinician and the chosen practice methods. Auxiliaries should not be allowed to practice beyond their competency level or license. For example, in states where assistant-placed restorations are legally permissible, the clinician should check any assistant-placed restoration before patient dismissal. Staff members should not make final diagnoses or handle patient clinical complaints without the clinician's involvement and consultation. Staff should be instructed to ask appropriate questions and relay the patient's answers to the clinician so the clinician can adequately determine what should be done.

Abandonment

Once endodontic treatment is initiated, the clinician is legally obligated to complete the treatment regardless of the patient's payment of any outstanding balance. This requirement is posited on the legal premise that any person who attempts to rescue another from harm must reasonably complete the rescue with beneficial intervention unless another rescuer (i.e., clinician) is willing to assume the undertaking.[50,158] Another view is that should a patient be placed in a position of danger unless further treatment is performed, the clinician must institute reasonable therapeutic measures to ensure that adverse consequences do not result.[174,240]

A clinician performing endodontic therapy should have reasonable means of communicating with patients after regular office hours to avoid a claim for abandonment. A recorded message is inadequate if the clinician fails to check for recorded messages frequently. Therefore answering services, pagers, and/or cell phones are required by the standard of care.

If the clinician providing endodontic therapy is away from the office for an extended period, a substitute on-call clinician should be available for any endodontic emergency and to answer patients' emergency calls. The endodontic treating clinician should arrange in advance for emergency service with a covering clinician. Leaving a name on the office answering machine or with the answering service without first determining the availability of the covering clinician is a mistake.

To avoid an abandonment claim, several prophylactic measures apply:

1. No legal duty requires a clinician to accept all patients for treatment. A private practice clinician may legally refuse to treat a new patient, despite severe pain or infection, except on the grounds of race or disability.[33,264] If treatment is limited to emergency measures only, the clinician must advise the patient that only temporary emergency endodontic therapy is being provided, and that endodontic treatment is incomplete. The clinician should record this information in the patient's chart. For example:

   "Emergency palliative treatment only. Patient advised endodontic treatment of tooth #8 needs to be completed, either here or with another clinician. Explained complications likely if not soon completed, including infection recurrence, tooth loss, or both."

   The patient should also be asked to acknowledge that treatment is limited to the existing emergency by endorsing an informed consent to emergency endodontics statement as follows:

   "I agree to emergency endodontic treatment of my tooth #8 and have been advised that (1) emergency treatment is for temporary relief of pain and (2) further root canal treatment of tooth #8 after emergency treatment is necessary to avoid further complications, including, but not limited to, pain, infection, swelling, tooth fracture, abscess, or tooth loss."

2. No legal duty requires a clinician to continue treating former patients on recalls or subsequent emergency care once treatment is complete. Thus completion of endodontic treatment for tooth #19 does not legally obligate the clinician to initiate endodontic therapy for tooth #3 if endodontic disease began months after the clinician completed treatment of tooth #19.
3. Any patient may be discharged from a practice for any arbitrary reason, except on the grounds of race or disability, so long as all initiated treatment is completed. Accordingly, a former patient who evokes memories of a "frictional" relationship, who is financially irresponsible, or who arrives at the office after an absence of several years with an acute apical abscess in a site where previous care was not rendered may legally be refused treatment.
4. It is not considered abandonment if a patient is given reasonable notice to seek endodontic treatment with another clinician, and the patient is willing to seek endodontic services elsewhere.[190] Thus if rapport with the patient dissolves, the clinician should not hesitate to suggest that the patient would be better served if any remaining endodontic treatment were performed by a different clinician.

The clinician may discontinue treatment, provided it is not done at a time when the patient's dental health will be jeopardized (e.g., in the middle of treatment). To discontinue treatment, the clinician should:

1. Notify the patient of the plan to discontinue treatment after a certain date.
2. Allow enough time for the patient to obtain care with another clinician, usually 30 days.

3. Offer to make emergency service available during the interim 30 days until a new clinician is obtained.
4. Provide diagnostic-quality records, copies of radiographs, and other pertinent clinical information in transfer records to the new treating clinician.
5. Allow the patient to select a new clinician or suggest referral by the local dental society if a referral service exists.
6. Document all of the above in the patient's records, including a copy of a certified letter sent to the patient notifying discontinuance of further treatment.

Expert Testimony

The standard of care a clinician must possess and exercise is particularly within the knowledge of dental experts. However, there are occasional exceptions where the conduct involved is within the common knowledge of laypersons, in which case expert testimony is not required. In determining whether expert testimony is required to establish negligence, one California court commented: "The correct rule on the necessity of expert testimony has been summarized by Bob Dylan: 'You don't need a weatherman to know which way the wind blows.' "[139]

Incorrectly operating on the contralateral side because of mismounted radiographs or marking the wrong tooth on an endodontic referral card is an example of negligent conduct within the common knowledge of laypersons for which expert testimony is not required.

Increasingly, courts act as gatekeepers regarding the admissibility of scientific expert testimony. Anecdotal comparisons appear compelling, but such evidence may be judicially excluded in the courtroom. Some experts rely solely on their skill for experience-based observation, rather than research testing of risk factors, such as occurs with epidemiologic research.

The U.S. Supreme Court (in the Daubert four-factors checklist[59]) advises that an expert's testimony may be reliably admitted into evidence based on the following:

1. Whether the expert's technique or theory may be tested or refuted
2. Whether the technique or theory has been the subject of peer review or publication
3. Known or potential rate of technique error
4. Degree of acceptance of a theory or technique within the relevant scientific community

Courts determine whether testimony is based on the application of scientific principle or clinical experience. In general, courts are flexible and adaptable in determining whether a bright line separates scientific and unsupported nonscientific evidence. Often technical and specialized knowledge gained though continuing education and scientific journals, rather than an expert performing the research, is considered sufficient so long as the expert's opinion complies with the Daubert principle.

State courts are not bound to follow the Federal Rules of Evidence, but many do comply.[18] Nonetheless, U.S. Supreme Court decisions influence state courts that consider placing limitations on expert testimony. State court trial judges may either be more liberal or more restrictive in admitting expert witness testimony. If the trial court judge denies admission of scientific evidence as unreliable, untrustworthy, or irrelevant, the end result may be to preclude an expert offering any opinion. On the other hand, the court may admit such evidence and instruct the jury members that they may consider the scientific basis for the expert opinions and give such evidence the evidentiary weight it deserves.

In *Weisgram v. Marley Co.*,[265] the U.S. Supreme Court held that under Federal Rule of Civil Procedure 50(a), either a district (trial) court or a court of appeals may enter judgment for defendant, notwithstanding the plaintiff's verdict, if either court determines that admitted expert testimony was unreliable and inadmissible under *Daubert v. Merrell Dow Pharmaceuticals, Inc.*[59]

National Practitioner Data Bank

Insurance carriers are obligated to report all settlements to the National Practitioner Data Bank. These data are only accessible to hospitals for staff privilege credentialing and state licensing boards but not individual patients.

Medical negligence occurring in hospitals is too often underreported.[61] The Public Citizens' Health Research Group report that more than half of U.S. hospitals have never reported an adverse incident to the National Practitioner Data Bank.[52]

Professional Negligence Incidence

In 2007, health care spending totaled $2.2 trillion, or 16.2% of the gross domestic product. Total spending for doctors' services was $393.8 billion.[259]

Harvard School of Public Health found that 97% of claims involving medical injury are meritorious.[203] A survey of federal judges found that 85% believed frivolous lawsuits were not a problem. Juries are more likely to rule in favor of a defendant than judges.[156,256]

Tort filings in state courts, which comprise only 6% of all filings, declined by 21% over the decade 1997-2006.[194] Tort actions in U.S. District Courts also dropped 21% (2003-2007).[256] Medical malpractice filings dropped 8% during this period. Contract cases, on the other hand, which are more likely to involve businesses, increased 23% over the same time period.[156,194]

A 2003 report submitted to Congress by the GAO found that malpractice awards are only one factor contributing to increases in premiums for medical professional liability insurance.[244] Other factors cited include falling investment returns for insurance companies and normal business cycles. The report concluded that assertions that insurance premiums are driving clinicians out of business and making health care inaccessible were "not substantiated or did not affect access to health care on a widespread basis." The report also stated that it is not possible to prepare a full analysis of the issue because comprehensive insurance data are not available.

Since malpractice premiums account for about 1% of health care spending, imposing caps in liability cases would therefore have essentially no impact on the cost of health care. Evidence that this unnecessary remedy for a perceived but absent wrong is the National Association of Insurance Commissioners' data from 1995 to 2000, which show new medical malpractice claims declined.

The existing civil liability system permits each state autonomy to regulate the resolution of professional liability actions within its borders. This is a hallmark of our American justice system.

The popular image holds that jurors are overly sympathetic to patients with unfortunate dental outcomes, regardless of whether anyone is to blame. However, research on juror attitudes demonstrates the opposite. Thus weak cases seldom succeed despite serious injuries.[22,244]

Some malpractice is inevitable. Even the best clinician is capable of making a mistake. About 5% of clinicians account for the majority of all malpractice claims, according to reports filed with the National Practitioner Data Bank. Among clinicians who have settled five or more malpractice claims, only 13.3% have been subject to professional discipline, according to the Public Citizens' Health Research Group's analysis of the data. Forty-five percent of otolaryngologists admit medical errors in all phases of their practice. However, even this proportion of clinicians reporting medical errors is underestimated.[220] A recent study estimated the number of fatal medical errors doubled in the preceding 3 years.[61]

Managed Care and the Employment Retirement Income Security Act

Ten states passed managed care liability laws that permit patients to sue managed care organizations for damages resulting from delayed or refusing authorizations for treatment the clinician recommended as medically necessary. A recent U.S. Supreme Court decision nullified those state laws for the 140 million Americans covered by health plans that are regulated by the Employment Retirement Income Security Act of 1974 (ERISA).[1] ERISA restrictions do not apply to government employees' dental insurance.

MALPRACTICE INCIDENTS

Screw Posts

Screw posts represent a restorative anachronism. The risk of root fracture is too great compared with the benefit, particularly when reasonable and superior passive alternatives exist (see Chapter 22). Even if the screw post is initially placed passively, the temptation to turn the screw is too great, considering human nature. Therefore screw posts are not a reasonable and prudent treatment choice.

Paresthesia Prevention

Endodontic surgery in the vicinity of the mandibular canal or mental foramen carries with it the significant risk of irreversible injury to the inferior alveolar and/or mental nerve. Consequently, the clinician must advise the patient in lay terms of the risk of temporary or permanent anesthesia or paresthesia before any surgery near these structures is performed. To document that adequate informed consent was provided, the clinician should have the patient execute a written informed consent form confirming that the patient was so advised. Informed consent is no defense if the surgery was negligently chosen or performed, because informed consent only applies to non-negligent treatment risks. CBCT imaging has greatly reduced if not eliminated entirely the likelihood of IANC perforation. CBCT provides diagnostic guidance before therapy. Also, a final diagnosis confirms or rules out IANC penetration post treatment, promoting prompt removal of foreign materials piercing the IANC.

A clinician initiating root canal therapy on a mandibular posterior tooth must have (1) an awareness of the vital neurovascular bundle containing the IAN, which commonly approximates the ends of these roots, and (2) a diagnostic-quality image that accurately demonstrates the IANC. If endodontics is done without adequate diagnostic radiographs, the patient is placed at great risk if there is anatomic variation or vital neural bundles lie in close proximity to these roots.[85,146,168,234,271] Overfilling and/or overinstrumentation of the root ends can cause traumatic and/or chemical injury to the IAN bundle, resulting in potentially permanent altered or total loss of sensation from paresthesia (partial numbness), anesthesia (total anesthesia), and/or dysesthesia (burning pain).

The risk of overfills containing toxic materials causing irreversible neuropathies results from (1) inadequate imaging of the proximity of both borders of the IANC (Fig. 11-23, *A-C*), (2) inadequate measurements during cone measurement, and (3) not limiting filling materials to within the confines of the shaped root canal space as further evident in CBCT.

The eugenol component of the root canal sealer part of the overfill is known to be cytotoxic. Consequently, endodontic overfill of the root apex is capable of producing not only mechanical damage[180] but also chemical injury. Accordingly, a prompt microsurgery referral to remove the injurious materials from the IAN inside the IANC nerve space before overfill material toxins are chemically set is mandatory.[206] Better yet is to take precautions to prevent ANY significant injurious overfill.

The use of electronic measuring devices such as an electronic apex locator is standard technology for accuracy when working deep within the root canal system. In addition to radiographs, an apex locator helps provide accurate length readings. If it is determined that the apex is in extremely close proximity to the IANC, extra precaution must be taken to prevent overextension of instruments or materials.

Precise measurements during cleaning, shaping, and obturation compacting stages of endodontics minimizes significant overfill incidents. Obturating filling materials are not only toxic to nerve cells but also create a mechanical pressure injury to the nerve cells themselves. Immediate microsurgical referral for retrieval of any overfill materials which "harpoon" the IANC protect against irreversible neuropathies (see Fig. 11-25, *C*).[206]

Serious mechanical and chemical injury to the IAN results from a lack of recognition of the overfill piercing the IANC and/or disregard for neuropathic symptoms the patient reports postoperatively that are consistent with neurologic deficits.

Referral to an oral surgeon/microsurgeon is time dependent. Pogrel's study demonstrated complete reversal of neuropathic symptoms secondary to overfill if microsurgery was done within 48 hours.[206] Two-thirds of Pogrel's patients gained significant improvement if microsurgery was done within 3 months of IAN overfill injuries. Delaying expeditious referral to a microsurgeon for removal of overfilled materials progressively worsens the toxic effects of the chemical injury over time. Delaying microsurgical referral risks permanent injury, owing to the time-dependent nature of overfill errors.

After 3 months, microsurgical delay will almost close the window of opportunity to prevent permanent neurologic deficits of altered sensation, with resulting pain, numbness, and painful burning symptoms extrusion overfills into the IANC can cause. Stat referral for microsurgical removal of paraformaldehyde-containing root canal filling materials and sealants

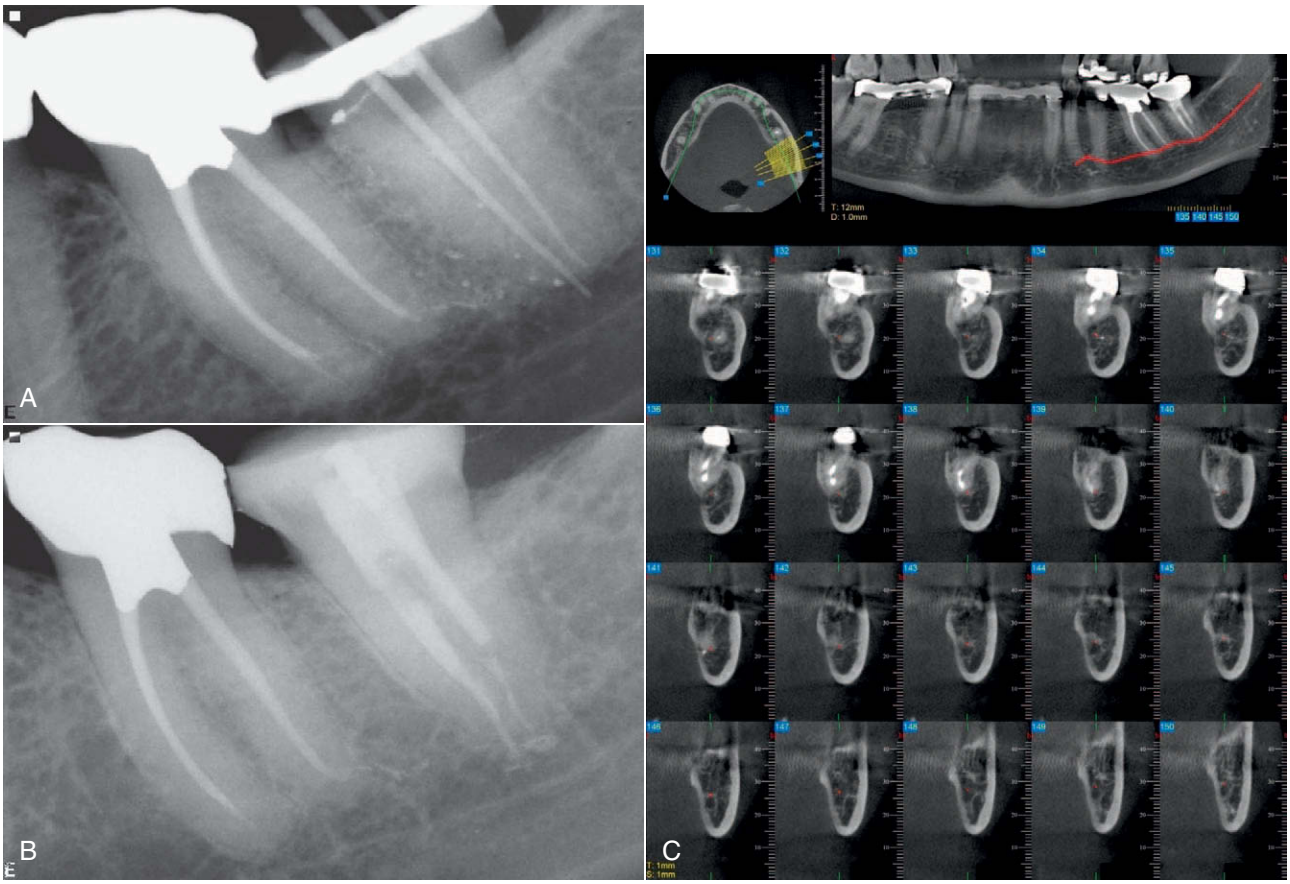

FIG. 11-23 A, Unclear periapical to show both cortical borders of inferior alveolar nerve canal (IANC). **B,** Cones placed into IANC, showing measurements beyond apices. **C,** Overfill into IANC better shown on cone-beam computed tomography (CBCT) than periapicals of **A** and **B.**

is even more critically time dependent because of the greater toxicity and mummifying effects of these powders when mixed into pastes (e.g., N2 and RC2B). Risks include anaphylactic shock.[34,99,115,155]

For needed stat referrals, the offending clinician should phone, write to, and e-mail the microsurgeon. Patients lack the expertise to promptly obtain critically time-dependent referrals. When time is of the essence, the clinician and staff must assume direct responsibility to assure the stat referral to a microsurgeon is promptly accomplished.

Treatment Failure

A clinician should not guarantee treatment success. It is foolish to assure the patient of a perfect result.[49] Endodontic failures may occasionally occur despite adequate endodontic care.[131,249] Nevertheless, negligent contributing factors to endodontic failures include perforation, missed or transported canal, uninstrumented portion of a root canal, bacterial infiltrates by way of a leaky coronal restoration contaminating the root canal filling,[48,237,241] overextension errors, and inadequate isolation of the tooth from salivary contaminants during instrumentation due to lack of a rubber dam.

To avoid claims based on failed endodontics, the patient should be advised in advance of treatment of the inherent (but relatively small) risk of failure (i.e., about 5% to 10%). It may be adequate to advise the patient of the high statistical probability of success in endodontics if the clinical condition of the tooth and the clinician's past success rate warrant such representation.[116,236] Clinicians should avoid quoting the national success rate of endodontics when (1) the patient's tooth is of questionable endodontic and periodontal status and (2) the clinician is known to have an unusually high endodontic failure rate—for example, a rate that varies markedly from national statistics, which also suggests referral to an endodontist.

An endodontic treating clinician is also liable for failure to disclose evident pathosis in the quadrant being treated. The patient should be advised of any periodontal disease that adversely affects the prognosis of abutment teeth for partial dentures, bridges, or an implant with a need for grafting if the endodontically treated tooth is lost. A clinician should also advise of cysts, fractures, or lesions of suspected neoplasms. In addition, the clinician must be careful not to ignore any evident pathosis that if untreated may adversely affect the dental or medical health of the patient. Again, a clinician who fails to plan treatment properly is planning for treatment failure.

The doctrine of informed consent protects both the clinician and the patient so that there will be no surprises or patient disappointment if a non-negligent adverse result occurs. Should such a failure or complication occur, the availability of a signed informed-consent form can serve as a reminder to the patient that the risk of complications, including failure, was discussed in advance of treatment and that unfortunately the patient's endodontic treatment fell outside the usual 90% or greater root canal therapy success rate.

Slips of the Drill

A slip of the drill, like a slip of the tongue, may be unintentional. Nevertheless, it can cause harm. When a cut tongue or lip occurs, it is usually the result of operator error. To paraphrase Alexander Pope, to err is human, to forgive, divine. To increase the likelihood that a patient will forego filing suit because of a cut lip or tongue, the clinician should follow these steps:

1. Inform the patient that the clinician regrets having injured the patient. This is not a legal admission of guilt in 29 states with "I'm sorry" protective statutes, but rather an admission that the clinician is a compassionate human being. In 2005, federal legislation to apply "I'm sorry" to all 50 states was proposed. A Senate bill was sponsored but has not yet been passed by Congress.
2. Repair the injured tissues or refer the patient to an oral or plastic surgeon, depending on the extent of the injury and whether a plastic revision is necessary if scarring is likely.
3. Advise the patient that the clinician will pay the bill for the referred treatment of the oral or plastic surgeon. Request the oral or plastic surgeon to send the bill directly to the clinician for payment. Send the oral or plastic surgeon's bill to the clinician's professional liability carrier. Some carriers will pay the claim under the medical payments provisions of the general liability policy for an "accident" rather than as a malpractice incident compensable under the professional liability policy. Call the patient periodically to check on healing, recovery, and follow-up plastic surgery.

Leakage

Long-term seal of the root canal system is determined apically by the sealer and coronally by the final restoration.[24,106,189,237] Root canal–filled teeth should be permanently restored without undue delay to prevent leakage contamination of the previously obturated canal system, since varying canal shapes from round to oval prevent a 100% seal.[63,64,164] Bonded seals covering the canal surfaces should be used to control any leakage after compaction until a permanent restoration is cemented. Besides an adequate coronal sealing, an adequate apical sealer should be well adhered to the canal walls.

The endodontic goal is to prevent bacterial contamination of the periradicular tissue by predictably providing adequately cleaned, shaped, and filled root canal systems. Any residual bacteria should be entombed in the root canal filling. A bacteria-tight apical seal should be designed to last long term with sealed portals to prevent reentry of microorganisms, which cause reentry recontamination and lead to endodontic failure.[63,241] Younger patients are more susceptible to bacterial penetration inside dentin tubules and thus recurring infections.[143]

Electrosurgery

Electrosurgery can cause problems if mishandled. Damage to the oral cavity caused by improper use of electrosurgical devices consists primarily of gingival necrosis, osteonecrosis, sloughing adjacent to the surgical field, and pulpal necrosis of affected teeth.

All equipment should be properly maintained and certified to meet the American National Standard (ADA specification no. 44 on electrical safety standards). Current equipment should be checked to see that units meet these standards and that electrical cords and other components are in good repair. Electrical receptacles should meet the requirements of the National Electrical Code for circuit grounding and ground fault protection. During use, the dispersive electrode plate should be well away from metal parts of the dental chair and the patient's clothing, because skin contact can cause burns. Use of plastic mirrors, saliva ejectors, and evacuator tips is strongly recommended.

Reasonable versus Unreasonable Errors in Judgment

Although a clinician is legally responsible for unreasonable errors in judgment, mistakes occasionally happen despite adherence to the standards of reasonable care. A mistake does not prove malpractice unless the mistake is caused by a malpractice error or omission.[112] For example, accessory or fourth canals on molar teeth are frequently difficult to locate and may tax the best clinicians. Failure to locate an accessory or fourth canal does not conclusively constitute an unreasonable error of judgment. Rather, this may represent a reasonable error of judgment in the performance of endodontics. Nevertheless, if the additional canal was readily apparent radiographically, the existence of a fourth canal should have been considered, and treatment should have extended to instrumenting and sealing it.

Incorrect Tooth Treatment

A reasonable, non-negligent mistake in judgment may occur because the clinician has difficulty localizing the source of endodontic pain. Vital pulps may on occasion be sacrificed in an attempt to diagnose the pain source, but it is unreasonable and therefore inexcusable to treat the wrong tooth if it is inadequately tested with pulp tests, misidentified on the referral slip, or if radiographs are mounted or read incorrectly. Also, treating large numbers of teeth endodontically (e.g., an entire quadrant) when attempting to localize chronic pain suggests pain is probably not of pulpal origin, and other differential diagnoses should be ruled out.

If the wrong tooth is treated because of an unreasonable mistake in judgment, the clinician should be compassionate, waive payment for all endodontic treatment, and offer to pay the fee for crowning the unnecessarily treated tooth.

Post Retrieval

Ultrasonic instruments will vibrate loose the cement around posts. The clinician can avoid overheating the post by proceeding slowly with a water coolant, periodically resting for cool down, and checking the post temperature periodically to be reasonably certain overheating is not occurring.[72,102,191] Fig. 11-16 demonstrates what happened when an endodontist negligently overheated the post during attempted removal, causing tissue necrosis, bone loss, need for augmentation procedures, irreversible pulpitis in an adjacent tooth, and the loss of two teeth.[204]

Broken Files

Leaving broken files behind without referring the patient to an endodontist for attempted microscopic retrieval and also not advising the patient of leakage potential may constitute

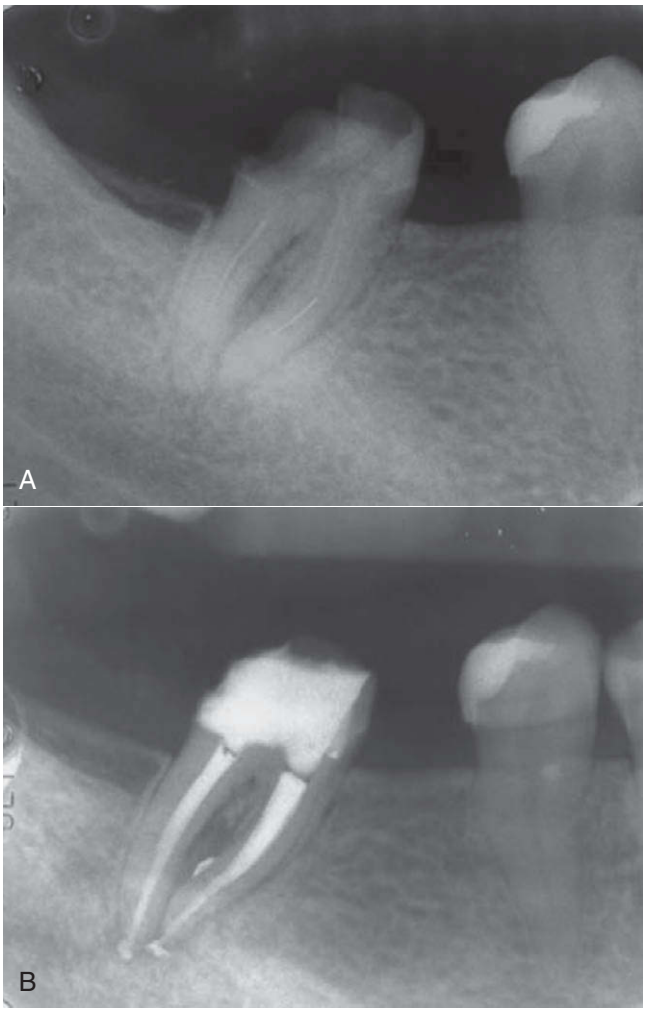

FIG. 11-24 A, Tooth #31 with three separated files, one in each canal. K-files used for cleaning canals and also obturation (1996). **B,** No apparent radiographic changes in 1998.

fraudulent concealment (Figs. 11-24 and 11-25). Patients should be informed of such mishaps for (1) referral consultation and/or treatment; (2) advising the patient, who on their own may seek a second opinion; or (3) disclosure, so as to return if a flare-up occurs.

Swallowing or Aspirating an Endodontic Instrument

Use of a rubber dam in endodontics is mandatory.[238] Even if the endodontically treated tooth is broken down and cannot be clamped, a rubber dam, regardless of required modification, should be used in all instances (see Chapter 5). Not only is microbial contamination reduced with the use of a rubber dam, the risk of a patient's aspirating or swallowing an endodontic instrument is eliminated (Fig. 11-26). Accordingly, if a patient swallows or aspirates a file, it is likely because of the clinician's failure to observe the standard of care. If a swallowing or inhalation incident does occur, the clinician should do the following:

1. Advise the patient that the clinician regrets what occurred.
2. Refer the patient for immediate medical care, including radiographic imaging, to determine if the instrument is lodged in the bronchus, esophagus, or stomach so that appropriate medical measures are taken promptly to remove it.
3. Offer to pay for the patient's out-of-pocket medical expenses and wage loss. Some professional liability

policies will cover the incident as "medical payment" for an accident and not as a malpractice claim.

Overextensions and Overfills

A common error in utilizing periapical or panorex imaging is presuming that when only one cortical border of the IANC is visible, the sole visible border is the superior border. Instead, virtually always when only one cortical border is clearly visible, it is the inferior cortical border.[168] (See Fig. 11-25, *B* periapical, which may appear to show only one cortical border, and Fig. 11-25, *C*, a clearer CBCT image of the same area showing both cortical borders.)

Misassumption of the IANC borders results in mismeasurement of the IANC location. Since the IANC is approximately 3 mm in diameter, misassuming the sole observable cortical canal border to be the superior border (rather than the inferior border) can result in an imprudent treatment decision to delay microsurgery if overfill occurs and the CBCT confirms an overfill inside the IANC. In Fig. 11-25, *B*, the defendant endodontist misdiagnosed the overfill as being superior rather than inside the IAN canal, with resultant permanent paresthesia from only watching and waiting for sensory return rather than referring for a stat microsurgical removal.

A very slight overextension of root canal filling with conventional obturation or sealants can occur without violating the standard of care (see Chapter 10). Gross overfill usually indicates faulty technique. Fig. 11-27, *A-B* illustrates gross overfill of calcium hydroxide, causing permanent paresthesia. Nevertheless, so long as the overextension is not in contact with vital structures such as the IAN or sinuses, permanent harm is unlikely unless the root canal is filled with a paraformaldehyde-containing sealant (causing a neurotoxic chemical burn type of injury which chemically diffuses through bone marrow and soft tissue spaces).

If, however, severe postoperative pain is foreseeable as a result of overextension, the patient should be advised of the likelihood of postoperative discomfort because of contact of the sealant material with surrounding tissue. Similarly, if the overextension is very slight and increased postoperative pain is unlikely, the patient need not be advised, lest it cause unnecessary alarm. A note should be made on the patient's chart of the overextension and the reason for not informing the patient, in case symptoms later manifest. The clinician should observe with close follow-up visits and patient phone calls that evening and the next morning to rule out severe postoperative persistent numbness and/or pain resulting from moderate to large overfills. Fortunately, slight to moderate overextensions with inert conventional endodontic sealers, such as gutta-percha with Grossman's sealant, often repair themselves and produce no irreversible changes without direct contact into the sinus or IANC.

Overextending the root canal filling material risks permanent consequences if the underlying IAN is initially "harpooned" with files. Portal of entry into the IANC results from overinstrumentation penetration. Flexible gutta-percha alone probably will not penetrate beyond the mature root into the IANC or other vital structures without prior excessive instrument perforation into the IANC.

Mental foramen distances can be overestimated on the panoramic radiograph. Panoramic radiography showed more deviation (+0.6 mm) from the perioperative measurement.[85,234] As noted earlier, paraformaldehyde-containing sealants can create cytotoxic chemical destruction of the IAN if placed in close proximity to, even though not directly contacting, the underlying IAN (see reference, Sargenti Opposition Society [SOS]).[224] On the other hand, conventional obturators and sealants usually require direct contact with the IAN before resulting permanent anesthesia, paresthesia, and/or dysesthesia occurs (Fig. 11-28). Consequently, the incidence of permanent sequelae with conventional filling materials is extremely low compared with the greater cytotoxic potential with paraformaldehyde-containing sealants.[195] Because of the higher risks associated with paraformaldehyde-containing endodontic materials, use of N2, RC2B, or similar toxic pastes is contraindicated and violates the standard of care. Permanent injury risk is substantially less likely with traditional eugenol-containing filling materials, a less toxic chemical than paraformaldehyde, which destroys and mummifies nerve tissues. When safer, less risky alternative effective therapy exists, it is unreasonable (and substandard) to elect an unsafe alternative methodology. Also, the doctrine of informed consent is highly relevant because it is contrary to public policy to request a patient to assume inherently dangerous treatment risks that are reasonably avoidable with safer and more predictable methodologies. When the risk exceeds the benefits, such risks are regarded as negligent and thus should be avoided and not undertaken.

Any significant overextension should be considered for immediate retreatment by attempted retrieval of the overextended gutta-percha. The clinician also has the option of immediately referring the patient to an endodontist for retrieval before the sealant sets. Conventional filling agents such as

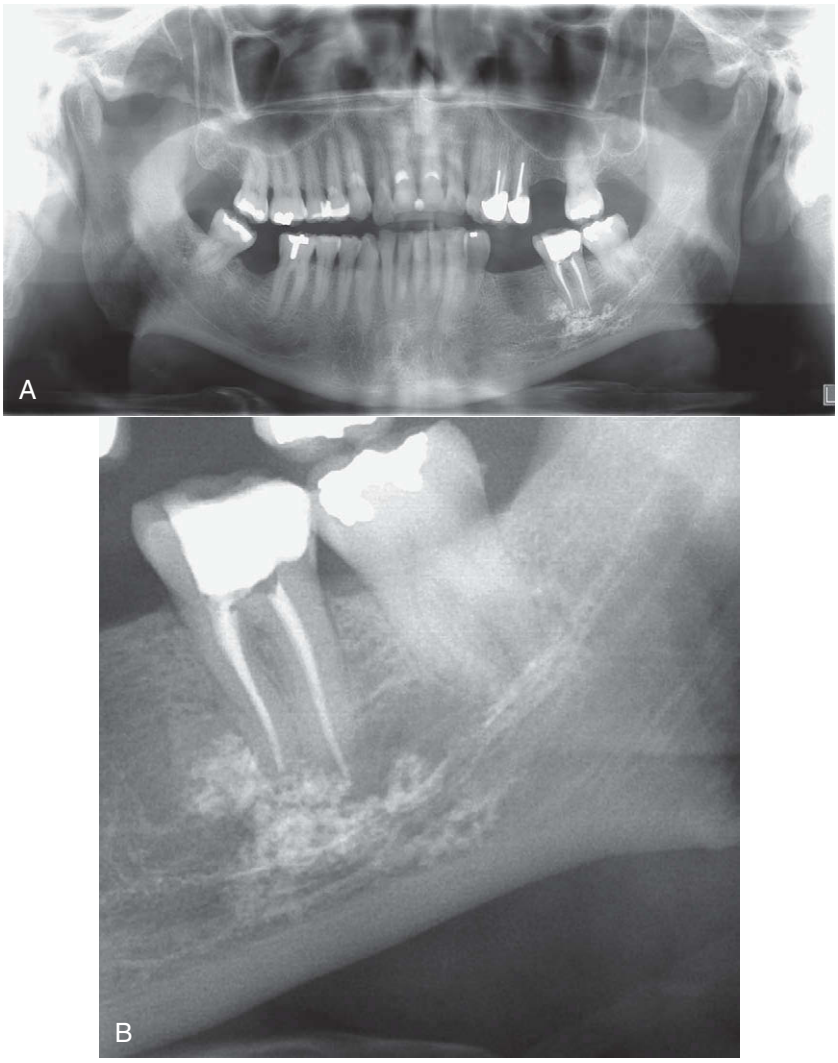

FIG. 11-27 A-B, Calcium hydroxide overfill, causing permanent paresthesia.

gutta-percha do not penetrate the cortical walls of the IANC unless preceded by prior penetration with overinstrumentation. This principle can apply to sinus perforation. If despite local anesthesia, the patient feels an electric shock during mandibular molar or premolar instrumentation, this may be a warning sign that the IAN was pierced with endodontic files. If this occurs, the root canal should not be filled; instead, periapical radiographs at different angles should be exposed with instruments in place to confirm whether any IAN penetration resulted. Removal of gutta-percha and sealants that have entered the IANC should be attempted as soon as possible (preferably no later than within the first 24 to 72 hours).[206] The eugenol component of the sealant causes an inflammatory reaction in a constricted space which is best relieved by retrieval. If retrieval fails, a decortication microsurgical procedure with an oral surgeon is indicated at the earliest possible time (preferably within the first 24 to 72 hours) owing not only to eugenol chemical toxicity but also eugenol reaction with gutta-percha, which causes expansion and thus a mechanical compression ischemic injury.[180,206]

Inflammatory edema that compresses and compromises blood supply to soft tissues and nerves in limited spaces with resulting ischemia is termed *compartment syndrome*.[230,274] Compartment syndromes are a group of conditions that result from increased pressure within a limited anatomic space, acutely compromising the circulation and ultimately threatening the function of the tissue within that space. Compartment syndrome occurs from an elevation of the interstitial pressure in a closed osseofascial compartment that results in microvascular compromise. The pathophysiology of compartment syndrome is an insult to normal local tissue homeostasis that results in increased tissue pressure, decreased capillary blood flow, and local tissue necrosis caused by oxygen deprivation. Compartment syndrome is caused by localized hemorrhage or postischemic swelling. The pathophysiology of compartment syndrome is a consequence of closure of small vessels. Increased compartment pressure increases the pressure on the walls of arterioles within the compartment. Increased local pressure also occludes small veins, resulting in venous hypertension within the compartment. The arteriovenous gradient in the region of the pressurized tissue becomes insufficient for tissue perfusion.

The clinician should have a high index of suspicion whenever a closed bony nerve compartment has the potential for

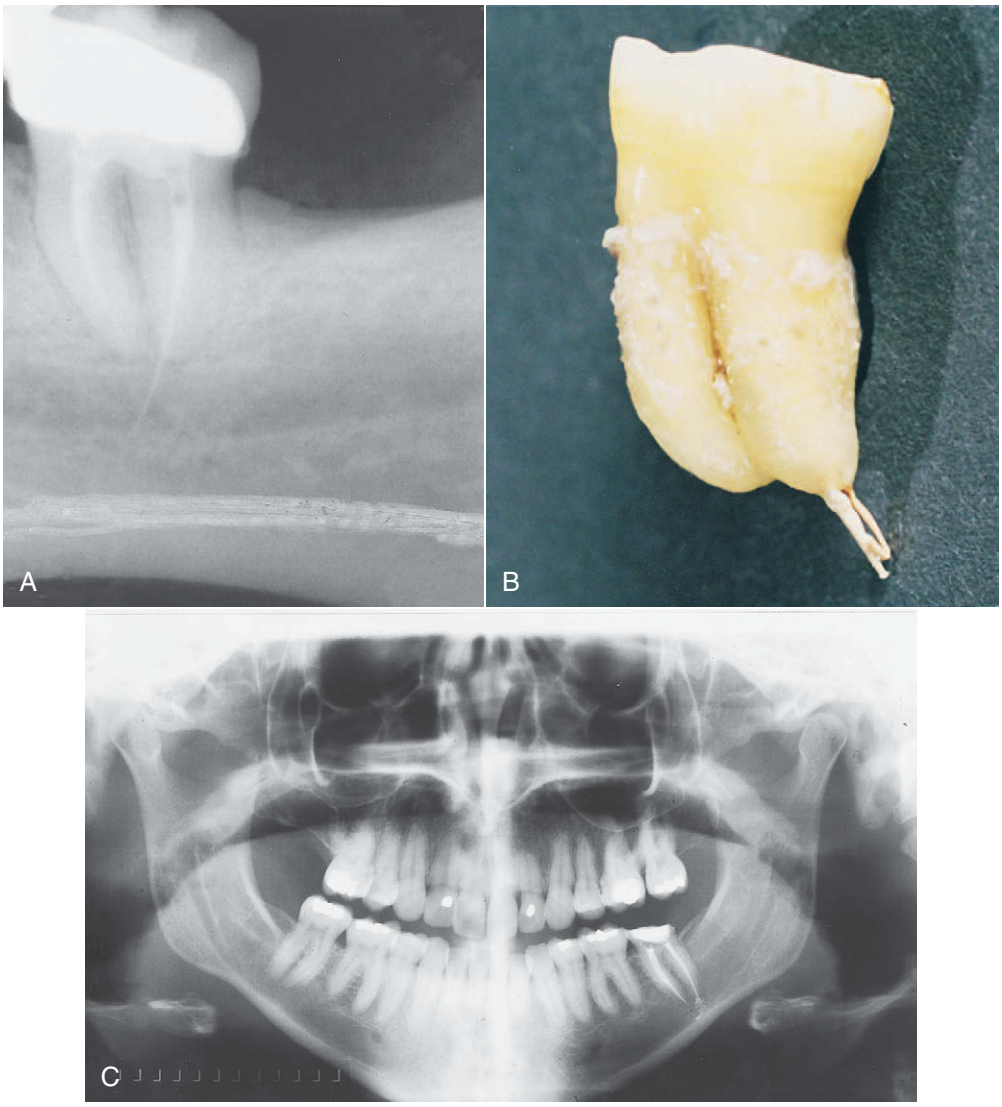

FIG. 11-28 A-C, Overextended gutta-percha and extracted tooth with gutta-percha intact.

bleeding or swelling. Compartment syndromes are characterized by pain beyond what should be experienced from the initial injury. Also, diminished sensation may be noted in the distribution of the nerve within a compartment that is being compressed, such as the IANC enclosed by bone on all sides.

Current Use of Silver Points

Based on what has been known for more than 3 decades, use of silver points in lieu of gutta-percha or other conventional endodontic filling materials represents a departure from the current standard of care. This is because silver points corrode in time, and a tight 3D apical seal is lost. Fig. 11-29, *A-C* represents gross overextension with a silver point that ultimately caused the loss of tooth #14 as a result of endodontic failure.

N2 (Sargenti Paste)

Dental literature reports that permanent paresthesias are associated with gross overfilling with paraformaldehyde sealant (N2) that are not usually associated or reported with conventional sealants (Fig. 11-30).[162,195] Current use of paraformaldehyde-containing endodontic sealants is not merely the result of a philosophic difference between two respectable schools of thought. Rather, the distinction is between the reasonable and prudent school of thought that advocates conservative conventional endodontics and the imprudent and radical school of paraformaldehyde providers who unreasonably risk permanent, deleterious injury with N2 overextensions. Regardless of the small number of clinicians professing to use N2, it is cytotoxically unsafe and should be avoided. A customary negligent practice by some clinicians is no defense to safe and prudent practice, which the standard of care requires. No matter how few or how many do it wrong never makes it right.

Clinicians may be liable for fraudulent concealment, intentional misrepresentation, or co-conspiracy if they discovered that a previous clinician's negligence is the cause of dental disease, and both the prior clinician and subsequent treater concealed the prior clinician's negligence. For instance, if a gross overextension of a paraformaldehyde packing or sealant is evident radiographically, and the patient reports that another clinician caused the overfill (that resulted in permanent lip and

chin anesthesia), subsequent treating clinicians may be liable for fraudulent concealment if they misinform the patient that the anesthesia will probably disappear shortly, and that using N2 merely reflects a philosophic difference rather than substandard practice. Reasonable clinicians who differ on therapies regard such differences as controversial. The difference between standard of care and substandard practice is not controversial but rather an indisputable difference between right and wrong. For instance, quackery based upon pseudoscience is not controversial, it is fraudulent practice.[25,185] Likewise, if the radiographs indicate sealant is inside the IANC, and the patient complains of persistent anesthesia, the patient should not be told to wait for return of sensation. The clinician should refer the patient immediately for microsurgical consultation regarding decortication and decompression surgery.

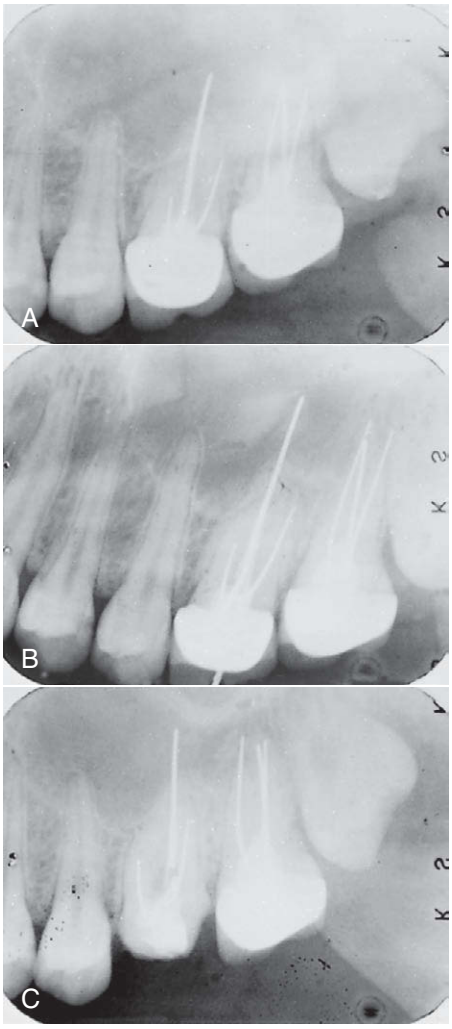

FIG. 11-29 Gross overfill into sinus with a silver point, which ultimately caused sinusitis and loss of tooth #14 as a result of endodontic failure.

The Federal Food, Drug, and Cosmetic Act prohibits interstate shipment of an unapproved drug or individual components used to compound the drug.[76] On February 12, 1993, the FDA dental advisory panel confirmed that N2's safety and effectiveness remain unproven. N2 may not be shipped interstate or distributed intrastate if any of the N2 ingredients were acquired interstate. Mail-order shipments of N2 from out-of-state pharmacies in quantities greater than for single-patient use are considered a bulk sales order rather than a prescription, thus violating FDA regulations.[46] A San Francisco jury awarded punitive damages against an N2-distributing New York pharmacy for knowingly shipping N2 in violation of FDA regulations, done with deliberate disregard for patient safety.[132]

Defective Restorations

Marginal gaps greater than 50 µm lead to cement dissolution and cause 10% of crown failures within 7 years after cementation. Dull or worn explorers substantially increase the likelihood of nondetection of open margins. A sharp explorer can detect margin defects as small as a 35 µm opening.[24] Accordingly, a sharp clinician should utilize a sharp explorer to detect open margins. Open crown margins contribute to endodontic failure and should be avoided (see Chapter 22).[34]

PROPHYLACTIC ENDODONTIC PRACTICE

Malpractice Prophylaxis

Most negligently injured patients do not sue.[35] Nonetheless, litigation serves a prophylactic purpose since litigation fears make some clinicians more careful and help promote professional guidelines. For example, after the American Society of Anesthesiologists adopted practice guidelines to reduce patient

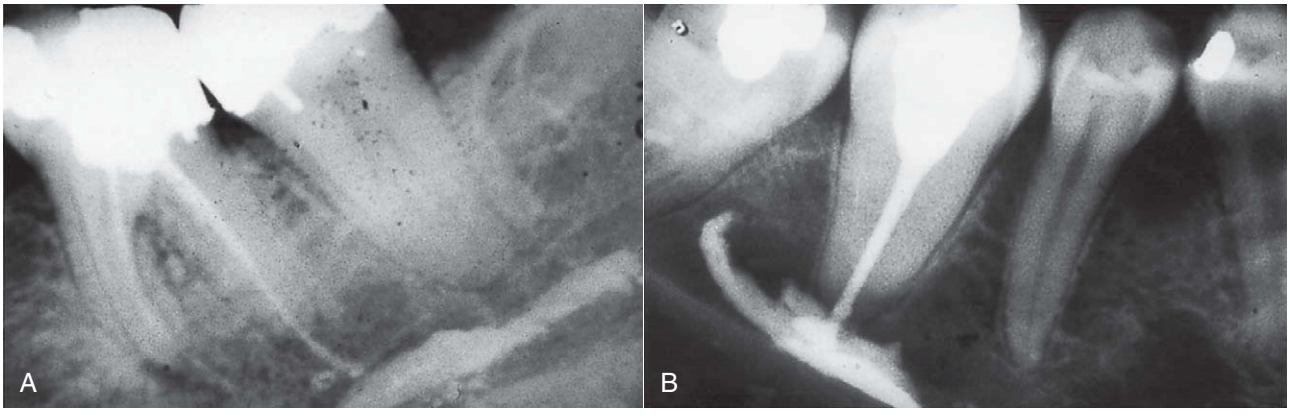

FIG. 11-30 A-B, Overextensions of Sargenti paste filling the inferior alveolar nerve canal. Both cases could have been avoided if the practitioners had selected a conventional sealing material and used a technique that emphasizes length control.

harm, deaths and professional liability premiums decreased dramatically.[204,228]

Disclosure Errors

Should dental negligence harm a patient, then full disclosure, including accepting the clinician responsibility along with providing an apology and explanation, results in the best outcome for the clinician and patient. Also, assurance of efforts to prevent a recurrence results in greater patient satisfaction and retains trust with the disclosing clinician to sustain a continuing clinician-patient relationship. Patients want to be told of treatment errors, regardless of whether the error can be corrected. One study in which there was full disclosure of negligently caused therapeutic errors resulted in only one patient thereafter seeking legal advice.[172] In the same study, patients paradoxically acknowledged, "It is realistic to expect that doctors will make errors … Patients have a right to expect that their doctors will not make errors." Nonetheless, virtually all patients concluded, "Patients should be able to trust their doctors to give them the right care." As noted earlier, apologetic expressions of sorrow or empathy for a patient's injuries are barred in evidence from being construed as admissions of fault in 29 states.[148] Protecting the patient's best interest includes telling the patient when negligent errors occur.

Periodontal Examination

Competent endodontic treatment begins with adequate diagnostic procedures. An adequate periodontal evaluation must accompany each endodontic diagnosis, which requires a diagnostic radiograph, clinical visualization, mobility recordings, evaluation of the periodontal tissues, and probing for periodontal pockets with a calibrated periodontal probe, particularly in furcation areas.[7,8,173]

Although endodontic treatment may be successful, tooth loss may result from progression of any residual, untreated periodontitis. Consequently, periodontal evaluation and prognosis are mandatory so that the patient and clinician can make an informed and intelligent choice about whether to proceed with endodontics, a combination of periodontal and endodontic treatment, or extraction.

Each tooth undergoing endodontic therapy (and adjacent teeth) should be probed with a calibrated periodontal instrument to obtain six measurements per tooth. Pockets of 4 mm or greater should be recorded on the patient's chart. If no pockets exist, WNL (within normal limits) or a similar abbreviation should be noted. Mobility should also be charted and classified class I, II, or III. Gingival recession, furcations, and mucogingival deficiencies should also be recorded.[7,8]

A clinician who treats with endodontic success but ignores loss of periodontal attachment may misdiagnose or fail to appreciate the risk of failure because of poor periodontal prognosis. It bears repeating that the endodontic treating clinician should not assume an adequate periodontal evaluation has been performed by another clinician or the referring clinician. Instead, an independent periodontal evaluation should be done with a calibrated periodontal probe and results recorded before initiating endodontics including noting absence of pockets or within normal limits.

If clinically significant periodontal disease is present, the endodontic treating clinician should consult with the restorative clinician to determine whether the periodontal disease will be properly treated or referred to a periodontist in conjunction with endodontic treatment. A patient should be advised of any compromise of the endodontically treated tooth's periodontal status to comply with required informed consent disclosure.

Temporomandibular Disorders

Occlusal prematurities can trigger temporomandibular disorders (TMDs) in patients with a prior TMD history, so during or following endodontic therapy for such a patient, it is essential that temporary and final restorations not open the bite or significantly alter existing occlusion.[157] Hyperocclusion is a potential TMD trigger that results from open bite or a contralateral side, particularly when a terminal abutment tooth is taken out of occlusion.

Preoperative and Postoperative Radiographs

Pretreatment, midtreatment, and posttreatment radiographs or digital images are essential for endodontic diagnosis and treatment.

1. A current, pretreatment, interpretable periapical radiograph is mandatory.
2. Measurement films or digital images are necessary to verify canal length (if an electronic canal-measuring device is not used) and the apical extent of the gutta-percha fill to the radiographic apex.
3. Posttreatment radiographs are essential for determining the adequacy of the endodontic seal or if further treatment is necessary (see Chapter 10).

Digital Radiography

Digital radiographic endodontic applications are ever increasing in accuracy.[113] The standard of care does not currently require digital imaging, because traditional silver halide radiographic film is a reasonable alternative. When there is more than one reasonably acceptable practice modality, a clinician who chooses either modality meets the standard of care. Fig. 11-31, *A* represents a distal open margin on tooth #30 (shown digitally) that is not evident in part *B* with plain-film radiography.

Advertised claims of 80% reduction in radiation with direct digital radiography (rather than film) assume the following[37,113]:

1. Ultraspeed D-speed film is used. (Ektaspeed E-speed film and the newer F-speed film reduce radiation 50% and 60%, respectively, while producing images of comparable quality to D speed.)[3]
2. No rectangular collimation is used, which reduces exposure another 30%.
3. No extra radiographs are taken to compensate for a smaller area. For instance, a 2 charged-coupling device (CCD) sensor has an active area smaller than size 1 film and may require an extra image with additional radiation exposure.

A digital x-ray image should never be modified to "enhance" the radiographic appearance of the original image. X-ray modification can be detected; in litigation, it can be devastating to the clinician's defense.

Periapical (PA) radiography is limited to only two dimensions. Newer 3D imaging systems for dental radiology use x-ray beams that are cone shaped. Cone-beam computed tomography can provide a more nearly accurate diagnosis.[54,97,127] In Fig. 11-32, *A-C* the PA does not show the

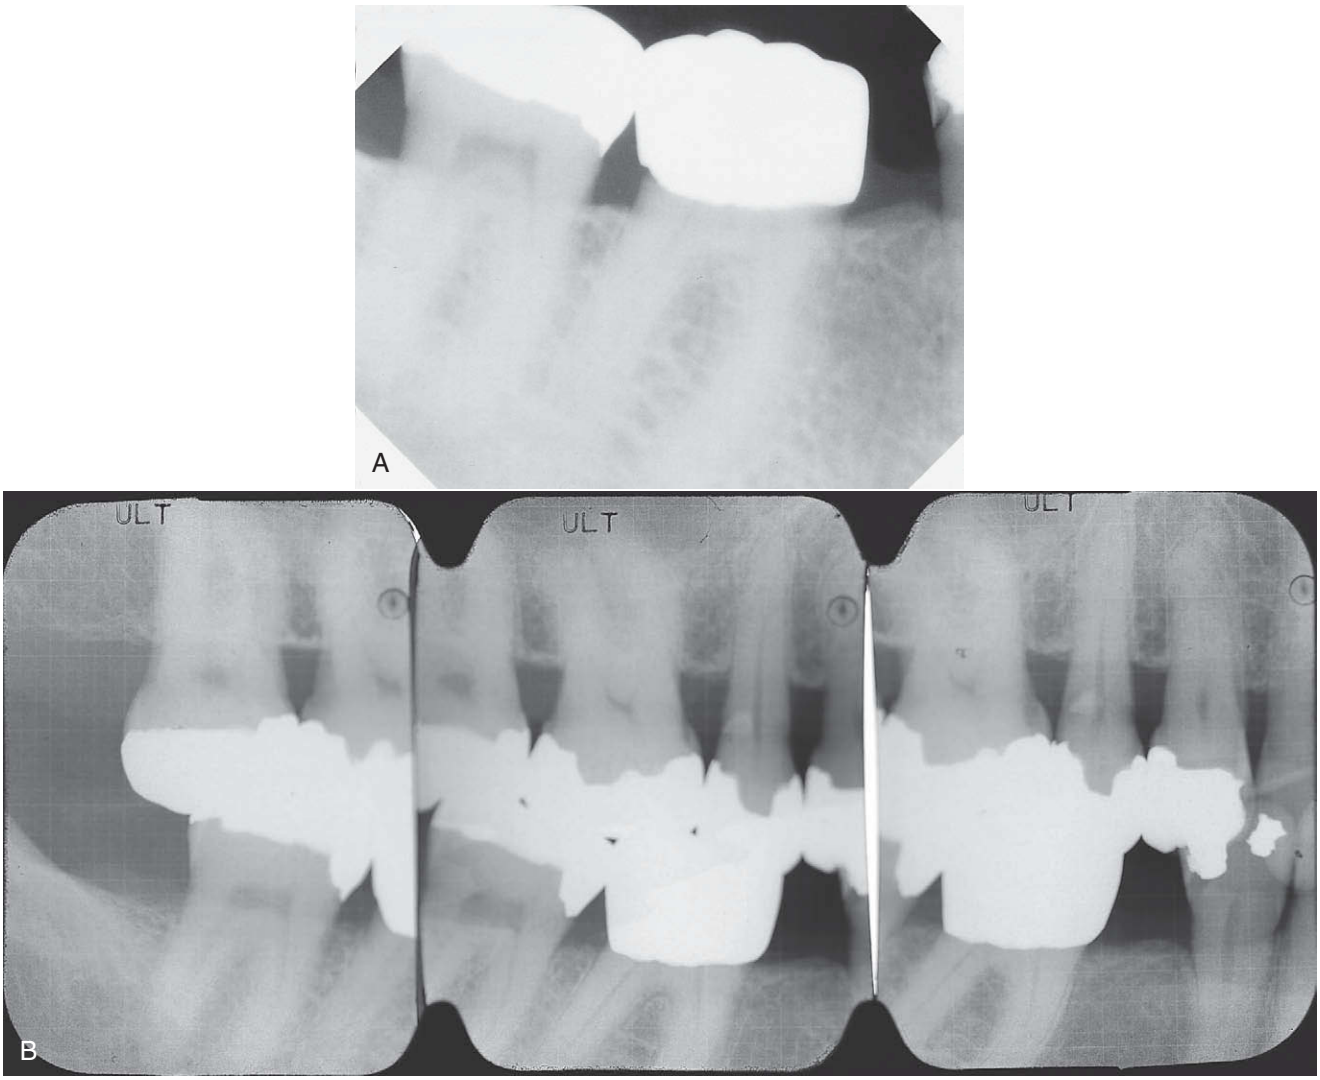

FIG. 11-31 A, Distal open margin on tooth #30 (shown digitally). **B,** Distal open margin on tooth #30 not evident with plain-film radiography.

transported canal and extent of short fill, which is more evident in the CBCT. Each CBCT scan produces three image views: axial, coronal, and sagittal.

CT scans enable evaluation of the true extent of lesions and their spatial relationship to important anatomic landmarks.[73] Fig. 11-33, *A-C* shows a bifid IANC not apparent on panorexes. CT scans may provide information important for retreatment decisions, especially apical surgery. CBCT[54,163,166] showed significantly more lesions than PA radiography, including expansion of lesions into the maxillary sinus, sinus membrane thickening, and missed canals; 34% of such lesions were missed by PA radiography.[163,166] Artificial bone defects in the antral surface were not detected with PA radiography. Because of overlapping roots, only 1 out of 14 furcation defects in upper molars were seen on PA radiography, but CT scans were able to identify all furcal defects. Second molars proved to be the most difficult for detecting lesions with PA radiography alone. Twenty-three teeth with lesions expanding into the maxillary sinus were detected by CBCT, of which only two teeth were seen with PA radiography. Thirty-five teeth with membrane thickening were identified with CBCT, of which 16 teeth were also detected with PA radiography. Fifteen teeth with missing canals were detected with CBCT, of which only four teeth were identified with PA radiography. In a study that compared the efficacy of PA radiography and CBCT in detecting periapical lesions in maxillary premolars and molars for apical surgery,[166] Lofthag-Hansen showed that 38% of maxillary posterior teeth lesions were undetected by PA radiography, despite the fact that an additional different angulated PA radiograph was taken.[163] Lesions associated with apices near the sinus floor had a higher probability of being missed with PA than lesions associated with apices located away from or overlapping the sinus floor. Expansion of the lesion into the maxillary sinus, thickening of the sinus membrane, missed canals, and presence of apicomarginal communications diagnosed with CBCT were more frequently detected with CBCT than with PA radiography.[163]

Apicomarginal communication is an important predictor for the success rate of apical surgery including evidence of undetected vertical fractures necessitating extraction; 83% of

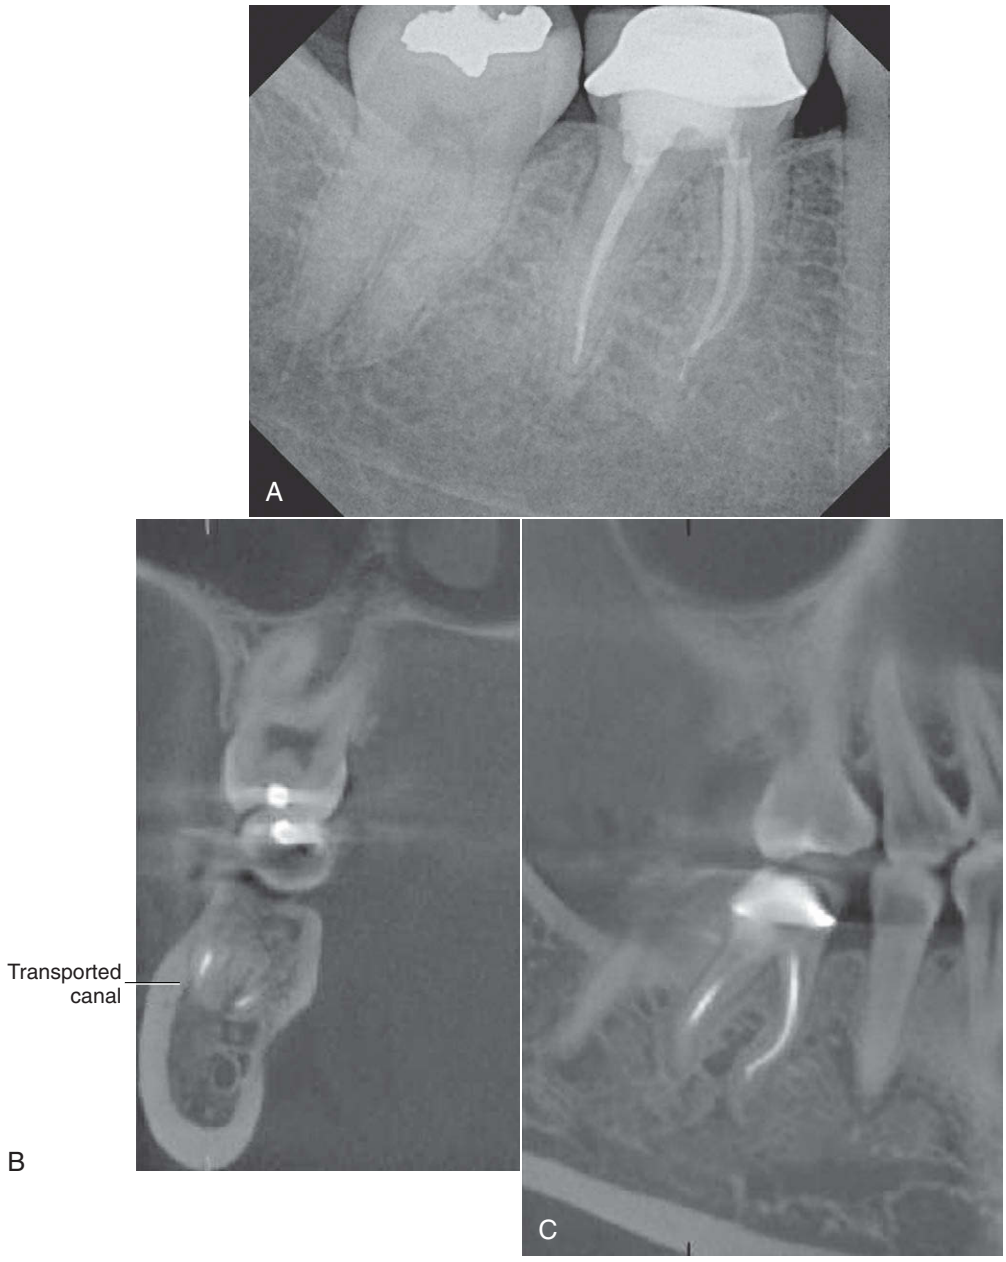

FIG. 11-32 A, Periapical (PA) view, which does not show full extent of transported and short-filled canal. Both deficiencies evident in **B** and **C** with cone-beam computed tomography (CBCT). **B,** CBCT Accuitomo of transported canal. **C,** CBCT Accuitomo of short-filled canal.

apicomarginal communications were not seen with PA radiography in the Lofthag-Hansen study.

If the radiograph shows a small distance between the periapical lesion and the sinus floor when the bony wall is thin, there is a high probability that an oral antral communication (OAC) can result, unless skillful care avoids sinus penetration during apical surgery. CBCT also allows the clinician to study the topography of the bony defect and assess whether the use of guided tissue membranes would be beneficial. Precise morphometric assessment of osseous relationships to the sinus is often inadequate with periapical radiography. Thus CBCT is invaluable in treatment planning for apical surgery, since 70% of cases studied revealed clinically relevant information not found in PA radiography.[166]

The probability of detecting lesions with PA alone was limited for teeth with apices in close contact with the floor of the maxillary sinus, for molars (in particular second molars), and when bone thickness between lesion and sinus was less than or equal to 1 mm. In summary, findings of lesion expansion into the sinus, sinus membrane thickening, missed canals, and presence of apicomarginal defects are more frequently diagnosed with CBCT than PA.[54,166]

Dental Fear

Dental fear may result in patients delaying or avoiding dental care. Frequent cancellations and missed appointments are characteristically associated with fearful dental

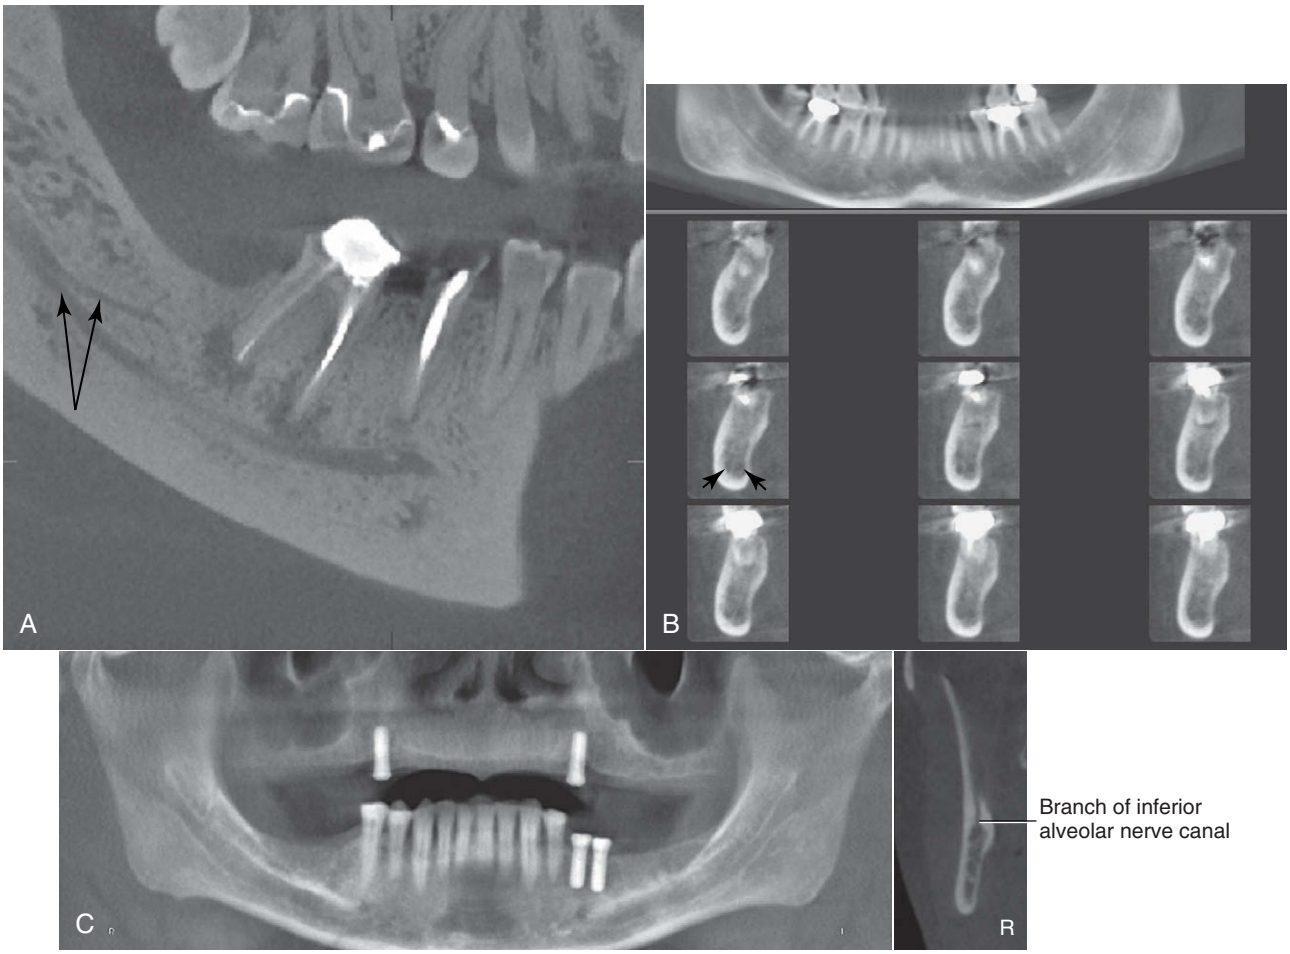

FIG. 11-33 A, Bifid inferior alveolar nerve canal (IANC) visible with cone-beam computed tomography (CBCT). **B,** Bifid canal visible with CBCT but not shown on panorex. **C,** Branch of IANC apparent on CBCT but not shown on panorex. *(Courtesy Gurminder Sidhu, DDS, MS.)*

patients. Although it is ordinarily a defense of contributory negligence if patients do not follow a clinician's treatment recommendations, the patient's advocate may contend that the defendant clinician negligently failed to diagnose a fearful patient. Fearful patients tend to avoid dental treatment because they believe it may exacerbate a prior traumatic dental experience. Referral to clinicians who specialize in treating fearful patients should be considered to facilitate comprehensive dental treatment and to avoid future emergency endodontic care because of repeatedly cancelled treatment visits.

Dental anxiety and finances are the two most important barriers to patients obtaining regular dental care. Fearful dental patients avoid necessary treatment, delay recalls, and are reluctant to undergo painful procedures. Therefore it is essential that such patients be identified for proper management or referral for fear-reduction therapy. A patient who experiences intense anxiety in the dental chair, together with a history of avoiding dental care, suggests a diagnosis of dental phobia. Fearful dental patients fear loss of control during clinical treatment and require reassurance and reaffirmation that they have the power to halt the procedure by raising a hand or using another appropriate gesture. After trust is gained, additional procedures may be performed.

In addition to desensitizing techniques, the use of proven topical-anesthesia delivery systems helps to ensure a relatively painless injection of local anesthetics. Topical-anesthetic patches and oral-anesthetic rinses may prove a valuable aid for pain management of the fearful patient.

The use of psychologic questionnaires, such as the Dental Anxiety Scale or the Modified Dental Anxiety Scale, may be helpful in identifying such individuals.[125] These simple questionnaires are short, quick, and easy to complete, and users are provided with cutoff scores that help the clinician identify patients who have psychologic special needs. In this way, the clinician will be in a position to assist the dentally anxious or dentally phobic patient in accessing dental health care.

Patient Rapport

Good patient relations are 15% dependent on the clinician's competency to cure and 85% dependent on the clinician's ability to assure the patient that the treatment being given will be done with the clinician's best judgment and care.

Rapport between clinician and patient reduces the likelihood the patient will sue, despite an adverse result. The clinician can develop rapport by demonstrating genuine interest in the patient and making the patient feel valued. Patients feel important if they are seated in the operatory within a reason-

able time after arriving. The longer a patient is kept waiting, the more frustration and animosity build. If the patient cannot be seen within a reasonable time, a staff member should communicate the reason and, if appropriate, offer to reschedule the appointment. Staff or the clinician should telephone the patient at the end of the day after any difficult procedure or surgery to check on the patient's status and remind the patient to follow postoperative instructions. The clinician should record any patient complaints, symptoms, and noncompliance with instructions. The latter can be used as evidence of patient contributory negligence if litigation occurs.

The clinician should remember that the patient lacks the information and expertise to evaluate quality and performance. Patients have their own experiences and perceptions and often rely on lay information when gathering facts about dental procedures and treatment options. However, clinicians should expect some patients (especially those with access to the Internet) to ask technical questions and expect sophisticated responses.

Rapport Building Blocks

Sir William Osler advised, "Listen to the patient. He is trying to tell you what's wrong with him." The best communicators listen more than they speak. When they do speak, it is mostly to clarify what the patient has said. Difficult clinician-patient relationships create poor communications. Improved understanding of the patient's complaints fosters better rapport, aids treatment, and reduces the likelihood of litigation.

In discussing the patient's complaints, the clinician should ask, "What do you think is causing the problem?" Otherwise, the clinician may solve the patient's dental problem while failing to solve the patient's perceived problem. Failing to clarify the patient's expectations about diagnoses and recommended treatment leaves the patient with unresolved worries and concerns. For instance, a patient may fear that a retained endodontic file is carcinogenic unless this fear is allayed with a careful explanation that it is not.

Unhurried Visits

Full attention to the patient's complaints, good eye contact, and respectful addressing of the patient gain rapport, improve communication, and prevent lawsuits. The clinician should avoid questions that require a yes-or-no answer and instead ask what the patient perceives as the problem, rephrase the patient's complaints to prevent miscommunication, and ask if the patient's complaints have been summarized accurately. Summarizing clarifies understanding by repeating important points. The clinician should also ask whether there are any remaining questions. Nonverbal communication is a powerful tool. The clinician should shake hands initially and comfort with an outstretched hand if pain is provoked.

Emotions are the dominant force behind most malpractice claims. Patients who feel misled, betrayed, or abandoned become angry and may seek vindication instead of simply seeking financial compensation. Thus the clinician should maintain a tactful and courteous approach and be attentive to the patient's needs and complaints. In addition, the clinician should always make sure that communications with the patient are clear, even to the point of being repetitious, by asking if the patient has any questions. The patient should never be abandoned in the middle of a course of treatment. Also, the clinician should always be available to provide follow-up care. Clinicians should avoid making telephone diagnoses. Instead, recommend an office exam to assess treatment needs.

Good telephone communication is a matter of asking the right questions, such as asking a patient complaining of postoperative swelling if there is difficulty breathing or swallowing, as well as the degree and location of swelling. In cases of suspected infection, clinicians should ask the patient or family member to call back with a temperature reading to verify the patient is afebrile.

Off-the-Cuff Diagnoses

One clinician misdiagnosed a patient's party guest's endodontic problem as "sensitivity caused by gum recession" and recommended a desensitizing toothpaste. Although the conversation took place in a social setting, a lawsuit can result based upon an inadequate diagnosis. Suggest instead a thorough office exam with diagnostic-quality radiographs or provide a referral.

Keeping Conversations Professional

Making light of a minor occurrence, such as the dropping of an instrument, with a quip about the clinician's "one drink too many" at lunch may seem funny at the time. However, it may not sound so funny if the patient soberly reiterates the quip to a jury.

The clinician must not let a patient's flattery of the clinician's abilities undermine one's best professional judgment. Heroic measures usually result in treatment failures, dissatisfied patients, and, ultimately, lawsuits for uninformed consent.

A patient dissatisfied with prior treatment that appears adequately performed should prompt the clinician to stop treatment. Young clinicians are more apt to walk into traps involving a patient's request for unreasonable treatment. A compassionate clinician who is able to communicate conscientious concern avoids many malpractice actions. Thus when an iatrogenic mishap occurs, it behooves the clinician to be frank and forthright with the patient. Moreover, negligence concealment may extend the statute of limitations. Most states with discovery statutes construe *discovery* as the date on which the patient discovered and/or reasonably suspected the negligent cause of the injury, not the date of the injury itself.[67,92,212,266] Further, belated discovery of injury from another clinician evokes a feeling of betrayal in the patient and destroys rapport that would otherwise dissuade the patient from instituting litigation. Beginning in July 2001, the Joint Commission on Accreditation of Health Care Organizations required hospitals to provide an honest explanation to patients regarding medical mishaps. These standards are designed to prevent errors and reduce medical negligence claim payouts. In 1999, the *Annals of Internal Medicine* concluded that "extreme honesty may be the best policy." A full-disclosure policy in a study involving a hospital in Lexington, Kentucky, showed that this hospital was in the top 25% of claim incidence, but it was also in the bottom 25% of claim payouts ($1.3 million over 7 years).

Fees

Clinicians should clarify fees and payment procedures before initiating treatment. If the dental treatment becomes more extensive than originally planned, the clinician should discuss

any increased charges and reasons for those charges with the patient before continuing treatment. Charging for untoward complications, such as extended postoperative visits or retrieving broken instruments, should be resisted.

An overzealous receptionist who places payment pressure on a dissatisfied patient, or a clinician who sues to collect a fee from an already displeased patient, may invite a countersuit for malpractice. Refunding fees or paying for the treatment fee of the subsequent treating clinician is usually much less expensive than 1 week in court and a jury award for a patient's pain and suffering. If clinicians must sue for a fee, they should do so only if treatment is beyond reproach and records substantiate proper diagnosis, treatment, and informed consent options.

Suing for unpaid fees continues to be a proven method for getting countersued for dental malpractice. The client who has paid fees in the past but who stops at some point is either unhappy with the dental service received or short of funds. Dealing with a patient's countersuit takes time, and collection of unpaid fees may prove difficult. The patient being sued may seek an attorney to scrutinize the clinician's records for a potential cross-complaint suit against the clinician who initiated the lawsuit for fee collection.

Some cross-complaints for dental malpractice lack merit, whereas others have genuine merit. Pain, suffering, and lost wages may provide a larger potential patient recovery amount than the clinician's fees in dispute. Whenever possible, clinicians should avoid suing patients for unpaid fees. Before considering suing, the clinician should discuss the fee situation with the patient and consider a payment schedule, fee reduction, or fee waiver.

The amount of money being awarded by juries is increasing. In 1999, a New York City jury awarded $3.5 million against a clinician who had replaced three amalgams with composites. To relieve postoperative sensitivity, endodontics was performed and subsequently failed. Chronic TMD followed the extraction, from which the patient was likely to suffer lifetime pain. In Michigan, two endodontists were disciplined in 2008 for sedation overdose after settling for $3.5 million.[224] In 2008, a Spokane, Washington, jury awarded $14.2 million for unnecessary TMJ surgery. In Fig. 11-34, a Los Angeles jury awarded $1.7 million against a periodontist who "harpooned" the IANC with his implant.

Incidence of Negligence

Medical errors or adverse events are estimated to occur in almost one out of four patient visits to a family practitioner.[218] A U.S. government study of the Institute of Medicine found that 152,000 avoidable deaths occur annually because of medical negligence.[93,95] In this government study, injury from medical care occurred in 3.7% of hospital admissions. Some 58% of these injuries were concluded to be preventable, and 13.6% were fatal injuries. The actual fatality numbers may be underestimated, since calculations were based solely on hospital chart review.

FIG. 11-34 Implant "harpooned" the inferior alveolar nerve canal.

Alcohol

Excessive alcohol consumption can contribute to a higher incidence of restoration corrosion from chronic regurgitation and vomiting from gastritis associated with alcohol abuse.[110] Corrosion can lead to coronal marginal leakage predisposing to endodontic failure. Accordingly, medical histories should include histories of gastric reflux disease, bulimia with associated habitual vomiting, gastritis, and excessive alcohol intake.

Post Perforation

Post selection is important for minimizing the risk of perforations. Generally, posts should not exceed one-third of the mesiodistal width of a tooth, should follow the canal anatomy, and should leave 4 to 5 mm for sealant in the opened post space; this is described more thoroughly in Chapter 23. When a tooth is already crowned, access to the root canal entrance surface should be located before rubber dam placement. This will aid in orienting the root's long axis, which may vary from the prosthetic crown's long axis. Fig. 11-35, *A-B* represents an endodontist's perforation of tooth #7 because of difficulty locating the entrance into the root canal apical to the pulp chamber.[82] Fig. 11-36 shows a general clinician's misaligned post and perforation of tooth #5.

Ordinarily, a careful clinician performing endodontic therapy should be able to avoid post perforations. If post perforation occurs, early diagnosis and treatment are important. Belated diagnosis and treatment substantially increase the risk of endodontic failure. If perforation is relatively small in size (i.e., 1 mm or less) and promptly diagnosed at the time of the post perforation, immediate treatment with intracanal sealants (MTA) in the area of the perforation will probably succeed. However, delayed diagnosis and treatment (beyond 24 to 72 hours) result in bacterial contamination in the area surrounding the perforation. Delayed perforation repair therapy can cause periodontal or endodontic lesions and lateral periodontal abscesses occurring secondary to delayed diagnosis, which usually prognosticates a high failure risk.

Perforation Prevention

Irreversible endodontic complication such as furcation perforation during pulpal chamber access is usually preventable with due care.[189] Furcation perforations are avoided by adhering to basic principles of pulpal chamber removal such as cleaning and shaping in a coronal rather than an apical direction. Innovative bur designs can access the pulp chamber without risking furcation perforation by preventing cutting or ditching of the pulp chamber by use of a non–end-cutting bur.[65]

Bleach Injury

Because of the varying shapes of the root canal system in the apical third after cleaning, shaping, and obturation, some residual bacteria may remain, which are entombed. Irrigation

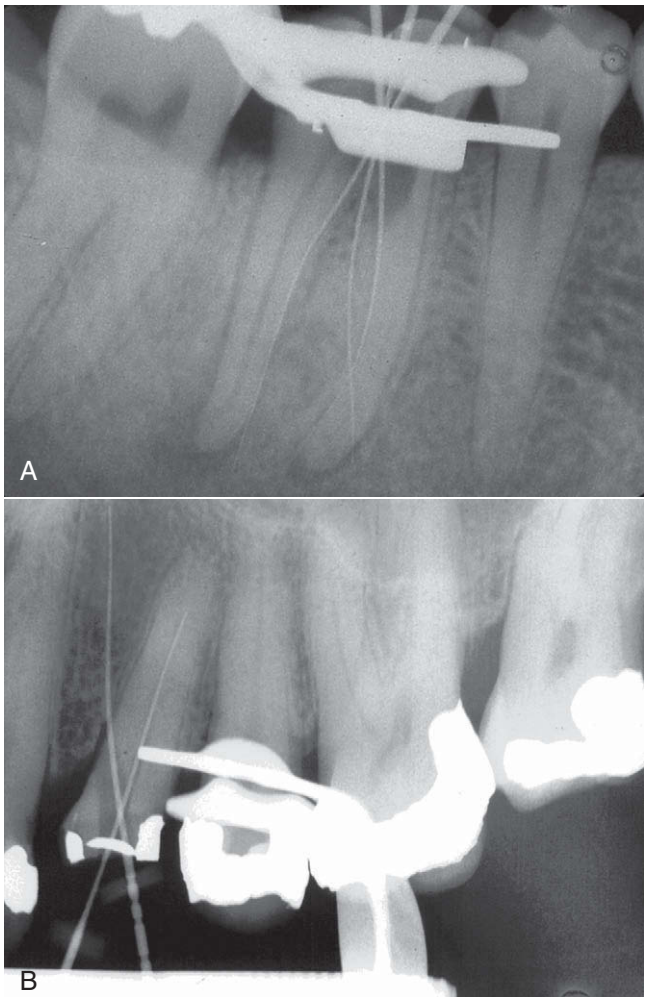

FIG. 11-35 Avoidable perforation. *(Courtesy Stephen Cohen, MA, DDS.)*

FIG. 11-36 Post perforation of tooth #5.

FIG. 11-37 Bleach injury.

with sodium hypochlorite is the usual disinfectant irrigant to minimize these remaining bacteria.[217] Apical or lateral extrusion occurs when bleach is extruded past the protective apical constriction or through a root perforation. The common denominators of bleach injuries are sudden severe pain and facial swelling.* Because of the clinician's concern for emergency treatment and the patient's pain, further endodontic therapy is deferred and usually not completed at the same visit. However, two cases report that compaction was completed the same visit, despite a bleach injury.[177,223] One article reports that subsequent flare-up may be related to the original bleach injury.[36]

Prevention of bleach extrusion is done with bleach syringes with safe, side-venting needles constantly moving to prevent hydrostatic pressure buildup from bleach fluid. Sodium hypochlorite is extruded into the periapical tissues during root canal therapy if excessive pressure is placed on the irrigating syringe, resulting in an expression of sodium hypochlorite beyond the apex. Subsequent pain is caused by the solution diffusing into the surrounding bone and soft tissue, causing swelling, tissue necrosis, and paresthesia. Surgery is usually contraindicated, and palliative treatment such as cold compresses accompanied by reassurance that most symptoms will dissipate is usually adequate.[151] However, if the bleach diffuses into vital nerve tissue of the infraorbital or inferior alveolar nerves, permanent paresthesia and occasional dysesthesia may result.[75,176,201,271] Figs. 11-37 and 11-38, *A-C* represent bleach injuries secondary to a root canal perforation. Paresthesia persists. Note the PA does not show the perforation, but the Accuitomo does.

Cores

Incorrect choice of cores can contribute to failure, including fractures. Some manufacturers (e.g., ESPE Premier, Norristown, PA, for Ketac silver) recommend against use of their core material unless at least two-thirds of the tooth remains before buildup. Failure to follow the manufacturer's directions can be considered when an expert determines whether the standard of care was met.

Resin-reinforced post-and-core systems show promise for structurally weakened incisors, but long-term longevity has

*References 2, 75, 151, 176, 201, 217, 211, and 271.

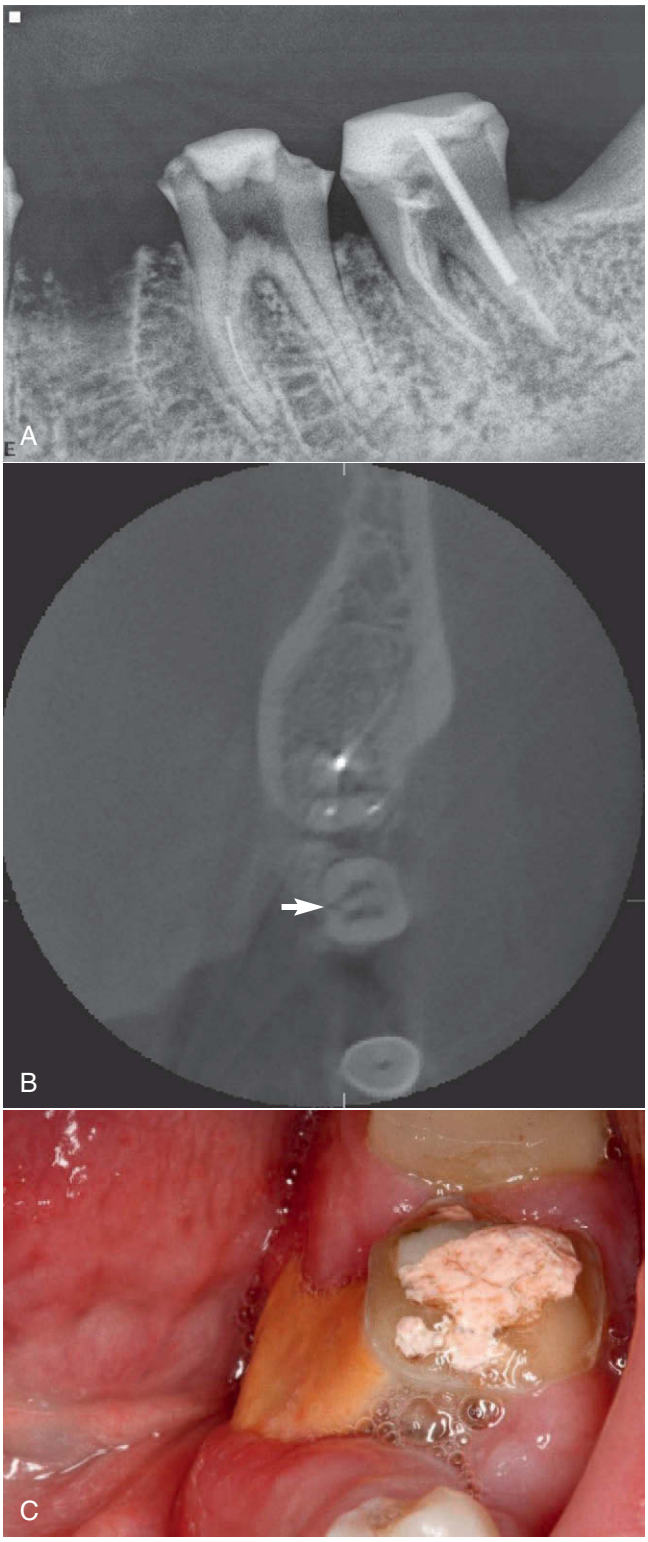

FIG. 11-38 A, Periapical tooth #19 showing fractured file but no perforation. **B,** Accuitomo cone-beam computed tomography (CBCT) showing perforation on the lingual side above the tooth #19 furcation. Perforation not evident in periapical view. Image demonstrates Accuitomo accuracy. **C,** Bleach extrusion through tooth #19 perforation, with resultant slough of lingual tissue.

not been reported. A ferrule or other counter-rotational core design is an important consideration for fracture resistance and retention,[126] although it has not been proved as statistically significant for the resin-reinforced core systems.[225]

Absorbable Hemostatic Agents

Absorbable collagen hemostatic agents should not be placed on or adjacent to peripheral nerves because of the potential for neural injuries, particularly in bony nerve canals.[80,162] Also, as such material is absorbed, its chemotactic properties promote collagen formation and scarring. Compression injuries of peripheral nerves in bony canals can result from expanding scar tissue. FDA adverse incident reports list 11 patients with severe neural defects, including paraplegia secondary to absorbable collagen products placed in the spinal canal for hemorrhage control. Thus the FDA warned of paralysis from absorbable hemostatic agents.[80,162] Accordingly, after hemorrhage is controlled with hemostatic agents, absorbable collagen agents should not be left in situ or near bony neural spaces. This will avoid having remaining hemostatic material cause swelling, pressure, or migration to adjacent neural tissues. The minimum amount of collagen agents necessary to achieve hemostasis should be used.

Pneumomediastinum (Air Embolus)

When performing endodontic surgery, a surgical handpiece should be used that ventilates air through the back of the handpiece rather than an air turbine that directs air into open tissue spaces. Pneumomediastinum, also known as *mediastinal emphysema,* may result from air embolisms dissecting down the neck facial planes from air forced into the submandibular or sublingual spaces contiguous with neck spaces.[27,243]

Broken Needle

Scanning electron microscopy (SEM) with an energy-dispersive x-ray spectrometer attachment can analyze whether a broken instrument is due to excessive operator trauma or manufacturing defect. Fig. 11-39 represents a combination of low-cycle bending fatigue and tensile overload. Accordingly, the local anesthetic needle likely fractured because of bending deformation as it struck the ramus.

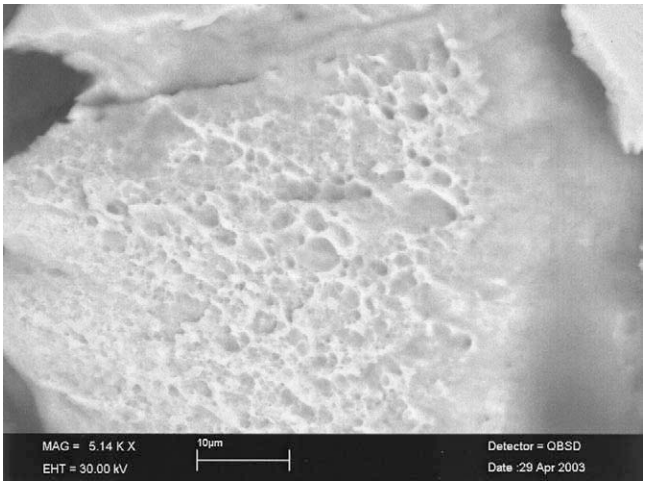

FIG. 11-39 Tensile overload shown in elongated ductile dimple voids.

Ductile rupture in metals results from shearing along planes that are oriented at 45 degrees to the tensile stress. Tensile "necking" results from multiple slipping deformations in all the 45-degree planes to the needle axis because of significant overload. Final rupture results from a combination of bending and tension. Fig. 11-40 shows the needle tip bent and blunted as it hit a hard object. No manufacturing defects were found. Fig. 11-41, *A-B* shows SEM views of the fracture. Fig. 11-41, *C* is a SEM view of the needle fracture taken at the hub side of the fracture. These illustrations demonstrate why longer 25-gauge needles should be used for mandibular blocks rather than shorter 30-gauge needles.[169]

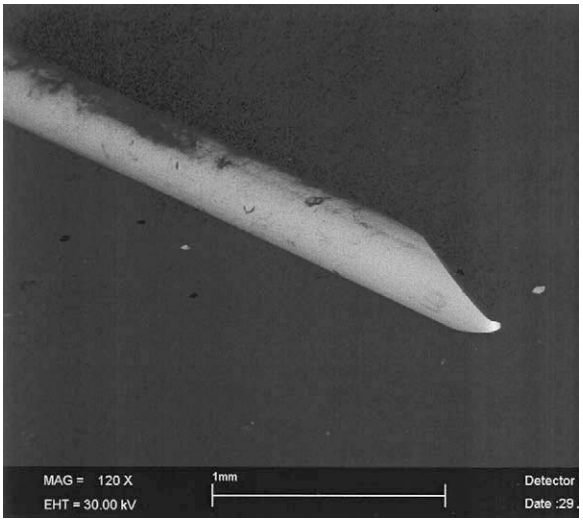

FIG. 11-40 Needle blunting of broken needle tip demonstrating striking hard object (ramus).

Sterilization

Nonsurgical use of the dental unit water supply should comply with the Environmental Protection Agency regulatory standard of less than 500 colony-forming units (CFU)/ml.

CDC guidelines require sterile water or sterile solutions for all surgical procedures.[152] Disinfected water from handpieces or ultrasonic devices is no longer acceptable as a water coolant during surgery. Instead, an ultrasonic device that can deliver a sterile irrigant during surgery should be used. Dental unit water lines are available with tubing that can be disposed or autoclaved for surgery. Some ultrasonic devices are also available with disposable tubing to maintain a sterile water coolant delivery system.

Digital radiographic devices that contact the oral mucosa region require a combination of barrier protective sheath and chemical disinfection in accordance with prudent manufacturers' directions.[122]

Rotary NiTi files likely contain bioburden material that after sterilization may act as a foreign body. Efficiency degradation after sterilization should suggest to the prudent clinician a single-use philosophy.[19]

Avoiding the Inferior Alveolar Nerve Canal

When placing implants or performing apicoectomies in close proximity to the mental foramen in the bicuspid region, the clinician should consider the anterior loop of the IAN, which usually ascends as it approaches the mental foramen, com-

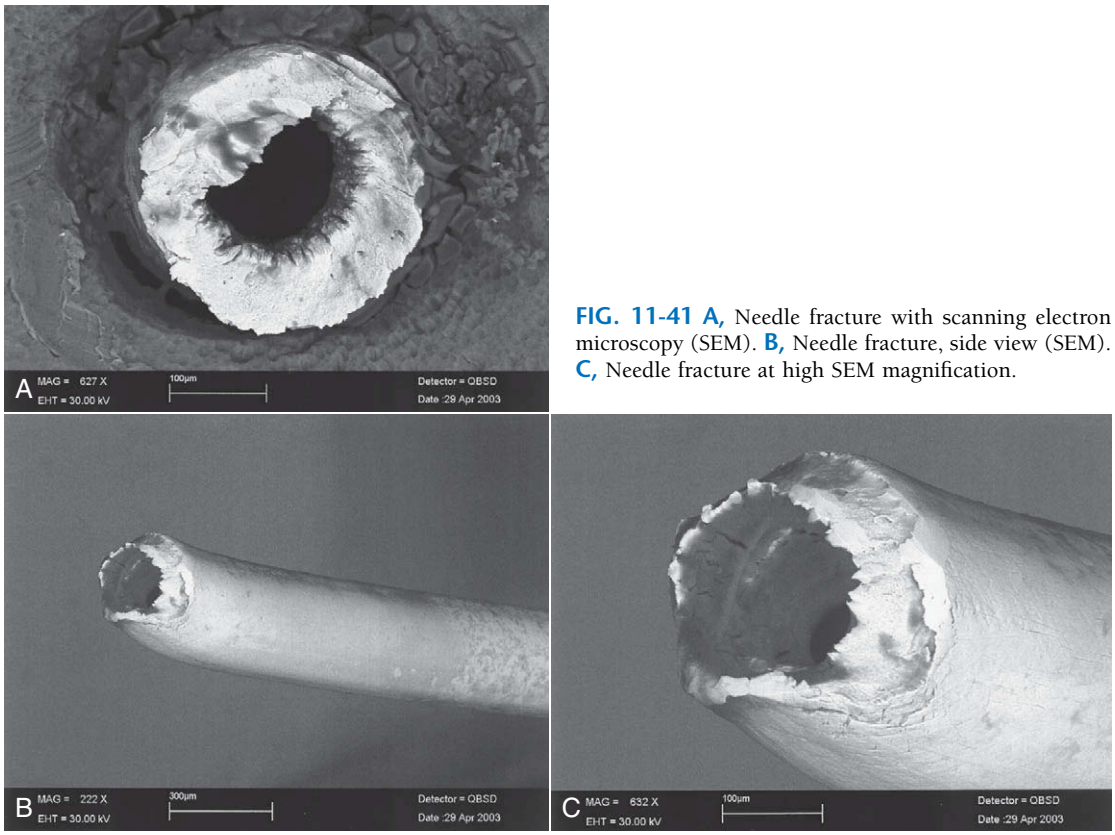

FIG. 11-41 A, Needle fracture with scanning electron microscopy (SEM). **B,** Needle fracture, side view (SEM). **C,** Needle fracture at high SEM magnification.

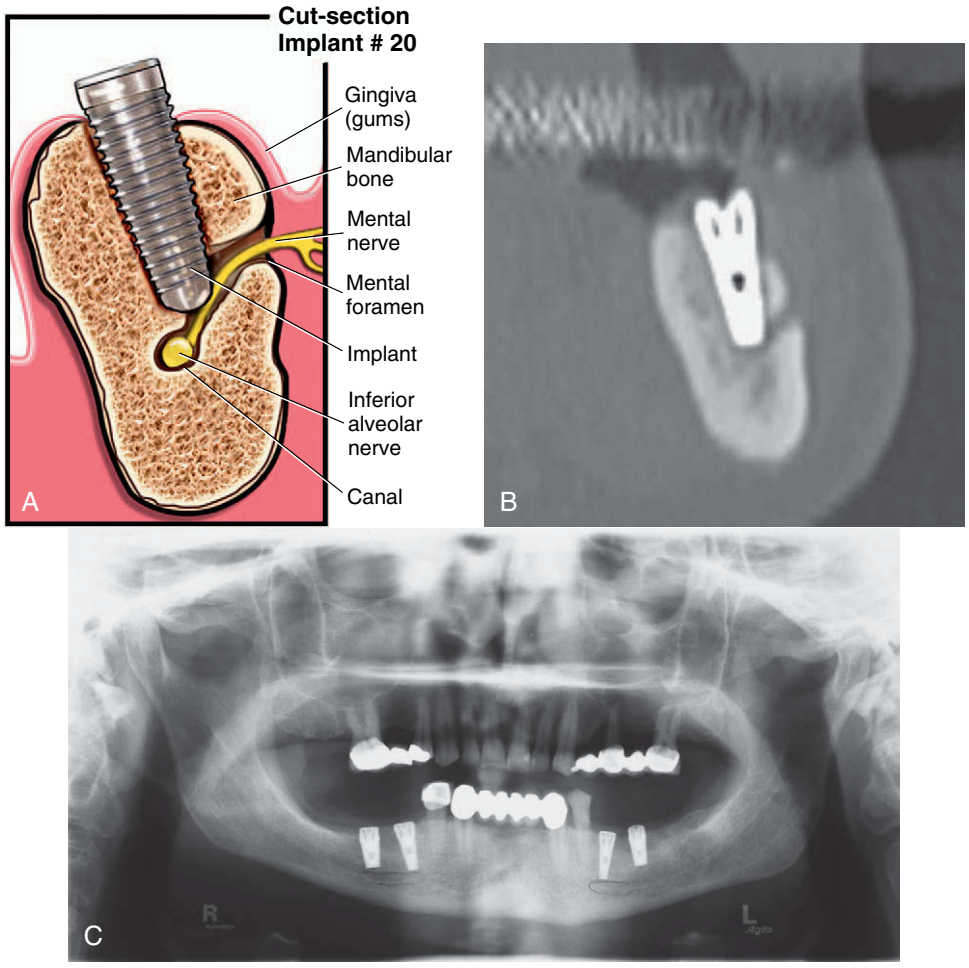

FIG. 11-42 A, Illustration showing implant placed into ascending inferior alveolar nerve canal (IANC). **B,** Cone-beam computed tomography (CBCT) image of implant into ascending IANC. Settlement of $915,000. **C,** Implant into IANC; immediate postoperative Panorex image. Same patient but with CBCT image.

pared with the IAN's more inferior location in the molar region (Fig.11-42, *A-C*[109]; this Los Angeles case settled for $915,000, with permanent dysesthesia). The IANC varies from buccal to lingual as it courses the length of the mandible. Thus, CBCT imaging aids in assessing the IANC location for planning implant placement or apical surgery.[54,73]

Mental Nerve

The mental nerve, as the terminal branch of the IAN, is at risk during elevation of the mandibular mucoperiosteum. Careful flap design and elevation are important to avoid mental nerve injury while working on the buccal surface of the mandible in the region of the mental foramen.[169] In performing incision and drainage in the region of the mental foramen, a diagnostically accurate radiograph is necessary to avoid incising through the course of the mental nerve.[63,146]

Medication Errors

The FDA has received over 95,000 reports of medication errors since the year 2000. Medication errors involve the wrong drug, an extra or wrong dose, omission of a drug, or administering a drug by the wrong route or at an incorrect time.[153]

Medication errors are often preventable.[247] Two major sources of errors in prescribing are poor penmanship and the use of error-prone abbreviations. Writing "1.0 mg" can be read as "10 mg" if the decimal point is not clearly visible. The FDA recommends that no trailing zeros be used when denoting doses expressed as whole numbers, and that preceding zeros be used whenever a decimal point is needed for a dose that must be administered as a fraction of a whole number (e.g., 1 mg; 0.5 mg). Recent drug label changes can be readily accessed on the National Library of Medicine's DailyMed website.

Posttrauma Therapy

The reader is referred to Chapter 17 for a full discussion of how to treat and manage patients who have sustained a traumatic injury.

Continuing Education

A clinician is legally obligated to maintain current knowledge in the field of endodontics. If not, the clinician may have only 1 year of knowledge (repeated 30 times) during the span of a 30-year career. By not maintaining continuing education

knowledge and updating clinical skills, a clinician may unreasonably condemn otherwise salvageable teeth because of inadequate diagnosis or treatment.

Millennium Management of Endodontic Advances

Technologic advances are touted as ideal endodontics. However, the standard of care is a minimal standard of reasonably acceptable practice rather than the perfect ideal. The reasonable and prudent clinician is not required to know and use all the latest technologic advances in endodontics. On the other hand, the reasonable and prudent clinician must keep current with available advances that are generally accepted and proved by research. Microsurgical endodontics is an example of improved endodontics technology; use of magnifying loupes or similar devices may prove inadequate for apical surgery or fractured instrument retrieval compared with microscopes. Therefore the clinician should adopt proven improvements in the endodontic field. Three-dimensional reconstruction of mandibles can be accomplished with cone-beam volumetric tomography to accurately locate the IAN or mental foramen. Fig. 11-43 shows an example of volumetric tomography usage for implant placement and/or apical surgery.

If studies demonstrate significantly superior results for some alternative to surgical endodontics, the informed consent standard of care may require that the patient be advised of the alternative technique, even if it is more expensive. There may be more than one path to success. So long as the clinician uses reasonably acceptable techniques and informs the patient of reasonable alternatives, the standard of care is met, but clinicians should remember that today's surgical advance may be tomorrow's retreat. For example, temporomandibular joint (TMJ) implants were inadequately tested technology on loading joints and proved virtually 100% disastrous.[77,209] Microscopic apical surgery has gained general acceptance, is performed by the majority of endodontists, and represents the current standard of care.[55,136,149]

Clinicians should evaluate the quality of peer-reviewed research articles for new products rather than accepting them at face value. A case report amounts to no more than the author's personal experience with one patient. Some authors report a "series" of patients if there are only two patients. A brash conclusion is to state something has occurred time and time again if similar findings were observed with only three patients. Valid scientific principles mandate that a test result can be replicated by other competent scientists duplicating a particular research protocol. If research cannot be duplicated, sweeping conclusions should not be made. Comparative effectiveness studies should demonstrate not only better results than a placebo but also relatively better results compared with similar marketed products tested under similar clinical conditions.

FIG. 11-43 Cone-beam computed tomography usage for implant placement and/or apical surgery.

Statistical Research

Statistical research conclusions may vary, since research protocols may not similarly control variables of population groups studied.[108,205] Discrepancies occur even within trials or among large trials. Meta-analyses of multicenter randomized controlled trials aim to reduce bias by estimating the effect size for outcomes and adverse effects after pooling all qualified research studies. This approach will not assist if the supporting randomized controlled trials are derived from confounded data from heterogeneous trials. Such research results represent an estimate of the average difference in the responses of the tested treatment groups. These differences in results of different centers from various test groups may reflect important distinctions in the clinical conditions of enrolled research subjects. Such distinctions may help identify subgroups of patients harmed by the researched product, although on average, treatment has an overall benefit.[124]

Since most research is currently controlled and sponsored by companies marketing a product, only favorable studies are usually submitted for publication. Literature reviews are prone to publication bias because journal editors are more likely to publish favorable rather than unfavorable conclusions. The most important use of literature review articles is to develop research questions that ultimately must be tested using a randomized controlled trial. Studies other than randomized controlled trials were the basis for prescribing hormone replacement therapy to millions of women to prevent cardiovascular disease. A randomized controlled trial of this therapy was terminated early because increases in cardiovascular disease and breast cancer were discovered.

Before the 1980s, pharmaceutical industry grants to academic institutions to fund studies by faculty members gave investigators total responsibility to design the study, analyze and interpret the data, write the papers, and decide where and how to report the results. Neither the investigator nor their institutions had other financial connections to sponsoring companies. Drug companies now finance most clinical research on prescription drugs. There is mounting evidence that research is skewed to make drugs look better and safer than research findings warrant.*

Negative results are often not published. For example, a study of 74 clinical trials of antidepressants found that 37 of 38 positive studies were published. Conversely, of 36 negative studies, 33 were either not published or published in a form that conveyed a positive outcome.[254]

*References 14, 88, 153, 159, 216, 222, 229, 239, 254, and 272.

Published clinical research is too often biased, usually by designing the studies in ways that will almost inevitably yield favorable results for the sponsor.[178,272] For example, comparator drugs may be administered at a too-low dose so that the sponsor's drug looks more effective, or at a too-high dose so that the sponsor's drug has relatively fewer adverse effects. Bias also takes the form of comparing a new drug with a placebo when the relevant research question is how it compares with an existing drug. A fair comparison would compare the new drug with an older FDA-approved drug at equivalent doses. As the former editor for 2 decades of the *New England Journal of Medicine* concluded in a 2008 JAMA article, "It is naive to assume bias is only a matter of a few isolated instances. It permeates the entire system. Physicians can no longer rely on the medical literature for valid and reliable information."[14]

Prudent clinicians do not adopt every new technology. Before adoption, such technology must have demonstrated benefits with acceptable levels of risk. It must also be adequately tested, with sufficient numbers of test subjects, over a significant length of time. Because manufacturers too often rush their products to market, newer products may not meet this criterion. Therefore, except for breakthrough technologic changes, a clinician will not likely be judged negligent for failure to adopt each latest device or technique. However, clinicians must keep in mind that in the information technology industry, 1 year is considered several generations, if not an eternity.[30,98] In general do not be the first nor the last to adopt improved technology.

The standard of care usually does not mandate incorporation of every new technology. However, in those states with informed consent laws that are based on what a prudent patient would want to know rather than what prudent clinicians should do, the patient may argue that an alternative technology or technique used by a different clinician would have been chosen had the clinician provided the patient with such information. Microscopic endodontics for broken file retrieval and CBCT to aid apical surgeries are pertinent examples.[54,127]

Other Clinicians' Substandard Treatment

Clinicians should not be overly protective of blatant examples of another clinician's substandard dental treatment. On discovery of apparent negligent treatment by a previous clinician, the clinician should consider investigation. Begin by obtaining the patient's written authorization for transfer of a copy of the previous clinician's records, including radiographs. If negligence is still suspected after reviewing the records, the clinician should consider talking with the previous clinician to learn the circumstances of what occurred during the patient's past treatment (after obtaining the patient's consent pursuant to HIPAA).

On discovery of a gross violation of the standard of care, a clinician has an ethical responsibility to report the matter to the local dental society, peer review, dental licensing board, or agency.[10,97] If the patient is misinformed and later discovers patently obvious negligent treatment, the subsequent clinician could arguably be sued as a co-conspirator to fraudulent concealment of the prior clinician's neglect.

Peer Review

If despite good rapport, candid disclosure, and an offer to pay corrective medical or surgical bills the patient is still unsatisfied, the clinician should consider referring the patient to peer review. Peer-review committees award damages for out-of-pocket losses but not for pain and suffering or lost wages. Consequently, even if the committee's decision is adverse to the clinician, the damage award will probably be less than a jury's verdict. If peer review finds for the clinician, the patient may be discouraged from proceeding further with litigation. Peer review proceedings, including the committee's decision, are not admissible in court.[43] Insurance carriers usually honor and pay a peer-review committee award, because a fair adjudication of the merits has been determined; the award is usually less than a jury would award. Defense costs, including attorney's fees, are saved with peer review.

Human Immunodeficiency Virus and Endodontics

A clinician may not ethically refuse to treat an HIV-seropositive patient solely because of such diagnosis.[60] Although in the 1980s, no federal law had clearly extended the protection of the handicapped laws to patients with AIDS, federal congressional action in 1990 extended this protection to the dental office setting with the passage of the Americans with Disabilities Act.[12] Many states already offer additional protection under state law.[40,62]

Confidentiality for patients disclosing their HIV status is important. An inadvertent disclosure to an insurance carrier or to other third parties without any need to know may result in cancellation of the patient's health, disability, or life insurance. This cancellation could result in a claim against the clinician whose office disclosed such information without authorization. Therefore, employees should sign the confidentiality agreement shown in Fig. 11-44. In signing this agreement, the staff may be alerted to the seriousness and importance of maintaining the confidentiality of patient health histories, because these histories may document AIDS, venereal disease, or other socially stigmatizing diseases.

If a patient requests that the clinician not inform the staff of his or her HIV status, the clinician should refuse to treat

DENTAL AUXILIARY CONFIDENTIALITY AGREEMENT

I, _____, have been informed by
(Dental Assistant)
_____, DDS, that all dental, medical, and
(Dentist Name)
financial information concerning patients is confidential.

As a condition of employment, I agree to maintain the confidentiality of all oral and written information, including treatment charts, and to not disclose such information to any unauthorized outside persons, including any family members, except upon request and authorization by the patient, the patient's agent, or supervising dentist.

I understand and agree that breach of this employment agreement shall constitute good cause for my discharge from employment. I acknowledge that I may be personally liable for any violation of a patient's privacy or civil rights including HIPAA committed by me without consent of the patient, or the patient's agent, or approval by above-named dentist.

Date: _____ _____
Signature of Dental Assistant

Witness: _____

FIG. 11-44 Dental auxiliary confidentiality agreement.

Dear Physician:

Your patient requires potentially invasive dental treatment that will likely result in transient bacteremia. Does the patient have a heart valve defect that increases the risk of infective endocarditis? If so, please advise of the diagnosed defect and recommended prophylactic antibiotics and dose for endodontic treatment or surgery with potential to invade the bloodstream. If you require the patient to have a current cardiac evaluation or echocardiogram to provide an answer, please advise both me and the patient, preferably in writing. Please also advise if your recommendation is in accordance with the enclosed American Heart Association current guidelines concerning bacterial endocarditis relating to dental treatment.

Thank you for your anticipated cooperation.

(Enclosure: current AHA guidelines)

FIG. 11-45 Sample of written physician recommendations.

that patient. This information is essential to staff members who may come in contact with the infection. An accidental needle stick with HIV-infected blood, which carries a risk of approximately 1 in 250 chances of seroconversion, may occur. Current medical protocol includes prophylactic administration of zidovudine (AZT), either to prevent or to slow the manifestation of AIDS from a deep, penetrating, accidental needle-stick exposure.

Although a treating clinician risks devastating a dental practice by informing patients that the clinician has contracted AIDS, the legal risk of not informing patients is much greater. The health care provider may be required to advise patients of positive HIV test results under the doctrine of informed consent (i.e., advising of a known risk of harm from accidental exposure).[66] Even if an uninformed patient never contracts AIDS, in those states that use a reasonable patient standard for disclosure of material risks of treatment (which could include accidental direct contact such as an unintended cut or needle stick), the patient may decide to bring an action for intentional concealment as a variant of informed consent and seek to recover emotional distress and punitive damages. Conversely, patients may be legally liable for intentionally misrepresenting their health history regarding their HIV status.[35]

Infective Endocarditis

If a patient's medical history shows valvular heart defects with regurgitation, the clinician should consult with the patient's physician to determine the necessity of antibiotic prophylaxis against infective endocarditis in accordance with current American Heart Association (AHA) guidelines.[269] If the physician does not appear knowledgeable about those guidelines, the clinician should provide a copy of the guidelines to the physician. If the physician advises deviation from AHA guidelines, the clinician should inquire why the physician feels that this is appropriate. The clinician should also record any discussions with the physician in the patient's chart and confirm the discussion and the physician's recommendation in writing (by fax and letter to the physician).

Communications with the physician should be specific, because dental treatment risks, such as overextension of files or filling material sealants that occur nonsurgically and may enter the bloodstream, may not be fully understood. A sample format is shown in Fig. 11-45.

Individuals who have undergone total joint-replacement surgery may arguably be at increased risk for bacterial infection to the artificial joint. Late joint infections (i.e., less than 6 months) may potentially occur as the result of bacteria introduced into the oral cavity. Antibiotic prophylaxis may be recommended for certain individuals with total joint replacements before specific dental procedures (as recommended by the AHA). The drugs (e.g., cephalexin, cephradine, amoxicillin) used to prevent the late infection of prosthetic joints differ slightly from those recommended by the AHA.[6,133] The treating orthopedist's recommendation is the guidepost clinicians should consider during the first 6 months after joint replacement surgery.

CONCLUSION

If the clinician performs endodontics within the standard of care as described in this chapter, there should be little concern that a lawsuit for professional negligence will be successful. Prophylactic measures suggested in this chapter should help lessen the likelihood of litigation by reducing, if not eliminating, avoidable risks associated with endodontic care.

Both the patient and clinician benefit from risk reduction.[94] To do it wrong does not take long, but it is far better for the clinician to take the extra precautionary time to do it right. We are a profession that deserves the public's trust, but only if that trust is earned. Clinicians deservedly earn public trust by providing safe and excellent quality patient care. The best prophylaxis against being sued is to protect the patient's best interest as our paramount goal. No matter how many others do it wrong never makes it right. Our ethical and legal obligation adheres to the identical bedrock principle, which is service to our patients first and foremost.
